Abstract: We study radiative heat transfer between two nano-emitters placed inside different types of closed cavities by means of a fluctuational-electrodynamics approach. We highlight a very sharp dependence of this transfer on cavity width and connect this to the matching between the material-induced resonance and the resonant modes of the cavity.

Two bodies kept at different temperatures and separated by vacuum exchange heat radiatively via the transfer of thermal photons. While this energy flux is limited at far separation distances by Stefan-Boltzmann's law, the pioneering works of Rytov [1] and Polder and Van Hove [2] showed that this limit can be overcome in the so-called near field, i.e., when the separation distance is small compared to the thermal wavelength (around 10 microns at ambient temperature). This amplification can be remarkable for materials supporting resonant modes of the electromagnetic field [3] (in particular polar materials supporting phonon-polaritonic resonances in the infrared region of the spectrum).

The possibility to transport this energy from a thermal source at distances larger than its thermal wavelength remains today a challenging problem which could find broad applications in a variety of the fields (e.g., thermal management and information transfer). With this respect, a remarkable attention has been paid during the past decade to the study of heat transport between two closely separated emitters or within a larger set of emitters, the main goal being to manipulate and tailor the radiative heat exchanges at the nanoscale. Some of these works have focused on the transfer between emitters in the proximity of a substrate or a cylindrical waveguide, showing how the two nano-emitters can couple through the surface resonance existing at the interface between this external body and vacuum and how this additional channel contributes to the transfer by amplifying or inhibiting it. More specifically, some works have considered the impact of confinement on the heat transfer between two nanoparticles, by placing them inside a planar cavity, revealing interesting effects [4–8]. However, they do not address at all the role played by the cavity width in the exchanged flux and especially how the presence of the cavity can make the heat transport strongly super-Planckian (far above the blackbody limit) at large separation distance between the emitters.

In this work we study the near-field radiative heat transfer between two nano-emitters placed inside a cavity (both planar and cylindrical) and highlight the crucial role played by the cavity width. More specifically, we unveil the major interplay between cavity resonant modes, whose frequencies are purely governed by the cavity width and material, and resonances existing at the interface between each nano-emitter and vacuum, giving the leading contribution to near-field radiative heat transfer in vacuum. We show that this interplay and the matching

of these resonances is at the origin of a very sharp dependence of heat transfer on cavity width, allowing for order-of-magnitude variations, as well as transitions from amplification to inhibition with respect to transfer in vacuum, with variations of the cavity width in the micron range. We also show that the characteristic distance at which the effect takes place depends on the geometry, providing a simple tool to choose the most convenient geometry depending on the desired distance. Our results pave the way to easier strategies to export and tune near-field super-Planckian radiative heat flux to distances larger than the thermal wavelength.

Abstract: We establish a correlation between Bound States in the Continuum (BIC), Fermi arcs, Weyl points, and singularities in far-field in a theoretical model. Experiments prove that without chirality, in materials or in nanostructures, around the BIC condition the far-field exhibits chiral behavior, confirming the existence of a Weyl point.

In recent years has it been demonstrated that Bound states in continuum, are intrinsically topological phenomena, revealing that BICs are singularities located at the vortex center (V-point) in the direction of polarisation of the far-field radiation [1]. Although more complex topological charges can be found in PhC slab, V-points located in Γ are generally associated with an integer topological charge while C-points, obtained with symmetry breaking, exhibit a split of the integer topological charge into semi-integer charges [2]. In literature, C-points are distinguished from BICs as they are linked to resonances with a finite quality factor [3], [4], [5]. However, through theoretical modelling and experiments, we will demonstrate C-points can also be related to the BIC condition.
We show the experimental existence of states with opposite chirality (Fig.1). These correspond to Fermi arcs connecting C-points with opposite winding, as confirmed by numerical simulations, which also validate the theoretical model.

Embedding plasmonic gratings for enhanced polarized photodetection and imaging in the near-infrared

T. Yu,[1,2] C. Zhang,[1,2,*] Y. Luo,[1,2] and X. Li[1,2,*]

Abstract: We proposed and experimentally demonstrated embedded plasmonic gratings, boosting hot electron generation and extraction efficiency. We achieved a 1.7 mA/W responsivity at λ=1455 nm, three times higher than non-embedded setups. We integrated the photodetector into a near-IR light imaging system, showcasing impressive polarized imaging capabilities.

In contrast to conventional semiconductor photodetectors constrained by energy bandgaps, hot-electron photodetectors (HE-PDs) leverage metal-semiconductor Schottky barriers to convert hot electrons into photocurrents. These devices offer several advantages, including adjustable Schottky barriers, ease of fabrication, sub-bandgap photodetection, room-temperature operation, and flexibility in wavelength and polarization tuning. However, their practical application has been limited by a low quantum efficiency due to inefficient hot-electron generation and extraction. Thus, surface plasmons (SPs), which are a kind of coherent oscillations of free electrons in metals, attracted the attention of researchers, since it provides an efficient way of harvesting light with confined and enhanced electric filed in nanoscale volumes [1−3]. Nevertheless, a critical and pivotal step continues to impede the efficacy of hot electron photoelectric detection: the collection of hot electrons. Even when hot electrons are efficiently generated within the metallic layer and reach the Schottky interface, only those meeting specific injection criteria [4−6] can successfully traverse the Schottky barrier, entering the semiconductor and contributing to the formation of photocurrent.

To overcome this limitation, we have introduced an innovative approach: embedding a metallic grating structure within our HE-PD. Unlike traditional designs with the metal grating solely on the substrate's surface, our device fully integrates the metallic grating within the silicon substrate. This design creates 3D Schottky barriers along both the planar and vertical sides of the plasmonic element, significantly expanding the momentum space and improving hot-electron injection efficiency. We present a remarkable achievement in the form of a narrow-band, geometrically tunable, and polarization-sensitive fully embedded Au/Si grating photodetector (FEG-HE-PD) designed for near-infrared applications, boasting high responsivity. By exciting surface plasmons (SPs), we induce a localized electric field in the Au film, resulting in an impressive optical absorption efficiency of approximately 85% and efficient hot-electron generation. Moreover, the embedded Au grating extends the momentum space, further enhancing hot-electron injection efficiency. The FEG-HE-PD exhibits exceptional performance, with a high responsivity of 2.5 mA/W in simulation and 1.7 mA/W in experiments, outperforming planar HE-PDs relying on Tamm plasmons and microcavities. Additionally, our device excels in responsivity and high-resolution imaging compared to typical grating-based HE-PDs that lack full embedding.

To demonstrate its suitability for polarization-sensitive photodetection, we present a photocurrent mapping (PCM) image under TM/TE polarization at 1450 nm. This showcases the successful application of our device in

single-pixel imaging systems. The embedded Au/Si grating photodetector, offering tunable wavelength capabilities and high polarization sensitivity, holds significant promise across various applications, including wavelength-sensitive photodetection, polarization detection, sensing, and imaging. Its silicon-based structure further enhances its practicality and appeal for real-world implementations.

Strong coupling between surface plasmons and magnetic polaritons in a borophene-based hybrid system

Ye Ming Qing[1,2,*]

[1]College of Electronic and Optical Engineering & College of Flexible Electronics (Future Technology), Nanjing University of Posts and Telecommunications, Nanjing 210023, China

Abstract: Borophene-based hybrid plasmonic structure enables strong coupling between surface plasmons and magnetic polaritons. This interaction leads to unique energy transfer, dual-band light trapping, and mode splitting characteristics, described by a coupled oscillator model. This innovative work offers a platform for light-matter studies and plasmonic device development.

The manipulation of light-matter interaction, particularly the strong coupling between incident waves and nanostructures, has garnered significant attention [1]. Two-dimensional (2D) materials hold promise for compact electronic and photonic devices due to their unique properties and thin dimensions. Compared to traditional metallic plasmonic systems, 2D materials like graphene and black phosphorus exhibit extreme field confinement, low dissipation, and easy controllability, enhancing light-matter interaction [2-8]. However, their low carrier densities (~ 10^{17} m^{-2}) limit plasmonic responses to infrared and terahertz bands. Finding 2D materials with higher carrier densities and plasmonic frequencies for optical manipulation beyond these regions is crucial. Monolayer borophene, a newly emerging 2D material, has attracted attention due to its high density of Dirac electrons (~ 10^{19} m^{-2}). It supports highly tunable confined plasmons in the visible and near-infrared regions, complementing other 2D materials. Recent studies have investigated borophene surface plasmons (BSP), exploring their plasmonic properties and coupling effects [9].

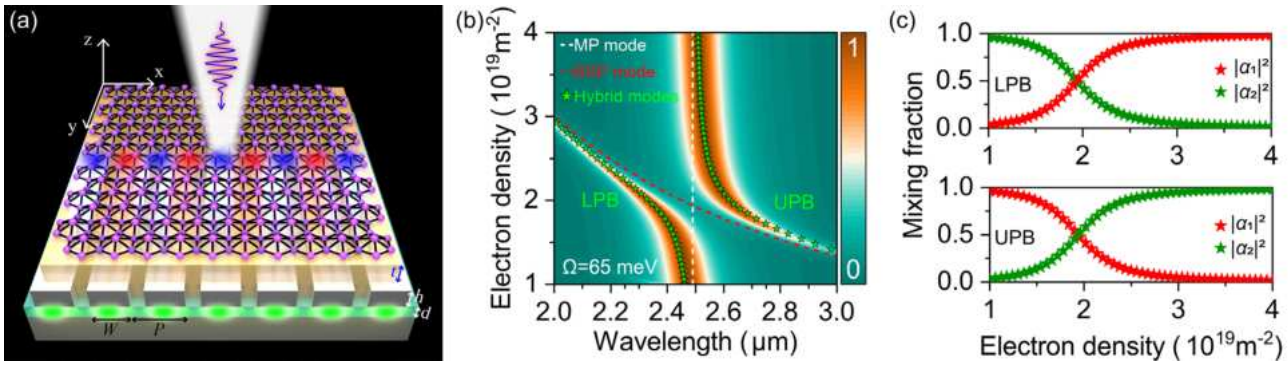

Fig. 1 (a) The schematic of the proposed hybrid borophene-based plasmonic system. (b) Absorption spectra of the proposed hybrid plasmonic system with varying borophene electron density. The red and white dashed lines are the theoretical dispersion relations of the BSP and MP modes, and the green stars are the analytical hybrid dispersion relations. (c) The mixing fractions of the BSP mode and MP mode in the polariton bands for the BSP-MP coupling.

Figure 1(a) depicts the proposed structure, composed of a continuous α-phase borophene monolayer, an insulator-covered subwavelength silver grating, a dielectric spacer, and a silver substrate. The structure's geometric parameters are: P = 100 nm, W =90 nm, t =20 nm, h =10 nm, d =8 nm. The insulator is Al_2O_3 (refractive index is 1.75), while the spacer is Si (refractive index is 3.42). The permittivity of Silver follows the

Drude model [3], and the monolayer borophene exhibits anisotropic conductivity, also described by a semiclassical Drude model [9]. As shown in Fig. 1(b), we investigate the strong coupling between BSP and localized resonance mode (MP) in the hybrid system. Using the inductor-capacitor circuit model and multilayer waveguide theory [3-5, 9-10], we predict MP and BSP resonant modes. Numerical simulations confirm the simultaneous excitation of both modes, enabling their coupling. The hybridization can be dynamically regulated by adjusting the borophene electron density, resulting in an anticrossing behavior with Rabi splitting of 65 meV and new hybrid polariton bands. This strong BSP-MP coupling behavior can be analyzed using the coupled oscillator model [3-6]. To gain a deeper understanding of the coupling process, we further retrieve the relative mixing fractions of the BSP mode and MP mode in the two polariton bands, which are shown in Fig. 1(c), which indicates the evolutionary behavior of BSP and MP in each hybrid band.

In summary, the coexistence of these two resonances fosters a coupling interaction that facilitates mode hybridization, energy-exchange channels, and enhanced light-absorption characteristics. Our innovative nanostructure exemplifies remarkable efficiency, charting a path for effective light modulation in terms of absorption or reflection. This breakthrough paves the way for potential applications in photonic and plasmonic technologies leveraging the unique properties of borophene.

Condensation and Transport of Organic Exciton-Polaritons from Bound States in the Continuum

A. M. Berghuis[1], J. L. Pura[2], G. W. Castellanos[1], M. Ramezani[1], D. R. Abujetas[3], S. Murai[4], E. van Heist[1], J. A. Sánchez-Gil[5] and J. Gómez Rivas[1]

Abstract: We show the formation of a polariton condensate from molecules strongly coupled to a bound state in the continuum in a metasurface of Si nanoparticles. We find that the condensation threshold depends on the excitation spot size, due to ballistic transport of the polaritons in the plane of the metasurface.

Bound states in the Continuum (BICs) are symmetry protected optical modes with theoretically infinitely long lifetimes due to the absence of the radiation to the far field. We show that a periodic array of Si nanoparticles supports a BIC with a suppressed radiation leakage at normal incidence due to quadrupolar character of the mode. This character results in a vanishing of the overlap integral of the mode profile at the surface with the radiation continuum. Theses properties make BICs an interesting platform for the investigations of light matter interactions.

We apply a layer of perylene dye molecules on top of this cavity. Due to the overlap of the resonance energy of the cavity and the energy of the excitons in the molecules, this system reaches the strong light-matter coupling regime, supporting polaritons that are partially photonic and partially excitonic. The partially photonic properties, give the polaritons their very low effective mass, enabling non-equilibrium Bose-Einstein condensation at room temperature. Condensation is reached at sufficiently high polariton concentrations and has to compete with the radiative decay of the polaritons to the ground state. The extremely long lifetime of the BIC gives the reservoir excitons more time to relax to the polariton band and reach the critical density for condensation resulting in a low threshold at pump fluences of ~4μJ cm^{-2} for a spot size of 0.1 mm^2. The emission from the polaritons provides a convenient way to probe the distribution of polaritons in energy-momentum space (Fig. 1). However, the symmetry protected BIC at normal incidence prevents emission from the condensate at this angle. Instead, the emission escapes from two points in momentum and energy space at very small angles (See Fig. 1 and 2a).

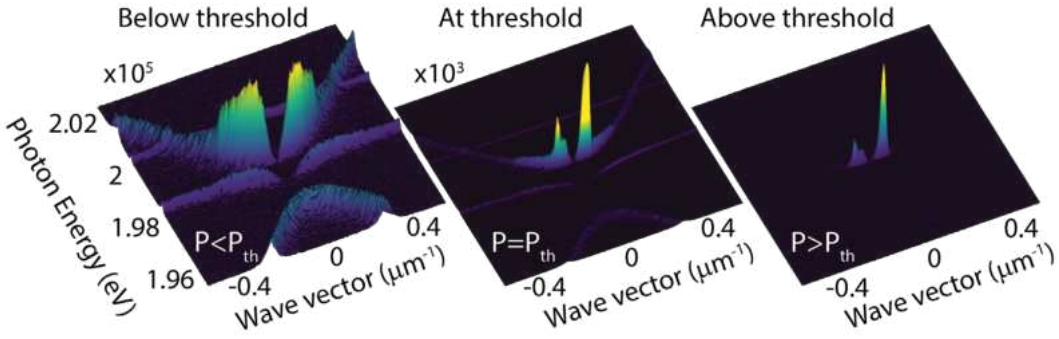

Figure 1 Emission in energy-momentum space from the molecules strongly coupled to the metasurface. (a) below condensation threshold, (b) at condensation threshold and (c) above condensation threshold.

We find that the required fluence for condensation is strongly dependent on the size of the excitation spot, where the threshold reduces for larges excitation spot sizes, while for very small excitation areas the molecules degrade before the condensation threshold is reached. We hypothesize that this effect is due to the transport of polaritons away from the excitation area. We model this observation by adding a term for the ballistic transport of polaritons to the rate equations for polariton condensation and numerically solve the equations for different initial excitation conditions. With this method, we explain both the spot size dependent threshold and the spatial distribution of the polariton condensate as measured above threshold (Fig 2 b and c).

These findings give a more complete understanding of the dynamics of polariton condensates and illustrate the importance of confining the polaritons when aiming for small scale and low threshold polariton condensates. The confinement could be achieved by designing a metasurface with a band structure with low group velocity or by creating a potential well to trap the polaritons.

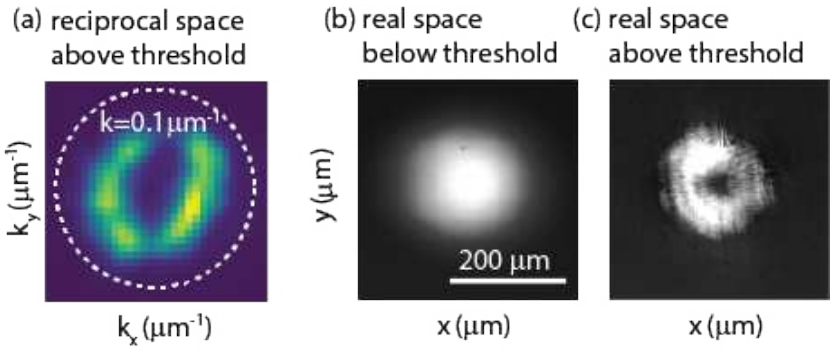

Figure 2 (a) Torus shaped emission profile in reciprocal space. (b) spatial distribution of the polaritons below threshold and (c) spatial distribution of the polaritons above threshold.

Plasmonics and metamaterials for controlling optical properties and device applications through strong light-matter interactions

Koichi Okamoto[1*]

[1] Osaka Metropolitan University, Japan
[*]corresponding author: OkamoT@omu.ac.jp

Abstract: In this study, we examine recent advancements in plasmonics and metamaterials, spotlighting progress in light manipulation across the UV to IR spectrum and highlighting applications in high-efficiency photonic devices, sensing, imaging, and quantum technologies. Additionally, we focus on innovative fabrication techniques that expand the frontiers of nano-optical engineering.

The recent breakthroughs in plasmonics and metamaterials signify a transformative shift in nano-optics and quantum technologies, enabling unprecedented precision in nanoscale light manipulation. Our research contributes significantly to this field, enhancing light-matter interactions and unlocking novel optical properties, thereby fostering innovation across various technologies[1-9]. Groundbreaking developments such as plasmonic bandgap structures, waveguides, and enhanced light transmission through nanohole arrays underline the potential of plasmonics in future nano-optical circuits and computing, essential for a technologically advanced society.

A key application of plasmonics is the enhancement of light emission efficiency in light-emitting diodes (LEDs) through metallic films that amplify photoluminescence, utilizing InGaN/GaN quantum well (QW) materials[1-3]. This advancement is critical for reducing energy consumption in lighting, as demonstrated by the development and commercialization of InGaN-QW-based LEDs, including white-light LEDs. However, the full potential of plasmonic LEDs, such as tuning the surface plasmon (SP) resonance wavelength across the UV and infrared spectra, remains to be realized.

Metamaterials, with their ability to flexibly tune SP resonance via strong mode coupling and metallic nanoparticles, offer unique optical properties for applications in biosensing, photocatalysis, and imaging. These advancements benefit from bottom-up fabrication methods, overcoming the limitations of traditional top-down microfabrication and enabling simpler, cost-effective production of plasmonic structures. Our research highlights the promise of full-color tuning using random plasmonic metamaterials, allowing adjustments to SP resonance peak through modifications such as spacer layer thickness[4-9]. This capability not only paves the way for full-color light sources and displays but also significantly improves resonance peak quality factors, suggesting applications in nanolasers and ultra-fast LEDs. Extending localized surface plasmon resonance (LSPR) into the deep UV region, through the use of aluminum for nanohemisphere structure fabrication, demonstrates plasmonics' adaptability and its role in developing efficient deep UV LEDs for applications like water sterilization and optical lithography[5-7]. Advancements in plasmonic and metamaterial technologies have also led to significant progress in sensing, imaging, and color tuning. For instance, the creation of metal nano-hemisphere gratings and NHoM structures has yielded impressive applications in colorimetric biosensing and enhanced fluorescence imaging[8]. By manipulating LSPR wavelengths through dielectric spacer layers, we have enabled full-color tuning, marking a significant step toward full-color displays and light sources with improved efficiency and reduced energy consumption[9].

In conclusion, the evolution of plasmonics and metamaterials represents more than a scientific breakthrough; it is a paradigm shift that is redefining the capabilities of optical technologies. The progress outlined here not only demonstrates the potential for improved light emission, sensing, and imaging but also paves the way for the exploration of quantum plasmonic effects and ultrafast optical communications. As the field continues to advance, the study of plasmonics and metamaterials is poised to lead nanophotonics into a future where the manipulation of light at the nanoscale knows no bounds.

Abstract: We demonstrate the realization of low-power, continuous wave-pumped second-order nonlinear optical processes with high efficiency from GaSe-assisted microfiber, and its application in the characterization of ultrashort optical pulses, with a broad measurable applicability for pico- and femto-second pulses.

Optical nonlinear frequency conversion in parametric processes includes harmonic generations, parameter oscillation and four-wave mixing has been widely applied to generate coherent light sources at new wavelengths, or with broadband spectrum, and to amplify weak signals. Unfortunately, the centrosymmetric nature of silica fiber precludes the realization of second-order nonlinear processes in optical fiber systems. Therefore, it has been a challenge to efficiently produce second-order nonlinear optical effects in a broad wavelength range under a continuous wave (CW) pump. In this work, we propose a simple strategy to efficiently realize the broadband and CW pumped second harmonics (SH), by transferring a crystalline GaSe onto a microfiber with phase-matching diameter, and characterize ultrashort pulses by incorporating the GaSe-assisted microfiber, as a frequency-doubling block, in an all-fiber interferometer. For an amorphous microfiber, by tailoring the waveguide chromatic dispersion in the fabrication process, material dispersion is compensated with mode dispersion, which makes the phase-matching approximately satisfied for SH.

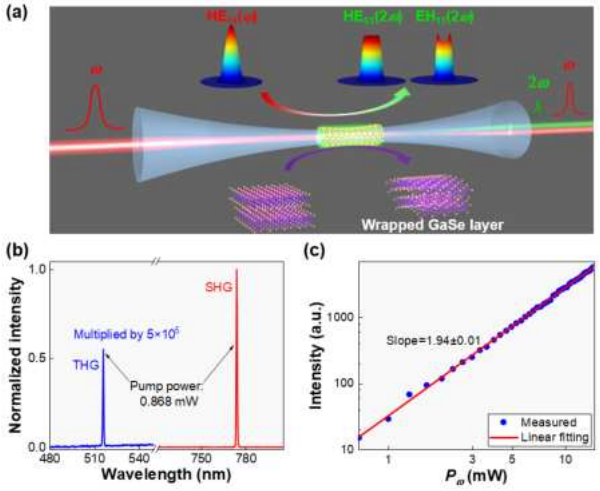

Fig.1 (a) Schematic of the microfiber for exciting SH, with the crystal structure and phase matched modes shown in the inset. (b) Spectra of SH at 775 nm and TH at 516.3 nm, pumped by a picosecond laser. (c) Power-dependence of SH when pump power of a CW laser is tuned from 0.7 to 14.5 mW.

Figure 1(a) schematically depicts the layered-GaSe coated microfiber for SH excitation and crystal structure of ε-GaSe used in experiments. To examine the device performance in the well-required C telecom band, the

1550 nm pulse light was incident into the microfiber from the picosecond laser, and the SH and third-harmonic (TH) spectra under 0.868 mW were measured and plotted in Fig. 1(b). With the assistance of crystalline GaSe layer, the SH and TH intensities have been greatly enhanced, compared with the intrinsic nonlinear signal from the microfiber. Considering the high conversion-efficiency, we replaced the pulse laser with a 1550 nm CW laser to excite the SH. According to the intensity evolution of SH signal shown in Fig. 1(c), CW-pumped SH scales quadratically with excitation power from 0.7 to 14.5 mW with a fitting slope of 1.94±0.01. The threshold of producing detectable SH in GaSe-transferred microfiber has been reduced to approximately 0.7 mW. Moreover, broadband SH spectrum is also achieved under the pump of a SLED source with a 79.3 nm bandwidth.

Further, by incorporating a GaSe-assisted microfiber into a Mach-Zehnder interferometer (MZI), we established an all-fiber autocorrelator for characterization of ultrashort optical pulses. Pulses to be retrieved were first split into the two arms of the interferometer and then overlapped, exciting the interferometric autocorrelated SH in the microfiber. By theoretical calculations, we investigated the dependence of an interferometric autocorrelation pattern on typical pulse parameters, including pulse shape, pulse duration, and unequal amplitude ratio of the two MZI arms. In the experiment, the autocorrelator shows high accuracy in measuring 7.13-ps, 1239-fs, and 683-fs pulses. In comparison with a commercial frequency-resolved optical gating, the relative errors are only 1.53%, 3.74%, and 6.86%, respectively. The proposed autocorrelator could be very compatible with current systems for future applications of in-fiber or on-chip ultrafast optical technology.

Light-matter strongly coupled states in optical microcavities using highly oriented organic molecular crystals

Kenichi Yamashita[1*]

[1]Faculty of Electrical Engineering and Electronics, Kyoto Institute of Technology, Japan
[*]corresponding author: yamasita@kit.ac.jp

Abstract: Organic microcavities offer promising avenues for achieving room temperature polariton states. This study delves into the ultrafast dynamics of polariton states and optical spin-orbit coupling within an optical microcavity utilizing highly oriented molecular crystals.

Strong light-matter coupling in optical microcavities has been extensively explored for both fundamental photophysical investigations and optoelectronic device applications.[1] Organic materials are particularly promising for the active layer of the microcavities due to their large exciton binding energies and strong transition dipole moments, essential for achieving the strong coupling regime at room temperature.[2] Another area of interest in organic microcavity studies is microcavity polaritons, which are nonequilibrium quasi-particles with both light and matter characteristics.

Specifically, microcavities employing highly oriented organic crystals offer various optical functionalities. The strong macroscopic transition dipole moment of organic Frenkel excitons is achieved through highly oriented molecular alignment. Therefore, when molecular orientation aligns along the in-plane direction of the microcavity, a significantly strong light-matter interaction ensues. A crystal of 2,5-bis(4′-cyanobipheny-4-yl)thiophene (referred as BP1T-CN) is one of the appropriate materials to meet these requirements. In high-Q optical microcavities utilizing BP1T-CN single crystals, we observed the formation of polariton modes with Rabi splitting energies as large as ~200 meV.[3] Moreover, under optical pulse excitation, polariton condensation, i.e., the bosonic condensation of excited polariton particles into the energy minimum of the modes, was achieved at room temperature.[4] The excitation and relaxation dynamics of polaritons and reservoir excitons were investigated using ultrafast time-resolved photoluminescence and transient absorption spectroscopies, demonstrating the ultrafast renormalization of polariton eigenstates due to the population of polariton particles.[4]

Another intriguing aspect of BP1T-CN microcavities is the polariton states with a specific dispersion property stemming from strong optical anisotropy. The highly molecular orientation of BP1T-CN crystals results in strongly anisotropic dispersion curves for the two orthogonally polarized cavity modes. Additionally, the transition dipole moments parallel and perpendicular to the molecular axis exhibit significantly different amplitudes. These features give rise to anisotropic light-matter coupling between the two orthogonally polarized polariton modes.[5] The interaction between these modes leads to diverse polarization conversion phenomena in wavenumber space, elucidated by the optical spin-orbit coupling Hamiltonian.[6]

Infrared photodetectors based on 2D heterostructures modulated by photogating

Jiong Yang[1,2*], Chao Zhang[1,2], Bining Sheng[1,2], and Xiaofeng Li[1,2]

[1]School of Optoelectronic Science and Engineering & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China

[*]corresponding author: jiongyang@suda.edu.cn

Abstract: Photodetectors based on 2D heterostructures can overcome bandgap limitations of individual 2D semiconductors and operate at long wavelengths. However, ultra-low interlayer absorptions result in weak photoresponsivity. Taking advantage of the photogating effect, infrared photodetectors based on 2D heterostructures are demonstrated to reach a photoresponsivity of 0.55 A/W at 1550 nm.

Infrared photodetection plays an important role in modern life and technologies, with many applications including optical communication, sensing, and night vision.[1-3] The core of photodetection lies in the efficient conversion of incident photons into electrical signals. In recent years, extensive studies on photodetectors are based on 2D materials and their heterostructures.[4-6] The working wavelengths of photodetectors are restricted by semiconductor bandgaps. Therefore, bandgap engineering of 2D semiconductors is critical for their applications in longer wavelength photodetections.

One of the frequently used methods to engineer bandgaps of 2D semiconductors is constructing their heterostructures. When forming the type-II band alignment in the heterostructure, efficient electron-hole separation into adjacent layers can occur, facilitating photodetection and photovoltaic applications.[7-9] However, interlayer absorptions are very low, typically 3 to 4 orders of magnitude smaller than intralayer absorptions,[10] resulting in low photocurrents and photoresponsivities. Photogating mechanism is a great but less investigated method in 2D heterostructures for achieving high photoresponsivity at an extended wavelength. Photogating modulation, in this case, is achieved by creating or eliminating charge carriers at or near the 2D heterostructures.

In this work, an infrared photodetector was fabricated based on a type-II heterostructure consisting of 1L MoS_2 and 1L $MoTe_2$ and operated in the photogating mode. The photodetector was in the field-effect transistor (FET) configuration. Spectral photocurrent measurements revealed broadband photodetection capabilities from 1100 to 1700 nm, beyond the energy band cut-offs of each monolayer. It was confirmed that the current was generated only between the source and drain electrodes by conducting photocurrent mapping under the 1550 nm illumination. The photoresponsivity of the 2D $MoS_2/MoTe_2$ photodetector was extracted to be 0.55 A/W under low-power 1550 nm illumination, thanks to the high gain of ~10^3 introduced by the photogating mechanism.

Significant loss suppression in metasurfaces via resonances coupling

Guangyuan Li*, Xiaoqing Luo, and Xueqian Zhao

Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences, China
*corresponding author: gy.li@siat.ac.cn

Abstract: We proposed and experimentally demonstrated significant loss suppression in plasmonic or all-dielectric metasurfaces via cooperative near-/far-field coupling or analogue of electromagnetically induced transparency, respectively. Both mechanisms are based on collective-collective resonances coupling, resulting to record high measured quality factors. We expect this work will advance the performance of related applications.

Metasurfaces, either plasmonic or all-dielectric, have emerged as a promising platform for a diverse range of applications, ranging from nanolasing, nonlinear optics, optoelectronic modulation, detection and biosensing to manipulation of electromagnetic field parameters, such as amplitude, phase, polarization, and wavefront. However, plasmonic metasurfaces suffer from inevitable absorption loss and scattering loss, especially in the visible regime, and all-dielectric metasurfaces suffer from considerable scattering loss although the absorption loss is zero or can be neglected. As a consequence, many of the hoped-for plasmonic devices and applications still seem a long way off or even end up unveiling fundamental limitations and dead-ends [1], and all-dielectric metasurface-based devices and applications have limited performance. How to effectively suppress the losses has been a long-standing challenge in the field of metasurfaces, especially plasmonic metasurfaces.

Recently, surface lattice resonances (SLRs), which are sometimes referred to as collective lattice resonances (CLRs), and bound states in the continuum (BICs) are two prevailing approaches for suppressing the losses of metasurfaces, and have been attracting increasing interest. Taking advantage of SLRs, the measured quality factors (Q-factors) of plasmonic metasurfaces reach up to 790 in the visible [2] and 2340 in the near-infrared regime [3]. Using BICs, measured Q-factor up to 23900 was reported [4] recently.

In this work, we propose and demonstrate a novel approach to further break the Q-factor record of plasmonic metasurfaces. It is based on cooperative near-/far-field coupling, which can be understood by the near-field strong coupling of two orthogonal SLRs supported by two silver nanorod arrays. The strong coupling further re-distributes the loss of the two SLRs, resulting in record high measured Q-factor of 3117, as shown in Figure 1.

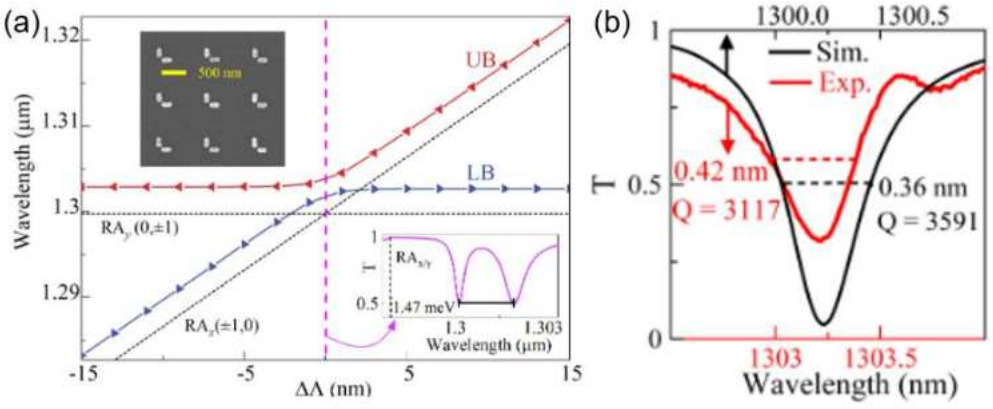

Figure 1. (a) Strong coupling of two orthogonal plasmonic SLRs in periodic L-shaped silver nanoantenna array, of which the SEM image is shown in the inset. (b) Simulated and measured transmittance spectra show that the simulated and measured Q-factors reach up to 3591 and 3117, respectively.

For all-dielectric metasurfaces, we propose and demonstrate metasurface-analogue of electromagnetically induced transparency (EIT) based on the coupling of two Mie SLRs, the electric dipole SLR (ED-SLR) and electric quadrupole SLR (EQ-SLR). We show that, compared with the high-Q EQ-SLR, the measured Q-factor is further improved by 1.2 times, from 2360 to 2750, which is more than five times of the record for metasurface-analogue of EIT [5]. This transparency window corresponds to strong slow light effect with group index reaching 12540, which indicates that the time delay through the 100 nm-thick Si metasurface is equal to that through 1.254 mm-thick vacuum [6].

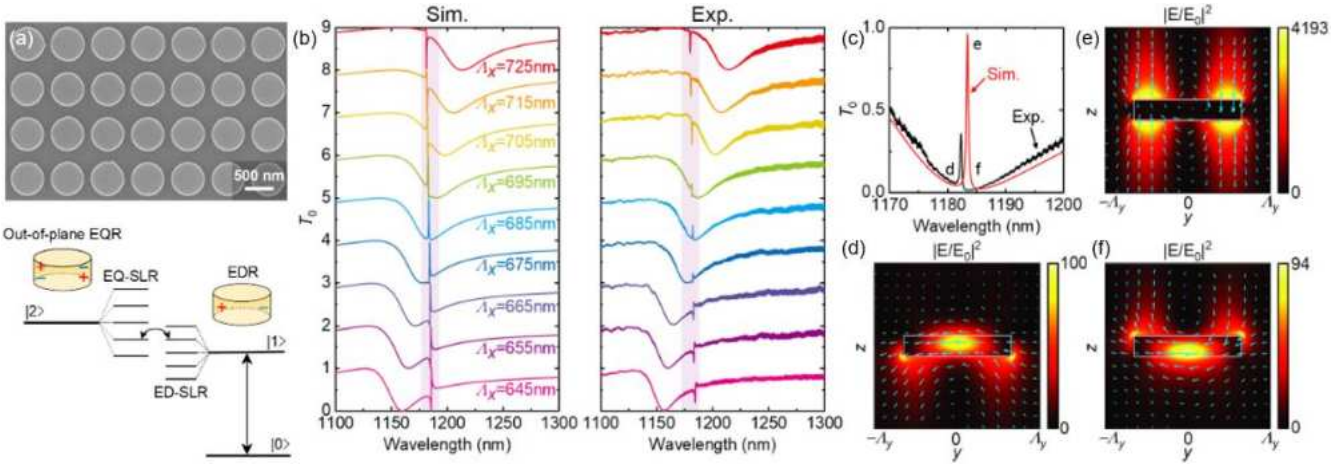

Figure 2. (a) SEM image of as-fabricated periodic Si nanodisk array and the operation principle of the EIT-analogue based on two Mie SLRs. (b) Comparison of simulation and measured transmittance spectra under normal incidence. (c) Zoom of transmittance spectra for Λ_x=685 nm. (d)-(f) Near-field electric field distributions at the wavelengths for the transmittance dips and the transparency peak in (c).

In summary, based on the strong coupling effect and the EIT effect between two SLRs, we demonstrated significant loss suppression in plasmonic and all-dielectric metasurfaces, respectively. We expect the obtained ultrahigh Q-factors will boost applications including emission enhancement, nanolasing, nonlinear optics, and biochemical sensing.

Integrated lithium niobate photonics: from communications to metrology

Y. Li[1*]

[1] State Key Laboratory of Precision Measurement Technology and Instruments, Department of Precision Instrument, Tsinghua University, Beijing 100084, China
[*]corresponding author: yli9003@mail.tsinghua.edu.cn

Abstract: By leveraging the tunable repetition rate of integrated lithium niobate (LN) electro-optic frequency combs, we achieved ambiguity-free distance measurement system. Based on integrated LN phase modulators, we achieved 16-channel optical phased array. To achieve mass production of integrated LN devices with high fidelity and low cost, we developed wet etching-based fabrication process for integrated LN.

With the blooming of artificial intelligence technology, the distant sensing systems are highly demanded by autonomous vehicles, smart home products, virtual and augmented reality (VR and AR) systems. Ideally, these sensing systems need an agile deployment, a high refreshing rate and a high precision to map the fast-changing environment in terms of 3D point cloud under various weather and illumination conditions. At present, the mainstream distance measurement technology is evolving from amplitude modulation (time of flight, ToF) LiDAR to frequency modulation (frequency modulated continuous wave, FMCW) LiDAR. FMCW, as a coherent detection method, shows a high precision, a high selectivity against ambient light, the intrinsic capability in speed sensing and eye-safety, leading to its fast emerging in several areas such as autonomous driving.

The key components of FMCW are frequency modulated laser and coherent receiver. The laser frequency of FMCW is chirped linearly (usually with triangular waveform in frequency), enabling resolving of the distance information from the frequency difference between the transmitted and received signals over one chirping period. Such a frequency difference is usually resolved via a discrete Fourier transform (typically fast Fourier transform, FFT), imposing limitation on the integral time. Such a limitation reduces the acquisition rate, and imposes higher requirement in the frequency chirping span, speed, and linearity of the FMCW laser. This is a main challenging that prevents FMCW from being widely used in many areas such as autonomous driving despites its advantages over ToF.

Here we demonstrate an electro-optic comb-enabled absolute distance ranging technology with megahertz acquisition rate. This technology combines novel distance measurement method and light source to achieve real-time absolute distance measurement with a high acquisition rate over an arbitrary distance. Based on an on-chip lithium niobate electro-optic frequency comb, the modulation frequency scanning coherent distance measurement system can achieve an acquisition rate up to 10 kHz and a precision better than 100 mm. This on-chip integrated lithium niobate electro-optic frequency comb is designed for a deep modulation depth, an arbitrarily tunable repetition rate, and a low power consumption, resulting in more frequency comb lines based on a commercially available continuous wave laser and a frequency-sweeping microwave source. All the comb lines are transmitted to a coherent ranging system, which carries out a temporal interference with high fineness. We show that real-time distance resolving can be achieved with only two adjacent interference peaks among many peaks generated over one modulation frequency chirping period, boosting the acquisition rate of LiDAR system for ambiguity-free distance measurement.

As an excellent material platform for integrated photonics, thin film lithium niobate (TFLN) boots the

performance of various integrated photonic devices such as integrated electro-optic modulators, integrated optical frequency combs, and nonlinear wavelength converters. The performance of these devices is highly dependent on the quality of nanofabrication method. Despite the fact that conventional inductively coupled plasma–reactive ion etching (ICP-RIE) can achieve TFLN microrings with intrinsic quality factor (Q-factor) as high as 10 million, this method still shows high cost, poor reproducibility, and low throughput.

Here, we achieved z-cut TFLN micro-racetrack with an intrinsic Q factor over 11.9 million using we etching method. In this method, we first deposit a 100-nm-thick silicon dioxide film on a TFLN sample (NanoLN) using plasma-enhanced chemical vapor deposition. Then, we use electron-beam lithography to write the pattern on the electron-beam resist (ZEP 520A). We then use ICP-RIE to transfer the pattern from the electron-beam resist to the silicon dioxide film. Subsequently, we wet etch the TFLN with a solvent consisting of H2O2, NH4OH and H2O with a ratio of 2:2:1 at a temperature of 85 Celsius. Following the wet etching, we remove the silicon dioxide mask using buffered oxide etch. Eventually, we anneal the sample at 250 Celsius for 2 hours in air to recover the potential damage induced by ion slicing.

Considering that wet etching is an isotropic process and lithium niobate (LN) crystal is anisotropic, wet etched LN structures show anisotropic features. Hence, the sidewalls of wet etched ridge waveguides along distinct directions show different lateral etching properties. Our results show that the wet etching properties along three main crystal axes (x, y, z) show apparent differences. These results can help us to design TFLN devices based on wet etching.

We evaluate the fabrication quality of wet etching by characterizing Q-factors of x-cut TFLN microring and z-cut TFLN micro-racetrack. We fabricate these TFLN structures based on a 600-nm-thick TFLN and 300-nm etching depth. We design the x-cut TFLN microring with a 120-μm radius, top widths of 1.4 μm and 2.6 μm for bus waveguide and microring waveguide, respectively. And, we design the z-cut TFLN micro-racetrack with a radius of 120 μm and 3000-μm straight sections. Moreover, we design the top widths of bus waveguide and micro-racetrack as 1.6 μm and 4 μm, respectively.

Our measurement results show that the loaded Q-factor of the TE0 mode of the x-cut microring is 1.12 million with a minimum normalized transmission of 0.076, indicating an under coupling and an intrinsic Q-factor of 1.76 million. Furthermore, our measurement results show that the loaded Q-factor of the TE0 mode of z-cut TFLN micro-racetrack is 7.16 million with a minimum normalized transmission of 0.043, corresponding to an under coupling and an intrinsic Q-factor of 11.9 million. Moreover, we measured the Q-factors in a relatively broad wavelength range to see the distribution of Q-factors. These results show that the average intrinsic Q-factors of the TE0 mode of x-cut TFLN microring and z-cut TFLN micro-racetrack are 1.25 million and 7.52 million, respectively.

In summary, we presented a wet etching method for the nanofabrication of TFLN, facilitating the mass production of high-performance integrated TFLN devices with low cost, high reproducibility, and high throughput.

Multi-wavelength single-mode plasmonic nanolasing in an “H”-shape cavity

Fajun Xiao*

Shaanxi Key Laboratory of Optical Information Technology, School of Physical Science and Technology,

Northwestern Polytechnical University, Xi’an 710129, China

*corresponding author: fjxiao@nwpu.edu.cn

Abstract: A near-infrared multi-wavelength plasmonic nanolaser is demonstrated by inserting InGaAs/GaAs multi-quantum-disk (MQD) nanowires into an “H”-shape cavity. The nanolaser shows a low threshold at room temperature benefited from the enhanced energy transfer between the excitons and the standing plasmon waves in the “H”-shape cavity. Our design may open up exciting prospects for ultra-compact photonic integrated circuits and high-throughput biochemical sensing.

Multi-wavelength plasmonic nanolaser is central to the quest of ultradense and versatile photonic applications, ranging from the on-chip optical communication and optical data storage to biological detection.[1] Previous works have established two kinds of cavity architectures, namely metal-insulator-semiconductor[2] and plasmonic lattice[3], to realize the multi-wavelength plasmonic lasing. Nevertheless, the insufficient optical feedback and mode selection strategies result in high lasing threshold and multi-mode operation with limited spectral purity and stability. Here, we demonstrate the first multi-wavelength single-mode near-infrared plasmonic nanolaser by leveraging a nontrivial “H”-shape cavity. This nanolaser is constructed by inserting InGaAs/GaAs multi-quantum-disk (MQD) nanowires into a metallic F-P cavity consisting of the Ag nanowire pair positioned on ultra-smooth Au film. Our design is endowed with strong optical feedback to enhanced the energy transfer between the excitons of MQD nanowire and the standing plasmon waves in the cavity. More importantly, the design is featured with a large flexibility in tuning the resonance wavelength, where multi-wavelength lasing with virtues of single-mode and record-low threshold is realized at the room temperature by spectrally matching MQD nanowires of distinct emission energies with the wedge-shaped metallic F-P cavity. Our study makes the crucial step towards the multi-wavelength plasmonic nanolasers with the unique features of single-mode and low-threshold, opening up exciting prospects for ultra-compact multiplexed photonics circuitry and high-throughput biochemical sensing. We believe that our results should be of interest to a broad range

Abstract: Using a Kelvin probe force microscope with external light sources, we image surface potential shifts in the nanoscale induced by the exciton–polariton coupling of MoS_2 monolayers and the plasmoelectric effect in zirconium nitride nanodisks.

A Kelvin probe force microscope (KPFM) is one of scanning probe microscopes based on an atomic force microscope which images surface potential differences or work functions differences in the nanoscale. While some KPFMs allow scanning in vacuum or in gas-controlled environment, most of KPFM measurements have been carried out in static conditions without any external excitations. In contrast, when KPFM measurements are performed with and without light irradiation, it is possible to image light-induced carrier shift or potential shift, making KPFM a powerful tool to study various effects caused by optical excitation such as plasmonic hot carriers and photocatalysts.

In the current talk, we present our recent works in which a KPFM combined with external light sources played a major role in imaging light-induced carrier shifts in the nanoscale. The first topic is the coupling between surface plasmons and MoS_2 exciton where the coupling caused the carrier shifts in the MoS_2 monolayers to the plasmonic gold grooves[1,2]. The second topic is on plasmoelectric effect which thermodynamically generates electric potential at off-resonant wavelengths. The surface potential shifts originate by the carrier shifts from the zirconium nitride nanodisks to the ITO glass substrate [3].

Optical Interplay between Triplet-Triplet Annihilation Upconversion Systems and Plasmons: Towards Upconverted Emission Enhancement

Kosuke Sugawa, Shota Jin, and Jotaro Honda

College of Science and Technology, Nihon University, Japan
*Kosuke Sugawa: sugawa.kosuke@nihon-u.ac.jp

Abstract: We have elucidated the effect of localized surface plasmon (LSP) resonance on a complicated triplet-triplet annihilation upconversion (TTA-UC) systems and endeavored to develop high-performance plasmonic TTA-UC systems. While the enhancement mechanism resembled conventional "metal-enhanced fluorescence," some quenching mechanisms via LSP resonance unique to the TTA-UC were demonstrated.

Among various upconversion technologies, the triplet-triplet annihilation upconversion (TTA-UC) systems, composed of sensitizer and annihilator molecules, have recently gained particular attention for integrating them into solar devices, bioimaging probes, anti-counterfeiting technologies, and more. TTA-UC has several advantages, including being driven by low-photon-density light (i.e., sunlight), being composed of low-cost organic molecules, and the ability to control excitation and emission wavelengths by manipulating the combination of sensitizer and annihilator molecules. The TTA-UC system can be driven by the following mechanisms: (i) generation of triplet-excited sensitizer molecules via photoexcitation and intersystem crossing, (ii) triplet-excited energy transfer from sensitizer to annihilator molecules, (iii) triplet-triplet annihilation between triplet-excited annihilator molecules (resulting in the generation of singlet-excited annihilator molecules), and (iv) fluorescence emission from the singlet-excited annihilator molecules. However, TTA-UC technology faces several challenges for practical applications. The processes (ii) and (iii), corresponding to Dexter-type energy transfer, are typically induced by molecular collisions. Therefore, systems embeded in solid matrices, where molecular diffusion is severely restricted, often exhibit reduced upconversion quantum yields. Moreover, the absorbance at the excitation wavelength for many sensitizer molecules is relatively low. Efforts have been dedicated to overcoming these challenges through various approaches. One strategy we have explored involves integrating metal nanoparticles that exhibit localized surface plasmon (LSP) resonance into solid-state TTA-UC systems. In this presentation, we will introduce some experimental attempts related to this research.

1. Enhancement and quenching of UC emission by LSP resonance[1]

We investigated the photophysical effect of LSP resonance of metal nanoparticles on solid-phase TTA-UC thin films. The TTA-UC system was designed with silver nanoprisms (AgPRs) with edge lengths of 27 ± 5 nm (small AgPRs: SAgPRs), 44 ± 5 nm (medium-sized AgPRs: MAgPRs), and 67 ± 10 nm (large

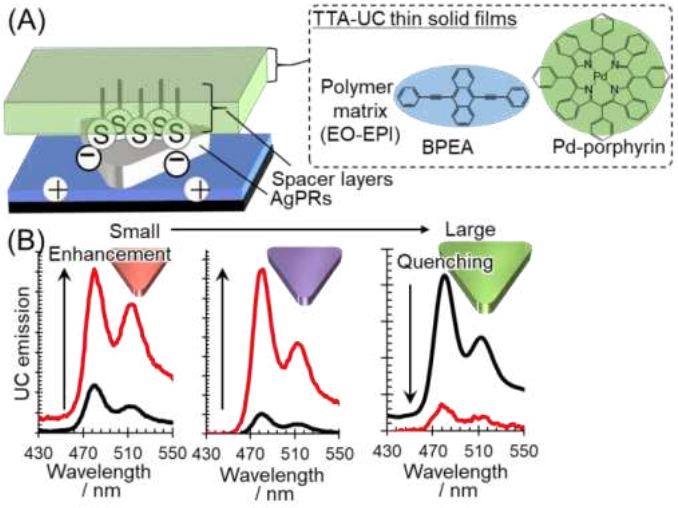

Fig. 1. (A) Schematic of plasmonic TTA-UC thin films. (B) Modification in UC emission induced by LSP resonance of AgPRs.

AgPRs: LAgPRs), inserted between a TTA-UC thin film and a quartz substrate (**Fig. 1**(A)). The TTA-UC thin film, with a thickness of 7.2 ± 0.6 nm, was composed of Pd-porphyrin as a sensitizer and BPEA as an annihilator within a polymer matrix. The UC emission (emission wavelength: 430-550 nm, excitation wavelength (λ_{ex}): 627 nm) from the TTA-UC system hybridized with SAgPRs and MAgPRs was enhanced by 3.7 times and 8.0 times, respectively, compared to the reference sample without AgPRs (**Fig. 1**(B)). This enhancement mechanism can be explained by the mechanism of "metal-enhanced fluorescence", namely, the photoexcitation enhancement of PdOEP and the Purcell effect on the singlet-excited BPEA. Conversely, the incorporation of LAgPRs significantly attenuated the UC emission. This can be attributed to the elevated radiative decay rate from the triplet-excited PdOEP caused by LAgPRs, which hinders the energy transfer from PdOEP to BPEA.

2. Optimal distance between TTA-UC thin films and AgPRs[2]

In "metal-enhanced fluorescence" by LSP resonance, the enhancement is highly sensitive to the distance between metal nanoparticles and fluorescent molecules. We investigated the optimal distance between metal nanoparticles and TTA-UC thin films for the efficient enhancement of UC emission. As shown in **Fig. 2**(A), we inserted alternating multilayer films made of polyethyleneimine and polystyrene sulfonate between AgPRs inducing the photoexcitation enhancement of sensitizer (PdOEP) and the TTA-UC thin solid films. The thickness of the multilayer films, prepared by the layer-by-layer approach, can be controlled on the nanometer scale. The maximum enhancement of UC emission was achieved when the distance between the TTA-UC thin film and AgPRs was 12.6 nm (**Fig. 2**(B)). This distance was considerably larger than the optimal distance (2.1 nm) for conventional metal-enhanced fluorescence using rhodamine 6G. This result suggests a significant quenching phenomenon induced in the TTA-UC mechanisms when AgPRs and TTA-UC thin films are in close proximity. From several experiments, we confirmed that AgPRs (or their LSP resonance) significantly quenches the triplet-excited DPA. This was verified by the fact that the triplet-excited lifetime of DPA ($\tau_{T,AgPRs}$) in the presence of AgPRs was considerably shorter than that in the absence of AgPRs (τ_T) as AgPRs and TTA-UC thin films approached each other (**Fig. 2**(C)). The shortened lifetime of triplet-excited DPA inhibited TTA (**Fig. 2**(D)), resulting in a significant attenuation of UC emission.

Abstract: We report strong interactions between quasi-bound states in the continuum formed in silicon-on-calcium-fluoride wafers and molecular vibrations. Owing to the small losses and strong optical confinement, we demonstrate silicon-based surface-enhanced infrared absorption with a large enhancement factor and sensitivity at the monolayer level.

Material-specific molecular vibrations and phonons in the mid-infrared regime are fundamental phenomena in analytical chemistry [1] and are often used to identify structural information about molecules, including chemical bonds and configurations [2]. Although its cross section exceeds that of the Raman scattering process, the absorption cross sections of molecular vibrations in infrared spectroscopy are still small owing to the small light-molecule interactions, which pose significant difficulties when detecting small amounts of molecules or thin-film adsorbates. Surface-enhanced infrared absorption (SEIRA) spectroscopy is a technique that can enhance the sensitivity of molecular absorption based on optical resonances and their strong interactions with nearby molecules. However, the large optical ohmic loss and collisional damping of metals remain obstacles in practical sensing devices. To overcome this challenge, we focus on all-dielectric nanostructures that realize diverse tunability of optical properties based on their Mie resonances, small material absorption losses, and low-cost fabrication. In particular, a specific resonant state of light called quasi-bound state in the continuum (qBIC) in an arrayed nanostructure allows for strong light confinement with high Q factors and resonant enhancement of the electric field [3], which is experimentally obtained by breaking the symmetry of the unit structure. Thus far, we have shown tailored coupling between qBICs and molecular vibrations from weak to strong coupling regimes and demonstrated an enhanced molecular signal at a specific asymmetry parameter [4]. The coupling conditions of the qBIC-molecule system were tuned by simply changing the asymmetry parameters, whereas the upper limits of the Q factors were determined by the downward leakage losses into the high-index substrate of the silicon-on-insulator wafer, which also limited the sensitivity of the molecular absorptions.

In this work, we report interactions between qBICs formed in Si on CaF_2 wafers and molecular vibrations. Owing to the smaller losses and stronger optical confinement, we demonstrate a silicon-based SEIRA with large enhancement factors. Figure 1(a) shows the proposed silicon metasurface. By changing the lengths of the upper and lower nanorods to $L + 2\Delta L$ and $L - 2\Delta L$, respectively, the symmetry of the unit structure was broken (asymmetry parameter $\alpha = 2\Delta L/L$), controlling the amount of radiation loss of the resonance mode emitted to the far-field. For the fabrication, a 500 nm thick amorphous Si layer was first deposited by radiofrequency sputtering on a CaF_2 substrate. The pair-rod nanostructures were then patterned using electron-beam lithography and deep silicon etching. Figure 1(b) shows a representative scanning electron microscopy (SEM) image of a fabricated metasurface with asymmetry parameter α = 9%. Next, polymethyl methacrylate (PMMA) of different thicknesses was spin-coated onto a bare BIC metasurface to spatially and spectrally couple the C=O stretching modes (approximately at 5.8 μm) of the PMMA molecules and qBIC resonance modes. The enhanced molecular

signal was obtained by calculating the transmission difference with and without PMMA molecules, as shown in Figure 1(d). We found that only the 6.2 nm PMMA thin film showed a clear enhanced molecular signal. The SEIRA enhancement factor given by $(I_{SEIRA}N_{bulk})/(I_{bulk}N_{SEIRA})$ [5], where I_{SEIRA} and I_{bulk} are the vibrational signals from a metasurface with and without nanostructures, respectively, and N_{SEIRA} and N_{bulk} are the respective numbers of molecules contributing to vibrational signals, was calculated to be over 10^2. This result was roughly comparable to that obtained for typical metal nanostructures. We attribute this high enhancement factor to the low losses of the silicon nanostructures on the CaF_2 substrate and the large near-field enhancement effects derived from qBIC resonances, opening a route toward realizing highly sensitive surface-enhanced infrared spectroscopy without using metals.

NanoOptoCraft: plasmonic MEMS, nanoscale patterning, and optical low-loss film

K. Yamaguchi[1*]

[1]Institute of Post-LED Photonics, Tokushima University, Japan

Abstract: The NEMS drives versatile plasmomechanical devices by utilizing MEMS techniques for precise spatial control. Adiabatic plasmon wires enable manipulation of nanoscale gaps. Alternatively, narrow gaps can be realized through single-deposition techniques using stencil lithography. As a common approach, the development of low-loss single-crystalline metal films promises advancements in nanooptical devices.

Surface plasmons (SPs), which are the collective oscillations of conduction electrons, play a pivotal role in manipulating light at the nanoscale through metallic nanostructures. This study explores the potential of nano-electro mechanical systems (NEMS) technology in the development of novel multifunctional plasmomechanical devices[1-4]. Initially, we demonstrate the applicability of conventional micro-electro mechanical systems (MEMS) techniques to create plasmonic structures by utilizing metallic slits modulated by an actuator to tune the surface plasmon resonance and optical phase with voltage control[1].

Our approach extends control to single nano-order motion and space, achieved through adiabatic plasmon wires consisting of a pair of simple 50-micrometer-long nano-wires. This allows manipulation within gaps ranging from several hundred to several tens of nanometers. The proposed plasmomechanical devices exhibit versatility, serving as surface-enhanced Raman scattering (SERS) sensors, gas sensors[2], nano-lenses[3], and components in a combined fiber system.

In parallel, a fabrication method was established for metal nanopatterns with narrow gaps, utilizing a single vacuum deposition method with a hexagonal lattice period stencil. This approach simultaneously fabricates disks, rings, and holes of varying sizes and spacings, enhancing the detection patterns for unknown molecules. This method offers flexibility for wearable biosensors by applying sequential nanopatterns to the films.

To enhance the practicality of these devices, we present the development of a low-loss single-crystalline silver and gold film[5-8]. This achievement was realized through the application of epitaxial growth and film-transfer techniques, offering potential advancements in the field of nano-optical devices with improved miniaturization and power efficiency[7, 8].

Abstract: A metasurface with a unit cell composed of a cluster of four hollowed cuboids to work at the VIS spectrum is proposed. By shifting the hole asymmetrically, a qBIC resonant mode that is very robust to perturbations of the cuboid structure is produced thanks to its particular electric field profile.

Metasurfaces have emerged as a promising platform for engineering BICs. In these structures, symmetry-protected BICs are eigenmodes situated above the light cone, possessing different symmetries than the incoming wave, rendering them unexcitable within the continuum of radiation modes. By introducing some kind of perturbation, pure BICs transform into quasi-BICs with a finite lifetime, narrow linewidth and arbitrarily high radiative Q-factor. Indeed, quasi-BICs have been intensely investigated in dielectric metasurfaces with symmetry breaking, such as by introducing geometrical asymmetry or using anisotropic materials [2]. Although in most cases the resonant near fields are mainly confined to the interior of the high-index subwavelength scatterers, thus providing limited light-matter interaction with the surrounding material, it is still feasible to achieve interaction at the interface, allowing for biosensing and integration with 2D materials [3], as well as in slotted regions [4]. Furthermore, it has been recently reported that asymmetric dielectric particles arranged in clusters can be used to achieve greater flexibility in obtaining the desired near-field configuration [5] and enhancing the sensing capabilities for refractometry [6]. The operation principle in the latter case is based on plasmon-like surface waves, which are delocalised over a wide area to provide a large interaction volume with the matter but are excited in an all-dielectric structure.

In this work, we investigate a GaP metasurface supporting delocalised quasi-BIC modes. The metasurface comprises a periodic array of hollow nanocuboids patterned on a glass substrate and designed to produce ultra-high Q-factor delocalised resonances. The authors previously demonstrated this structure for toroidal responses [7,8], but the cluster arrangement has advanced features. The perturbed quadrumer arrangement retains C4v symmetry, thus allowing for polarization-independent optical response for normally incident planewaves [9]. By shifting the cuboids or a hole in the middle asymmetrically, the Brillouin zone is doubled producing a qBIC resonant mode with an antiferroelectric field configuration, which is very robust to large perturbations of the cuboid structure thanks to its particular electric field profile [9]. In addition, the resonant mode dispersion is investigated, revealing interesting features, such as low birefringence along the ΓM contour of the metasurface Brillouin zone and very low dispersion for the TM polarization along the ΓX direction [9]. Finally, this metasurface operates close to 785 nm, which is highly relevant for Raman spectroscopy.

(a) (b) (c)

Figure 1. Field structures for the investigated electric dipole mode in a metasurface with a single cuboid unit cell: magnitude of the (a) in-plane and (b) out-of-plane electric field vector. The arrow plot in both cases shows the distribution of the inplane magnetic field. (c) Band diagram of the investigated supermode along the ΓX and ΓM contour of the irreducible Brillouin zone. For oblique incidence (off-Γ point) the band splits in two branches corresponding to different polarization. The insets show the norm of the electric field calculated at $\{kx = 0.06, ky = 0\}$ and $\{kx = 0.06, ky = 0.06\}$ in units of $(2\pi/p)$ [9].

Abstract:

We fabricated the two-dimensionally chiral Au nano-windmills (Au-NWs) by electron beam exposure and lift-off process on the Fabry-Pérot nanocavity of TiO_2 on Au-film. The chiroptical responses on Au-NWs with different geometric structures coupled with nanocavity in far and near fields are discussed.

Introduction

Many studies have investigated the interactions between circularly polarized light (CPL) and chiral molecules. Localized surface plasmon resonances (LSPRs), which are collective oscillations of conductive electrons of the metallic nanostructure, confine propagating light near the nanostructures and enhance the localized electric field (near field). Recently, it has been reported that a modal coupling between the LSPR and Fabry-Pérot (FP) nanocavity modes induces the enhancement of the near-field intensity and exhibits the homogeneous near-field distribution over LSPR particles.[1-3] Theoretical and experimental studies have shown that the interaction between plasmonic nanostructures and incident light could generate twisted near fields on the nanostructures[4-7]. In this study, we fabricated the two-dimensionally chiral Au nano-windmills (Au Au-NWs) on the FP nanocavity of TiO_2 on Au-film. We discussed the chiroptical responses on Au-NWs coupled with nanocavity.

Experimental

The Au nanostructures were fabricated by using electron beam (EB) exposure and lift-off techniques on SiO_2 substrate coated with the titanium oxide (TiO_2/SiO_2) and TiO_2 coated Au/SiO_2 ($TiO_2/Au/SiO_2$). The TiO_2 thin film with a thickness of 170 nm was deposited by an atomic layer deposition reactor at 300 °C. $TiCl_4$, and H_2O were used as precursors for the deposition. A ZEP520A (Zeon Co.) was employed as a positive resist. This study used a high-resolution EB system operating at 125 kV for sample fabrication by changing the exposure dose. After development, a 2-nm-thick titanium layer was first deposited via sputtering as an adhesive layer, followed by a 30-nm-thick Au film deposition. Lift-off was performed by successively immersing the sample in the resist remover (ZDMAC, Zeon Co.), acetone, methanol, and ultrapure water. Morphologies of nanostructures were analyzed by field-emission scanning electron microscopy (FE-SEM). Electromagnetic simulations were performed with the finite-difference time-domain (FDTD) solutions software packages (Lumerical, Inc.) to simulate the far-field reflection spectra and the electric field distribution in the near field. A plane wave light source circular polarization was irradiated to structures from the air side. Perfectly matched layer boundary conditions were imposed in the light propagation (z) direction. In the plane perpendicular to the light propagation (x and y) direction, periodic boundary conditions were applied on each boundary.

Results and Discussion

Figures 1a-c show the SEM images of three types of Au-NWs: Au-NW1, Au-NW2, and Au-NW3. Because The structural line width of Au-NW3 was broader than that of Au-NW1, the geometric two-dimensional chirality of Au-NW1 was clearer than that of Au-NW3. Figures d and e depict the near-field distribution on Au-NW1 on

TiO_2/Au/SiO_2 under left and right circularly polarized light irradiations calculated by the FDTD numerical simulation. The near-field distribution showed different responses under left and right CPL irradiations based on the two-dimensional chirality of the Au-NW1. We discuss the far-field and near-field spectra of the Au-NWs coupled with the nanocavity.

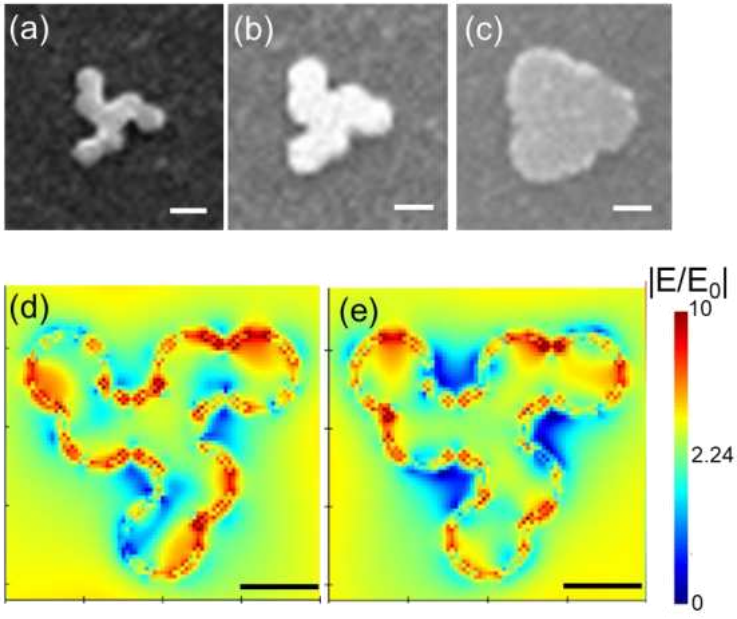

Figure 1. (a-c) FE-SEM images of Au-NW1 (a), Au-NW2 (b), and Au-NW3 (c). The scale bars indicate 200 nm. (d, e) Near-field intensity distributions on Au-NW1 on TiO_2/Au/SiO_2 under left (d) and right (e) CPL. The scale bars indicate100 nm.

Abstract: Carbon nanotube (CNT) forest metamaterials grown on nano-spherical substrates show flat reflectance in the visible range, showing potential for solar absorption and photonic computing applications through controlled electromagnetic resonance and isotropic optical characteristics.

Metamaterials have emerged as a frontier in manipulating electromagnetic waves, with carbon nanotubes (CNTs) representing a novel class of metamaterials that harness the unique electronic and optical properties of CNTs for advanced photonic applications. Recent progress in nano-scale lithography, such as UV and electron beam lithography, has paved the way for developing highly efficient and functional devices composed of nano-scale metamaterial circuits for energy conversion and computational applications. These advancements are underscored by the ability of metasurface to induce electromagnetic resonance at the nanoscale, which is critical for the miniaturization and enhancement of device performances. The precision offered by top-down lithographic techniques is approaching physical limits, yet the demand for finer patterning continues to grow. In this scenario, carbon nanotubes (CNTs) stand out due to their intrinsic one-dimensional structure and self-organized pattern formation, which open new avenues for metamaterial design in the optical range. As depicted in Fig. 1, our work encompasses the integration of fine patterning through Focused Ion Beam (FIB) micro-fabrication and the exploration of bottom-up processes that lead to self-aligned and self-assembled metamaterials. These processes yield CNT metamaterials with distinctive photonic properties such as enhanced infrared absorption, tunable color profiles, and VIS-IR wavelength selectivity. The figure displays the versatility of CNT forest metamaterials, highlighting the precise control of growth density and alignment critical for large-scale applications in devices such as solar heat absorbers with tailored wavelength selectivity.

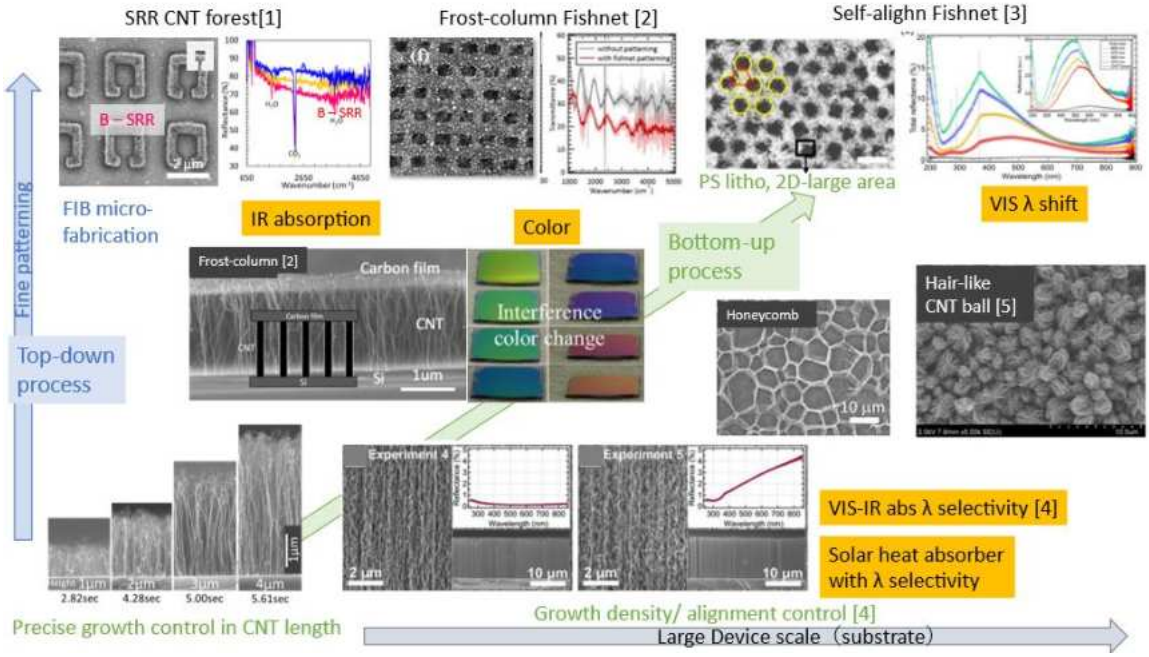

Figure 1. Fabrication of carbon nanotube forest metamaterials and their optical properties. [1-5]

CNTs were grown on FeOx-ZrO_2 MARIMO (Micro/Mesoporous Architected Roundly Integrated Metal Oxide) nano-scale spherical substrates in the thermal CVD process. Morphological characterization of the resultant metamaterials was conducted using SEM and Raman spectroscopy to evaluate the vibrational modes, indicating the quality of the CNTs. The optical properties were studied through spectrometry to measure the total and diffuse reflectance across the visible spectrum.

The SEM images (Fig.2 (a)) reveal a consistent and dense forest-like arrangement of CNTs with all-angle alignment attributable to the nano-spherical substrate geometry. This configuration contributed to flat reflectance spectra within the visible region (Fig.2(b)). The Raman spectrum in Fig.2(c) displays distinct G, D, and 2D bands, confirming high-quality multi-walled CNTs of G/D ratio ~ 2. Such a flat reflectance spectrum and the uniformity of CNT alignment indicate the material's potential for selective electromagnetic resonance control, a key factor for enhancing the efficiency of photonic devices.

The all-angle alignment of CNTs on spherical substrates exhibits the potential for isotropic optical behavior, a highly sought-after feature in photonic materials. This could lead to advancements in the design of solar wave absorbers with improved efficiency, benefiting solar power technology. Additionally, the uniform photonic response holds promise for the burgeoning field of photonic computing, where waveguides and switches require precise light control.

Abstract: We study dense, spherical clusters made of hundreds of randomly packed plasmonic nanoparticles. We find that, using a spatial dispersion formalism, these clusters can be described as much simpler equivalent, homogeneous spheres, revealing the presence of artificial magnetism, but also of a longitudinal mode localized at the cluster borders.

Clusters made of small, plasmonic resonators, like gold or silver nanoparticles, have been an extensive source of research in nanophotonics, both before and after the emergence of the concept of metamerials. Within the field of metamerials, such clusters have been put forward as nanosize building blocks, or "meta-atoms", which could be fabricated using bottom-up, chemical techniques such as self-assembly and colloidal engineering [1]. Research efforts have for example focused on fabricating clusters able to generate a magnetic response, in order to assemble them into 3D metamaterial structures exhibiting artificial magnetism at optical frequencies [2]. Also, more recently, efforts have been devoted to fabricating clusters which could act as "Huygens scatterers," i.e., particles that scatter light with extreme asymmetry, only in the forward direction, when illuminated by a plane wave [3,4]—a feature that could lead to the obtention of metasurfaces with extraordinary capabilities to manipulate wavefronts.

In this work [5], we study the latter case of spherical clusters, made of hundreds of small plasmonic nanoparticles (here, gold nanoparticles with radius 7 nm), randomly packed together with a variable particle density or volume fraction f. Optical properties of interest, like the scattering of an incoming wave onto the cluster, and the resulting Mie coefficients, can be very accurately calculated by means of numerical simulations of like T-matrix techniques. However, such calculations become highly computationally-intensive when the number of particles in the cluster reach a few hundreds, as in realistic situations. Moreover, results from T-matrix computations do not easily lend themselves to any physical interpretation of the behavior of the internal medium composed of the plasmonic particles.

We therefore set to determine whether it is possible to describe the electromagnetic behavior of such dense plasmonic clusters with effective parameters carrying out a more intuitive picture, like electric permittivity, magnetic permeability and so on. The so-called "homogenization" of dense particulate composites is a notoriously difficult issue. No mixing law is known to efficiently describe the resulting homogenized medium except for very dilute cases (f below a few percents), and the current state of theory does not even provide clear criteria to delineate when homogenization is possible or not.

To address this issue, at least empirically, we computed the multipolar response of clusters up to 80 nm in radius and up to a particle density fraction f=44% using high-precision T-matrix calculations. Within the range of explored sizes, we find that scattering from the clusters involves an overall electric dipole Mie term, magnetic dipole, electric quadrupole, magnetic quadrupole; higher order multipoles remain insignificant. Then, we compared the obtained results with the multipolar response calculated for spheres of the same radius, but filled with a fictitious homogeneous medium. The values of the constitutive parameters (like the electric permittivity)

of the fictitious medium inside the homogeneous spheres were adjusted until an accurate agreement between the Mie coefficients of the homogeneous sphere and those of the real cluster was found, through a careful fitting procedure. When such a fit was obtained, we considered that the homogeneous spheres qualified as electromagnetic equivalents of the clusters, at least from the point of view of their scattering properties.

For clusters with small particle densities ($f < 0.15$), it was enough to use an equivalent medium with an effective dielectric permittivity only to reproduce the scattering from the clusters. But for higher densities, we found that other parameters need to be introduced. This is obviously due to the intricate, multiple interparticle couplings occurring in these systems, giving rise to "spatial dispersion" phenomena. Spatial dispersion arises frequently in complex systems, when the response of the medium becomes non-local, i.e., the polarization at one spatial point depends on the value of the electromagnetic field over a more or less spread area around it. Using a weakly spatially dispersive description for the internal medium of the homogeneous spheres, we found that it was indeed possible to successfully fit the scattering properties of clusters even in the densest cases, with f as high as 44% [5].

This weak spatial dispersion description involves three intuitive effective parameters characterizing the equivalent medium, with a transparent physical significance: -i- an electrical permittivity as in the dilute cases; -ii- a magnetic permeability, confirming that artificial magnetism emerges naturally in dense random clusters, due to particle couplings without the need of a specific ordering; -iii- a third parameter related to longitudinal waves in the system. The appearance of the latter is due to the fact that spatially dispersive systems not only support standard transverse electromagnetic waves, but also longitudinal ones; the inclusion of the longitudinal mode is required to obtain a proper fitting of the clusters. Our study shows that the longitudinal mode is strongly localized at the borders of the clusters [5].

Longitudinal modes have been largely ignored in the description of metamaterials with artificial magnetism (self-assembled or not), but this is unjustified on theoretical grounds. Our description, inclusive of the longitudinal mode, should be seen as an attempt at providing a better and more consistent approach, but still easy to understand physically.

In conclusion, our work [5] offers the opportunity to reproduce the electromagnetic properties of dense clusters with simpler equivalent, homogeneous spheres, over a wide range of particle densities. Such equivalence can be put to use when designing e.g. metasurfaces or other structures involving plasmonic clusters, for example by substituting them with the equivalent spheres in simulation steps ahead of fabrication, thereby drastically cutting down computational costs and allowing to explore a wider range of possible designs.

Optical properties and luminescence control of Ag/TiO_2 stacked metasurfaces using out-of-plane quadrupole resonance

T.Y. Lo[1], S. Murai[1*], and K. Tanaka[1]

[1]Graduate school of Engineering, Kyoto University, Japan
[*]corresponding author: murai@dipole7.kuic.kyoto-u.ac.jp

Abstract: In this study, we experimentally and numerically elucidated the optical properties of a bilayer metasurface system exhibiting out-of-plane quadrupole resonance characteristics and demonstrated the potential for bilayer metasurfaces system in directional light source application.

1. Introduction

Metasurface stickers, embedding periodic nano-structures into transparent elastomers, offer advantages such as easy attachment and detachment, even from material surfaces where direct fabrication of metasurfaces is challenging. In previous research, by utilizing the stacked metasurfaces, the fluorophore layer sandwiched between two metsurfaces can simultaneously achieve the highest efficiency in absorption enhancement and light extraction within individual metasurface[1]. In this work, we employed the out-of-plane quadrupole resonance exhibited by the first-layer Ag sticker to enhance the interaction between the first and second layers[2]. By controlling the interlayer distance, we elucidated the variations in their optical properties. Finally, we demonstrated the unique directional photoluminescence enhancement behaviour originated from the interaction of out-of-plane quadrupolar mode inside the two layers and provided the insight of their application in directional light sources.

2. Results and Discussion

Fig.1 illustrates the out-of-plane electric field distribution in the quadrupole resonance region for varying interlayer distances between two metasurfaces. As the two layers approach to each other, the quadrupole resonance of the first layer gradually extends into the underlying TiO2 metasurface. This out-of-plane oscillating electric field (Ez) forms as a new excitation source, inducing in-plane magnetic SLR within the bottom TiO2 metasurface[Fig.1(c)].

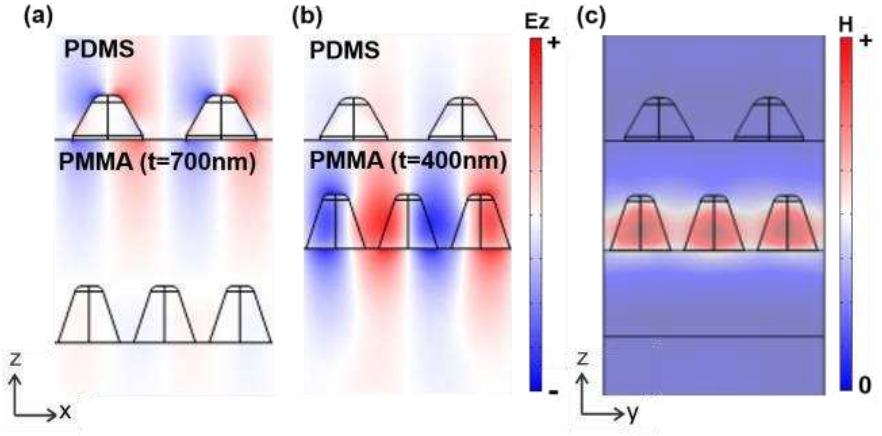

Fig 1. Numerical simulations of the out-of-plane electric field component (Ez) and magnetic field (H) distributions of Ag/TiO2 stacked metasurfaces separated by (a) 700 nm, (b and c) 400 nm.

Fig.2(a-b) shows the directional photoluminescence enhancement of the bilayer metasurfaces system with varying interlayer distances. As shown in Fig.2(b), with decreasing interlayer distance, the photoluminescence enhancement factor significantly and monotonically increases, while the directionality gradually converges towards ±5 degrees. This behavior can be attributed to the combined effect of the reduction in interlayer distance, leading to enhanced absorption in the bottom TiO2 metasurface, multiplied by the intensified field strength induced by mSLR.

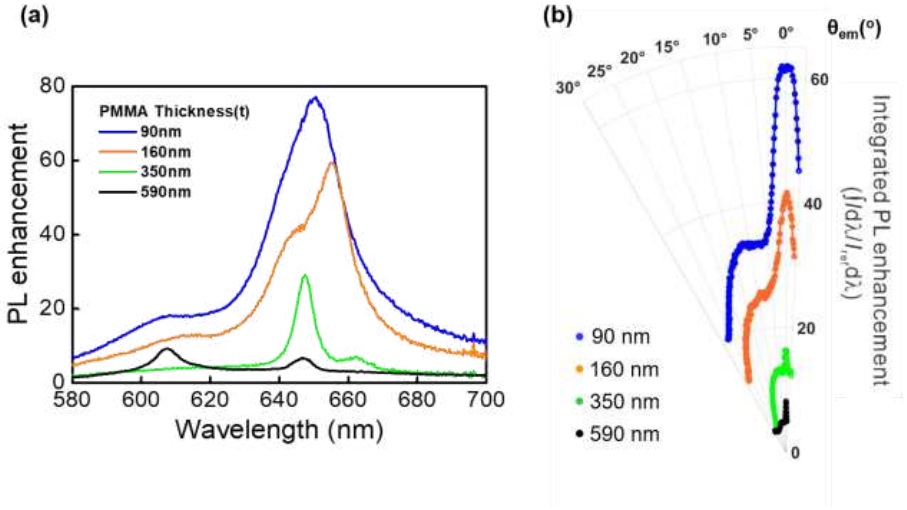

Fig 2. (a) PL enhancement spectra of Ag/TiO2 stacked collected at θem = 0 o. (b) PL enhancements calculated from the spectrally integrated PL intensity for the Ag/TiO2 stacked metasurfaces with various interlayer distances presented in a polar plot.

3. Conclusion

This study, for the first time, demonstrates both experimental and numerical simulations results showcasing the optical characteristic variations of bilayer metasurfaces at various interlayer distances. It also provides insights into their application in directional photoluminescence enhancement for the combination of the layered emitters.

Abstract: In the evolving field of nanophotonics, the study of gain-enhanced metal nanoparticles presents numerous theoretical and practical possibilities. In recent years, our research group has focused on centrosymmetric gain-enhanced nanoparticles, exploring their dynamic behaviors and the intricate interplay between quantum and electromagnetic phenomena.

These systems present a largely unexplored field ripe with potential and offering a wealth of possibilities, both theoretically and in application.

In a pivotal work [1], we identified substantial behavioral changes in single metal nanoparticles within active gain mediums, particularly across the emission threshold. The interplay between local field enhancement and the corresponding depletion of population inversion, in fact typically leads to a Spatial Hole Burning (SHB) driven mode-cascade which is a phenomenon as fascinating as difficult to pinpoint in a formal theoretical framework. Notably, this cascade is absent in small nanoshells whose single-mode emission properties can be completely described with a quasi-static time-dynamic model [2].

The electromagnetic behavior of nanoshells in emissive regimes is however just one aspect of their intriguing properties. Even below the emission threshold, the ability of gain to locally amplify plasmonic fields renders these nanoparticles suitable for a wide array of applications. For instance, in this work [3], we demonstrated how the integration of externally pumped gain elements intrinsically alters the behavior of nanoshells in an optical tweezers configuration, showcasing their diverse functional capabilities. It's important to note that the conversion of electromagnetic energy into heat, a critical factor in evaluating the effect of an externally pumped nanoshell in an optical force field, was not considered in that particular study. However, we have made significant progress in this area and will be presenting some new results that delve into this aspect.

Finally, our earlier models within the quasi-static limit, while insightful, faced limitations when applied to larger particles and multi-modal phenomena such as SHB-driven mode cascades. To address this, we have developed a new time-dynamical model based on Mie Vector Spherical Harmonics [4], representing a significant advancement in the study of gain-enhanced nanoparticles. Although this new approach does not fully describe the emission regime yet, it does allow us to predict the transient states preceding emission and represents an essential step forward in the direction of a model able to adequately describe the full electromagnetic

phenomenology of these systems. Moreover, by means of this approach we have also been able to unravel a new phenomenon occurring in the sub-emissive regime: when gain is injected at the desired frequencies, higher-order and less intense modes can be selectively enhanced, allowing for a tailored spatial shaping of the electromagnetic field around the particle.

The ongoing exploration of gain-enhanced metal nanoparticles is revolutionizing the field of nanophotonics, centrosymmetric gain-enhanced nanoparticles hold promise for diverse applications. Our studies contribute to a deeper understanding of their fundamental properties and practical applications. From enhancing the operational dynamics in optical tweezers to developing advanced theoretical models. As we continue to push the boundaries of this research, we anticipate unlocking even more of their untapped potential, leading to innovative solutions in nanotechnology and beyond.

Abstract: Manipulating ultrashort laser pulses unlocks versatile applications in laser processing, quantum state encoding, ultrafast bio-chemical reactions, and optical communication. Our study demonstrates femtosecond-scale pulse shaping with silicon Huygens' metasurfaces, enabling control over pulse dynamics. Our experimental results align closely with simulations, underscoring precise pulse manipulation capabilities.

The precise tailoring of ultrafast pulse shaping holds great promise across various domains, from laser material processing and quantum state encoding to ultrafast bio-chemical reactions and optical communication [1,2]. Optical metasurfaces, which can exert precise control over incident light fields, have emerged as a powerful tool for pulse shaping [3]. In recent years, low-loss resonant dielectric Huygens' metasurfaces gained substantial recognition for their capacity to precisely adjust the phase of incident light while maintaining nearly 100% of its original intensity [4]. In this study, we demonstrate the ability to shape pulses at femtosecond time scale using semiconductor Huygens' metasurfaces integrated into the Fourier plane of a 4-f system as shown in Figure 1. Our approach leverages spatially variant silicon metasurfaces at the Fourier plane of the setup, allowing us to selectively tune the phase and amplitude of the individual frequencies of an incident Gaussian pulse. The metasurfaces consist of locally periodic square arrays of silicon nanocylinders featuring a spatial variation of their geometric parameters (lattice constant and radius). They were designed and fabricated to induce three distinct temporal effects on the input pulse: pulse splitting, pulse stretching and pulse rectification. We utilized a Ti:Sa laser in combination with an optical parametric oscillator to generate ultrashort Gaussian input pulses at the central wavelength of 1500 nm and detected the output pulses by using the frequency-resolved optical gating method. Furthermore, the complex transmission of the fabricated metasurfaces was investigated by imaging interferometry. Figure 2 illustrates both simulated and experimental pulse profiles for both input and output signals. To demonstrate pulse stretching, we successfully fabricated a metasurface that stretches a Gaussian pulse width from 229 fs to 489 fs. In the case of pulse splitting, we fabricated a metasurface that transforms a single Gaussian pulse into two distinct Gaussian pulses with a separation of 524 fs. Finally, for pulse rectification, we have observed a nearly vertical rise and fall in temporal intensity profile in experiment although the consistency of the peak amplitude over time remains a challenge. This inconsistency can likely be attributed to fabrication errors in the diameters of the nanocylinders and surface inhomogeneities. Overall, the pulse characteristics observed in these experiments matches our numerical simulations, confirming the

metasurfaces' ability to generate desired pulse shapes. Furthermore, the resonant features of pulse shaping Huygens' metasurfaces can unlock additional opportunities for nonlinear optical effects, excitation of emissive materials, regarding pulse-shaping without the need for spectrally spreading the pulse [4] and spatiotemporal shaping [1].

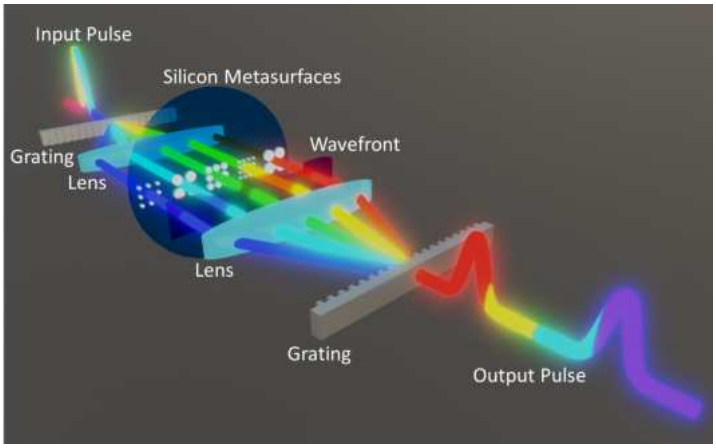

Figure 1 An artist's impression of a silicon Huygens' metasurface demonstrating pulse splitting effect using a 4-f configuration.

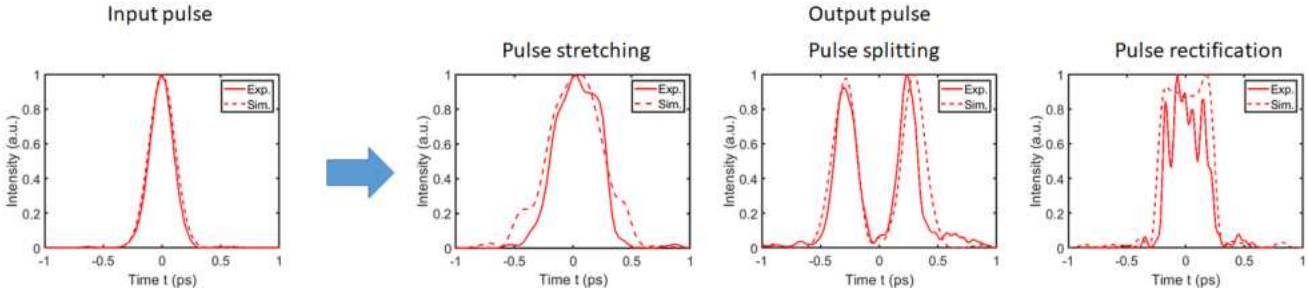

Figure 2 Input and output pulse profiles both in simulation and experiment. Numerical calculations of the pulse profiles shaped by the silicon metasurfaces were performed using COMSOL Multiphysics. Experimental data was acquired and analyzed using a standard frequency-resolved optical gating method integrated into a pulse detection system after the 4-f optical setup.

Abstract: The bottom-up fabrication of metasurfaces with correlated disorder on large surfaces permits excellent control over light propagation characteristics and unlocks applications in the context of light management in solar cells. This contribution comprehensively describes the design, fabrication, and characterization of such devices with increasing complexity.

Metasurfaces with correlated disorder can be fabricated on large scales using a dedicated bottom-up process. Here, PMMA nanoparticles with predefined size statistics are immersed into a solution of a given ionic strength. By suitably functionalizing ordinary substrates so that their surfaces are weakly positively charged, the dip-coating of the substrate into the applied solution allows the nanospheres to be deposited onto it at a controllable density into a pattern characterized by nearly-hyperuniform disorder [1]. These hyperuniform structures are characterized by a suppressed variation of the particle density, like in a periodic structure. However, at the same time, they have the same properties in all directions at short distances, so they respond in an isotropic manner. Their scattering response is structured, their response is wavelength insensitive, and they can be designed deterministically. Metasurfaces made from high-index discs can be fabricated when using these arrays of PMMA nanospheres as an etch mask for an underlying high-index thin film. Then, additional degrees of freedom come into the game by controlling the multipolar contribution of the scattering characteristics of the individual discs.

In a sequence of contributions [2-5|, we have demonstrated the basic optical function of such disordered metasurfaces when designed to operate in the Huygens regime, i.e., when the induced electric and magnetic dipole moments are suitably balanced to suppress back-reflection. That property, combined with the vanishing structure factor of the hyperuniform interfaces, which suppresses scattering in the forward direction, and the possibility to fabricate these metasurfaces on large scales, at low costs, and in a short amount of time, makes them appealing structures for an integration into a solar cell with the purpose of light management. In essence, these metasurfaces suppress reflection and scatter light into oblique directions to maximize the absorption in the solar cell.

In our latest efforts [6], we have demonstrated that by combining these hyperuniform metasurfaces with slightly more conventional graded anti-reflection coatings, we can make the best out of the two worlds and suppress most optimal the spurious reflection from a solar cell and maximize the light absorption. Selected results are shown in Fig. 1. At the conference, we will provide all the details that concern the design, fabrication, and characterization of such devices and convincingly demonstrate that the chosen bottom-up fabrication route is a promising approach to reach structures that serve most optimal their anticipated purpose.

Creating Meta-Atoms Based on Gold Nanoparticle Assemblies on Polymer Microspheres

H. Yabu[1*]

[1]Advanced Institute for Materials Research (WPI-AIMR), Tohoku University, Japan
[*]corresponding author: hiroshi.yabu.d5@tohoku.ac.jp

Abstract: Fabrication of polymer microspheres densely accumulated with noble metal nanoparticles on their surface, and their applications as sensors and in metamaterials will be shown.

Particles that accumulate noble metal nanoparticles on the surface of dielectric particles can become 'meta-atoms', the building blocks of metamaterials that utilize plasmon absorption with independent of incident angle of light. Efforts have been made to realize such meta-atoms by electroless plating of silver on the surface of dielectric particles like silica or polymer microspheres, or by adsorbing noble metal nanoparticles such as gold. However, challenges existed in controlling nanoparticle size, as well as their arrangement and density.

We have reported a method for fabricating polymer microspheres with nanostructures mixing various types of polymers, using the Self-ORganized Precipitation (SORP) method, which involves adding a poor solvent to a polymer solution and removing the good solvent by evaporation to obtain a dispersion of polymer microspheres. When polystyrene (PS) and amino-terminated polybutadiene (PB-NH2) were mixed and fabricated using the SORP method, core-shell type microspheres were obtained[1], with positively charged PS as the core and PB-NH2 as the shell (Figure 1)[2]. Subsequently, by mixing a dispersion of uniformly sized gold nanoparticles, composite microspheres were obtained, where the gold nanoparticles were densely arranged on the surface due to electrostatic interactions.

The resulting composite microspheres have been demonstrated to be applicable as dispersed surface-enhanced Raman scattering (SERS) substrates[3] for analyzing adsorbed molecules, as meta-atoms in the visible to near-infrared region[4], and as probes for antigen-antibody reactions with high optical density[5].

Aggregation of Core/Shell Quantum Rods in Composite Polymer Film for Polarization Conversion

Y. Okazaki[1*], S. Kubota[1], K. Hachiya[1], and T. Sagawa[1]

[1]Graduate School of Energy Science, Kyoto University, Japan

Abstract: In this presentation, we introduce an approach for achieving both isotropy in the absorption process (low $P_{\text{LP-Abs}}$ value) and anisotropy in the emission process (high $P_{\text{LP-Lum}}$ value) by controlling aggregation formation of luminogens in uniaxially stretched luminogen/polymer composite films.

Linearly polarized luminescent (LPL) materials are attracting attention for a variety of applications including power-saving display and anti-counterfeit printing. In general, LPL materials that exhibit large polarization degree in light emission process ($P_{\text{LP-Lum}}$) also exhibit large polarization degree in light absorption process ($P_{\text{LP-Abs}}$) due to the orientation of the electronic transition dipole moment. Therefore, from the viewpoint of efficient light energy use, achieving both isotropy in the absorption process (low $P_{\text{LP-Abs}}$ value) and anisotropy in the emission process (high $P_{\text{LP-Lum}}$ value) has been considered as a challenging issue. In this presentation, we introduce an approach for overcoming this trade-off relationship by controlling aggregation formation of luminogens in uniaxially stretched luminogen/polymer composite films.

In this study, we selected CdSe/CdS core/shell quantum rod (QD) as highly emissive LPL source. QD synthesized by hot-injection method was mixed with poly(ethylene-*co*-vinyl acetate) (EVA) in toluene and was drop-casted on a glass substrate. The obtained QD/EVA composite film was peeled off from the glass substrate, stretched uniaxially, and reattached to the glass substrate. The obtained film (LPL_{QD} film) showed red-colored strong photoluminescence (PL) under UV light at 365 nm. When the PL was observed through linear polarizer placed in parallel direction to the stretching direction, it was clearly brighter than that observed through linear polarizer placed in perpendicular direction. For the quantitative evaluation, PL spectral measurements with polarization setup were performed. The large $P_{\text{LP-Lum}}$ value (0.63) at around 640 nm was confirmed under irradiation of depolarized 450 nm light. The $P_{\text{LP-Abs}}$ value was also calculated from PL intensities excited with parallel and perpendicular linearly polarized 450 nm light. Interestingly, the calculated $P_{\text{LP-Abs}}$ value (0.32) was clearly smaller than the $P_{\text{LP-Lum}}$ value (0.63). To investigate this phenomenon, we studied the effect of excitation wavelength on the PL peak position. All PL peak positions showed same wavelength even under different excitation wavelength. In addition, detection energy dependence on PL excitation (PLE) spectra was also studied and was no significant dependence was observed. These results indicate that the energy transfer between aggregated QRs in LPL_{QD} film involve in the observed polarization conversion phenomenon.

In this presentation, we will discuss about the detail mechanism of polarization conversion phenomenon observed in LPL_{QD} film.

Abstract: Recently, we developed Mie resonant crystalline Si nanospheres in the size range of 100-300 nm dispersible in solution. Colloidal dispersions of Si nanospheres enable the formation of functional composites with different materials for photonic applications utilizing enhanced light matter interactions.

High index dielectric nanoparticles exhibit electric and magnetic Mie resonances and provide opportunities for manipulating and enhancing the light-matter interactions. The dielectric nanoantennas have been usually fabricated by electron beam lithographically on the solid substrate and thus the applicability of the solution-based assembly techniques have been limited compared to the plasmonic counterparts since gold and silver colloids that are commercially available.

In this talk, we present development of colloidal dispersion of perfectly spherical silicon nanoparticles dispersible in alcohol by thermal disproportionation of silicon monoxide at very high temperature (>1450°C) followed by chemical etching. We also developed monodisperse silicon nanoparticles by applying density gradient centrifugation process for the size separation.[1-4] Figure 1a shows the solution in which different sized silicon nanoparticles are dispersed. The solutions exhibit bright scattering colors depending on nanoparticles sizes. TEM image in Fig. 1b shows the monodisperse silicon nanoparticles with highly spherical shapes. In addition, Figure 1c demonstrates high crystallinity of the particle.

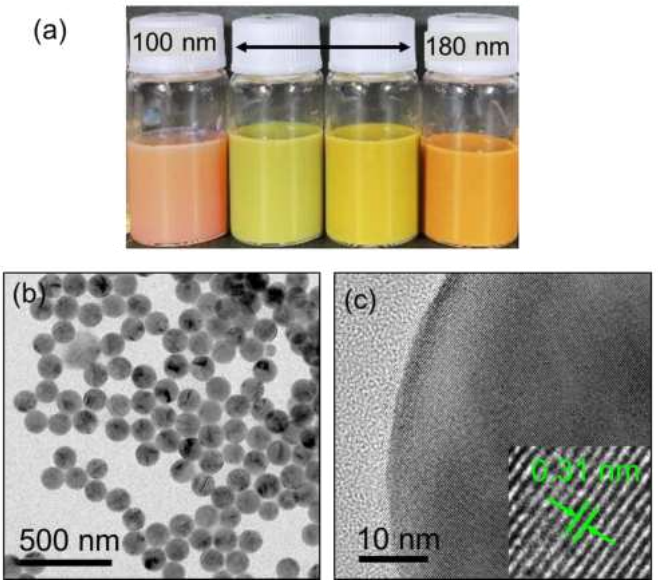

Figure 1. (a) Photo of colloidal suspension of Si nanoparticles with different average diameters. (b, c) TEM and HRTEM images of Si nanoparticles, respectively.

In this work, we also introduce the development of functional composites composed of a Si nanoparticle core and a metal and a transition metal dichalcogenide shell.[5-7] A Si-core/Au shell nanoparticles were produced by covering the surface of a Si nanosphere by Au (Si@Au). Figure 2a shows the STEM-EDS images of a Si@Au nanoparticle, demonstrating the formation of a core/shell structure.[5] We demonstrate the dark hybridized mode characteristics of the core-shell nanoparticles by the optical microscopy. Figure 2b and c demonstrate the successful formation of a Si@MoS_2 nanoparticle with ~5 MoS_2 layers. From the scattering spectroscopy on a single Si@MoS_2 nanoparticle, we show the spectral splitting of the magnetic dipole (MD) mode by the coupling with excitons in a MoS2 shell.[6]

Abstract: We fabricate all-inorganic, high refractive index optics, including metalenses, waveguides, and diffractive optical elements, via nanoimprint lithography with TiO_2 nanoparticle dispersion inks and report full-wafer fabrication of visible wavelength metalenses with absolute efficiencies greater than 80%. Atomic layer deposition is used as a post treatment to tune refractive index from 1.9 to 2.25 using less than 20 cycles.

Planar metalenses, waveguides, and diffractive optics are enabling for augmented reality, displays, compact precision imaging, 3D sensors, and other applications. Current approaches to all-inorganic metalenses involve time, materials, and cost intensive subtractive fabrication on semiconductor process platforms. For example, metalenses operating in the infrared are fabricated out of silicon, employ small device footprints, and are entering commercialization via subtractive processing. Visible wavelength devices, however, cannot be fabricated out of silicon and require high refractive index (RI) materials transparent in the visible, such as TiO_2, that are difficult to etch. Moreover, visible wavelength devices. such as waveguides for smart glasses, often require large device areas, presenting additional economic challenges for subtractive processing. Additive fabrication via nanoimprint lithography (NIL) in which devices are printed using stamps replicated from a master offers an efficient, cost-effective alternative manufacturing pathway.[1-4] We fabricate all-inorganic, high refractive index optics via NIL with TiO_2 nanoparticle dispersion inks.[2,3] The all-inorganic components offer better performance and superior mechanical and optical stability relative to devices produced via NIL using polymer/nanoparticle composites. We demonstrate full-wafer fabrication of visible wavelength metalenses lenses with absolute efficiencies greater than 80% (93% relative efficiency). We employ atomic layer deposition (ALD) as a post-imprint treatment that enables tuning of the refractive index from 1.9 to 2.25 using less than 20 cycles, which improves lens efficiency.[3] Tuning RI of the imprinted optics to match that of the substrates removes concerns about residual layer thickness, resolving an important issue for some applications. Additional cycles of ALD are used to precisely tune feature dimensions and feature spacings. Finally, we demonstrate the excellent optical and material stabilities of the all-inorganic imprinted optics.

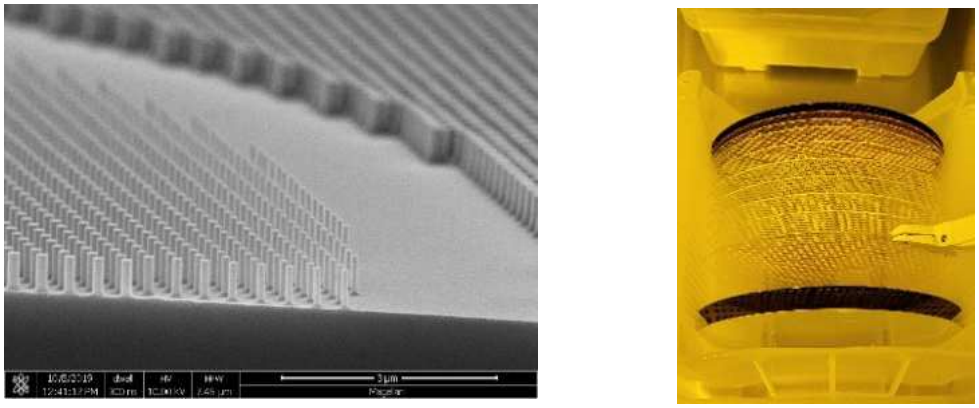

Figure 1. SEM image of a visible wavelength metalens prepared via direct NIL using nanoparticle dispersion inks (left)[1]. A cassette of wafers containing 1000 metalenses on each wafer produced via direct NIL (right).

Transient dissipative structures in surface plasmon polaritons propagation

S. Derevyanko[1*] **and M. Spector**[2]
[1]School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer Sheva, Israel
[2]Schwartz/Reisman Science Education Center, Rehovot, Israel

Abstract: We suggest an easily configurable dynamical method of creating a transient periodic plasmonic lattice in a metal film by temperature induced variation of the dielectric permittivity. We demonstrate a range of effects from dissipative plasmonic crystal to induced electromagnetic transparency.

SPPs are coupled waves of electrons and light that travel along metal-dielectric interface. They can be very tightly focused, react to the surface properties, create strong electric fields near the edge, and be easily manipulated by engineering designs. These features make SPPs useful for many purposes, such as detecting molecules, making thin solar panels, producing new colors of light, enhancing light emission, connecting optical devices, switching fast signals, and computing with light, among others [1].

In the context of Drude theory of conductivity the electrons oscillate in response to the pump electric field. In this model the non-zero imaginary part of the dielectric constant is determined by electron-electron (e-e) and electron-phonon (e-ph) scattering rates. These in turn can be enhanced by various temperature effects. Therefore, by providing an external heat-dissipation source one can heat the electron and lattice subsystem and thus modulating the loss as experienced by a propagating SPP.

To model these effects, one often uses the so-called two temperature model (TTM) where the electromagnetic energy dissipated in the bulk of the metal acts as a source of heat [2]:

$$\begin{aligned} C_e\left(T_e\right)\frac{\partial T_e}{\partial t} &= \nabla\bullet\left[K_e\left(T_e,T_l\right)\nabla T_e\right]-G\left(T_e-T_l\right)+p_{abs} \\ C_l\left(T_l\right)\frac{\partial T_l}{\partial t} &= \nabla\bullet\left[K_l\left(T_l\right)\nabla T_l\right]+G\left(T_e-T_l\right) \end{aligned} \tag{1}$$

Here T_e, T_l are the temperatures of electron and lattice respectively, $C_{e,l}$ and $K_{e,l}$ are the heat capacities and thermal conductivities of the electron and lattice respectively while G is the electron-phonon coupling factor related to the rate of energy exchange between the electrons and the lattice. The energy dissipation caused by the pump field is proportional to the imaginary part of the dielectric permittivity and the intensity of the external electromagnetic field $p_{abs} \propto \varepsilon'' \left|E\right|^2$.

There are two possibilities as to how one can engineer the properties of the electron and lattice subsystems and thus control the losses experienced by the propagating SPP. In the first one [3] we can illuminate the metal-dielectric interface by two orthogonal strong pulsed beams in the near infra-red region inducing the effective periodic structure in the absorbed energy density (Figure 1a). The spatially periodic variation of the absorbed energy p_{abs} is transferred via TTM model (1) into effective transient spatially periodic variation of the electron and lattice temperatures (Figure 1b) which modulates the losses in the Drude model (the imaginary part of

dielectric permittivity) which affects the SPP propagation and creating a *dissipative plasmonic crystal* which can have different lifetimes depending on the relation between the incident pulse duration and the temperature diffusivity.

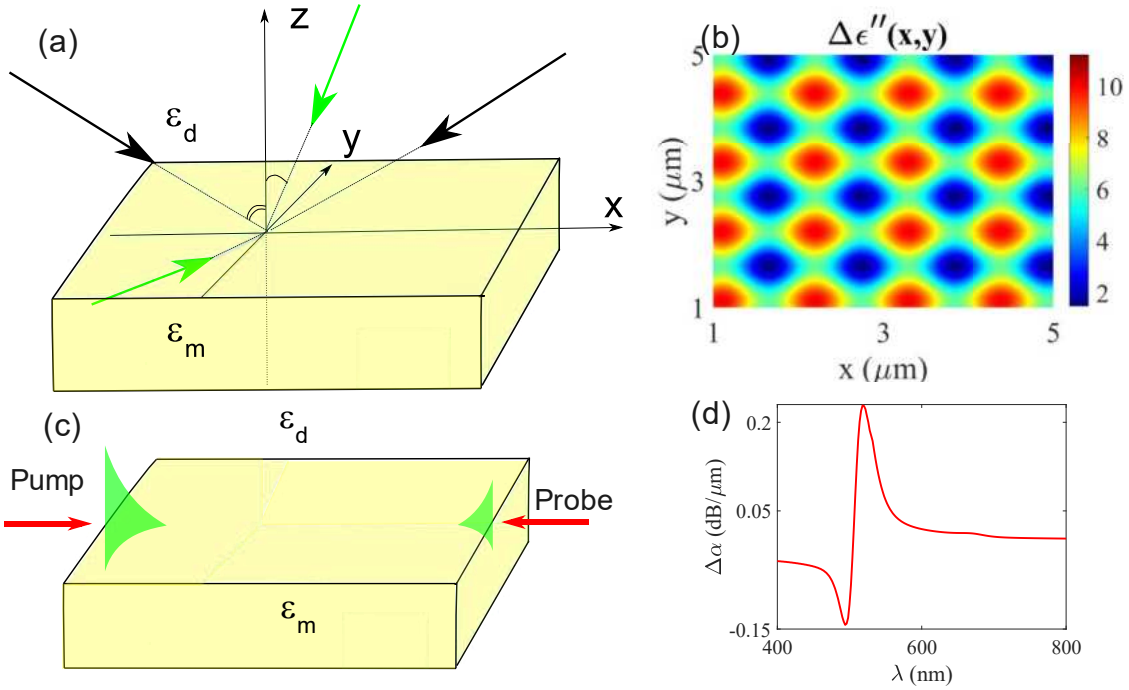

Figure 1. (a) The schematics of crossed-beam irradiation creating the transient plasmonic crystal (b) induced spatial variation of the imaginary part of the dielectric constant (c) basic pump-probe configuration (d) relative change of the absorption coefficient after pulse transit. The negative values correspond to decreased absorption.

In the second opportunity instead of using an external irradiation one can use to contra-propagating SPPs in the pump-probe configuration [4] – Figure 1c. In these settings the source of energy absorption p_{abs} is provided by a strong pump SPP and the induced change of the electron-lattice subsystems modulates the imaginary part of dielectric permittivity via interband transitions leading to increased propagation of the probe SPP in the visible-NIR region which manifests itself as an transient induced transparency of the sample.

Optical to Terahertz Frequency Conversion using near Zero-index Nonlinear Hybrid Waveguides

C. Sheng*, X. F. Ma, N. Y. Wang, R. Z. Cao, C. Sheng, S. N. Zhu, and H. Liu

National Laboratory of Solid State Microstructures and School of Physics, Collaborative Innovation Center of Advanced Microstructures, Nanjing University, Nanjing, Jiangsu 210093, China

Abstract: Terahertz communications has emerged as an excellent candidate for the next generation of wireless communication networks. Despite of significant advances, one still looks for a high-efficiency terahertz source using nonlinear optics. Here, we propose near zero-index nonlinear hybrid waveguides to realize a high generation efficiency of terahertz waves.

Recent years have witnessed significant advancements in the fifth generation (5G) wireless communication networks. However, with the explosive growth of global wireless data traffic which increases by ~ 50% annually, 5G faces significant challenges in meeting the demands of this exponential growth. As a result, sixth generation (6G) wireless communication networks are expected to fill the gap. In this context, Terahertz (THz) wireless communications is considered a promising candidate for 6G networks. Motivated by these factors, the development of THz sources has been eagerly anticipated, as they possess distinctive characteristics including ultra-low noise, ultra-low power consumption, high integration, and ultra-fast modulation. Despite recent advancements in creating THz radiation using electronic, photonic, and hybrid approaches, THz sources that fulfill all the requirements of THz communications still face challenges. For instance, conventional electronic approaches to generate THz radiation have limitations in modulation speed, electronic-photonic hybrid approaches encounter unresolved issues related to integration and miniaturization, and photonic approaches need to improve the conversion efficiency from optical waves to THz waves for practical applications. Recently, the efficient generation THz waves [10] via on-chip difference-frequency generation (DFG) has attracted attention, since it has a unique advantage in the integration, the low-cost and the low-noise. Yet, its low conversion efficiency also urgently needs to be further optimized.

On the other hand, metamaterials[1], composite materials engineered through the structuring of subwavelength constituents, offer unparalleled flexibility in the engineering of optical materials. They enable the realization of unique and intriguing properties, including negative or zero refractive indices. Consequently, the emergence of metamaterials has led to various unprecedented applications such as perfect lenses, invisibility cloaks , and even artificial black holes. Besides of these passive linear optical elements, there have been significant advancements in metamaterials-assisted nonlinear optical processes, encompassing phase mismatch-free harmonic generation, direction-independent four-wave mixing, second-harmonic generation, and optical rectification. Notably, state-of-the-art THz sources based on nonlinear optical rectification in zero-index materials have attracted substantial attention due to their efficient generation and manipulation of broad THz waves. However, the discrete and bulky nature of these THz sources hinders their practical application in THz communications. Additionally, the broad bandwidth of these sources fails to meet the requirement of narrow-linewidth necessary for THz communications. Recently, there have been proposals and implementations of on-chip zero-index metamaterials [2,3] that manipulate nonlinear optical processes. Nonetheless, the utilization of zero-index metamaterials in integrated photonic devices to generate continuum THz waves has not

been reported thus far.

In this work, we propose a theoretical approach utilizing near zero-index nonlinear hybrid waveguides for achieving high-efficiency generation of THz waves via on-chip DFG at the telecom wavelength (Fig. 1(a)-Fig. 1(c)). Specifically, we design an optical metamaterials waveguide and a conventional hollow rectangular metallic waveguide to respectively achieve an effective refractive index of zero at telecom and THz frequency. Thanks to the simultaneous realization of near zero index both at the optical and THz waves, we have eliminated two major bottlenecks in the conversion from optical wave to THz waves: phase mismatch and weak nonlinear optical-THz waves interactions. We thus obtain the conversion efficiency as high as 3.95×10^{-3} W^{-1}at 3.21THz with a compact size on this integrated nonlinear hybrid waveguide (Fig. 1(d)).

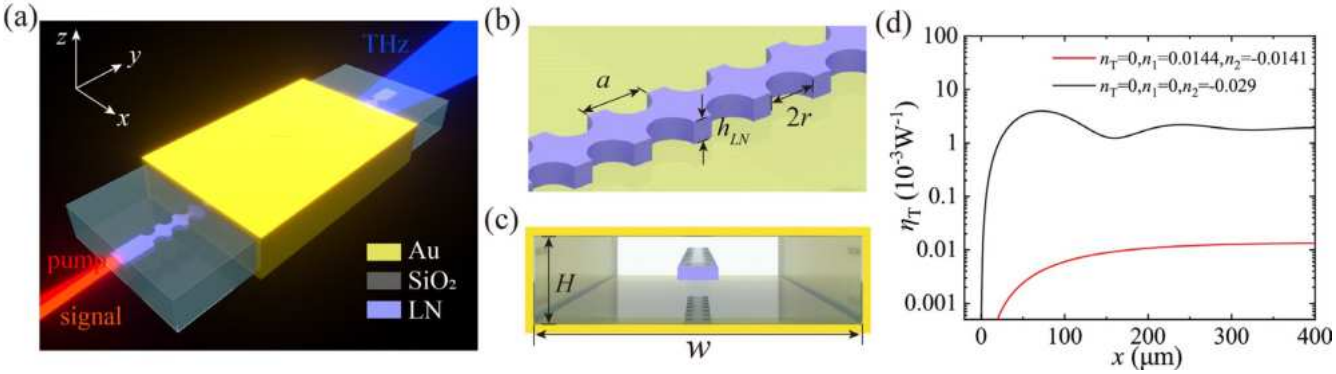

Fig.1 (a) Schematic of the designed hybrid waveguide consisting of the optical LNOI corrugated waveguide and the THz metallic rectangular Waveguide. (b) Schematic of the optical LNOI corrugated waveguide. (c) Schematic of the THz metallic rectangular waveguide. (d) Conversion efficiency versus propagation distance under the case when the refractive index is zero only for THz waves and for both THz waves and pump light.

In summary, we have presented a theoretical and numerical analysis of a highly efficient on-chip THz source based on a compact nonlinear hybrid waveguide. By leveraging the unique properties of the zero-index medium, we have successfully addressed the challenges of phase mismatch and weak nonlinear optical-THz waves interactions in the process of DFG, resulting in an impressive conversion efficiency of 3.95×10^(-3) W^(-1) over just the propagation length of several THz wavelengths. Notably, our proposed nonlinear hybrid waveguide achieves simultaneous zero refractive indices for both telecom waves and THz waves, which, to the best of our knowledge, is the first demonstration of such a feat. In future works, the conversion efficiency can be further improved by reducing the loss in such a nonlinear hybrid waveguide. Furthermore, our approach holds promise for applications in other on-chip nonlinear and quantum processes, including spontaneous parametric down-conversion and four-wave mixing.

Abstract: We report a new design of acoustic metamaterial for broadband insulation and natural ventilation. The unit cell consists of an Archimedean spiral channel and a straight pipe alongside, allowing fresh air flow and mode cancellation. It shows over 15dB transmission loss over a broad bandwidth of around 1000 Hz.

Background

Conventional noise barriers, such as walls and plates, have ideal acoustic performance. However, they also block the airflow and harm natural ventilation and cooling performance. In a low-flow state, sound insulation and ventilation of fresh air can be achieved simultaneously. A typical design is a plenum window [1]with partially opened double-glazing structures that prolong the attenuation path of noise and allow a certain degree of natural ventilation. There is still a large room to improve the insulation efficiency. The acoustic louvers [2] with a similar mechanism are widely used in heavy mechanical plant rooms, HVAC systems, and public buildings. The plenum windows and louvers require large dimensions for low-frequency performance. The emergence and development of metamaterials can help to solve the conflict between device size and wavelength. The precise control of the Fano resonance [3] introduces perfect sound insulation with structures having considerable open area. In such a kind of metamaterial, the resonant state from the meta-structure and the continuum state from the host medium in the opened area leads to the Fano-like interference, and a zero-transmission point can be observed. This phenomenon can be explained by the cancellation of resonant modes. Normally, the symmetric and anti-symmetric modes of resonance have an alternating distribution along the frequency axis. Near the resonant frequency, the dynamic behavior is dominated by the corresponding resonance state. With proper design, it is possible to have a point where the resonance state at both sides achieves an equilibrium state so that the transmission mode is canceled, referring to Fig. 1.

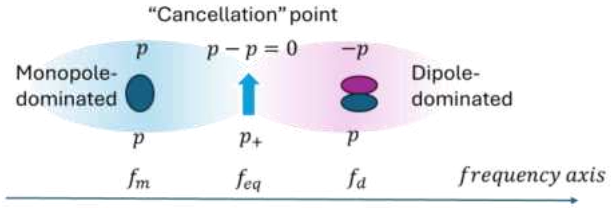

Fig. 1. Schematic of the mode cancellation. In this picture, f_m and f_d are the resonant frequencies of monopole and dipole modes, respectively; f_{eq} is the frequency where the two modes contribute equally to the state and cancel each other.

Many binary unit cells can realize the mentioned unity reflection state, such as a hollow structure surrounded by helical blades [4, 5], and a space-coiling structure with a side tube [6]. These structures inspired our design with better mechanical strength and lower working frequency.

Design and results

According to the Fano-like metamaterial, we find the binary unit cell requires a slow-wave-propagation part for resonance and an open area for ventilation; a gradient design of the resonator has better impedance matching to the host medium. Here, we adopt a gradient Archimedean spiral to slow down the wave propagation for low-frequency resonance. Two side channels are for the ventilation. The spiral shown in Fig. 2(a) is described by

$$r = a + b\theta,$$

where b, and c are constants adjust the spiral's radius and curvature distribution. The thickness of the block along wave propagation direction is about one-fourth of the shortest wavelength in the working band.

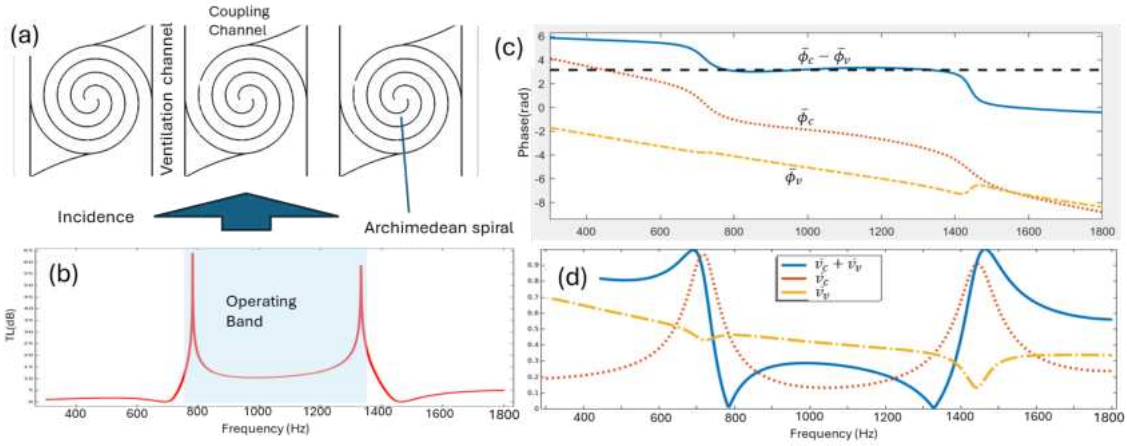

Fig. 2. The spiral metastructure's acoustic performance. (a) shows the geometry. (b) The transmission loss under normal incidence, in the operating band, $TL > 15dB$. (c) and (d) are the phase difference and amplitude summation of the transmitted ports. The subscription c represents coupling channel, while v denotes the ventilation channel.

In our design, the ventilation channel occupies 30% of the total area, offering considerable ventilation efficiency. The mode-cancelation point is located at 780 Hz and 1330 Hz, where the summation of mean velocity at the transmitted side is zero, which is illustrated in Fig. 2(d). Meanwhile, the phase difference between the coupling channel and the ventilation channel is $180°$ over a large frequency range. The out-of-phase radiation from the two channels eliminates each other and leads to a stop band.

To conclude, the reported spiral meta-structure shows broadband sound insulation with sub-wavelength thickness. The mode cancellation phenomenon has been observed through numerical results. This new type of metamaterial has great potential in green buildings.

Abstract: Integrated phase-change photonic memory devices are of much current interest due to their ability to provide a platform for fast, low-energy in-memory and neuromorphic computing. Here we explore the use of plasmonic enhancement of such devices to increase programming speed, reducing energy consumption and enable direct electrical access.

Integrated phase-change photonic memory devices offer a novel route to non-volatile storage and computing. Such devices generally consist of integrated waveguide structures onto which are fabricated small phase-change memory cells (e.g., $Ge_2Sb_2Te_5$, or GST), with an example being as shown in Fig. 1(a). When combined with photonic crossbar arrays and microring resonators, such photonic phase-change devices can deliver non-von Neumann forms of in-memory and neuromorphic photonic computing (see e.g. [1,2]). In the short-to-medium term, such photonic processors are probably most likely to find application as accelerators for specific processor intensive tasks, such as the matrix-vector multiplications that lie at the heart of much of today's artificial intelligence and machine learning approaches. For such applications, it is always desirable to increase computing speeds and decrease energy consumption. Moreover, since the vast majority of today's computing is carried out electronically, it is also desirable to have a seamless monolithic co-integration of electronics and photonics. One way in which these desirable features might be achieved, is via the incorporation of plasmonic antennas into the basic integrated phase-change photonic cell, and it such methods that we discuss here.

One simple approach to introduce plasmonic enhancement is to deposit plasmonic antennas on top of the phase-change cell itself, as also shown in Fig. 1(a). Here, the excitation of plasmonic resonances by the optical mode propagating in the waveguide increases the effective electric field in the GST region between the two plasmonic antennas, so increasing the optical contrast (the difference in optical transmission along the waveguide for the active GST region in its amorphous and crystalline states). This can be seen in Fig. 1(b), where the optical contrast as a function of the length of the plasmonic antennas is shown: considerable contrast is maintained (> 20%) in spite of the interaction volume with the GST being orders of magnitude smaller than in the case of a conventional cell design. More importantly, the reduced interaction volume gives rise to a very significant reduction in the time and energy required to program the GST cell (i.e. to switch it between its crystalline and amorphous states), again of around an order of magnitude or more [3]. The use of plasmonic antennas on top of the GST cell also gives access to relatively low-energy programming (switching) of the GST layer via the use of external lasers, as shown in Fig. 1(c). Here, a VCSEL laser is position above the GST cell and excites the dimer antenna from above; this leads to resonant absorption for certain antenna lengths, so improving the energy efficiency of the switching/programming of the GST layer.

The introduction of metal layers to provide plasmonic enhancement of the integrated phase-change photonic cell also brings with it the possibility for dual-mode electrical-optical operation of the device. By this we mean that the GST cell can

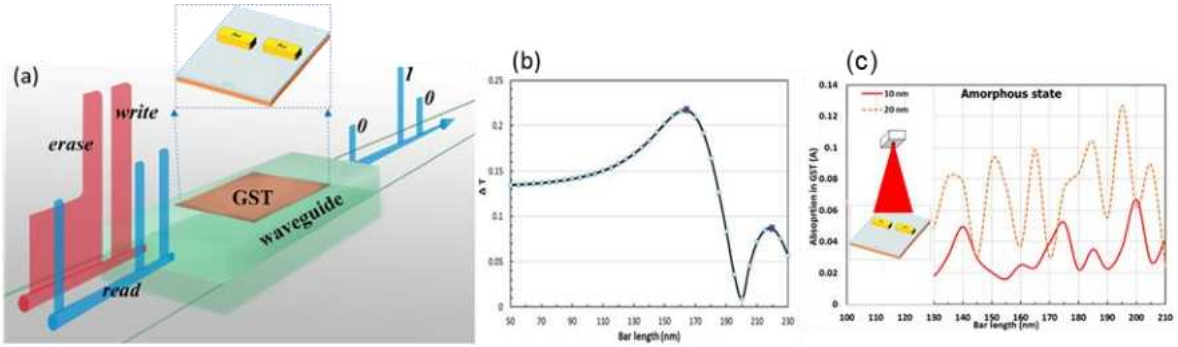

Figure. 1: (a) Schematic of a conventional integrated phase-change photonic cell showing a GST 'patch' on top of a SiN waveguide and (inset) a plasmonically-enhanced version of the GST cell. (b) The optical contrast (difference in normalized transmission for crystalline and amorphous active volumes in the GST cell) as a function of the length of the two antennas of the plasmonic cell. (c) A proposed alternative programming approach in which a VCSEL laser illuminates the plasmonic cell from above, leading to resonant absorption for certain antenna sizes.

be programmed (crystallised/amorphised) and its state read back both electrically and optically. This in turn brings closer the possibility of seamless integration of phase-change photonic processors with existing electronic hardware. An example of such a dual-mode electrical-optical device is shown in Fig. 2(a). The device consists of a shallow etched SiN waveguide which is used to efficiently route optical power to a nanoscale gap formed between two gold electrodes, into which is deposited the active GST region [4]. The functionality of the gold electrodes in this case is threefold: first, they form a metal–insulator–metal waveguide that guides and confines light into a nanoscale volume; second, they provide a means for reading the phase-state of the GST cell by measuring its conductance electrically; third, as a result of a designed-in nanoscale constriction running along the length of the nanogap, the application of a voltage pulse across said constriction produces a localized heat source to switch/program the GST cell. Successful electrical switching, with simultaneous optical readout, of such a cell is illustrated in Figs. 2(b) and 2(c) respectively.

Optical induced temperature change for ionic thermoelectric applications

D. Zhao*, M. N. Liao, and M. P. Jonsson

Linköping University, Sweden

Abstract: The low energy density part of solar radiation that cannot be directly utilized by photovoltaics composes 80% of the total solar energy. Those energy was converted into heat by transparent meta-surface and black absorber to drive the operation of ionic thermoelectric devices.

In the background of energy crisis and environmental problems, more and more research are focusing on developing new technologies to generate clean and sustainable energy. As the largest available renewable energy source, the radiation from the sun would be capable of powering 100% of the worldwide demand in electricity. So far, the conversion of solar energy into electricity can be via solar thermal plants (20%) or solar cells (15-40%), such that a large amount of energy in the form of natural heat remains unused. The enormous amount of natural and waste heat is mostly stored in large volume warm fluids ($T < 250°C$). It is challenging to convert this low energy density heat into useful electricity with existing technology.

Thermoelectric material that can direct convert heat into electricity has attracted intensive research interest. As the emerging family member, ionic thermoelectric materials are mostly composed of earth abundant elements (C, N, O, H, S, etc.) and are easy to process. Moreover, the ionic thermal voltage generated in electrolytes can be 50 to 150 times larger than commercial electronic thermoelectric materials [1]. Hence, we combined the solar induced temperature change with ionic thermoelectric devices, which could generate an output voltage.

We have investigated the function of plasmonic Au-nanohole structures and black absorber in converting solar radiation into a temperature gradient across an ionic thermoelectric cells. Plasmonic metasurfaces are nanostructured metal surfaces that interact strongly with light via excitation of collective charge oscillations (i.e., plasmons). This leads to nonradiative damping and local heat generation. Meta surface with nano-holes were used to interact with light as well as the electrodes in ionic thermoelectric cells [2]. Moreover, the continues Au electrode could be used as a thermistor for temperature monitoring spontaneously. A heat of 7K was observed on the top electrode under solar radiation. A temperature difference of 2 K formed across the device and generate thermal voltage of 15 mV. We further improved the responding time of the output voltage by introducing a pyroelectric layer [3]. A sharp peak in output voltage appeared within 10 s in addition to the thermal voltage upon solar radiation, which enables radiation detection applications.

As a semi-tranparent surface, Au Nanohole based plasmonic structure could effectively convert 20% of solar light into heat to generate a thermal voltage in iTE devices. Meanwhile, black absorber typically absorbs over 95% of the solar radiation, which makes them more powerful in terms of light to heat conversion. The composite of carbon nanotube and cellulose nanofibers was investigated as the heater in iTE devices together with radiative cooling materials [4]. A temperature difference of 20K could be generated in the device exposed to the same solar radiation.

ABSTRACT: We studied the ultrafast dynamics of near-field coupling of "dark" and "bright" resonators in electromagnetic-induced transparency (EIT) metamaterials. Given the picosecond pump fluences of 8 J/m^2, we can dynamically change the optical response of the system and obtain the transient transmission change up to more than 100%. Along with this remarkable modulation depth, the knowledge of near-field coupling in complex systems will facilitate the application of ultrafast optical devices.

Electromagnetic-induced transparency (EIT) was observed for the first time in three-level atomic systems in quantum optics, when a narrow transparent state appeared in an opaque medium with a wide absorption range [1]. EIT is the result of destructive quantum interference between different pathways to the excited state. The conceptual analogue of EIT-metamaterials (EIT-MMs), proposed by Liu et. al. [2], is based on the destructive interference of two or more resonant modes that have comparable resonant frequencies, resulting in an EIT window. Due to its large dispersion, the electromagnetic wave stays longer in the medium, so-called slow light. Understanding the destructive interference and near-field coupling in EIT-MMs is crucial to optimally use this interesting phenomenon.

Our EIT-MM structure is composed of gold antennas on top, chromium as a buffer layer, and a silicon substrate underneath. As can be seen from Fig.1a, there are a vertical bar working as a dipole antenna and a pair of horizontal bars that form a quadrupole antenna under incident electromagnetic waves propagating in transverse-electric (TE) mode (inset). When they are separate, only the dipole antenna can be excited (Fig. 1b). Fig. 1c shows the static transmittance spectra of EIT-MMs obtained with FTIR spectroscopy in TE mode. When the two resonators are placed close together (g_2 = 0.1 μm), they will couple via near-field, opening an EIT transmission window. As the gap size broadens to 0.15 μm, the EIT window shrinks and it vanishes if g_2 = 0.2 μm (Fig. 1).

To study the dynamics of the EIT effect, we used a time-resolved pump-probe spectroscopy at the free electron laser facility FELIX, Radboud University, Nijmegen, The Netherlands (Fig. 2a) [3]. A train of short (2 ps) laser pulses is guided to the measurement setup and each pulse is split into a pump pulse and probe pulse. The pump takes most of the energy (95%) and was varied from 1 to 8 J/m^2 in our experiment. The given excitation sources allow us to trigger the nonlinear optical processes in the EIT structures. The arrival time of the probe relative to the pump is controlled through a delay stage, allowing us to evaluate the dynamics in the time domain of the excited state of the system after intense pump excitation. As can be seen from Fig. 2b, the system immediately responds to resonant excitation by the pump (delay of 0 ps) as the transmittance initially increases from 0.2 to 0.4 and relaxes to the original transmittance level after about 33 ps.

The mechanisms underlying the transient probe transmission change include hot electrons generation when using the pump wavelength close to the plasmonic resonance of “bright” resonators, followed by the hot carrier injection through the metal-semiconductor barrier. These processes take less than a picosecond. After that, the energetic electrons, accelerated by plasmon-induced field enhancement, will collide with bound electrons in silicon, creating additional electron-hole pairs in the so-called impact ionization (IMI) process, which leads to carrier multiplication in silicon. It changes the refractive index and conductivity of the support and thereby shifts the antenna modes, which is reflected in the probe transmission. The IMI rate and decay processes occur on time scales

from a few tens to hundreds of picoseconds [4]. This work sets the base for understanding the temporal and spatial response of EIT resonance and its coupling effect, paving the route toward optically-driven modulators and ultrafast optical devices.

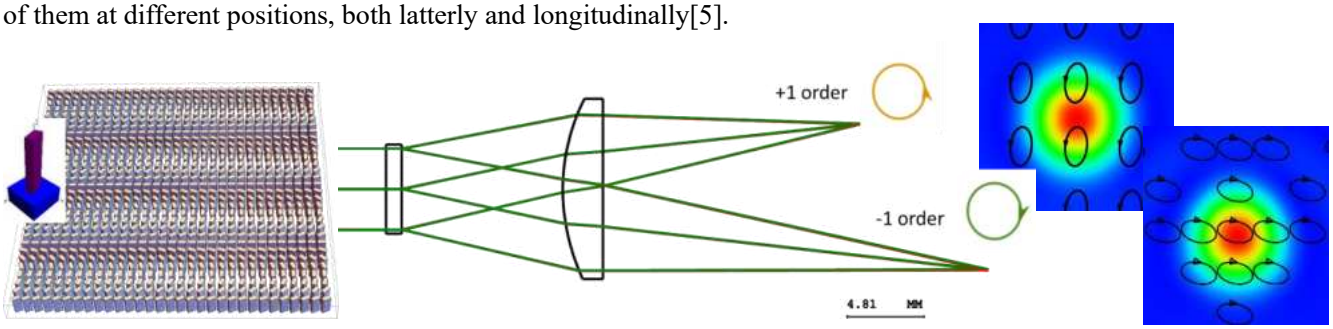
Abstract

A fully automated design flow has been developed at Synopsys for hybrid metalens systems by combining macro-scale ray tracing and nano-scale electromagnetic solver. Optimum design can be automatically obtained to match desired targets. Furthermore, by taking manufacture errors into account, manufacturing aware design flow can target first print correct design.

Summary

To meet the growing demand for powerful and user-friend tools for metalens/metasurface design, Synopsys developed MetaOptic Designer (MOD), the first fully automated inverse design tool for metalens/metasurface[1]. For a given meta-atom library and incident condition, MOD can generate the best metalens layout possible to meet the specified design targets, including near-field, far-field, or modulation transfer function (MTF). Shown in Figure 1 is a design case for a desired image display.



(a) (b) (c)

Figure 1. Optimization results for holographic image display (a) Desired target, (b) Meta-Atom used, optical system schematic, and optimized metasurface; (c) optimized result.

Flat and thin metalenses have great advantages over conventional curved and refractive lenses, especially with the potential of massive production with mature semiconductor fabrication technology. However, it is not feasible to completely replace refractive lenses at the current stage. In most applications, metalenses are used in hybrid optical systems to perform certain functions together with refractive lenses[2]. To design such hybrid systems, we combine both ray optics and electromagnetic optics so that refractive lenses designed in CODE V[3] can be included in the metalens design[4]. Co-design of both refractive lenses and metalenses can also be done efficiently by interfacing two products to achieve high performance from complex systems. Shown in Figure 2 is a co-designed hybrid optical system

to split left-hand circularly polarized (LCP) light and right-hand circularly polarized (RCP) light, and then focus each of them at different positions, both latterly and longitudinally[5].

(a) (b) (c)

Figure 2. Co-design a hybrid optical system for polarization beam splitter. (a) Illustration of optimized metasurface and meta-atom, (b) sketch of the optical system, (c) focused LCP and RCP beams.

Manufacturing error is inevitable during the fabrication process. As a result, the processed metalens/metasurface (Figure 3(c)) is usually different from the intended design (Figure 3(b)). To take manufacturing limitations and constrains, such as overetch, sidewall angle, roughness, etc. into account, we perform processing simulation using Sentaurus Lithography[6] to obtain manufacturing aware meta-atoms (Figure 3(d)) from which to build the meta-atom library. Metalenses/metasurfaces (Figure 3(e)) built with the manufacturing aware library naturally compensate the manufacturing errors so that their performance more closely matches the design targets.

(a) (b) (c) (d) (e) (f)

Figure 3. Manufacturing aware design flow (a) Ideal meta-atom library, (b) design based on ideal meta-atoms, (c) manufacturing predicted design, (d) manufacturing aware meta-atom library, (e) manufacturing aware design, (f), simulation results.

One of the design examples we tested is a f/5 metalens 1mm in diameter using Si_3N_4 meta-atoms. The focusing efficiency of the ideal design (Figure 3(b)) is 77.2% while the manufacturing simulated design (Figure 3(c)) gives 64.0% with 17.1% discrepancy. The manufacturing aware design (Figure 3(e)), however, has compensated the fabrication error and yields 78.4% efficiency with only 1.6% difference from the initial ideal design.

Abstract: We developed a nanofabrication method of 3D metamaterials based on focused-ion-beam irradiation-induced folding of low dimentional materials, which can similarly constructed 3D free-standing nanostructures and devices in the research and development of photonics. The optical characteristics of 3D plasmonic “nanograters” composed of free-standing Au films was studied, and the unusual and well-scalable Fano resonances at wavelengths ranging from 1.6 to 6.4 mm were observed, which holding great potential applications in multi-resonance differential sensing and optical communication.

The 3D metamaterials (MMs) can realize the effective constituent properties and be tuned in all propagation directions at various frequencies. Specially, nanoscaled 3D MMs responded at higher frequencies, such as in the infrared and visible regimes, remains an active focus of research. Many 3D nanofabrication technologies have been developed in decades, such as layer-by-layer stacking, multilayer electroplating, direct laser writing and ion-beam irradiation, etc. However, the fabrication technology of nanoscale 3D MMs with a hierarchical geometry remains challenging. Here, we developed a fabrication method of focused-ion-beam (FIB) folding of metallic cantilevers to construct self-supporting 3D MMs. The fabrication process employed FIB nanopatterning combined with in situ irradiation-induced folding of metallic thin-film structures. The result indicated that this method can be used to produce complex 3D metamaterials with ease and is also feasible for the production of 2D arrays of millimeter-sized 3D elements, which have practical uses in many optical applications.
In this summary, our works focused on metamaterials of U-type nanograters consisting of an array of vertical U-shape splitring resonator patterns standing along an edge of horizontal subwavelength rectangular holes. The 3D metamaterials exhibited scalable unusual Fano resonances at wavelengths ranging from 1.6 to 6.4 mm, a very strong dependence on the refractive index of the surrounding medium, with a high refractive index sensitivity, was observed. What's more, the behavior of each resonance can be modulated independently.These suggested that the local modifications to the phase and amplitude of the light wave front on a subwavelength scale induced by the nanograter structures profoundly influence the propagation of the incoming light, thereby suggesting that such nanostructures may be applied in a wide range of optical applications, including high-performance plasmonic sensing.

Abstract: We introduce a technique for wide-gamut structural coloration of a pre-processed metamaterial in 33k DPI resolution by continuous-wave laser irradiation with an average power of 10 mW. The basis of the metamaterial is self-assembled AL-PS nanosphere arrays, in which controllable material oxidation and deformation allow optical response tuning.

Conventional coloration techniques in textiles, paints, and printing often involve hazardous components, including heavy metals like lead and carcinogenic compounds [1]. Laser printing with structural colors on non-toxic materials is emerging as a promising technology to address this problem [2-4]. These structural colors originate from the interaction of nanostructures with light, causing diffraction, resonance, and interference effects that produce color without the need for pigments or dyes. Up to date, the best-performing laser coloration techniques in terms of resolution, throughput, color gamut coverage, and scalability rely on ultrafast pulsed lasers [3,4].

In this work, we present a pre-processed metamaterial based on self-assembled nanoparticles and an experimental setup for low-power laser-induced coloration of this material (Figure 1a). As depicted schematically on Figure 1a, the base unit of the metamaterial is a polystyrene nanosphere covered with a layer of aluminum polycrystalline film. Figure 1b shows results of FDTD modelling with reflectance spectra calculated for periodic arrays of a base unit with modified oxidation layer and unit shape. Our computational analysis reveals that by altering the oxidation layer of the metallic film, we can tune the resonance amplitude in the material's optical response. Additionally, deforming the spherical unit shape enables us to shift the resonance across the visible spectrum, thereby generating a spectrum of colors in the reflected light. Experimentally, we achieve such control over material by a tightly focused CW laser with variable power and exposure time. We collect experimental data for reflectivity spectra of 39 color samples and compute corresponding chromaticity values (Figure 1c)

The fabricated metamaterial is compatible with a flexible substrate, thus paving the way for the concept of 'structural paper' for laser color printing. By using a laser diode with an average power of 10 mW, we achieve laser coloration in a high-resolution of 33k DPI with the broadest gamut reported. To the authors' knowledge, the controllable gamut of color obtained with this technique also exceeds the best results currently available with inverse design [5]. With this approach, we expect that structural color laser printing can become more accessible to small-scale and end-user applications.

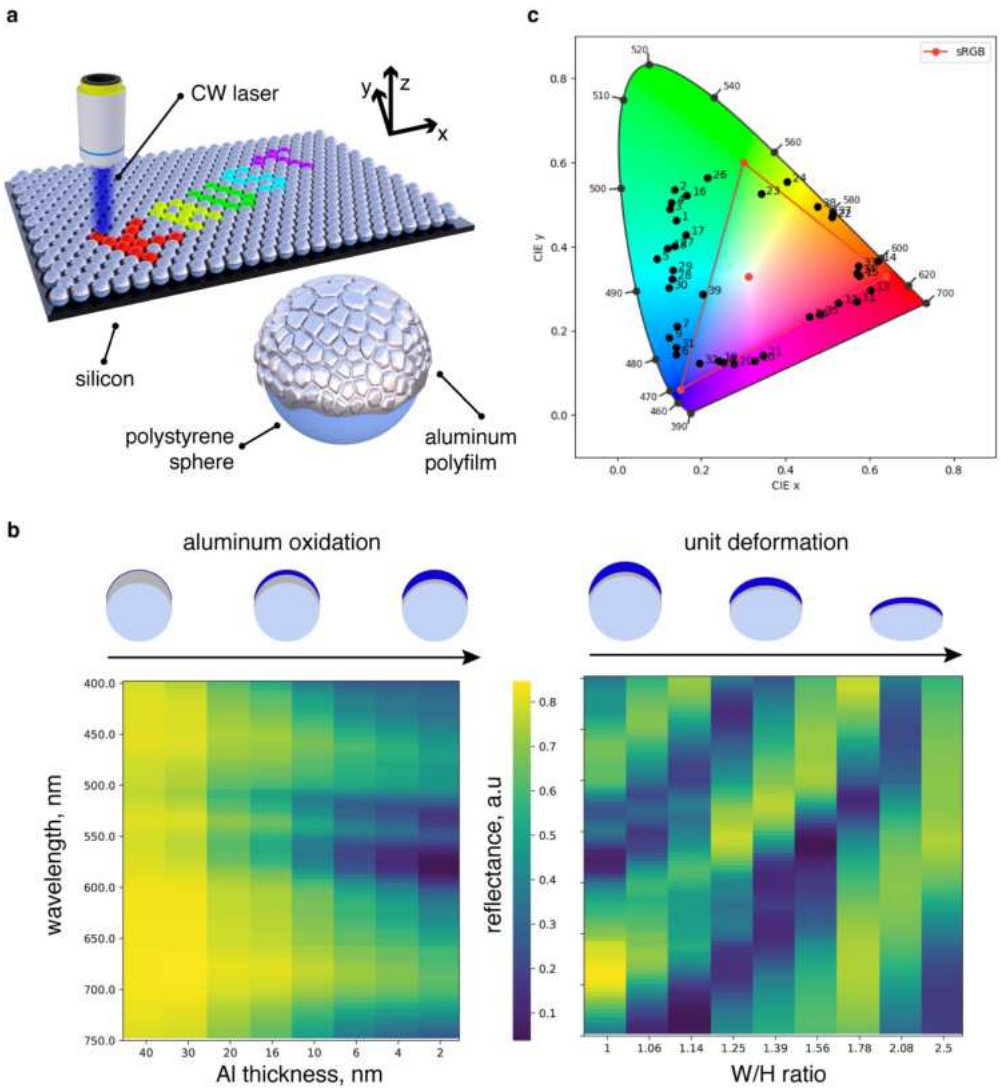

Figure 1. a - conceptual image of a described laser coloration approach and schematic image of metamaterial base unit; **b** - reflectance spectra of simulated structures; **c** - CIE 1931 chromaticity diagram with plotted chromaticities of obtained samples.

Abstract: Meta-lenses, utilizing artificial nanoantenna arrays, offer ultra-thin, aberration-free optics, enhanced by deep learning for improved imaging and sensing. We've developed intelligent binocular meta-lens systems for computer vision applications like particle image velocimetry (PIV), underwater vision, and assisted driving, achieving compactness and high accuracy in multimodal perception.

Meta-lenses are advanced flat optical devices composed of artificial nanoantenna arrays.[1] It can manipulate the wavefront of light with the advantages of ultrathin, compact, and no spherical aberration. With the support of deep learning, meta-lens demonstrated various advanced imaging and sensing applications. We have developed a series of intelligent binocular meta-lens systems with novel applications of particle image velocimetry (PIV), underwater stereo vision, edge-enhanced depth perception for ill-posed regions, and assisted driving vision.[2,3] Traditional PIV methods require multiple cameras and conventional lens systems for image acquisition to resolve multi-dimensional velocity fields. It introduces complexity to the entire system. The 3D velocity field can be obtained by the binocular disparity and particle image displacement information of fluid flow, as shown in Figure 1(a). The measurement error of vortex-ring diameter is $\approx$1.25% experimentally validates via a Reynolds-number (Re) 2000 vortex-ring. Meta-lens PIV demonstrates a new development trend for the PIV technique for rejuvenating traditional flow diagnostic tools toward a more compact, easy-to-deploy technique. For underwater imaging, the binocular meta-lens is specifically designed and fabricated with superhydrophobicity. With deep-learning support, this stereo vision system can realize real-time depth imaging (see Figure 1(b)). Our imaging results show that depth measurement accuracy is down to 50 μm. For edge-enhanced depth perception solving the ill-posed regions, we propose a novel stereo-matching neural network, H-Net, as depicted in Figure 1(c). Our edge-enhanced system provides prompt responses in less than 0.15 seconds. This edge-enhanced depth perception meta-lens imaging system will significantly contribute to accurate 3D scene modeling and computer vision. We also developed a stereo vision meta-lens imaging system for assisted driving vision, a comprehensive perception including imaging, object detection, instance segmentation, and depth information. Our binocular meta-lens offers a comprehensive multimodal perception for scene understanding of machines, benefiting the computer vision applications of human-computer interaction, machine navigation, autonomous driving, and augmented reality.

Abstract: The thermoplasmonic detection is a newly emerging application of the rapidly growing and promising field of thermoplasmonics. Despite the exploitation of the heat generated by gold nanoparticles in biomedical applications (e.g. photothermal therapy), the understanding of the influence of nanoscale photothermal processes is still subject to debate.

In this scientific context, this work aims to provide a better understanding on the thermoplasmonic mechanism leading to efficient and sensitive detection by evaluating the performances of the plasmonic nanoplatforms as thermoplasmonic generators. Specifically, various shapes of gold nanoparticles were synthesized and their intrinsic capabilities to convert light to heat were assessed by the determination of their photothermal conversion efficiencies in aqueous solution. Moreover, the photothermal performances were monitored with respect to nanoparticle's concentration, excitation wavelength and power of the excitation source at the interface with the colloidal solution. The most efficient nanoparticles were further immobilized onto different substrate types, respectively glass, paper and polymeric membrane, followed by the monitoring of their photothermal properties after immobilization. By controlling the self-assembly's formation process, it resulted that the photothermal properties of the plasmonic nanoplatforms can be modulated according to one's needs. Furthermore, by the functionalization of the plasmonic nanoplatforms with target molecules, the light-to-heat conversion performances show modifications, which can be attributed to the mass effect by the determination of the cooling constant. Thus, the obtained results contribute to the consolidation of the versatile thermoplasmonic detection technique and represent a stepping stone in the development of simple plasmonic nanoplatforms with reduced fabrication costs, facile and user-friendly implementation in thermoplasmonic-driven biomedical applications.

Abstract: In the past decade, metasurfaces have become a paradigm for engineering electromagnetic space due to their strong interaction with light or wave. However, mastering the cross- wavelength modulation of spatial light over the entire electromagnetic spectrum remains a challenging task. Here, we experimentally demonstrate an avenue towards hyperband multifunctionality in a single metasurface based on double-walled carbon nanotubes (DWCNTs). As a proof of concept, the proposed DWCNT-based metasurface integrates three typical functionalities including microwave selectivity, terahertz diffusion, and optical transparency.

The rapid advancement of wireless communication, digital circuits, and radar detection technologies has led to higher demands for modern electronic devices with integratable and versatile functionalities. Metasurfaces, emerging as a new class of subwavelength ultra- thin flat components, have brought disruptive innovations to the electromagnetic and nanophotonic fields. Despite the maturing developments of customized metasurfaces in specific scenarios, limited working wavelength and fixed wave manipulation remain the common defects[1]. The fixed EM properties of traditional materials enable desired responses only at specific wavelength, which limits the configuration of cross wavelength devices[2]. Recently, the electrical characteristics of DWCNT are selectable from semiconducting to conducting by controlling synthesis parameters, which promotes the development of electronic devices composed entirely of carbon materials[3]. Here, we propose a novel strategy to realize cross-wavelength multi-functionalities in an all-carbon metasurface as shown in Figure 1. Three typical functionalities including microwave frequency selectivity, Terahertz diffusion and optical transparency are realized simultaneously in a single metasurface whose resonant structures are fully made of DWCNT materials.

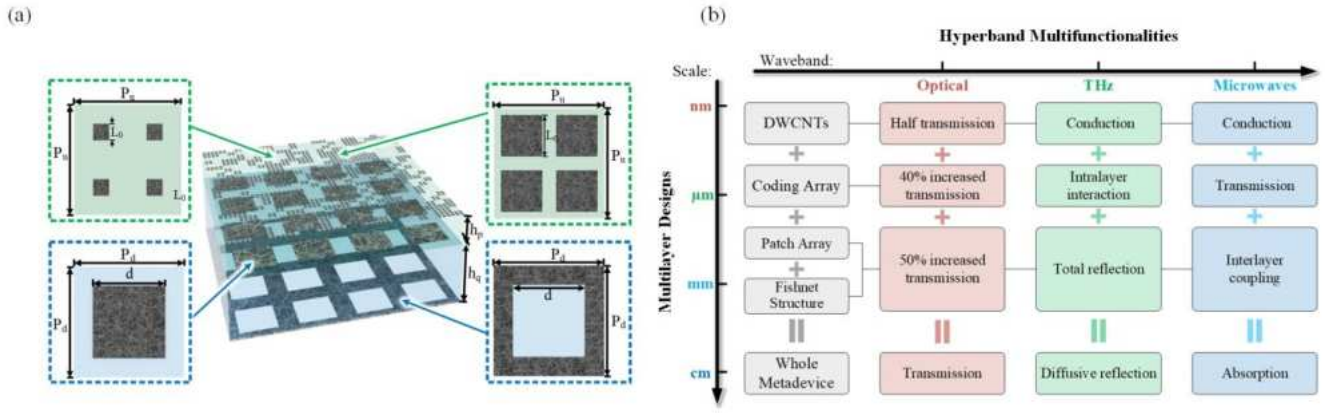

Figure 1 (a) Structural configuration of the DWCNT-based metasurface and (b) the working principle.

The proposed DWCNT-based metasurface is pictorially depicted by a three-dimensional schematic, which

consists of successively transferring thin layers of DWCNT coding array, polymer film, DWCNT patch structure, quartz glass and DWCNT fishnet structure from top to bottom. All these patterned layers are made of periodic subwavelength resonant elements and their periodic lengths are set to P_u = 150 μm and P_d = 10 mm, respectively. Therefore, the response frequency of the DWCNT coding array and the DWCNT patch/fishnet structure are correspondingly located in the THz and microwave regions to achieve different electromagnetic functions. In addition, the dielectric layers are selected as optically transparent polymer film and quartz glass materials, and they are set as h_p = 200 μm and h_q = 2 mm respectively to provide thin-film interferences for THz and microwave.

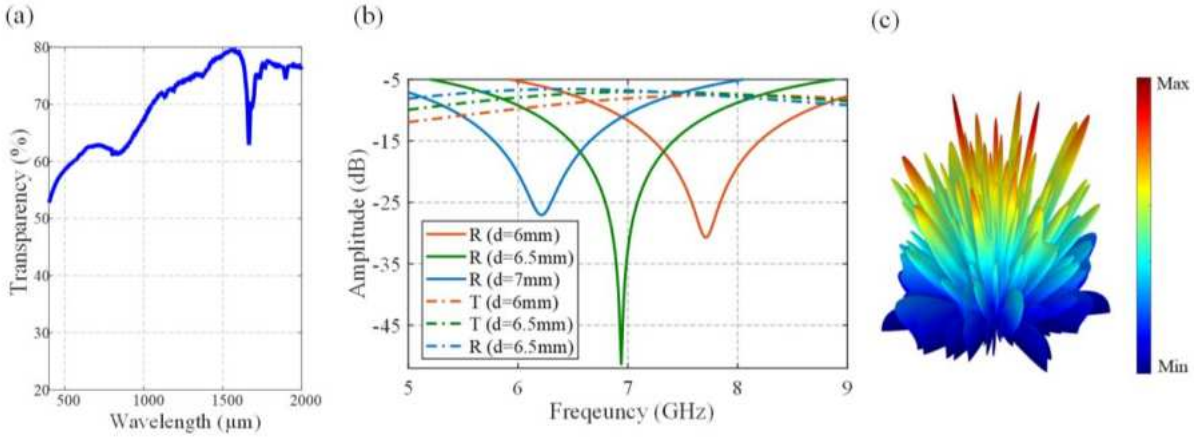

Figure 2 (a) Optical, (b) microwave and (c) terahertz responses of the proposed DWCNT-based metasurfaces.

From an optical point of view, we have quantitatively analyzed the transmittance of the proposed multilayer metasurface. Figure 2(a) illustrates that the proposed DWCNT-based metasurface enables over 60% transmittance in the wavelength range of 500 -2000 nm. To engineer the microwave responses, we simulated the reflection and transmission spectra of the proposed metasurface with different parameter d in Figure 2(b), which showing a sharp peak of reflection coefficients at resonant frequencies. For example, when d = 6.5 mm, the peak value of the reflection coefficient R is -48 dB while the transmission coefficient T is nearly -6 dB. When increasing the parameter d from 6 to 7 mm, the operating frequency of our DWCNT- based metasurface is tunable over a range from 6.2 GHz to 7.7 GHz. Furthermore, the THz scattering pattern of the proposed metasurface at 0.81 THz is demonstrated in Figure 2(c), showing diffusion-like scattering pattern randomly distributes the electromagnetic energy into numerous directions, which likes an electromagnetic wave impinging onto a rough surface, with significantly suppression of the radar cross section. In a word, we have designed a hyperband multifunctional metasurface capable of full- spectrum control of EM waves from microwaves to visible light, indicating great potentials in smart skin, electronic countermeasure, wireless communication system.

Abstract: Conducting polymers possess excellent reversible tunability for optical and electrical properties, enabling their various applications ranging from organic (opto)electronics to nanophotonics. In this talk, I will present our latest studies on conducting polymer devices for terahertz and infrared photonic applications.

Conducting polymers possess redox-tunable optical and electronic properties and have been explored in various areas, including electrochemical transistors, electronic skins, and thermoelectric generators. Recently, we reported their applications for plasmonic nanoantennas for near infrared applications, showing promising redox-state tunability towards spatiotemporally dynamic metasurfaces. In this study, we combined conducting polymers with sustainable cellulose nanofibrils (CNF) to form optoelectronic devices for tunable terahertz (THz) and infrared (IR) photonic applications.

The tunable electrical and optical properties of conducting polymers originate from the difference of their redox states, where at the oxidized state the polymers possess a high charge carrier density, while the charges are neutralized at the reduced state. Such redox state modulation can be realized by various ways, and in this talk, we chose both chemical and electrical switching approaches.

I will first present a conducting polymer-cellulose aerogel and demonstrate that it can provide broadband reversible tuning of THz transmission between 13% and 91% through chemical approach, while maintaining specular reflection loss below -30 dB in both states. We associate the exceptional THz modulation with the anomalous optical conductivity peak of conducting polymers, which enhances the THz absorption in its oxidized state while it decreases the reflection in its reduced state. We believe that such switchable THz materials provide a promising route towards large and broadband THz modulation for next-generation intelligent THz devices.[1]

By structural modification, we obtained a flexible conducting polymer-cellulose paper with highly suitable properties for electrically controlled IR devices. Both the specular reflection and emissivity could be modulated with large amplitudes (more than 40%) *via* the polymer redox state. This enabled various new application scenarios, where we focused on tunable radiative coolers, dynamic thermal camouflage, infrared anti-counterfeiting tags, and infrared dynamic displays. The devices are sustainable, cheap, flexible and mechanically robust, providing a versatile materials platform for active and adaptive IR optoelectronic devices.[2]

Abstract: In this study, we propose a fabrication-efficient way to enhance the tuning range of mid-infrared resonances based on graphene field-effect transistors. A tuning range in the mid-infrared of 700 nm is more than two times larger than the range presented in previous studies on similar devices with multiple resonances.

Conventional metasurfaces are “passive”, i.e., their properties are determined at the design stage. It is, however, highly desirable to develop real-time controlled metasurfaces for advanced photonics applications. There have been reports on tunable metasurfaces based on thermal, electrical, mechanical, and optical stimuli.[1-3] Among the materials considered for active metasurfaces, graphene, one of the most famous two-dimensional (2D) materials, has attracted a lot of attention.

The devices shown in Figure 1a consist of a monolayer graphene sheet which was grown by chemical vapor deposition and transferred onto a SiO_2/p^{++} doped Si layer. The metasurface is designed as a stack of 30 nm Au/10 nm Pd/10 nm Al_2O_3/graphene (Metal-Dielectric-Graphene – MDG) layers. A similar metasurface without the Al_2O_3 layer (Metal-Graphene – MG) is used as a reference. Reactive ion etching was used to create a rectangular graphene sheet. A plasmonic antenna array was fabricated on the graphene sheet by electron beam lithography (EBL), followed by molecular beam epitaxy (MBE) of 10 nm Al_2O_3, 10 nm Pd and 30 nm Au, and lift-off. Metal contacts (10 nm Ti and 200 nm Au) were deposited on top of the graphene sheet by EBL and MBE. The reflectance of the hybrid metasurfaces is calculated by FDTD simulations (Lumerical Solutions, Inc.).

We used in-situ current-voltage (I-V) measurements in the FTIR setup to study the reflectivity of the device for different gate voltages, ranging from -200 V to 100 V. As shown in Figure 1b (MG-metasurface) and Figure 1c (MDG-metasurface), the tuning range of mid-infrared resonances is enhanced compared to metasurfaces without barrier layer, i.e., from 300 nm to 700 nm for the 7.3 μm resonance and from 110 nm to 140 nm for the 4.7 μm resonance.[4] To further optimize the tunability, which suffers from the required high gate voltage related to a thick SiO_2 dielectric spacer, the spacer is replaced by an ultra-thin high-k dielectric layer allowing to tune the charge carrier concentration of graphene with a low gate voltage (-3 V to 3 V). All components of this device are made of complementary metal–oxide–semiconductor (CMOS)-compatible materials, providing pathway for large-scale production.

In conclusion, we propose a fabrication-efficient approach to resolve current limitations of electrically tunable graphene-metal metasurfaces. In the mid-infrared we achieve an increase of the reflectance modulation from 26% to 36%, together with a broad tuning range of 700 nm, which is more than twice as large as that reported in previous studies on similar multiple resonance devices without insulating interlayer.[4] Our

experiments are carried out in a graphene field effect transistor configuration, which offers in-situ monitoring of graphene's electrical response while recording the reflectance spectrum from an FTIR microscope.

Abstract: thermal scanning-probe lithography allows a direct-write fabrication route to create plasmonic nanostructures on top of exfoliated transition metal dichalcogenide (TMDC) crystals. This plasmonic-excitonic hybrid structure can be exploited to investigate heat diffusion at the nanoscale.

Semiconducting transition metal dichalcogenides (TMDCs), such as MoS_2 and WS_2, have emerged as promising candidates for next-generation optoelectronic devices, owing to their remarkable electronic and optical properties. They exhibit room-temperature excitonic effects and, when thinned down to a three-atom-thick monolayer, they are direct-gap semiconductors, endowing them with a strong photoluminescence (PL) signal. This makes TMDCs an excellent playground for exploiting light-matter interaction at the nanoscale.

By coupling a TMDC monolayer with metallic nanostructures exhibiting localized surface plasmon resonances (LSPR) it becomes possible to realize hybrid photonic systems for fundamental studies and novel applications. Within this framework, the excitons of the TMDC and the LSPR are viewed as optical resonators whose spatial coupling and spectral overlap can be freely tuned by engineering their nanoscale characteristics. Additionally, hybrid TMDC/plasmonic systems can be exploited as novel platforms to investigate the heat dynamics at the nanoscale, exploiting the thermoplasmonic effect of the plasmonic counterparts for locally generating heat, and the temperature dependence of the PL energy to act as a nano-thermometer.

Realizing these hybrid structures is by all means a complex task, that typically combines nanolithography approaches to deterministically fabricate the plasmonic counterpart with delicate growth-and-transfer methods to introduce the TMDC in the system. The issue with the realization of these systems is that the direct fabrication of plasmonic structures onto TMDCs with energetic particles (electrons, ions) is prone to damage these materials, whereas the transfer of TMDCs onto fabricated structures tends to be an aleatory process.

In this contribution, we exploit thermal scanning-probe lithography (t-SPL) as a viable alternative to electron-beam lithography or focused-ion-beam etching to directly write plasmonic nanostructures onto previously fabricated large-scale exfoliated 2D materials [1,2]. t-SPL works similarly to an atomic force microscope (AFM) with a heating tip; the desired pattern is written on a thermosensitive resist while acquiring a topological image of the sample. After gold deposition and resist lift-off, we are left with gold nanostructures over our TMDC. We demonstrated the appeal of this technique, fabricating regular, evenly spaced, 15 nm-thick plasmonic nanodisks (NDs) on square lattices onto monolayer- and bilayer-thick regions of TMDCs. Large-area MoS_2 monolayers were exfoliated from a bulk natural crystal following a procedure adapted from Ref. [3], that allowed to obtain homogeneous areas of TMDC with lateral size in excess of hundreds of μm.

The array of nanostructures consisted of a square arrangement of NDs with a nominal diameter of 200 nm and a gap of 400 nm over areas of 30×30 μm^2, realized onto monolayer and bilayer MoS_2. The NDs in object exhibit a LSPR at λ=1250 nm photon wavelength (1.0 eV), within the band gap of MoS_2. Figure 1 reports an AFM map of

the Au NDs fabricated over monolayer MoS_2. Round NDs are clearly observable on a square lattice.

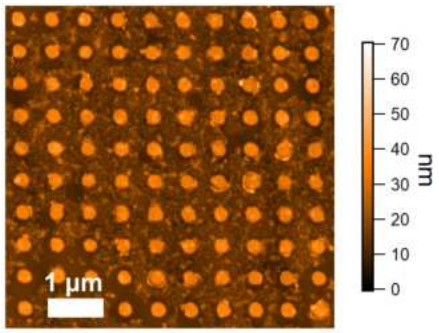

Figure 1. AFM image of Au NDs on monolayer MoS_2.

In order to verify that the fabrication procedure did not affect the structure and the optical functionality of the TMDC, Raman and PL spectra were acquired from pristine areas and from areas that had undergone fabrication. The results are reported in Figure 2. It can be clearly seen there that the fabrication has left the structural and optical functionalities intact.

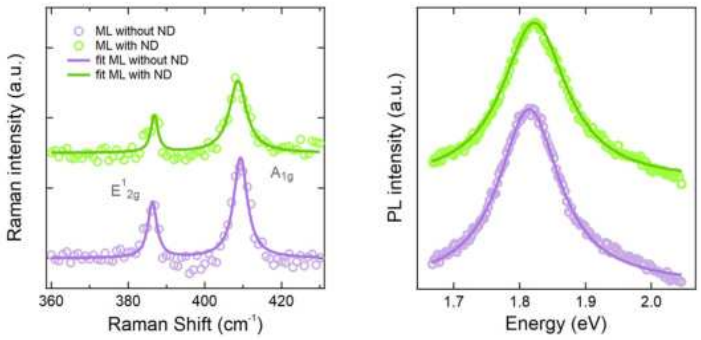

Figure 2. Left: Raman signal of monolayer MoS_2 with and without fabricated NDs. Right: PL signal of monolayer MoS_2 with and without fabricated NDs.

Summarizing, we report the application of a non-invasive nanofabrication method for realizing plasmonic nanostructures onto monolayer TMDCs while leaving their structure and functionalities intact.

Abstract: We introduce laser-based 3D printing through multi-photon lithography as an effective approach for fabricating 2D, 2.5D, and 3D structures with high resolution. Furthermore, we demonstrate these structures' capabilities to control electromagnetic radiation, offering interesting applications from the visible to the THz regimes.

Periodically arranged structures, ideally smaller than the wavelengths of interest, can effectively manipulate electromagnetic radiation through their design and material characteristics [1]. These structures often exhibit unique optical properties, making them highly suitable for a wide range of applications in optics and photonics across a broad spectral range.

A powerful technique for fabricating these structures across this extensive regime is laser-based 3D printing via multi-photon lithography (MPL). This method enables true 3D printing with ultrafast lasers without the need for masks, a vacuum atmosphere, or harsh chemicals [2]. Beyond true 3D printing, MPL also effectively supports 2D and 2.5D fabrication, making it a highly versatile tool for manufacturing structures of varying complexity designed to control electromagnetic radiation efficiently.

MPL was successfully employed to fabricate 2D, 2.5D, and 3D structures and demonstrate their application from visible wavelength to the THz regime. These structures can be inspired by nature, where, for example, certain organisms develop sophisticated surface structures for advanced light-matter interactions [3]. Another source of inspiration comes from classical metasurfaces that allow for the control of amplitude, phase, and polarization of electromagnetic radiation through precisely engineered 2D unit cells [4].

To specifically enhance MPL's efficiency for 2D and 2.5D structures, MPL was conducted in a photosensitive thin film, as illustrated in Fig. 1. These thin films were produced using spin-coating, primarily employing a hybrid photoresist synthesized via a sol-gel process. This approach significantly improves the axial resolution in MPL, positively impacting the printing speed. Notably, 2D and 2.5D structures on a 1 cm² area could be printed in just 1.5 hours using this technique.

To demonstrate the versatility of MPL, structures were fabricated on various reflective substrates, including glass, silicon (Si), and silicon-on-insulator (SOI). Specifically, we showcase the application of these structures to generate angle-insensitive coloration, inspired by the blue Morpho butterflies, as anti-counterfeit features. Furthermore, large-area metasurfaces were fabricated to modulate the dielectric permittivity atop an SOI wafer. This facilitates the coupling of an incident wave to leaky photonic modes guided in the Si device layer at discrete wavelengths—a phenomenon known as guided-mode resonances (GMRs), highly benefical for mid-IR spectroscopy. Additionally, 3D low THz-metasurfaces were explored, focusing on electromagnetically induced

transparency (EIT). In this context, we investigated that two metallic split-ring resonators (SRRs)—one exhibiting asymmetry—can generate such an extraordinary effect, proving highly effective for sensing applications. The EIT effect arises from asymmetric features, which induce a shift in the magnetic dipole moment. As a proof of concept, such 3D structures were fabricated via MPL and subsequently post-processed using selective electroless plating with silver. The structures were characterized using time-domain spectroscopy (TDS). The resulting optical properties compared to the simulations.

Slime mold algorithm for topology optimization of photonics structure

K.S. Edee[1*] and P. Bonnet[1]

[1]Université Clermont Auvergne, Clermont Auvergne INP, CNRS, Institut Pascal, Clermont-Ferrand F-63000, France.

Abstract: We introduce an innovative approach to photonics structure design, incorporating the slime mold algorithm (SMA) [1], a gradient-free metaheuristic optimization method, in tandem with the topology optimization (TO) method, and utilizing a spectral modal method. Through the integration of TO with SMA, (TO-SMA) we achieve successfully metagrating designs [2].

In this paper, we present the application of the Slime Mold Algorithm (SMA) to topology optimization for a 1D dielectric metagrating (see Fig. 1), within the framework of a spectral method. The primary objective of this design is to formulate a 1D metagrating composed of a sequence of nanorods and air gaps with varying widths, strategically optimized to efficiently redirect incident plane wave power into a specified transmission order. The proposed SMA initiates by generating a random set of widths for the nanorods and air gaps. A corresponding set of binary permittivity functions is defined for this sequence of nanorods/air gap widths. However, since our focus is on a Topology Optimization (TO) method, we apply a blurring process to this initial population. This process transforms the discrete set of widths into a continuous sequence of permittivity functions. A noteworthy aspect and a key feature of our proposed method lie in the choice of the filter employed during this blurring process. Instead of opting for classical Gaussian or binary functions as filters, we introduce the Schwartz function. The shape of the function can be significantly altered by adjusting some of its key parameters, providing enhanced flexibility and control over the continuous permittivity function at each iteration during the optimization process.

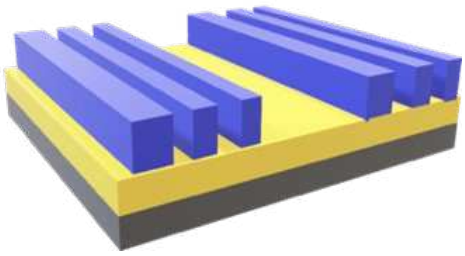

Figure 1 : A 1D deflector to be designed

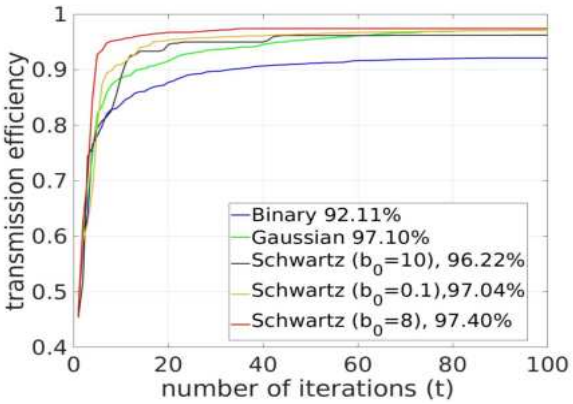

Figure 2: Performances of the TO-SMA using different filter functions: the Schwartz, Gaussian and binary functions

In Fig. 2 we emphasize the impact of the Schwartz function on numerical results, we compare the

performance of TO-SMA using the Schwartz filter with different shapes. This assessment involves a comparison with Gaussian and binary functions. The Schwartz filter demonstrates a remarkable ability to converge rapidly towards high-performance solutions. A flow chart of the proposed algorithm is shown in Fig.3

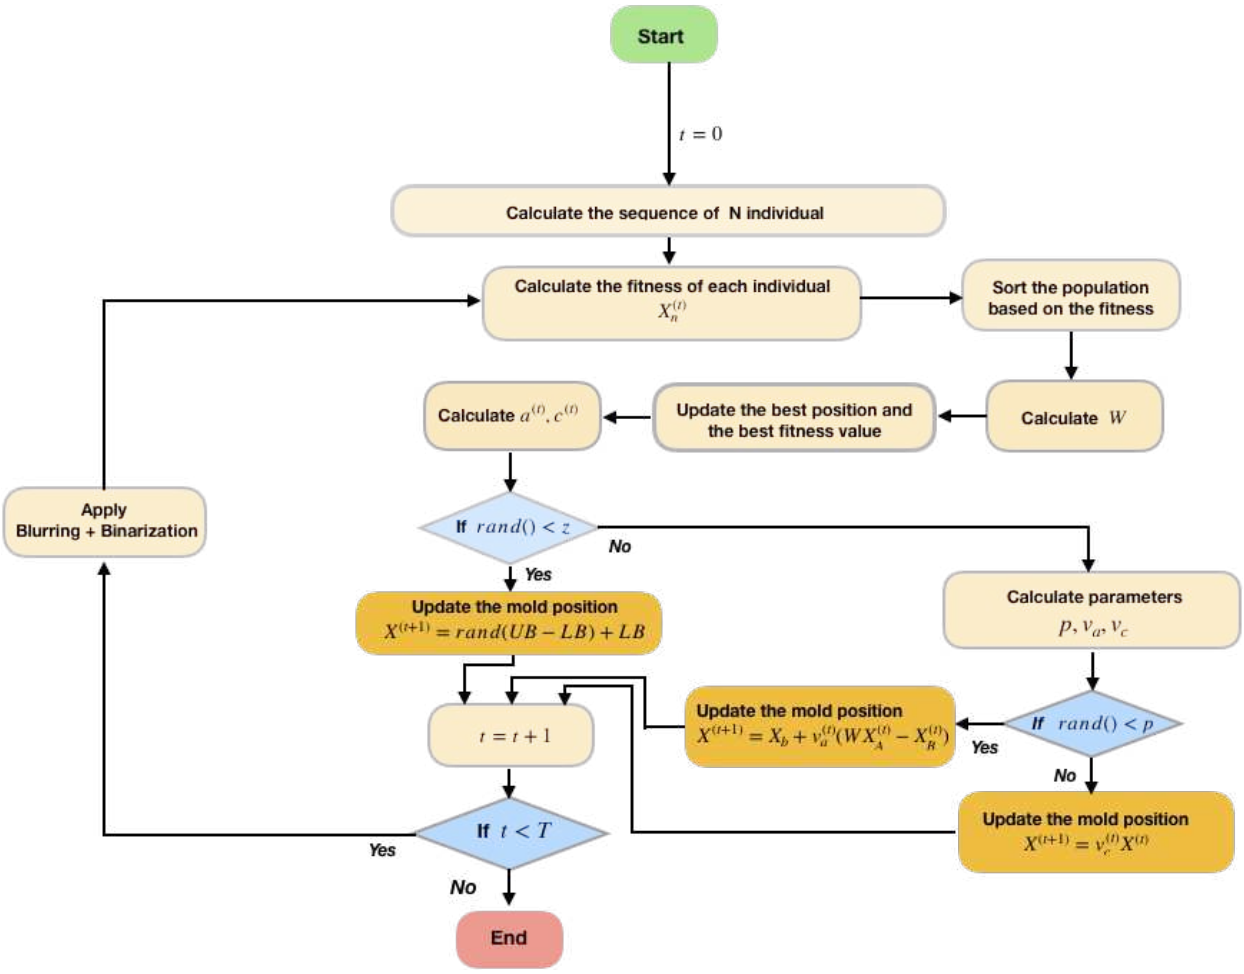

Figure: 3 A flow chart of the algorithm

Abstract: We report a combined experimental-theoretical investigation on more than three orders of magnitude enhancement in the second and third harmonic generation from plasmonic metasurfaces in the visible and UV ranges. Our experimental results are validated by our unique microscopic, hydrodynamic model for linear and nonlinear interactions in metal surfaces.

In the last few decades, both experimental and theoretical nonlinear optics (NLO), have focused on illuminating thick materials under phase matching conditions in the low absorption spectral range, to maximize the bulk nonlinear (NL) interaction and achieve very high NL efficiencies. The NL polarization term plugged into the Maxwell's equations, primarily consists of the electric-dipole/bulk contribution ($\chi^{(2)}$) while other contributions coming from the surface or magnetic effects, are usually many order of magnitude smaller and thus neglected. However, as the material thickness is reduced down to nanometer size, the bulk nonlinearity reduces drastically producing second (SH) and third harmonic (TH) signals with efficiencies of the order of 10^{-7}-10^{-13}, thus becoming comparable to surface nonlinearity, electric quadrupole and magnetic sources [1]. In this scenario, optical nanomaterials have emerged as a very promising platform to capture new and unique aspects of light localization and light-matter interaction at the nanoscale. The rapid development in nano-fabrication techniques lead to precision designs of subwavelength optical metamaterials (nanospheres, gratings, pillars etc.). But soon it became clear that classical NLO theories rely on approximations that cannot fully explain metals/metallic nanostructures, the observed effects and an effort is needed to fully describe the behavior of light propagation and interaction at the nanoscale and in particular in metasurfaces.

Here we porpose a novel approach to face this problem that considers in first place the nontrivial problem of how the strategic materials used in the photonics nanostructure fabrication (i.e. metals, semiconductors, or conductive oxides) respond to linear and NL excitation by ultrashort laser pulses in different spectral range. These studies, performed on layers a few nanometers thick, remove the usual approximations and identify new mechanisms that may trigger the interaction, and must be consistently accounted for in the theoretical models in order to understand the physics involved. Recently we have studied, both experimentally and theoretically, the behavior of different materials and gained new understanding about the basic physical mechanisms responsible for their optical response. Our theoretical approach is based on a Maxwell Hydrodynamic model that accounts for competing surface, magnetic, and bulk nonlinearities arising from both free (conduction) and bound (valence) electrons and preserves linear and NL material dispersions, nonlocal effects, and the influence of hot electrons [2]. Our previous studies on SH and TH generation from 20 nm and 70 nm-thick gold nano layers allowed us to extract its basic physical intrinsic properties [4].

However, the NL efficiency from nanolayers are extremely low. An important enhancement can be envisaged by tailoring and enhancing the NL optical properties of metals in specifically designed metasurfaces by taking profit of plasmonic resonances responsible for the strong spatial confinement of electromagnetic field near the surface of the metal. The properties of the nanostructures are determined by the geometrical (shape, size, and sharpness) and physical parameters (dielectric functions at a given wavelength) of both the metal and the surrounding dielectric materials. A strong plasmonic

interaction can significantly enhance light-matter interaction, and generate very large surface nonlinearities [3,5], giving rise to HHG conditions under relatively low input laser intensities. This enables the manipulation of optical fields with unprecedented spatial (far beyond the diffraction limit) and time resolutions.

Fig.1 shows several of the considered configurations and demonstrates the E-field localization within two kinds of SP surface plasmonic localization (E-field is confined around the corner of a 2-D grating [5], E-field is confined inside a nanohole). Our very recent results from the 2D nanograting show that under the right excitation conditions we can achieve between three and five orders of magnitude enhancement factor in the SH and TH harmonic generation (Fig 1(a)). Although a more sophisticated quasi-3D structure consisting of nanoholes in gold, provides more tunability and shaping of the plasmonic resonance, however the NL enhancement is much lower. Fig-1(b) shows the narrow plasmonic resonance centered around 790 nm, both measured and simulated using Finite Difference Time Domain, the depth and position of which depends on the period of the hole pattern, the diameter and depth of the hole and thickness of the gold layer deposited on top. Under the resonant illumination conditions as in ref 5, the nanoholes show a TH enhancement factor of ~100 (Fig-1(c)).

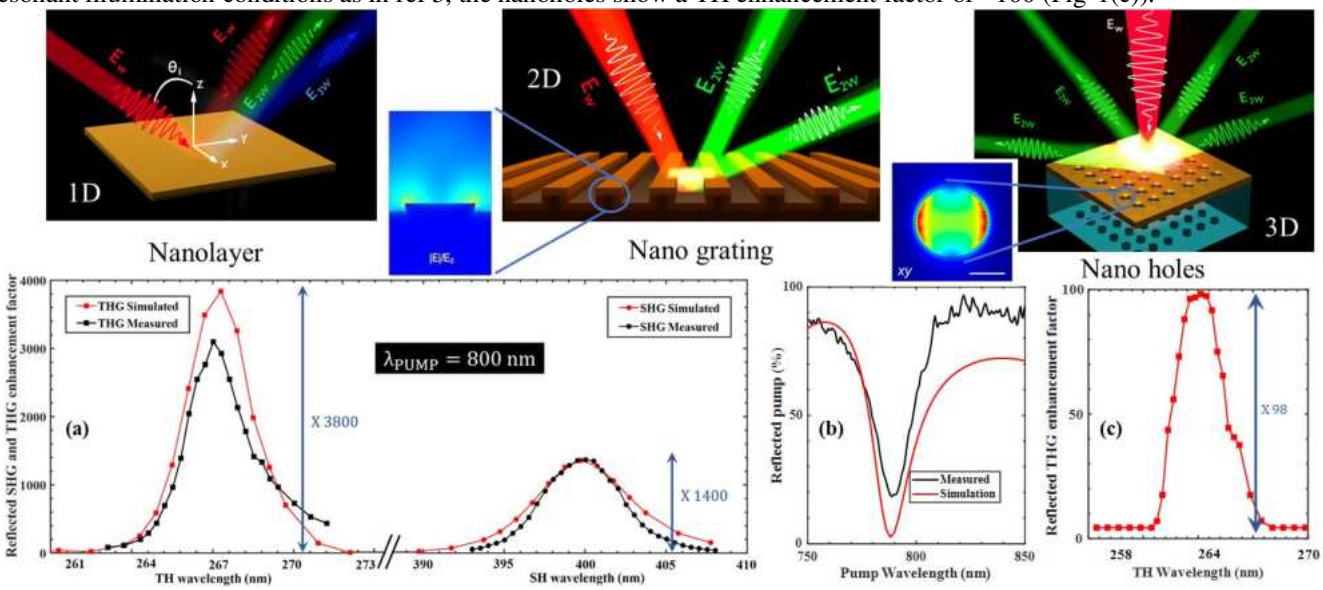

Fig 1. Examples of 1D, 2D and 3D nanostructures, light confinement and enhancement in nonlinear interaction [4-5]

Plasmon induced NL generation can be directional or diffused, the periodicity of the structures may enable constructive interference of the generated SH/TH in certain directions, producing diffraction orders, proving experimental retrieval of the total generated SH/TH to be challenging. A 2D grating will diffract in the plane of incidence while the diffraction from a 3D structure is more complicated (Fig-1). Our sophisticated detection system and precision calibration enables us to detect and quantify SH/TH efficiencies, and corroborate our theoretical and experimental observations of shape, spectral width, and maximum amplitude of the spectral response.

Apart from Au, successful detection of SH from few nm thick aluminium also unraveled remarkable consequences of resonant absorption, a critical role that bound electrons play in light-matter interactions across the optical spectrum. Precise engineering of metasurface geometry and modern fabrication methods promise very well-tailored plasmonic structures and is the way to produce compact higher frequency light sources embedded with nonlinear components beam-deflecting, metalenses, meta-holograms, orbital-angular-momentum (OAM) beams etc [3].

Synthesis and plasmonic properties of Fe_3O_4-Au-Pd hybrid nanoparticles

Y. Yokota[1*] and Mao. Takeda[1]

[1] Department of Materials and Life Sciences, Faculty of Science and Technology, Sophia University, 7-1Kioicho, Chioyoda, Tokyo 102-8554, Japan

Abstract: In this study, we focused on iron oxide to magnetically resolve noble metal nanoparticle arrays or to construct noble metal nanoparticle three-dimensional structures. By adding gold and palladium to iron oxide nanoparticles synthesized in the liquid phase, we developed a method for synthesizing iron oxide-gold-palladium nanoparticles (Fe_3O_4-Au-Pd nanoparticles) that can be recovered with a magnet.

The fabrication of metasurfaces and metamaterials requires the precise 2-D or 3-D alignment of noble metal nanoparticles. In the past, for example, controlled orientation of Pd nanosheets [1] was achieved by liquid-phase synthesis. In this study, we focus on iron oxide with magnetic force as a means to resolve the alignment of noble metal nanoparticles by magnetic force or to construct a three-dimensional structure of noble metal nanoparticles. In addition, when used as individual nanoparticles, the nanoparticles are light in weight and need to be collected by centrifugation after the reaction is completed in order to be reused. As noble metals to be combined as nanoparticles, we used not only gold, which can induce high electric field enhancement by localized surface plasmon resonance, but also Pd, which has high catalytic activity. By adding Au and Pd to iron oxide nanoparticles synthesized in the liquid phase, we developed a method for synthesizing iron oxide-gold-palladium nanoparticles (Fe_3O_4-Au-Pd nanoparticles) that can be recovered using a magnet.

The Fe_3O_4 nanoparticles were prepared by coprecipitation of iron (II) chloride tetrahydrate and iron (III) chloride hexahydrate with ammonia water dropwise in the liquid phase [2]. After collection and purification with a magnet, the Fe_3O_4 nanoparticles were protected with a surfactant, CTAB, and $HAuCl_4$ was added to synthesize Fe_3O_4-Au nanoparticles. Fe_3O_4-Au-Pd nanoparticles were then synthesized by adding H_2PdCl_4. The synthesized nanoparticles were collected with a magnet, measured for absorbance, and observed for shape by scanning electron microscopy (SEM) and transmission electron microscopy (TEM).

Fig. 1(a) shows the absorption spectra of the synthesized Fe_3O_4 nanoparticles (blue line) and Fe_3O_4-Au nanoparticles (red line), respectively. The absorbance spectra of Fe_3O_4-Au nanoparticles show a clear peak at a wavelength of 525 nm, which are attributed to the plasmon resonance of the Au nanoparticles. From the absorption spectrum in Fig. 1(b), the Fe_3O_4-Au-Pd nanoparticles have a larger absorbance toward longer wavelengths and may show

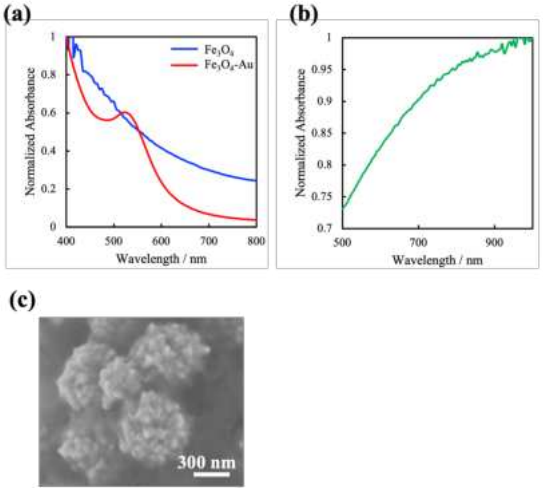

Fig. 1 UV-Visible absorption spectra of (a) Fe_3O_4 and Fe_3O_4-Au nanoparticles and (b) Fe_3O_4-Au-Pd hybrid-nanoparticles. (c) SEM images of Fe_3O_4-Au-Pd hybrid-nanoparticles.

a peak after 1000 nm. When Pd is grown on the surface of Au nanoparticles, the localized surface plasmon resonance-derived peak is also reported to become broadened [3], so this change can be considered to be due to Pd growth. Fig. 1(c) shows SEM images of Fe_3O_4-Au-Pd nanoparticles. For the Fe_3O_4-Au-Pd nanoparticles, a needle-like growth shape was observed on the surface. Although not shown in the figure, TEM and EDS mapping confirmed the presence of Fe, Au, and Pd in the nanoparticles. From these results, the amount of Pd deposited on the surface relative to the Fe_3O_4-Au nanoparticles was large, which may have shifted the absorption peak derived from plasmon resonance to the long wavelength side.

In conclusion, we were able to synthesize hybrid nanoparticles with a diameter of about 200 nm that can be recovered by a magnet that exhibits a plasmon resonance peak in the near infrared by adding Au and Pd to the liquid phase synthesized iron oxide nanoparticles.

Abstract: In this study, we present an assembly technique based on the use of the capillarity force and allowing the obtaining of metasurfaces from silicon nanoparticles. Particularly, we will present the use of such technique to obtained complicated pattern thus paving the way to the fabrication of engineering metasurfaces.

In our synthesis technique, we simply grind bulk silicon to obtain nanoparticles[1]. This technique allows us to obtain in solution Si nanoparticles with a diameter ranging from 80 nm to about 250 nm. By centrifugation steps, it is possible to obtain a final mean size of about 120 nm ± 20 nm.

In the second step, nanoparticles are deposited in a pattern obtained by electron lithography. This technique, based on the assistance of capillary forces, makes it possible to obtain large surfaces from a colloidal solution of nanoparticles, as shown schematically in figure 1a. In this step, nanoparticles in solution are deposited in patterns formed in a PMMA layer. Figure 1b shows nanoparticles of two different sizes distributed in a complex pattern with a fill rate close to 100%. During the lift-off step, the Si NP arrays remain well organized on the substrate. We carried out a systematic study of nanoparticles sorted by four sizes of size patterns. This enabled us to obtain a regular square pattern of 4 nanoparticles separated by 600 nm and formed by nanoparticles of diameter D1≈300 nm, D2≈250 nm, D3≈200 nm and D4≈150 nm. To take our analysis a step further, we measured the average size of nanoparticles on the drawing containing 4 types of holes (add sizes) and the corresponding RGB colors.

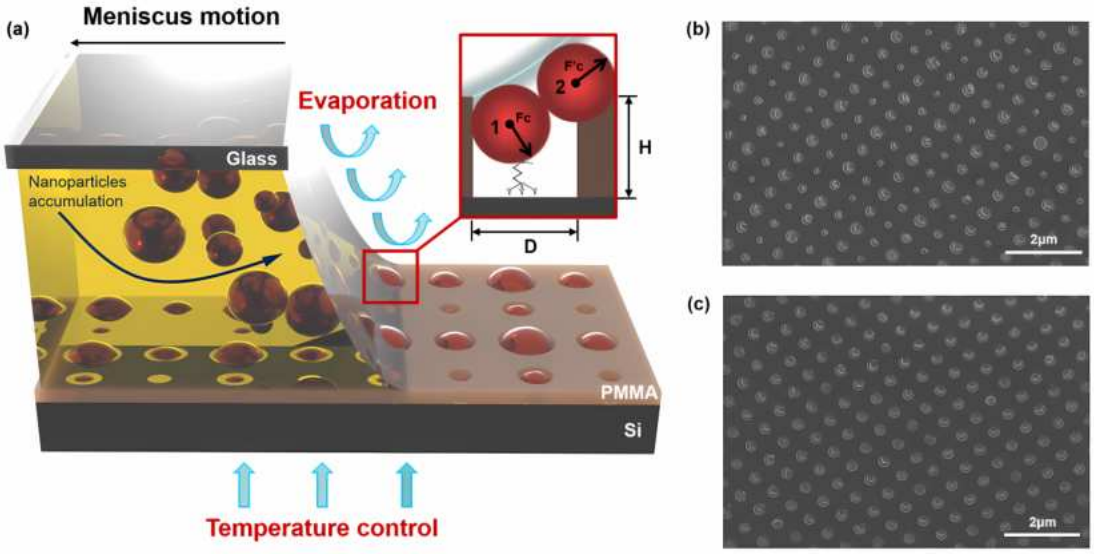

Figure 1. NP assembly. (a) Schematic diagram of capillary force assisted Si NP assembly process. SEM

micrograph of a randomly selected assembly (b) area 1 and (c) area 2 showing the deposition of single NPs.

We have demonstrated that it is possible to organize naonaoparticles obtained in solution on a surface using a technique that is relatively simple to implement and compatible with all nano-lithography techniques.

All-Garnet Magnetooptical Microcavity

Taichi Goto[1,*]

[1]Research Institute of Electrical Communication, Tohoku University, Japan
[*]corresponding author: taichi.goto.a6@tohoku.ac.jp

Abstract: Magnetooptical device using magnetic domains have attract many interests because of its quick response and large diffraction angle. To develop these devices, we grew all-garnet magnetooptical microcavity using rf ion-beam sputtering, showing nano-scale magnetic domain and a large Faraday rotation angle.

Magnetooptical devices, including magnetooptical Q-switched lasers [1], spatial light modulators, optical isolators [2], and magnetic holographic memory, have attracted significant interest due to their unique properties. In these applications, a large magnetooptical response and small magnetic domains are crucial parameters. However, achieving a large magnetooptical response with magnetic films that exhibit tiny magnetic domains is challenging due to the relationships among film thickness, magnetooptical response, perpendicular magnetic anisotropy, and magnetic domain width. As thickness increases, so does the magnetooptical response. Conversely, perpendicular magnetic anisotropy decreases due to the relaxation of strain between the film and the substrate, leading the easy axis of magnetization to orient in-plane and resulting in the disappearance of magnetic domains from the magnetic film. Hence, in this study, we employed a microcavity structure to achieve a large magnetooptical response and tiny magnetic domains generated by perpendicular magnetic anisotropy.

Magnetic garnet films were epitaxially grown on a gadolinium gallium garnet (GGG) substrate using RF ion beam sputtering [3]. During growth, the sample temperature was maintained at 900°C. Two types of magnetic garnets, cerium-substituted yttrium iron garnet (Ce:YIG) and GGG, were alternately grown to create Bragg mirrors. Within the Bragg mirror, a defect layer, twice as thick, was introduced to provide a localized mode within a photonic band gap and enhance the Faraday rotation angle. This structure is referred to as a microcavity or magnetophotonic crystal. The Ce:YIG and GGG have slightly different lattice constants, generating lattice strain, perpendicular magnetic anisotropy, and magnetic domains.

The magnetic domains of the fabricated Bragg mirror and microcavity were observed using a magnetooptical microscope, as shown in Figure 1. The width of the magnetic domain was less than 500 nm, and the domain wall width was less than 100 nm. The detail will be shown in the symposium.

The Faraday rotation angle was enhanced by the microcavity resonance at a near-infrared wavelength. Therefore, large magnetooptical responses and tiny magnetic domain structures were simultaneously obtained using the all-garnet magnetooptical microcavity sample.

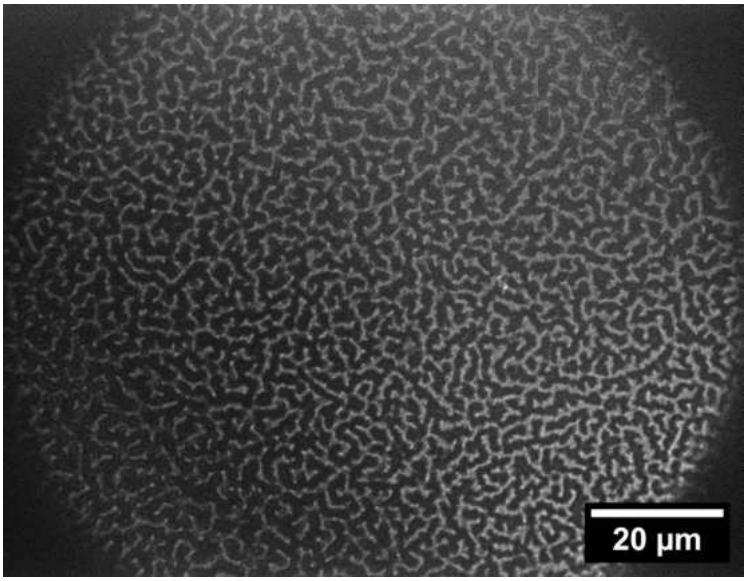

Figure 1. Magnetooptical microscope image of the sample. The observed wavelength was 470 nm. The magnetic field was not applied to the sample.

Abstract: This talk will discuss the novel use of microscale concave interfaces (MCI) for generating structural colors through total internal reflection interference. Highlighting both theoretical understanding and experimental research, it promises significant applications in information display, traffic safety, and photonics.

In our daily lives, both humans and machines utilize various colors to decipher and process critical information. As the field of modern physics has advanced, our understanding of color generation has significantly expanded, enabling the characterization of diverse coloration phenomena. These phenomena range from optical dispersion, exemplified by prism-induced rainbows; spectrally selective absorption, observed in chemical pigments and resonant photonic structures; to thin-film interference, visible in the iridescence of bubbles and oil slicks. Among these, structural colors are particularly noteworthy for their reliance on geometric optimization to produce color, eschewing traditional pigments or dyes. This method of coloration has piqued the interest of the scientific and industrial sectors due to its innovative ability to manipulate light flow.

A notable advancement in this realm is the exploration of total internal reflection (TIR) interference through microscale concave interfaces (MCI), as recently proposed [1,2]. This mechanism stands apart from conventional coloration processes, presenting both exciting possibilities and significant challenges for incorporation into large-scale displays and sensors. This presentation aims to delve into a combined approach of fundamental and experimental research to demystify the physical underpinnings of MCI. Emphasizing the exploration of an unambiguous physical mechanism for this new MCI structure, our discourse is grounded in systematic experimental characterization [3]. As a result of this characterization, we realized a previously unseen multiple concentric ring phenomena, as shown in **Fig**. **1**.

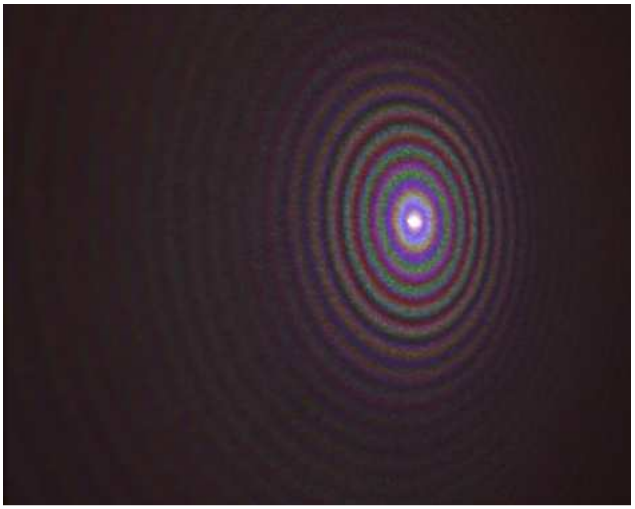

Fig. 1| Multiple concentric rainbow rings generated by an MCI sample containing polystyrene microspheres with a mean diameter of 42μm.

Building on these insights into novel optical interface structures, we will highlight advancements in selected hybrid technologies spanning both visible and infrared display and spectroscopy [4]. The realization of these cutting-edge reflective coloration strategies is anticipated to drive pivotal technological breakthroughs, particularly in information display applications. Furthermore, the development of micro-optics structures is set to propel research and development efforts, with wide-ranging impacts from enhancing traffic safety [5] to anti-counterfeiting and optical encryption [6-10].

Abstract: This study aimed to investigate the growth process of thin films on a nanostructured surface and to analyze the perspective to use such elements in micro lasers. Optical characterization revealed the presence of Fano-like resonance phenomenon in such single-layer structure, surrounded by a lower refractive index media. Moreover, we demonstrate a 5 μm thick photonic multilayer structure composed of alternating high- and low-index materials, providing angular selectivity of light. The proposed 2D photonic structure can be considered as a promising component for intracavity spatial filtering and polarization control, even in high-power microlasers.

In micro-lasers, especially in high-power emission regimes, the spatial quality of the laser light beam deteriorates. Typically, a confocal arrangement of lenses with a diaphragm in the focal plane is used for intracavity spatial filtering; however, such conventional filtering requires access to the far-field domain. Conventional filtering is impossible in microlasers due to the lack of space in micro-resonators to access the far-field. Therefore, a novel concept for compact and efficient spatial filtering is necessary.

This work presents the investigation of 2D periodic structures made by conformal deposition of dielectric thin films on the modulated surface, where the deposited layers repeat the primary surface [1,2]. The investigation revealed that Fano-like resonance can be exited even in a periodically modulated single layer with a higher refractive index than the surrounding media. The proposed structure shows high angle-wavelength sensitivity of light transmission/reflection, which can be used to manipulate the properties of the beam radiation perpendicular to the surface. Moreover, we experimentally demonstrate a 5 μm thick photonic multilayer structure composed of alternating high- and low-index materials providing spatial filtering in the near-infrared frequencies with a 2° low-angle passband. Depending on the architecture, such spatial filtering may be performed in transmission or reflection with the incidence of radiation perpendicular to the surface. Furthermore, due to the linear structure, such elements can work as 0° AOI polarizers.

Fg.1. The image of fabricated sample (left) and transmission spectra of nanostructured coating polarizer for both S and P polarizations (right).

In the presentation, the overview of different technologies to form conformal coatings on periodically modulated surfaces will be presented. As the proposed 2D photonic structure can be considered a promising component for intracavity spatial filtering, the integration into microchip laser will be presented. A significant reduction of M^2 and brightness increase of two times was recorded for the microchip laser when the fabricated spatial filter was used as one of the resonator mirrors. Moreover, the investigation on resistivity to laser radiation and further improvements will be presented.

Abstract: We have developed a method to control the spin-orbit coupling of light by embedding emitters within liquid-crystal microcavities. We explore light-matter interactions in both weak and strong coupling regimes, which extend beyond traditional optical properties. This approach has enabled us to achieve tunable lasing, including dual and circularly polarized lasing.

Metamaterials are artificial materials engineered to achieve properties not found naturally, using specialized functional units. Especially, these structures are designed to manipulate electromagnetic waves in unique ways. The physics of microcavities has become rich over recent decades, enhanced by the diversity of materials that can be embedded within them. These materials can significantly alter cavity mode properties, and conversely, the response of the materials can be influenced by the cavity, extending beyond optical properties.

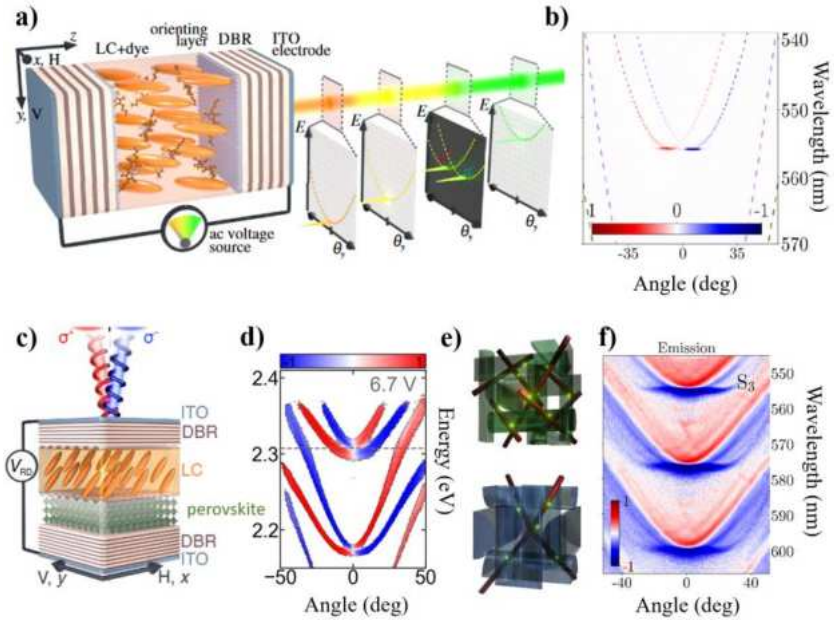

Figure a) scheme of the tunable dye-doped LC microcavity [5]; **b)** lasing in RD spin-orbit regime [5] (experiment); **c)** schematic representation of the LC microcavity with the two-dimensional (2D) hybrid organic-inorganic perovskite layer [7,8]; **d)** circularly polarized emission in strong light-matter coupling [7] (experiment, Stokes S_3 parameter); **e)** Blue phase LCs in phases BPI and BPII (top and bottom respectively): 3D self-organizing photonic crystal [10]; **f)** circularly polarized emission from a laser dye-doped blue phase integrated within a microcavity (Stokes S_3).

We have developed a method to electrically control the spin-orbit coupling (SOC) of light using specially designed photonic structures – birefringent microcavities (**Fig. a**). These consist of a 2-3 μm thin liquid crystal layer enclosed between two parallel distributed Bragg reflectors deposited on transparent electrodes. In solid-state systems with broken inversion symmetry, SOC gives rise to the Dresselhaus and Bychkov-Rashba

SOC Hamiltonians, key to spintronics, topological insulators, and superconductors. Unlike SOC in solid-state matter, which is challenging to manipulate, birefringent optical cavities offer substantial tunability of photonic modes. This has led to observing an optical analog of the spin Hall effect and creating artificial gauge fields for parameters extending far beyond those previously considered experimentally and theoretically [1]. We discovered Rashba-Dresselhaus spin-orbit coupling in a photonic system and showed control of an artificial Zeeman splitting [2]. Additionally, we've shown how to structure light so its polarization mimics spins in a ferromagnet, forming half-skyrmions (merons) [3]. Recently we observed an optical analog of persistent spin helix, reciprocal Young's and Stern-Gerlach experiments [4], and a new type of chiral Rashba-Dresselhaus lasing [5] (**Fig. b**). Our results illustrate an effective approach to engineering artificial gauge fields and synthetic Hamiltonians with photons for the simulation of nontrivial condensed matter and quantum phenomena, promising new directions in topological photonics [6-8], non-Hermitian systems [6,9] and condensates of light. By embedding emitters within birefringent microcavities, we explore light-matter interactions in both weak [5] (**Fig. a,b**) and strong coupling regimes [7-8] (**Fig. c,d**).

The platform we proposed opens new possibilities in topological photonics [7-9]. Beyond the standard lithographic methods, our approach with liquid crystal cavities enables the creation of self-organizing macro-molecular structures, whose sizes and shapes can be controlled by temperature or electric fields. Our team has successfully integrated a self-organizing liquid crystal structure – specifically, a blue phase, whose structure can be regarded as a 3D photonic crystal (**Fig. e,f**) – within a microcavity [10]. Additionally, these periodic photonic structures allow for precise control over optical modes, enhancing their functionality and application potential.

Abstract: We use time- and energy-resolved single particle spectroscopic imaging to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single β-$NaYF_4:Yb^{3+}:Tm^{3+}$ upconverting nanoparticles (UCNPs) supported on self-assembled chiral metasurfaces[1]. By examining the effects at the single particle level, we assess the plasmon-enhanced radiative decay and polarization of upconversion luminescence on metasurfaces self-assembled from tetrahedral Au nanoparticles. We obtain a statistical description of UCL emission enhancement in the Tm-doped UCNPs and map out the statistical distribution of excitation and luminescence enhancement on plasmonic substrates[2–4]. We use both wide field and confocal scanning spectroscopic imaging of single UCNPs on and off the plasmonic substrates in combination with energy and time resolved spectroscopy, and compare these results to a coupled rate equation analysis to elucidate the energy transfer upconversion enhancement mechanisms. The results obtained are compared to Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate.

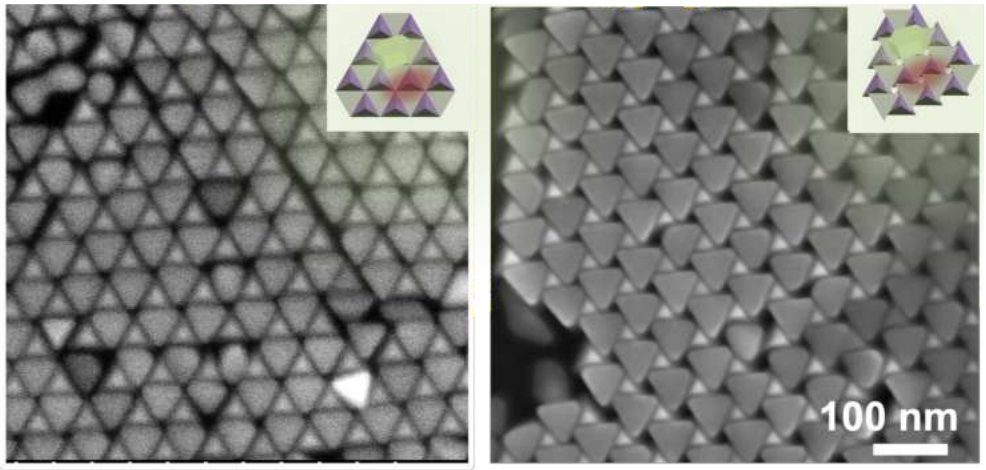

Figure: SEM images of self-assembled symmetric (left) and chiral (right) metasurfaces obtained by self-assembly of Au tetrahedra. Inset: Schematic of self-assembled metasurfaces supporting single UCNPs.

Advanced Computational Electromagnetics for the Analysis and Design of Nanophotonic Devices

Refined Quantum Hydrodynamic Model for Deep Nanoscale Plasmonics with Noble Metal and Dielectrics

Xue-Wen Chen[1,2*]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, China.
[2]Wuhan Institute of Quantum Technology, Wuhan, China.

Abstract: Quantum hydrodynamic model has become a versatile and efficient tool for plasmonics at the deep nanoscale, but the current model is in principle only applicable to simple metals, not for noble-metal structures. We present a refined quantum hydrodynamic model to effectively account for various effects from noble metals.

Plasmonic resonances of metallic nanostructures, especially those made from noble metals, have the capability of confining light down to the deep nanometer scale. As optical fields are concentrated below ~10 nm and towards the Thomas-Fermi screening length scale, the nonlocal and quantum effects of conduction electrons become significant. The quantum hydrodynamic model (QHDM) directly computes the conduction electron density and current by solving a hydrodynamic equation. The equation retains the quantum and many-body effects with internal energy functionals and viscoelastic tensors of conduction electrons. Consequently, the QHDM could account for various quantum effects with affordable computational cost, and thus outstands as a promising method for studying nanoplasmonics.

However, the existing QHDMs are designed for simple metals. The application to noble metals hasn't been duly justified. For noble metal, while the direct effect from the d-band (or bound electrons) could be depicted with a background optical permittivity in Ampere's law, the indirect effect from these d-band electrons on the conduction electrons has not been taken into account. In addition, when the noble-metal structures interface with dielectrics, the electron affinity of the dielectrics near the interface should be properly described. Here we report a refined QHDM, where the missing effects of the d-band electrons are identified and included [1]. The near-field effects of the d-band electrons and electron affinity of the dielectric are encompassed with an extra potential U_{aff} in the refined QHDM [2]. Material-independent model parameters are fitted with density functional theory (DFT) calculations for simple metal. Our calibrated QHDM is lastly benchmarked against DFT and time-dependent DFT for Ag, Au and Al nanostructures interfacing with dielectrics. We expect our QHDM would be a valuable asset for the rapidly developing field of extreme nanophotonics.

Slime mold algorithm for topology optimization of photonics structure

K.S. Edee[1*] and P. Bonnet[1]

[1]Université Clermont Auvergne, Clermont Auvergne INP, CNRS, Institut Pascal, Clermont-Ferrand F-63000, France.

Abstract: We introduce an innovative approach to photonics structure design, incorporating the slime mold algorithm (SMA) [1], a gradient-free metaheuristic optimization method, in tandem with the topology optimization (TO) method, and utilizing a spectral modal method. Through the integration of TO with SMA, (TO-SMA) we achieve successfully metagrating designs [2].

In this paper, we present the application of the Slime Mold Algorithm (SMA) to topology optimization for a 1D dielectric metagrating (see Fig. 1), within the framework of a spectral method. The primary objective of this design is to formulate a 1D metagrating composed of a sequence of nanorods and air gaps with varying widths, strategically optimized to efficiently redirect incident plane wave power into a specified transmission order. The proposed SMA initiates by generating a random set of widths for the nanorods and air gaps. A corresponding set of binary permittivity functions is defined for this sequence of nanorods/air gap widths. However, since our focus is on a Topology Optimization (TO) method, we apply a blurring process to this initial population. This process transforms the discrete set of widths into a continuous sequence of permittivity functions. A noteworthy aspect and a key feature of our proposed method lie in the choice of the filter employed during this blurring process. Instead of opting for classical Gaussian or binary functions as filters, we introduce the Schwartz function. The shape of the function can be significantly altered by adjusting some of its key parameters, providing enhanced flexibility and control over the continuous permittivity function at each iteration during the optimization process.

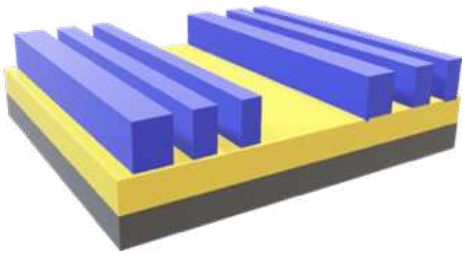

Figure 1 : A 1D deflector to be designed

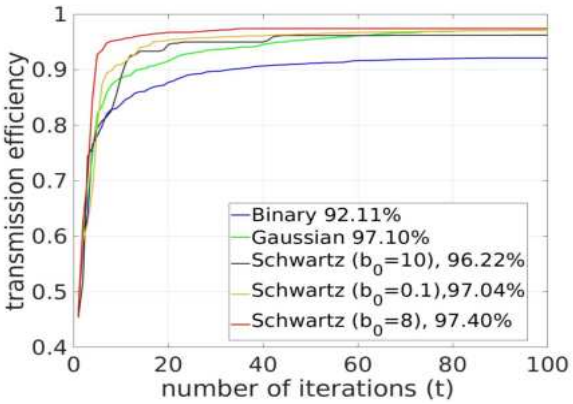

Figure 2: Performances of the TO-SMA using different filter functions: the Schwartz, Gaussian and binary functions

In Fig. 2 we emphasize the impact of the Schwartz function on numerical results, we compare the

performance of TO-SMA using the Schwartz filter with different shapes. This assessment involves a comparison with Gaussian and binary functions. The Schwartz filter demonstrates a remarkable ability to converge rapidly towards high-performance solutions. A flow chart of the proposed algorithm is shown in Fig.3

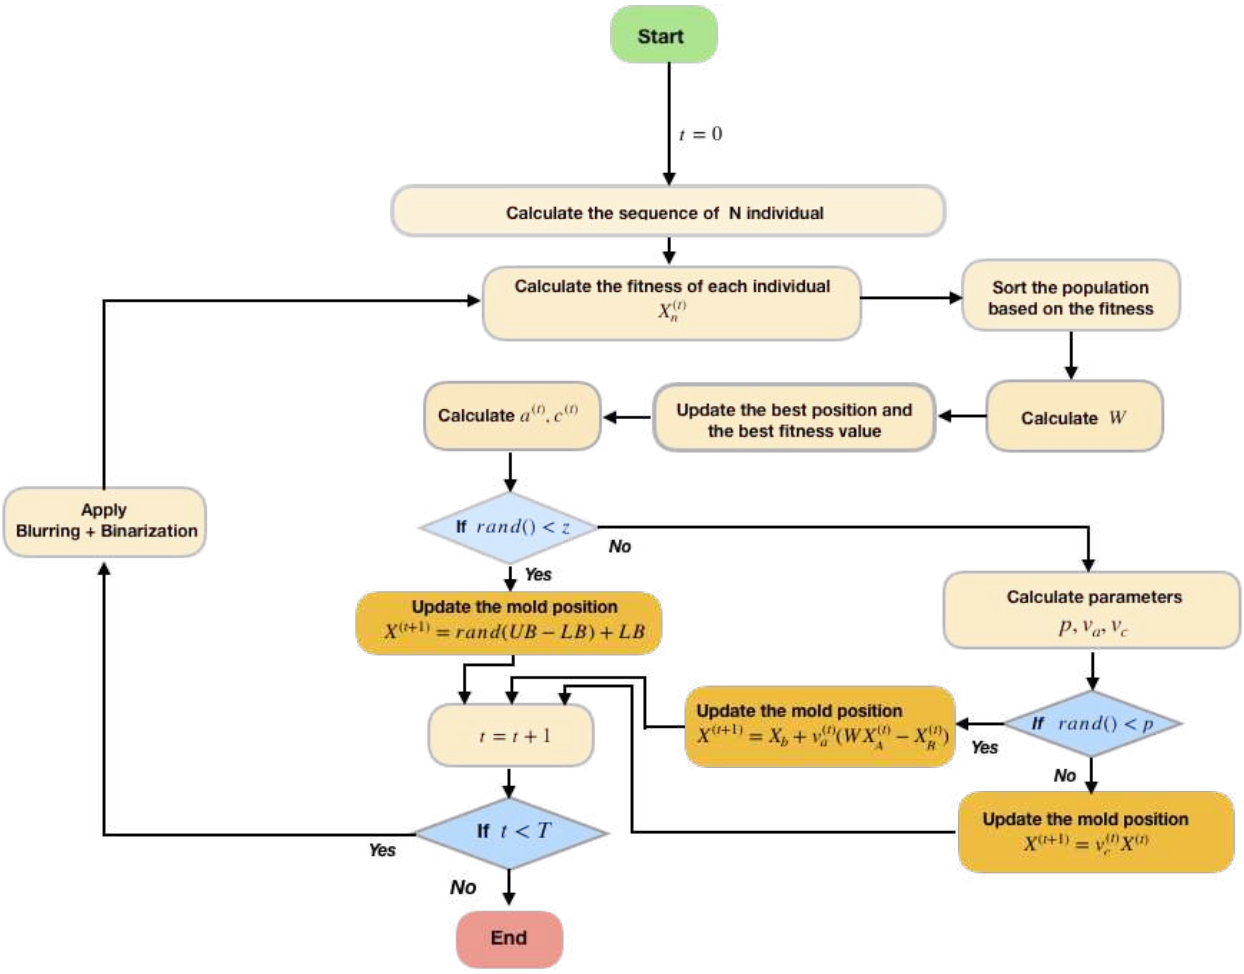

Figure: 3 A flow chart of the algorithm

Nanophotonic chirality transfer to dielectric Mie resonators

E. Mohammadi[1], T. V. Raziman[1], Alberto G. Curto[1,2,3*]

[1] Department of Applied Physics and Eindhoven Hendrik Casimir Institute,
Eindhoven University of Technology, Eindhoven, The Netherlands

Abstract: Nanophotonics can boost the weak circular dichroism of chiral molecules. One mechanism relies on creating fields with high optical chirality at the molecular position using resonators. Here, we elucidate how the reverse interaction between molecules and the resonator, called chirality transfer, can produce stronger circular dichroism in dielectric Mie resonators.

Chiral molecules exist in right- and left-handed forms known as enantiomers. Their biological functionality depends on handedness, which makes chiral sensing crucial to biochemistry and medicine. Circular dichroism (CD) can detect the handedness of enantiomers through the differential absorption of circularly polarized light. However, it is typically very weak, particularly at low molecular concentrations. To overcome this, nanophotonics offers enhanced optical chirality to increase the interaction of light with chiral molecules. Nanophotonic structures such as metal and dielectric nanoparticles can generate chiral fields at the location of the chiral molecules.[1,2] The resulting CD enhancement is proportional to the average value of the optical chirality over the chiral sample volume. It is challenging to obtain high average values because high optical chirality usually occurs in hotspots with limited volumes.

Here, we show that the reverse interaction between chiral molecules and nanoresonators is also relevant and can dominate chiral sensing with dielectric nanostructures. A chiral molecule can transfer its chirality to an achiral dielectric resonator, resulting in chiroptical signals orders of magnitude higher than those from optical chirality alone. The underlying physics is the back action of the chiral molecules onto the nanostructures through dipole-dipole interactions. For right- and left-handed circularly-polarized excitations, the presence of the chiral molecules changes the otherwise equal electric fields (and thus the dipole moments) in an achiral nanoparticle. Consequently, the circular dichroism of the system consisting of a nanoresonator and chiral molecules arises from both chirality transfer and optical chirality. Most studies thus far focused *ad hoc* on only one of these two mechanisms, which has been a source of mismatch between experimental results and theoretical predictions and prevented a rational design of nanostructures.

We demonstrate that chirality transfer to dielectric resonators offers higher CD enhancement compared to metallic ones thanks to the tunable co-existence of electric and magnetic resonances.[3] We derive closed-form equations revealing its dependence on the molecular chirality (Pasteur parameter), molecule-resonator distance, and the resonator Mie coefficients. Our complete theoretical framework allows us to find the fundamental upper limits for chirality transfer for electric and magnetic Mie resonances. Importantly, we clarify the different requirements for CD enhancement based on the chirality transfer and optical chirality mechanisms. We decompose the contribution of chirality transfer to CD into electric and magnetic terms and recognize the

magnetic contribution as responsible for the unique performance of dielectric resonators. Finally, for practical purposes, we introduce a dielectric metasurface composed of silicon disks showing a 900-fold CD enhancement. Our insights into chirality transfer and its opportunities pave the way towards more efficient nanophotonic platforms for ultrasensitive chiral detection.

Consensus ADMM for Photonic Design

Hyeonhee Kim[1], Myungjoon Kim[1], Zeyu Kuang[2], Owen D. Miller[2,*], and Jonghwa Shin[1,*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon, 34141, Republic of Korea
[2]Department of Applied Physics and Energy Sciences Institute, Yale University, New Haven, CT 06520, USA
[*]corresponding authors: owen.miller@yale.edu, qubit@kaist.ac.kr

Abstract: We propose a novel photonic design approach by formulating the problem as quadratically constrained quadratic programming and applying a consensus-based alternating direction method of multipliers. We demonstrate that for a metalens design, our algorithm outperforms conventional inverse design methods, achieving superior outcomes in terms of solution quality and optimization speed.

Photonic design plays a pivotal role in modern optics to create devices with enhanced functionalities. Inverse design processes, often leveraging gradient-based optimization, have been used to design numerous optical devices. However, the inherent highly nonconvex nature of the objective functions often leads to convergence at local optima of poor quality. In contrast, a fundamentally different strategy has been proposed, leveraging the well-established convex optimization theories and algorithms. The photonic design problem is formulated as a quadratically constrained quadratic programming (QCQP) and subsequently the QCQP is translated into semidefinite programming by relaxation [1]. This translation makes possible to obtain computational bounds of defined objective values. More recently, this QCQP formulation has been applied to photonic design problems, enabling the derivation of physical structures through convex optimization techniques under sparse conditions [2].

Here, we introduce a novel algorithm for photonic design that directly tackles general QCQP by employing the alternating direction method of multipliers (ADMM). The ADMM is well-established convex optimization algorithm, well-suited for distributed and parallel computation [3]. This algorithm has been demonstrated to be effective in addressing general nonconvex QCQP using the consensus method [4]. We reformulate the photonic design problem into a consensus optimization framework as follows:

$$minimize \quad \boldsymbol{p}^{\dagger}\boldsymbol{A}_0\boldsymbol{p} + 2\Re\{\boldsymbol{b}_0^{\dagger}\boldsymbol{p}\} + \boldsymbol{c}_0$$

$$subject\ to \quad \boldsymbol{z}_i^{\dagger}\mathbb{D}_i\{(\boldsymbol{G_0} - \boldsymbol{\chi}^{-1})\boldsymbol{z}_i + \boldsymbol{e_{inc}}\} = 0,$$

$$\boldsymbol{z}_i = \boldsymbol{p}, \forall i = 1,2,\dots,m,$$

where the global variable $\boldsymbol{p}$ represents the polarization field and objective functions are defined with the Hermitian matrix $\boldsymbol{A}_0$, vector $\boldsymbol{b}_0$, constant $\boldsymbol{c}_0$. Additionally, each local variable $\boldsymbol{z}_i$ is constrained to satisfy a weighted quadratic form of the Green's function integral equation. The key step of the algorithm is to separate QCQP, each characterized by a single constraint. At each iteration, the separated problems are solved independently and update global variable to reflect a consensus among the local variables. Through a series of iterations, the local variables gradually align with the global variable, thereby achieving a consensus while minimizing the objective functions (Figure 1.a).

As a proof of concept, we demonstrate metalens design with the objective of maximizing light intensity at a specific point within a two-dimensional space. Consensus-ADMM shows faster convergence (T^{ADMM}=430s) and better objective value (f_{obj}^{ADMM}=1.4) than conventional adjoint-based optimization ($f_{obj}^{adj} = 1.2, T^{adj} = 5500s$).

The solution achieved is feasible, indicating that the optimized polarization fields are physically realizable (Figure 1.b). We convert the field into corresponding metasurface structure and the device shows focusing incoming light toward the designated target point (Figure 1.c).

In summary, we have proposed an innovative optimization framework for photonic design problems, utilizing a convex optimization algorithm. This approach demonstrates enhanced performance over traditional optimization methods, presenting its potential for further advancements and integration with additional optimization strategies. This framework can be widely applicable to a broad spectrum of problems in linear optics and photonics.

Optimizing Metasurface Design for Interference Lithography: Achieving Two-Dimensional Bravais Lattices with Arbitrary Motifs

Myungjoon Kim[1], Nayoung Kim[1], and Jonghwa Shin[1,*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon, 34141, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: Periodic metasurface masks are utilized in interference lithography. In this study, we demonstrate that through the inverse design of metasurfaces, it is possible to achieve all two-dimensional Bravais lattices with any desired motifs by manipulating the amplitude, phase, and polarization of individual diffraction beams.

Proximity-field nanopatterning (PnP) is considered a promising technology for creating 3D nanostructures through the interference and diffraction of light sources. The PnP method uses binary gratings to produce multiple diffraction orders from a single incident beam. The pattern created by the process is determined by the design of the grating masks. Recently, the inverse design of metasurface masks in the PnP process has been proposed, presenting the potential for patterning that was previously unachievable. [1, 2, 3].

We can model the PnP system mathematically to analyze how an incident beam, after passing through a periodic metasurface mask, is diffracted into multiple coherent beams described by $\boldsymbol{E}_i(\boldsymbol{r}) = E_i \boldsymbol{p}_i \exp(\boldsymbol{k}_i \cdot \boldsymbol{r} + \varphi_i)$, where $\boldsymbol{r}$ corresponds to the position vector, and $\boldsymbol{p}_i, \boldsymbol{k}_i,$ and φ_i are the polarization vector, wavevector, and phase offset i^{th} diffraction beam, respectively. The resultant interference pattern is defined by $I(\boldsymbol{r}) = |\sum_i \boldsymbol{E}_i(\boldsymbol{r})|^2$. Ultimately, the nanopattern generated by the PnP process is determined by applying a simple threshold to this intensity pattern.

The five types of two-dimensional Bravais lattices, including rectangular, square, centered rectangular, hexagonal, and oblique, are determined by their primitive vectors. These primitive vectors for every Bravais lattice are obtained from the diffracted beam by selecting specific orders, in conjunction with the period of the metasurface and the wavelength of the source [3]. Moreover, the motifs within these lattices can be customized at will through adjustments in amplitude, phase, and polarization of diffraction beams. For example, to achieve a rectangular lattice, orders {-3, -1, +1, +3} are selected, with all other orders being suppressed. In such four-beam configuration, diverse motifs, from circular to V-shaped, can be implemented by modifying the relative amplitude and phase for each polarization.

We present the inverse design of bilayer metasurface mask for PnP that manipulate each diffraction beam. Using adjoint-based topology optimization, the PnP system, featuring a period of 1 μm and a wavelength of 355 nm, is optimized under conditions suitable for fabrication. We illustrate that the optimized metasurface effectively induces the desired diffraction amplitude, phase, and polarization. We further demonstrate that adjusting the geometric configuration of metasurfaces enables the creation of a variety of lattice distances and motifs within rectangular lattices.

Plasmonic semiconductor waveguides with tunable nonlinear optical response

G. Álvarez-Pérez[1,*], H. Hu[1], and C. Ciracì[1]

[1]Center for Biomolecular Nanotechnologies, Istituto Italiano di Tecnologia, via Barsanti 14, Arnesano, 73010, Italy
[*]corresponding author: gonzalo.alvarezperez@iit.it

Abstract: We design tunable nonlinear plasmonic waveguides made of heavily doped semiconductors to boost third harmonic generation. Employing a hydrodynamic nonlocal description, we calculate the power transfer and nonlinear efficiency. Our work has applications in advancing the realization of all-semiconductor photonic integrated circuits and all-optical neural networks.

Heavily doped semiconductors offer a promising platform for realizing nanoscale nonlinear optics due to their distinctive characteristics. Compared to noble metals, semiconductors exhibit much lower free carrier densities and smaller effective carrier masses. These differences lead to stronger nonlocal effects and larger nonlinear active volumes, surpassing those achievable with noble metals by up to 1000 times. Moreover, the limitations imposed by anharmonic potentials on the nonlinear susceptibilities—$\chi^{(2)}$ and $\chi^{(3)}$— that limit the nonlinear response of dielectrics do not apply to free-electron nonlinearities, thus making heavily doped semiconductors a unique platform for developing nanoscale nonlinear elements in photonic integrated circuits.

Nonlinearities in heavily doped semiconductors are fundamentally nonlocal and are linked to the kinetic energy of the free-electron gas. This behavior can be accurately modeled using a set of hydrodynamic equations of motion, akin to classical fluid dynamics [1-3]. Building on this, here we design nonlinear plasmonic waveguides using heavily doped semiconductors to boost third harmonic generation. Our chosen material platform is InGaAs/InP due to its broad appeal for the future exploitation of plasmonic nonlinearities in all-semiconductor photonic integrated circuits. To model the nonlinear response of the structure, we develop a generalized framework that employs a hydrodynamic nonlocal description and allows for the computation of second harmonic (SH) and third harmonic (TH) free-electron nonlinearities in hybrid plasmonic waveguides made of both heavily doped and undoped semiconductors (Fig. 1a). Our method allows studying the structure on a two-dimensional cross-section, thereby circumventing the challenges posed by the scale mismatch between surface effects and overall mode propagation in three-dimensional simulations.

The general solution is shown to be the sum of the solutions with and without free electron nonlinearities. Both can be expressed as linear combinations of the eigenmodes of the system, which in turn can be determined using an eigenmode solver that we implement in Comsol Multiphysics with a customized weak form (Fig. 1b,c). This approach is valid under the undepleted pump approximation, assuming minimal modulation of the refractive index by the pump's strength.

This framework allows for the calculation of the power transfer from the fundamental frequency mode to the second and third harmonic and predicts the efficiency of the nonlinear waveguide (Fig. 1d). This includes direct and cascaded processes, along with third-order lattice nonlinearities, allowing to optimize the structure of the

waveguide to maximize the nonlinear efficiency. Additionally, given the tunability of the plasma frequency in heavily doped semiconductors, gating effects can be implemented to actively tune and control the plasmonic nonlinearities through external stimuli, a critical step towards the practical implementation of these advancements. Our nonlinear plasmonic waveguides could be integrated in all-semiconductor photonic circuits and could, for instance, play a key role in emulating, through optical means, the nonlinear activation function—a critical part of the computational capability of neural networks.

Adaptive Meshing Using A Posteriori Error Estimation

Albin J. Svärdsby and Philippe Tassin

Department of Physics, Chalmers University of Technology, 41296 Göteborg, Sweden

Abstract: We present our work on adaptive meshing of electromagnetic simulations based on a posteriori error estimation. We present our implementation and demonstrate that our adaptive meshing technique can lead to faster convergence with lower memory footprint, especially for simulations of complex three-dimensional nanophotonic structures.

It is becoming increasingly important to solve large computational models of nanophotonic devices efficiently, with low memory footprint and short wall-clock times. This is important for, e.g., inverse design—the computer-aided selection of a device geometry with a desired optical response—which requires a large number of successive simulations in gradient-descent optimization techniques or an even larger number of independent simulations in data-driven inverse design using machine learning [1]. One way to achieve more efficient computational models is to make use of adaptive meshing [2]. Adaptive meshing is today often based on geometric considerations, i.e., small geometric features are meshed more densely. However, it would be much more effective to base adaptive meshing on a calculation of the relative error of mesh elements.

In this contribution, we will present our work on adaptive meshing based on a posteriori error estimation [3]. We implement a technique that involves a computationally cheap, secondary finite-element model and is able to calculate the relative contribution to the simulation error of each individual mesh element [4]. This we can in turn use to strategically refine and coarsen the mesh of an electromagnetic simulation.

We show how the method works and we present a number of example, allowing us to study the time complexity compared to traditional meshing. This suggest that our adaptive meshing method is able to speed up simulations for large electromagnetic models. We discuss a number of pitfalls and provide guidance for best practice when using adaptive meshing.

We acknowledge support from Chalmers' Excellence Initiative Nano and from the Swedish Research Council under Grant No. 2020-05284. The training data generation and ANN training were performed on resources provided by the Swedish National Infrastructure for Computing (NAISS), at the Chalmers/C3SE and KTH/PDC sites, partially funded by the Swedish Research Council under Grant No. 2022-06725.

Hardware-Accelerated FDTD Simulation

Zongfu Yu, Tyler Hughes, Shanhui Fan
Flexcompute, Inc

In this talk, we will demonstrate the application of novel computing hardware to electromagnetic simulation. We will discuss how electromagnetic simulation compute requirements motivate new approaches to hardware architecture. Then, we will demonstrate how our technology leverages these understandings to enable the simulation and design of novel photonic devices at speeds and scales not possible with conventional approaches.

First, we will discuss the specific computing requirements of electromagnetic simulations, specifically the FDTD method. A simplified model of simulation performance based on computing speed and memory bandwidth will be presented. This understanding intuitively demonstrates a fundamental problem with the CPU-based simulation technology that is most commonly employed in both industry and academia. We show how to overcome this limitation through the application of novel computing hardware platforms with a high memory bandwidth, such as GPUs, to electromagnetic simulations, and discuss performance bounds achievable through this framework.

Next, we will introduce our FDTD solver (Tidy3D), which leverages these understandings to perform cloud-based electromagnetic simulations. We will give several examples of Tidy3D outperforming conventional CPU-based FDTD solvers by orders of magnitude in both speed and maximum problem size. We will also provide a basic overview of the features and capabilities provided by this solver and its interface. Specifically, we will give an explanation of how to perform "inverse design" using this framework, which is a method that enables automated design of devices based on a user-defined objective function. We demonstrate how machine learning libraries are integrated with our solver to perform the automatic differentiation needed.

Finally, we will show examples of how we and our collaborators have leveraged this technology to enable novel findings in various applications. Topics will include (a) three-dimensional modeling of large scale photonic integrated circuits (b) full-wave simulation of large area metasurfaces (c) using electromagnetic simulation to answer long standing questions in fundamental physics.

Quasinormal mode expansion theory for mesoscale plasmonic nanoresonators with an analytical treatment of nonclassical electromagnetic boundary condition

Abstract: We propose a quasinormal mode (QNM) expansion theory for mesoscale plasmonic nanoresonators with nanometric feature sizes. Our theory can analytically unveil the impact of nonclassical quantum effects described by the nonclassical electromagnetic boundary condition (NEBC) on the optical response and thus provides an efficient tool for various design tasks.

For plasmonic nanoresonators, the QNM expansion theory, in which the source-excited electromagnetic field is expanded upon the basis of source-free eigen/resonance modes of QNMs, can provide an analytical dependence of electromagnetic field on the excitation source and frequency, and therefore is physically intuitive and computationally efficient [1]. However, for mesoscale plasmonic nanoresonators with highlighted nonclassical quantum effects, which can be fully described by the NEBC using the surface-response Feibelman *d* parameters $d_\perp$ and $d_\parallel$, the QNM expansion theory is still in its infancy [2-5]. For the case of non-perturbative NEBC and with the presence of excitation source, a QNM expansion theory with an analytical dependence on the NEBC, which is crucial for a transparent and fast analysis of the impact of NEBC on the mesoscale plasmonic response, is still absent.

In this talk, we report a rigorous nonclassical QNM expansion theory with an analytical dependence on the non-perturbative NEBC (incorporating both $d_\perp$ and $d_\parallel$) for mesoscale plasmonic nanoresonators [6]. By taking the easy-to-solve classical QNMs under classical electromagnetic boundary condition (CEBC) as a complete set of basis functions, the source-excited nonclassical electromagnetic field $\mathbf{\Psi}$ under NEBC can be rigorously expanded as,

$$\mathbf{\Psi}(\mathbf{r},\omega)=\mathbf{\Phi}(\mathbf{r})^{\mathrm{T}}[i(\omega\mathbf{I}-\mathbf{W})-\mathbf{K}(\omega)]^{-1}\mathbf{b}(\omega)\,, \tag{1}$$

where $\mathbf{r}=(x, y, z)$ are Cartesian coordinates, ω is the real-valued excitation angular frequency, $\mathbf{I}$ represents the identity matrix, and $\mathbf{W}$ is a diagonal matrix with the complex eigenfrequency ω_p of the pth classical QNM $\mathbf{\Psi}_p$ as its pth diagonal element. $\mathbf{\Phi}^{\mathrm{T}}$ is a row vector with its pth element being $\mathbf{\Psi}_p$. $\mathbf{b}(\omega)$ is a frequency-dependent column vector with its pth element β_p describing the excitation of $\mathbf{\Psi}_p$ by the external source. The matrix $\mathbf{K}(\omega)$ depends on both $d_\perp$ and $d_\parallel$ *in an analytical way*, with its pth-row and qth-column element $\kappa_{p,q}$ describing the coupling between $\mathbf{\Psi}_p$ and $\mathbf{\Psi}_q$ caused by the NEBC. Starting from Eq. (1) (called Model 1), we can further solve the source-free ($\mathbf{b}=\mathbf{0}$) nonclassical QNMs under NEBC, and then expand the source-excited ($\mathbf{b}\neq\mathbf{0}$) electromagnetic field (called Model 2A) and Green's function tensor (called Model 2B) upon the basis of nonclassical QNMs. Our theory exhibits high physical intuitiveness and computational efficiency if the optical response of resonator is dominated by a small set of classical QNMs. For example, by considering the two dominant classical QNMs in the numerical example in Fig. 1, the eigenfrequencies $\omega=\tilde{\omega}_p$ (p=1, 2) of

nonclassical QNMs is given by

$$\omega=\frac{1}{2}\left[(\sigma_1+\sigma_2)\pm(\sigma_1-\sigma_2)\sqrt{1-4\kappa_{1,2}\kappa_{2,1}/(\sigma_1-\sigma_2)^2}\right], \tag{2}$$

where $\sigma_q=\omega_q-i\kappa_{q,q}(\omega)$ (q=1, 2). Equation (2) explicitly unveils the impact of NEBC-induced cross coupling between different classical QNMs (represented by $\kappa_{p,q}$ with $p\neq q$) on the nonclassical QNMs which is not considered in previous theories [3-5].

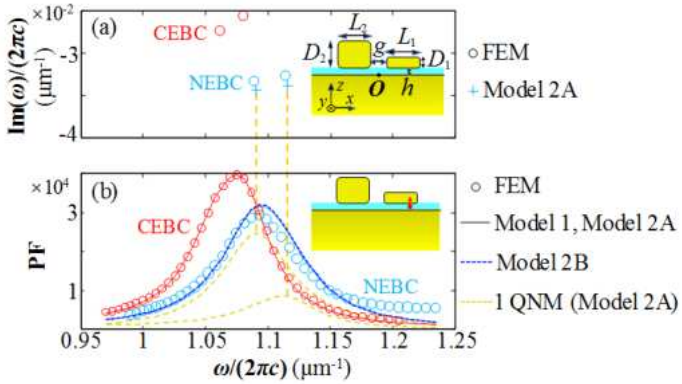

Fig. 1. (a) Complex eigenfrequencies of the two dominant QNMs with the highest quality factors for an asymmetrical dimer of gold nanowires (lengths L_1=60 nm, L_2=72 nm) with square cross-sections (side lengths D_1=20 nm, D_2=110 nm) on gold substrate (g=15 nm, h=6 nm). c is the light speed in the vacuum. (b) Frequency spectrum of Purcell factor (PF) for the excitation by a z-polarized point source (red dot) at (x, y, z)=(g/2+L_1−d, 0, h/2) (origin denoted by O) in the AlO_x nanogap (blue layer). The circles and other curves show the full-wave finite element method (FEM) results and theoretical predictions, respectively. The yellow-dashed curves show the respective contributions from the two dominant nonclassical QNMs.

Effective Medium Theory for Photonic Parallel Universes

Yun Lai[1*]

[1] National Laboratory of Solid State Microstructures, School of Physics, and Collaborative Innovation Center of Advanced Microstructures, Nanjing University, Nanjing 210093, China
[*]corresponding author: laiyun@nju.edu.cn

Abstract: Conventional wisdom tells us that a physical space corresponds to only one optical medium, e.g. an optical space cannot behave like vacuum and glass simultaneously. Surprisingly, this fundamental limitation can be broken in photonics. Here, I demonstrate multiple effective media associated with one physical space, effectively creating photonic parallel universes.

The development of metamaterials in the past decades have significantly expanded the realm of effective medium theories. Extraordinary effective parameters such as negative, near-zero, and indefinite values have been realized, which can be numerically retrieved via effective medium theories. Nevertheless, a fundamental law is obeyed all the time, i.e. one physical space can only correspond to one optical effective medium. This law is intuitive, as it is obvious that a space cannot be occupied by two media or two objects simultaneously.

Now, imagine that a physical space occupied by a metamaterial can behave like two distinct optical media, e.g. vacuum and glass, with different refractive indices and impedances. In other words, such a metamaterial has two independent effective media, one is vacuum and the other is glass. This amazing phenomenon turns out to be surprisingly feasible, around a certain working frequency. The choice of the effective media depends on which surface of the metamaterial the external photons choose to enter. In this sense, photonic parallel universes, corresponding to different optical media, have been realized at the same physical space.

We have established an effective medium theory to explain this unprecedented phenomenon of photonic parallel universes. Our theory is validated by simulations and microwave experiments. Deep learning can be applied to design parallel universes efficiently. This concept creates a plethora of exciting new phenomena, such as cladding-free waveguide systems [1, 2] and photonic wormholes [3].

Space-time metasurfaces for photonics

S. Vezzoli[1*], A. Hartwood[1], and R. Sapienza[1]

[1]Imperial College London, United Kingdom
[*]corresponding author: svezzoli@imperial.ac.uk

Abstract: Metamaterials control light by acting on its momentum, yet they are static devices and bounded by energy conservation. Here we discuss spatial and temporal diffraction in a film of Indium Tin Oxide, as a first step towards a space-time metasurface for photonic applications.

Metamaterials have revolutionised the way we control light waves. By engineering light scattering on sub-wavelength scales, one can design exotic new materials and applications, like invisibility cloaks and negative refraction. Yet, static metamaterials only act on the momentum of light and thus are still bounded by Lorentz reciprocity and energy conservation. A dynamical metasurface, whose optical response can be arbitrarily modulated at the speed of light through a time-varying complex refractive index n(t), would offer access to the manipulation of the frequency spectrum and a whole new range of functionalities. Yet, despite the abundance of theoretical proposals [1], experimental realisations remain elusive, due to the challenge of finding a material platform that can support large and ultrafast modulations without incurring damage.

Here I will discuss our first steps towards optically driven metasurfaces for photonics, based on Indium Tin Oxide, an epsilon-near-zero material with strong nonlinearities and ultrafast time response [2]. I will report on our recent demonstration of double-slit time diffraction from a deeply subwavelength and resonant film of Indium Tin Oxide in the near-infrared [3], the first step towards the creation of more complex time modulations. I will then discuss one possible extension of this experiment to the visible range, which employs the non-perturbative modulation of second harmonic generation at the time-varying interface. Finally, I will present our most recent results, aimed at coupling space and time modulations in a time-varying medium: the observation of slits that diffract light both in time and space. These results represent the basic building blocks for the generation of complex spatiotemporal modulations and one of the first evidence of synthetic motion at optical frequencies.

Abstract: We study lasing of plasmonic BIC modes with topological charge 0, ±1 and -2. We evidence a loss-driven topological phase transition in the lasing mode, as the scale of the unit cell is varied. Our work shed light on the interplay between non-Hermitian systems and the topology of polarization singularities.

Bound states in the continuum (BICs) are general solutions of wave equations that arise as topological defects protected by system symmetries. In photonics, BICs show a winding of the light polarization around a specific momentum, akin to a vortex with a non-trivial topological charge [1-2]. These modes are also known as polarization singularities, and have extremely-high quality factors, which, in combination with their topological origin, may open opportunities for designing novel topological photonic devices [3].

We study BICs in plasmonic lattices composed of complex unit cells containing multiple gold nanoparticles [4-5]. The system is brought to the lasing regime by combining it with a dye molecule liquid acting as a gain medium. These structures exhibit lasing emission with non-trivial polarization properties attributed to BICs. Combining group theory with a careful lattice design demonstrates that different BICs with distinct topological charges can lase in various regimes, as the internal structure of

the unit cell is varied. Using T-matrix simulations, we confirm that the modes' quality factors undergo a loss-induced topological transition. Our findings are further supported by finite element method simulations, where we see that the modes' electric field intensity distribution in the unit cell changes significantly due to losses, despite the symmetry of the modes being the same. As our results introduce a versatile new platform for studies of non-Hermitian topological polarization singularities, we will also discuss our recent unpublished results on topological photonics.

Singularity and topology in structured near fields

Shubo Wang[1,2*], Tong Fu[1], Shiqi Jia[1], Jie Peng[1], and Ruo-Yang Zhang[3]

[1]Department of Physics, City University of Hong Kong, Hong Kong, China

Abstract: Under external excitations, simple metal structures can generate strong near fields with rich subwavelength vector properties. These near fields can exhibit complex structures of polarization with interesting topological and singularity properties fundamentally connected to the real-space topology of the metal structures.

Simple metal structures can generate strong near fields under external excitations due to their plasmonic response. The near fields are characterized by full vector properties in the subwavelength scale, offering rich degrees of freedom for manipulating the various properties of light, including intensity, polarization, phase, etc. Besides, the near fields can induce strong light-matter interactions with broad applications in optical sensing, optical metrology, and optical micromanipulations. Therefore, it is essential to understand various properties of optical near fields and uncover their relationships with the geometric and material properties of optical structures.

For a single metal scatterer under the illumination of external light, the interference of the electromagnetic multipoles induced in the scatterer can give rise to polarization singularities in the near fields, including C points and V points [1, 2]. The C points are particularly interesting because they carry intrinsic optical chirality that can be applied for chiral sensing and discrimination [3, 4]. In addition, the C points carry nontrivial topological properties that can be characterized by both a polarization index and a phase index. We find that the total index of the C points on the smooth surfaces of metal structures is fundamentally decided by the Euler characteristic of the structures and is irrelevant to the geometric details or external excitations [2]. The C points grow from the structures' surfaces and extend to free space to form C lines. Their merging and bifurcation are determined by the conservation of the phase index.

Since the near fields are nonuniform and exhibit complex structures, their spatial variation can give rise to a geometric phase, which generally comprises two parts: the spin-redirection geometric phase and the Pancharatnam-Berry geometric phase. We find that the geometric phase of the near fields in finite-sized metal structures can be applied to define a spin Chern number $\mathbb{C}_{\mathrm{spin}}$. Unlike the Chern number in the momentum space of periodic systems, this real-space spin Chern number has an intrinsic relationship with the topology of the metal structures [5]:

$$\mathbb{C}_{\mathrm{spin}}(M) = \frac{1}{2\pi}\oint_M \mathbf{\Omega}_{\mathrm{spin}} \cdot d\mathbf{S} = \sum_i I_{\mathrm{pl}}(\mathbf{r}_i) = \chi(M)$$

Here, $\mathbf{\Omega}_{\mathrm{spin}}$ denotes the spin Berry curvature of the near fields, $I_{\mathrm{pl}}(\mathbf{r}_i)$ denotes the polarization index of the singularity at $\mathbf{r}_i$, and $\chi(M)$ is the Euler characteristic of the manifold M (i.e., the surface of the optical structure). The above equation indicates that the spin Chern number of optical near fields is quantized and equal to the Euler characteristic of the optical structures and thus decided solely by the number of "holes" in the structure's surface. We verified the above equation by conducting full-wave simulations for metal structures with different Euler characteristics and under different excitations.

Electron-tunneling-induced thermoelectric effects

M. Gómez Viloria[1], R. Messina[1*], and P. Ben-Abdallah[1]

[1]Laboratoire Charles Fabry, UMR 8501, Institut d'Optique, CNRS, Université Paris-Saclay, 2 Avenue Augustin Fresnel, 91127 Palaiseau Cedex, France
[*]corresponding author: riccardo.messina@institutoptique.fr

Abstract: We introduce direct (Seebeck) and inverse (Peltier) thermolectric effect induced by electron tunneling between closely separated conducting films: a transverse temperature gradient applied along one film induces a bias voltage in the second, whereas an electric current passing through one film can allow to extract or deliver a thermal power.

Thermoelectric effects are the direct conversion of the temperature difference inside a material into a bias voltage (Seebeck effect) and the conversion of an electric current flowing through this material into a negative or positive thermal power (Peltier effect). The efficiency of a thermoelectric system can be evaluated with the figure of merit ZT, depending on the Seebeck coefficient of the material, as well as on its electrical and thermal conductivities. Recent efforts have been performed to manipulate these quantities in order to increase the ZT [1,2].

We have recently shown [3] that when two planar substrates are placed in the extreme near field (distances in the nanometer range and below), in addition to evanescent photons tunneling across the vacuum gap and inducing an amplification of heat transfer [4], also phonons and electrons can tunnel through the vacuum gap and contribute as additional channels to energy transfer. By introducing a general formalism to describe this multi-channel energy transfer, we have shown that for metallic bodies electron tunneling becomes the dominant effect close to contact [3].

Here we introduce thermoelectric effects induced by the tunneling of electrons between two coupled conductors separated by a small gap [5]. When the size of this gap is sufficiently small and a temperature difference is applied along one of two conductors, a spatially varying density of free charges can be induced across the gap by tunneling effect giving rise to a drift and a diffusion current into the second conductor. Conversely, when a bias voltage is applied along one of the conductors, a heat flux can be extracted from or inserted into the second conductor. We develop a general theory to describe these thermoelectric effects between two metallic films and analyze its main characteristics with respect to the separation gap and films thicknesses, showing that in some scenarios their performance can exceed the classical thermoelectric properties of bulk material. These thermoelectric effects could be exploited for nanoscale energy conversion and to develop solid-state refrigeration devices.

High-Accuracy DDA

O. D. Miller[1*]

[1]Dept of Applied Physics and Energy Sciences Institute, Yale University, New Haven, CT, USA
[*]corresponding author: owen.miller@yale.edu

Abstract: The discrete dipole approximation (DDA) is a simple but typically low-accuracy simulation technique. We describe two straightforward modifications that reduce the error from first order to fourth order in resolution. We demonstrate fast, accurate simulation in the regime DDA typically struggles: high-complexity, three-dimensional structures with large refractive indices.

Thermal radiation at the nanoscale, electroluminescence, single and dual radiative heat engines

J. Legendre[1], T. Châtelet[1], M. Thomas[1], O. Merchiers[1], and P.-O. Chapuis[1*]

[1]Centre for Energy and Thermal Sciences of Lyon (CETHIL), CNRS – INSA Lyon, Villeurbanne, France
[*]corresponding author: olivier.chapuis@insa-lyon.fr

Abstract: At the crossroad of nanophotonics and energy harvesting, a novel class of heat engines in the near field is being developed. Building on the experimental confirmation of near-field thermophotovoltaics and on the physics of light-emitting diodes, dual radiative heat engines, e.g. thermophotonic ones, are attractive for heat-to-electricity conversion and refrigeration.

Thermal emission can be described with the Poynting vector associated to the electromagnetic field generated by the random fluctuations of electrical charges in matter. Such approach known as fluctuational electrodynamics has proved to be extremely powerful in the last two decades, being able to address radiative heat transfer involving objects of sub-wavelength size or short distances [1]. In these two regimes, Planck's blackbody law, known to be an upper bound for the radiative exchange of large opaque surfaces, does not apply anymore. In particular, it was shown that near-field radiative heat transfer induces fluxes that exceed the prediction limited to propagative waves (blackbody limit) [2] and that the exponent and constant involved in the Stefan-Boltzmann law are distance dependent when the bodies are close [3]. The strong radiative power increase observed in the near field is attractive for energy-harvesting applications where radiation is converted into electricity. An increased electrical power output could indeed be obtained in near-field thermophotovoltaics (TPV) [4].

(a) (b)

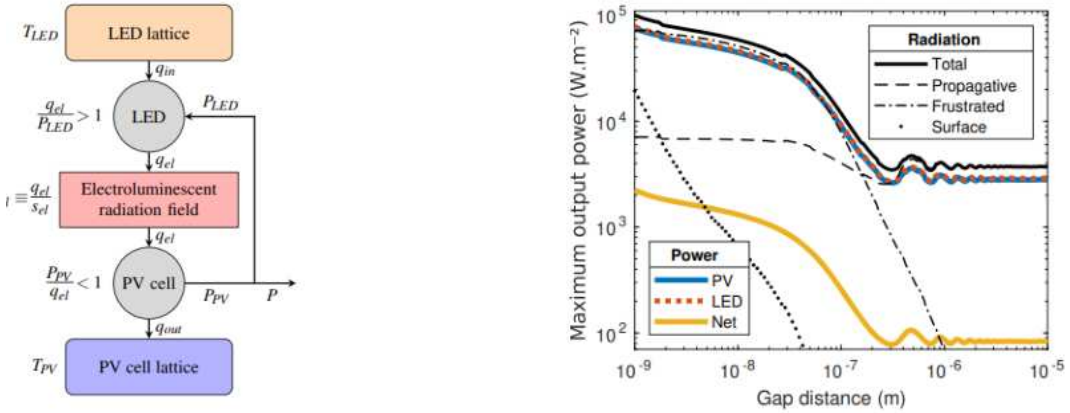

Figure 1. (a) Schematic of a thermophotonic energy harvester, highlighting the LED heat pump and the PV cell heat engine as elements of the dual radiative heat engine. (b) Radiative power exchanged (black) and power output of an ideal GaAs near-field thermophotonic device as a function of gap distance. Internal quantum efficiency, describing non-radiative losses, is spectrally flat with a value of 0.9.

Another way to surpass Planck's blackbody limit at a given wavelength is to generate electroluminescence, as exemplified by the bright emission of light-emitting diode (LED), which is another optoelectronic device based on pn or pin junctions. Interestingly, LEDs and TPV cells can be seen respectively as heat pumps and heat engines, i.e. radiative heat engines. The combination of a hot illuminating LED and a wavelength-matched illuminated room-temperature PV cell is known as a thermophotonic energy harvester [5], since the net electrical power produced can be positive in spite of the LED consumption. As it is made of two optoelectronic components, such a device is a dual radiative heat engine. We have studied the conditions for operation of such engine both in the far field and in the near field, where the harvested power is expected to be larger. This is done either in a detailed-balance approach [6] or by fully considering temperature and spatially-dependent losses associated with non-radiative recombinations [7]. In the second case, fluctuational electrodynamics is coupled to a numerical code solving the drift-diffusion equations able to account for high carrier injection and discontinuity of the valence/conduction bands in heterostructures. One advantage of such devices over TPV ones is their working temperature, expected to be significantly lower (few hundreds of degrees Celsius).

The versatility of these devices allows also designing a thermophotonic refrigerator if the LED, initially at room temperature or below, is cooling by extracting heat from its surroundings [8]. In general, exploiting the phase space opened by the combination of these optoelectronic devices seen as heat engines allows selecting thermodynamic performances such as high efficiency (Carnot-like) or large power output, depending on the targeted application.

Quantum Effects in Plasmonic/Nonlinear Meta-Surfaces: Development and Applications of Maxwell-TDDFT Method

T. Takeuchi[1], M. Uemoto[2], and K. Yabana[3,*]

[1]Metamaterials Laboratory, RIKEN Cluster for Pioneering Research, Japan
[2]Department of Electrical and Electric Engineering, Kobe University, Japan
[3]Center for Computational Sciences, University of Tsukuba, Japan

Abstract: We develop a computational method coupling time-dependent density functional theory for electron dynamics and Maxwell equations for light propagation. We apply the method for various nonlinear and/or nonlocal optical phenomena where quantum electronic motion is significant, including plasmonic and semiconductor meta-surfaces.

As the size of nanoparticles decreases in meta-surfaces, quantum effects become more pronounced in their optical response. Most commonly seen is the effect of surface spill-out of electrons, and as the distance between nanoparticles decreases, the effect of tunneling currents flowing between nanoparticles appears. As the intensity of the pulsed light increases, nonlinear light-matter interaction becomes significant. High order harmonic generations from dielectric meta-surfaces have been attracting interest. To describe the optical response of meta-surfaces with such quantum and/or nonlinear effects, it is important to develop a method that simultaneously describes the quantum dynamics of electrons and the propagation of light. We have been developing a theoretical and computational method for the interaction of optical pulses with various materials based on the time-dependent density functional theory (TDDFT), either within the jellium approximation, which replaces the detailed atomic structure with smooth positive background charge, or by an ab initio calculation. Coupling Maxwell equations with electronic motion described by TDDFT, nonlinear and/or nonlocal light propagation of pulsed light can be described. The method has been implemented in an open-source software SALMON, developed by the authors' group [1]

To connect electron dynamics described by TDDFT and light propagation by Maxwell equations, we make

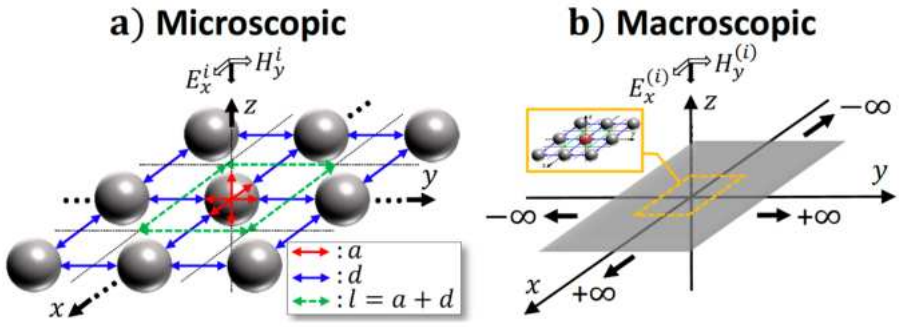

Fig. 1: Schematic description of computational method for small nanoparticles. (a) In microscopic scale, we solve time-dependent Kohn-Sham equation with periodic boundary condition. (b) In macroscopic scale, meta-surface is treated as uniform thin layer with two-dimensional current density.

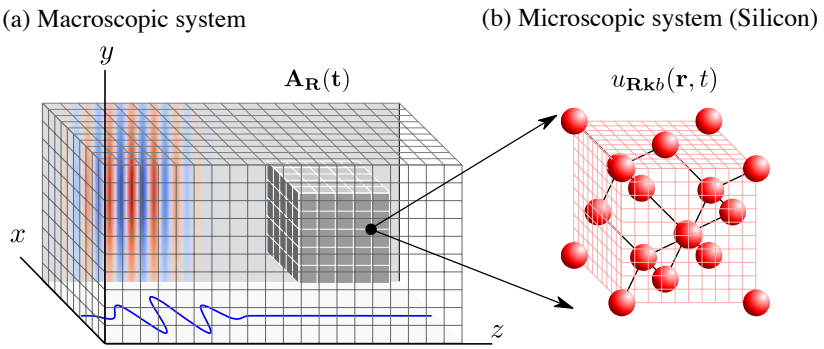

Fig. 2: Schematic description of computational method for large nanoparticles. (a) In macroscopic scale, Maxwell equation is solved in course-grid. (b) In microscopic scale, electronic motion is described assuming electronic motion in an infinite system under a spatially-uniform, time-dependent electric field.

use of a course-graining approximation. We explain it for two distinct cases: For nanoparticles whose size is less than a few nano-meters, we can describe electronic motion by solving time-dependent Kohn-Sham (TDKS) equation, the basic equation of TDDFT, for the nanoparticle in real time and real space. To connect with macroscopic Maxwell equation, we make a course-graining approximation that produces 2D current. (See Fig. 1)

For nanoparticles whose size is comparable to the wavelength of light (a few hundred nano-meters), it is impossible to solve the TDKS equation for electrons in the nanoparticle. Instead, we make use of a course-graining approximation for the nanoparticle: The nanoparticle is considered to be composed of a number of small cubes and electronic motion in the cubes is described by the TDKS equation for an infinitely periodic system under a spatially-uniform electric field (See Fig. 2). In this method, although we cannot take into account the surface effects, nonlinear light-matter interaction can be fully taken into account.

We have been applying both methods for various phenomena. The former method has been applied to investigate quantum effects in plasmonic meta-surfaces. Effects of quantum tunneling and electron spill-out have been reported in the linear [2] and nonlinear [3] responses. The latter method has been applied to investigate light propagation under extremely nonlinear conditions such as high harmonic generations in thin films [4,5] and nonlinear light propagation in semiconductor meta-surface [6].

Computing free-electrons Kerr nonlinearities in semiconductor plasmonic systems

C. Ciracì[1*] and H. Hu[1]

[1]Center for Biomolecular Nanotechnologies, Istituto Italiano di Tecnologia, Italy
[*]corresponding author: cristian.ciraci@iit.it

Abstract: We present a time-domain numerical approach based on finite-elements to solve hydrodynamic equations for free-electrons and demonstrate giant free-electron Kerr nonlinearities supported by the longitudinal bulk plasmon mode in heavily doped semiconductors.

Ultra-fast nonlinear optical response in integrated systems is a long-standing sought-after technological achievement that could enable manipulation of light on extremely short timescales and small volumes, allowing for efficient and high-performance photonic integrated circuits. This rapid response is fundamental for applications in telecommunications and data processing, including artificial intelligence training algorithms [1].

Nonlinear optics traditionally hinges on the interaction between light and dielectric materials, often requiring propagation for distances much longer than the involved wavelengths. On the other hand, the use of the metals in plasmonics as a way to confine radiation below diffraction limit has open a path toward miniaturization of nonlinear optical systems. The nonlinear response in a plasmonic structure is due to the collective motion of free electrons under an external radiation field. These oscillations are ultimately related to the kinetic energy of the free-electron gas and can be modelled by a set of hydrodynamic equations of motion in analogy with a classical fluid [2], i.e.:

$$\ddot{\mathbf{P}} + \gamma\dot{\mathbf{P}} = \frac{n_0 e^2}{m}\mathbf{E} + \beta^2\nabla(\nabla\cdot\mathbf{P}) + \mathbf{S}_{\mathrm{NL}}^{(2)} + \mathbf{S}_{\mathrm{NL}}^{(3)} \tag{1}$$

$$\mathbf{S}_{\mathrm{NL}}^{(3)} = -\frac{1}{e^2 n_0^2}\left(\nabla\cdot\mathbf{P}(\dot{\mathbf{P}}\nabla\cdot\dot{\mathbf{P}} + \dot{\mathbf{P}}\cdot\nabla\dot{\mathbf{P}}) + \dot{\mathbf{P}}\cdot\dot{\mathbf{P}}\nabla\nabla\cdot\mathbf{P}\right) - \frac{1}{27}\frac{\beta^2}{e^2 n_0^2}\nabla(\nabla\cdot\mathbf{P})^3 \tag{2}$$

Compared to traditional dielectric nonlinearities that can be described by a local susceptibility tensor, free-electrons nonlinearities are intrinsically nonlocal and depend on the product of field gradients and the electron density, which might vary at deep subwavelength scales.

We employ a time-domain numerical method based on finite-elements to solve Eqs. (1)-(2) coupled with Maxwell's equations. We apply the hydrodynamic model to a system based on heavily doped semiconductors and we demonstrate giant free-electron Kerr nonlinearities supported by the longitudinal bulk plasmon mode.

Is photonic band topology rare or common?

T. Christensen[1]

[1] Department of Electrical and Photonics Engineering, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark
[*] thomas@dtu.dk

Abstract: Overall, rather common. Although intensely researched for more than a decade, it remains unclear whether photonic crystal band topology is a rare or common feature. I will present our answers, obtained from statistical analysis of high-throughput symmetry-based calculations in two-dimensional photonic crystals, and spanning stable, fragile, and high-order band topology.

Put differently, what are the odds of finding band topology in "generic" photonic band structures and what do these odds depend on? To address this, we have analyzed roughly half a million two-dimensional, randomly generated photonic crystals across the eleven symmetry settings that admit a symmetry-based diagnosis of photonic band topology [1]. Our answers span stable topology, both in time-reversal symmetric and broken settings, fragile topology, and higher-order topology associated with corner filling anomalies. By analyzing the statistics of these calculations, we determine that most varieties of photonic band topology are rather common – and certainly more common than earlier associations might suggest; conclusions that are broadly consistent with recent findings from the condensed-matter context. Some topological features remain scarce, however, including "cumulatively" fragile topology (i.e., sets of fragile bands connected to zero frequency) which is virtually absent in our dataset. Similarly, certain symmetry settings, such as C_3, are far less amenable to hosting topological bands. We find that the prevalence of photonic topology is mostly affected by crystal symmetry, modal polarization, and geometric features – and only to a lesser extent by dielectric contrast and the amplitude of time-reversal breaking effects.

While our findings demonstrate that topology is mostly a rather common attribute in photonic band structures, our results also demonstrate that it is rare to find photonic band topology simultaneously with good spectral features (e.g., well-separated topological nodal features or gaps). This underscores the central and enduring design challenge in photonic topology. More broadly, the underlying dataset, individual data samples, and identified parameter trends may serve as guidelines to realizing new photonic topological phases in experiments.

Time allowing, I will also discuss the outlook for whether frequency-isolated photonic Weyl points can exist at the maximal high-symmetry points of the Brillouin zone, which can be addressed using $\mathbf{k}\cdot\mathbf{p}$ and graph theory.

THz Plasmonic Detectors Based on Field-Effect Transistors with Metallic Diffraction Grating Metasurfaces

A. Satou[1*] and T. Otsuji[1]

[1]Research Institute of Electrical Communication, Tohoku University, Japan
[*]Corresponding author: akira.satou.d2@tohoku.ac.jp

Abstract: We review our recent experimental and numerical studies on terahertz (THz) plasmonic detectors based on field-effect transistors with metallic diffraction grating metasurface structures for fast, ultra-sensitive, and room-temperature-operating THz detection.

To realize beyond-5G (6G/7G) wireless communication networks, where the use of the THz bands for the wireless carrier frequencies is assumed, fast, highly sensitive, and room-temperature-operating THz detectors are required. For this purpose, we have developed THz plasmonic detectors based on field-effect transistors (FETs) with metallic diffraction grating metasurface structures [1]. The plasmonic detectors utilize an efficient coupling of incident THz waves with two-dimensional (2D) plasmons in transistor channels via diffraction grating metasurfaces, which also serves as gate fingers, and their hydrodynamic nonlinearities to generate rectified photocurrent. In this talk, we review our recent experimental and numerical studies on the THz plasmonic detectors towards their applications to wireless communications.

With a conventional 1D grating THz plasmonic detector (Fig. 1(a)), the polarization component of the incident THz wave in the channel-width direction cannot be coupled with the 2D plasmons in the channel-length direction, so that the responsivity for that polarization direction is weak. To overcome this, we proposed a new 2D diffraction grating metasurface structure (Fig. 1(b)) which comprises the one-dimensional (1D) grating gate fingers and floating metallic rectangular patches (i.e., 2D nano-antennas). The nano-antennas act as a grating coupler in both channel-length and channel-width directions and also enable an efficient conversion of the THz wave polarized in the channel-width direction into a plasmon mode oscillating in the channel-length direction, as demonstrated by electromagnetic simulation in Fig. 1(c) [2]. A THz pulse detection measurement on fabricated plasmonic detectors based on InGaAs-channel high-electron-mobility transistors (HEMTs) with the 1D and 2D grating structures verified that the strong alteration of the polarization characteristics of the output photovoltage due to the introduction of the nano-antennas, as shown in Figs. 1(d) and (e) [3]. More flexible control of polarization characteristic of the responsivity is expected by designing the nano-antenna metasurfaces [3].

Moreover, we have succeeded in a significant enhancement of the detector responsivity by a newly discovered three-dimensional (3D) rectification effect in InGaAs-HEMT-based detectors with the gate-readout configuration at a forward (positive) gate bias voltage application [4]. The 3D rectification effect is a multiplication of horizontal hydrodynamic nonlinearities of 2D plasmons with a vertical diode-like current nonlinearity at the heterobarrier between the InGaAs channel and the InAlAs barrier layer (Fig. 2(a)). As shown in an electromagnetic simulation of the electric field distribution in a detector with a 1D grating structure upon the THz radiation incidence (Fig. 2(b)), the excited 2D plasmon generates a strong vertical field between the gate and channel that drives the diode-like current at the heterobarrier. We experimentally demonstrated that the internal current responsivity of a fabricated 1D grating-gate detector exponentially enhances as the gate bias voltage increases and that its characteristic agrees excellently with the I-V characteristic (Fig. 2(c)) [4]. Device simulation to reveal deeper physics inside the 3D rectification effect will be the subject of future work.

Abstract: We report on advancing machine-learning techniques for improving nanophotonics experiments and device designs with applications in thermophotovoltaics, reflective optics, and lightsail technology as well as for on-chip quantum photonic components and super-resolution imaging.

Applying machine learning techniques to nanophotonics promises to advance on-chip circuitry, imaging, sensing, energy, and quantum information technology. In this talk, we discuss machine-learning assisted techniques in photonic inverse design optimization, measurements, and simulations. Our approaches showcase the use of new techniques for platform applications in thermophotovoltaics, reflective optics, quantum photonic circuitry and lightsail technology. We demonstrate the effectiveness of autoencoders and diffusion models for compressing the vast design space of metasurfaces into a smaller search space. By employing global optimization via adjoint methods or quantum annealing, one can find the optimal metasurface designs within the smaller space constructed by the autoencoder. We also apply machine learning approaches to advance measurements through super-resolution imaging, clustering algorithms for fabrication techniques, and attention networks for semiconductor authentication.

Fast Multi-channel Full-wave Solver and Inverse Design with Augmented Partial Factorization

Chia Wei Hsu[1*]

[1]Ming Hsieh Department of Electrical and Computer Engineering, University of Southern California, Los Angeles, California 90089, United States
[*]corresponding author: cwhsu@usc.edu

Abstract: I will describe a numerical approach called "augmented partial factorization" (APF) that bypasses the computation of unnecessary quantities to enable single-shot full-wave computation of the complete response of multi-channel optical systems and efficient inverse design. APF can reduce the computing time by orders of magnitude compared to existing frequency-domain methods.

We need full-wave solutions of Maxwell's equations to make quantitative predictions about wave propagation and scattering in multi-channel systems such as aperiodic metasurfaces, disordered media, and channel [de]multiplexers. However, these simulations are often prohibitively slow given the multiple length scales and large number of input channels involved. Conventional methods have two deficiencies: (1) After discretizing Maxwell's equations on a basis, they solve for all unknowns in this large basis, which may contain millions to billions of elements even though we only extract much fewer data points from it (e.g., the amplitude of light scattered to the directions of interest). (2) A loop over the many inputs is repetitive.

In this talk, I will describe a more efficient strategy that computes only the quantities of interest. Any set of linear responses in the frequency domain can be written as a generalized scattering matrix $CA^{-1}B$ where A discretizes the Maxwell differential operator, the columns of matrix B contain different input source profiles of interest, and the rows of matrix C contain different output projection profiles of interest. Instead of evaluating the full-basis solution $X = A^{-1}B$, we directly compute the orders-of-magnitude-smaller projected matrix $CA^{-1}B$ through a partial LU factorization of an augmented matrix $K = [[A, B]; [C, 0]]$ as shown in the figure below. Doing so is equivalent to a partial Gaussian elimination that projects the Green's function A^{-1} onto the inputs B and outputs C, bypassing the forward and backward substitutions that solve for the many unknown variables in $A^{-1}B$. This approach, which we call "augmented partial factorization" (APF) [1], is ideal for multi-channel problems since it jointly handles all inputs without a loop over them. It is exact and applicable to any discretization scheme in any dimension.

APF can reduce the computing time by three to seven orders of magnitude while lowering memory usage without compromising accuracy [1]. This drastic speed-up enabled us to perform full-wave simulations of scattering matrix tomography and other imaging methods [2] and demonstrate the enhanced correlations in the backscattering direction for entangled photon pairs scattered from disorder [3]. We also developed multi-channel gradient computation using APF and used it for the inverse design of aperiodic metasurfaces [4].

We developed an open-source APF solver called MESTI (Maxwell's Equations Solver with Thousands of Inputs) in Julia [5] and MATLAB [6]. It uses finite-difference discretization on the Yee grid. MESTI supports any relative permittivity profile, any set of input source profiles, any set of output projection profiles, and comes with PML and the common boundary conditions. Multithreading and MPI are supported via the MUMPS linear-solver package.

If time permits, I will mention fundamental thickness bound [7] and efficiency bound [8] for multi-channel optical systems, and inverse designs that reach these bounds and break performance records [9].

Abstract: We illustrate a methodology for designing sub-relativistic dielectric laser accelerators. We focus on slot waveguides where an optimal taper can ensure particle-wave synchronicity and maximum energy gain. The optimization is carried out through a physics-based approach, which is validated by comparison with a downhill simplex method searching algorithm.

Several scientific and industrial applications would benefit from miniaturized particle accelerators with a reduced cost compared to the state-of-the-art equipment. However, it is well known that the performance of conventional accelerators is limited by metal breakdown and by the power required to guarantee large accelerating gradients. In this framework, laser-driven accelerating structures made of dielectric materials have been conceived, by exploiting commonly used nano-fabrication technologies [1]. This approach can be effective for miniaturization of particle accelerators, since dielectrics exhibit a larger breakdown threshold with respect to metals and powerful laser sources are available for telecommunications. As a matter of fact, dielectric waveguides are a promising platform which overcomes the limitations of side-pumped geometries, because the accelerating field is a guided mode co-linear with the particles. In this context, it was reported that slot waveguides composed of high-index dielectric strips placed over a substrate (see Fig. 1) can be employed for acceleration of sub-relativistic electrons if synchronization between particles and field is guaranteed by tapering the waveguide cross-section [2].

In this work we have investigated optimization methodologies for design of a tapered waveguide tailored for particle acceleration. In details, we adopt a physics-based approach aimed at maximizing the output energy gain by imposing that the phase velocity is equal to the particle velocity at each cross section. This procedure is rather efficient from a computational point of view since it requires a simple parametric study of the modal properties of the slot waveguide in combination with solution of single-particle relativistic dynamics. Moreover, numerical optimization has been carried out by using the Nelder-Mead method (also called downhill simplex method), which allows to determine the optimum value of a figure of merit in a multidimensional space [3]. Comparison between the optimal width *a* of the high-index strips determined through the previously mentioned techniques is reported in Fig. 2 for two different lengths of the accelerating waveguide. Notice that for shorter structures agreement between different methods is excellent, whereas results tend to diverge for longer waveguides (see Fig. 3). This is an expected result due to the field approximation used in [3], where a proper model correction was also envisaged.

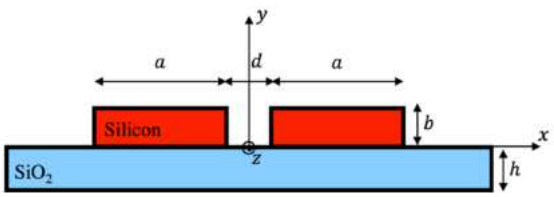

Figure 1. Schematic view of the cross-section of a slot waveguide composed of silicon strips over a silica substrate [2].

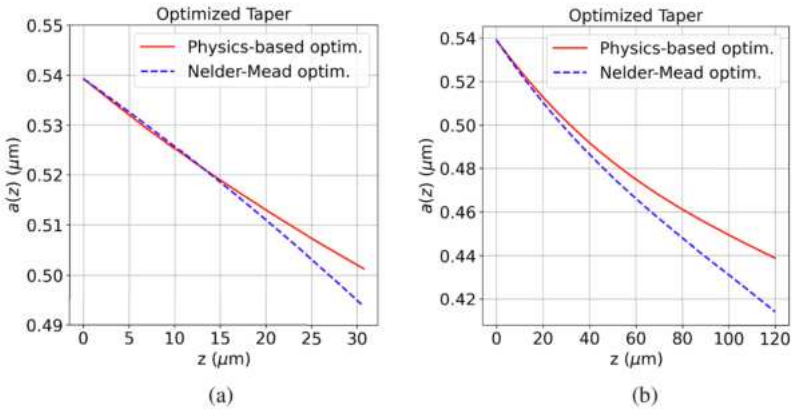

Figure 2. Optimal taper profiles obtained with the physics-based approach (red lines) and the Nelder-Mead algorithm (blue lines), respectively. (a) $L = 30\ \mu m$. (b) $L = 120\ \mu m$.

Temporal effects due to the pulsed nature of the accelerating field have also been investigated. It is indeed well-known that conventional metallic structures typically work at room temperature with low repetition rate (tens of Hz). Instead, dielectric particle accelerators can achieve MHz repetition rates, and even CW operation can be envisaged. In this scenario, short pulses are characterized by larger peak power, but the interaction length can be limited by low group delay and by waveguide dispersion. Notice that in general longer pulses exhibit an opposite behavior. In this study the effect of pulse duration has been analyzed, with the goal of identifying a recipe for choosing the pulse duration that maximizes the energy gain.

Quantifying Symmetry of Metasurfaces and Eigenmodes for Optimisation Design

Matthew Parry[1,*], Andrey A. Sukhorukov[1], and Dragomir N. Neshev[1]

[1]ARC Centre of Excellence for Transformative Meta-Optical Systems (TMOS), Department of Electronic Materials Engineering, Research School of Physics, Australian National University, Canberra, ACT 2600, Australia

Abstract: We demonstrate a novel technique to numerically quantify the symmetry of metasurface eigenmodes. We show its application to the optimization of a metasurface laser for multiple objectives such as enhancing pump absorption by four times relative to a Fabry-Perot cavity as well as controlling the mode dispersion.

Symmetry has recently become an important element of metasurface (MS) design, finding uses in the engineering of quasi-bound states in the continuum, chirality, geometric phase and the effective permittivity and permeability of MSs. The properties of the individual modes themselves can also be determined by symmetry, such as in the engineering of Dirac cones from the overlap of modes of certain symmetries. At the same time, inverse design methods are becoming increasingly important for the engineering of specific linear and nonlinear responses [1]. It is clear that an important advance can be made in metasurface applications if one is able to introduce symmetry constraints on both the MS design and the selection of modes in inverse design algorithms.

We demonstrate a novel technique to numerically quantify the symmetry of both MSs and their eigenmodes [2] through the example of an Up-Converting Nano-Particle (UCNP) based MS laser [3]. In contrast to conventional active media, the absorption band of the UCNPs is at longer wavelengths than the lasing spectral band (Fig. 1(a)). In [3], UCNP MS laser was demonstrated, however, the MS was only resonant at the lasing wavelength, having no enhancement for the absorption. Therefore, new dielectric MS designs are required to increase the infrared absorption with low dispersion to increase the acceptance angle. These goals can be achieved by selecting modes of a particular symmetry and here we demonstrate a novel technique to numerically quantify the mode symmetry so that it can be included as an optimization objective [2].

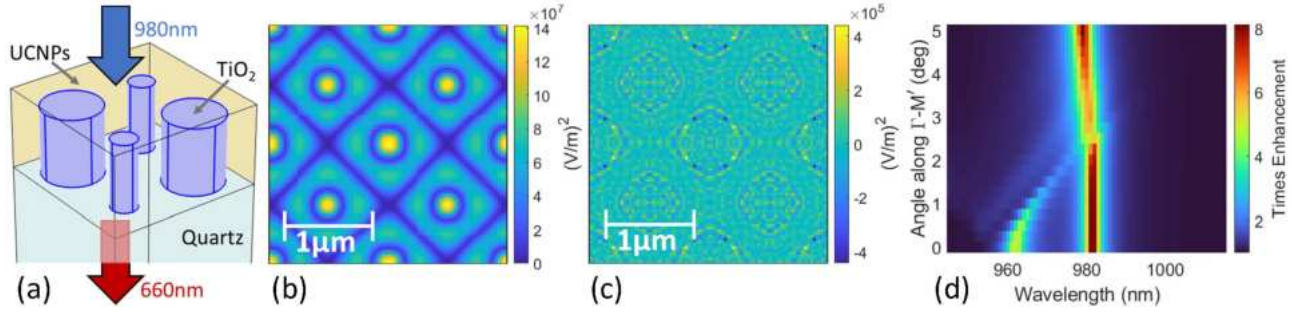

Figure 1. (a) Conceptual diagram of lasing up-conversion. (b) A scalar field with C_{4v} A_1 symmetry, over four unit cells. (c) The effect of applying the C_{4v} B1 projector to the field in (b). (d) The absorption enhancement, relative to a thin film, of the optimized metasurface.

The MS design is of C4v symmetry (Fig. 1(a)), which means that some of the modes will have the symmetry of the C4v E irreducible representation. These are degenerate, polarization independent modes with relatively

low dispersion (as required for the absorption band) for P-polarised incident light. They are also bright modes since the E irreducible representation has the same symmetry as a vector and they will therefore couple to the radiation channels. We accordingly wish to select only these modes for the absorption band and therefore require a method to recognize the symmetry of a mode from an eigenfrequency study.

Since the lattice modes in a MS have either transverse electric or transverse magnetic fields, we can characterize the vector field by taking a slice through the center of the MS. We express the fields (such as that shown in Fig. 1(b)) as a vector and then subdivide this vector space by symmetry [2]. We can therefore test for the presence of a particular symmetry by projecting the vector representing the field onto the subspace for the symmetry to be tested for. For example, the mode in Fig. 1(b), chosen for illustrative purposes, has C4v A1 symmetry. That is, it is symmetric across the horizontal and vertical as well as both diagonal mirror symmetries. If we project this vector onto the C4v B1 subspace then we get the result shown in Fig. 1(c), which is two orders of magnitude weaker. We can then use the ratio of the magnitude of this projected vector to that of the original vector to quantify the degree to which it has the given symmetry. We have thus formulated a numerical method that distinguishes between the MS eigenmodes by their symmetry.

For the optimisation of the absorption band, we used this symmetry analysis technique to eliminate all modes that are not of C4v E symmetry and then optimized for absorption within the UCNP layer. In Fig. 1(d) we can see an up to 8-fold enhancement of absorption for the optimized design relative to a UNCP thin film without the MS. This can be compared to a Si-UCNP-Si Fabry-Perot cavity, which would only provide and enhancement of 2.23 times. Note that the emission enhancement would be approximately the square of this figure since the up-conversion process is sequential two-photon absorption.

To demonstrate the general utility of projection operators we also formulate a universal definition of MS asymmetry and use it to numerically quantify the polarization of quasi-bound states in the continuum. We use these developments to provide a deeper understanding of MS asymmetry and its relationship to the mode quality factor. We also provide an analysis of the interaction of MS asymmetry and eigenmode symmetry in the context of third harmonic generation (THG). The method presented is algorithmic in nature and thus also amenable to use in optimisation routines.

In summary, we have developed a powerful technique based on projection operators that allows one to numerically quantify the symmetry of both MSs and their eigenmodes. With this new technique we designed a MS with resonances at both the absorption and lasing bands of a UCNP based MS laser and used our technique to ensure that these two modes have the properties required. We have also used projection operators to optimize a MS for THG. We believe that these projection operator techniques will be of general use wherever symmetry considerations must be taken into account in MS design.

Efficient modelling and tailoring of nonlinear wavefront and enhanced third harmonic generation in dielectric metasurfaces

V. Myroshnychenko[1]

[1]Theoretical Electrical Engineering and CeOPP, Paderborn University, Paderborn, Germany
viktor.myroshnychenko@gmail.com

Abstract: We present an effective geometry optimization approach for tailoring phase and amplitude of the third-harmonic wavefront with a high emission efficiency using dielectric metasurfaces. We demonstrate optimal metasurface designs operating as a third harmonic beam deflector and possessing a strong third harmonic generation originating from a multi-mode Fano mechanism.

Dielectric metasurfaces provide a unique platform for efficient harmonic generation and optical wavefront manipulation at the nanoscale [1]. Tailoring phase and amplitude of a nonlinearly generated wave with a high emission efficiency using resonance-based metasurfaces is a challenging task that often requires state-of-the-art numerical methods. Here, we propose a simple yet effective approach combining a sampling method with a Monte Carlo method to design the third-harmonic wavefront generated by all-dielectric metasurfaces composed of elliptical silicon nanodisks [2,3]. Using this approach, we theoretically demonstrate the full nonlinear 2π phase control with a uniform and highest possible amplitude in the considered parameter space. This allows us to design metasurfaces operating as third harmonic (TH) beam deflectors capable of steering light into a desired direction with high emission efficiency (Figure 1). The TH beam deflection with a record calculated average conversion efficiency of 1.2×10^{-1} W^{-2} is achieved [2].

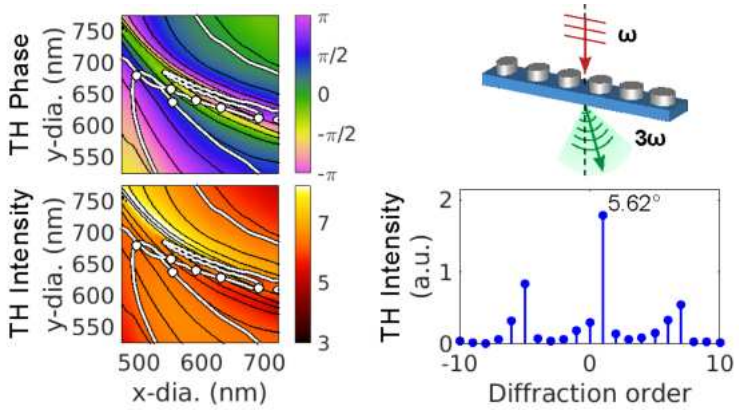

Figure 1. An artistic view of a designed supercell of a dielectric metasurface with tailored phase and amplitude used for nonlinear beam deflection. The TH phase and intensity maps are used to select the nanodisks generating the required phase and amplitude.

By employing the Monte Carlo protocol to sample over a large ensemble of geometrical parameters, one can also find the optimal metasurface designs possessing strong enhancement of third harmonic generation (THG). We demonstrate one example where extremely enhanced TH is generated by the interaction of an ultra-narrow high-Q quadrupolar magnetic mode with the two broad electric dipole and electric quadrupole

modes, which are spectrally brought so close together that they form what we call a 'Super-Fano' resonance (see Figure 2). The theoretically predicted behaviour of the metasurface is experimentally verified by linear and nonlinear transmission spectroscopy. We achieve a THG enhancement up to ~900 compared to an unpatterned amorphous silicon film of the same thickness and an absolute conversion efficiency of $\eta_{max} \approx 2.8 \times 10^{-7}$ at a peak power intensity of 1.2 GWcm^{-2} and a pulse duration of 80 fs [4].

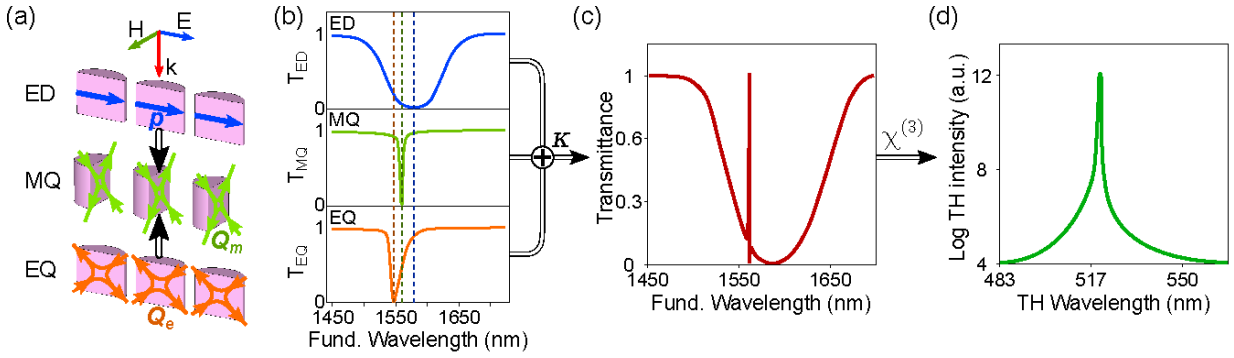

Figure 2. (a) Illustration of the enhanced third harmonic generation scheme by the multi-mode Fano resonance mechanism involving electric dipole, magnetic quadrupole, and electric quadrupole modes. (b) Transmittance spectra associated with the corresponding modes forming single resonances. (c) The resultant transmittance spectrum originated from coupling of these three modes with the coupling strength κ, forming the Fano-like sharp asymmetric resonance profile. Modeling and Implementation of Asymmetric Angular Transmittance

M. A. A. Abouelatta[1*] and K. Achouri[1]

[1]Swiss Federal Institute of Technology in Lausanne (EPFL), Switzerland
[*]corresponding author: mahmoud.abouelatta@epfl.ch

Abstract: We demonstrate theoretically and experimentally how asymmetric angular transmittance may be achieved using a meta-grating. We develop two approaches for predicting the response of this system based on generalized sheet transitions conditions and effective polarizabilities. This concept may find applications in the design of compact spatial analog processing systems.

Metasurfaces have enabled precise manipulation of the amplitude, phase, polarization and even frequency of electromagnetic waves. Yet, controlling how light responds at different angles of propagation, an ability that is a critical aspect for enabling analog computing or spatial processing in very compact optical systems, remains one of the main ongoing challenges in metasurface design. In this work, we develop a meta-grating system that exhibits angular asymmetry in transmittance. As depicted in Figure 1, the meta-grating reflects TM light which is incident from the left side, while it efficiently transmits TM light which is incident from the right side. This is evident in the magnetic field distributions shown in the far left and right sides of Figure 1 for incidence angles equal to 55° and -55°, respectively.

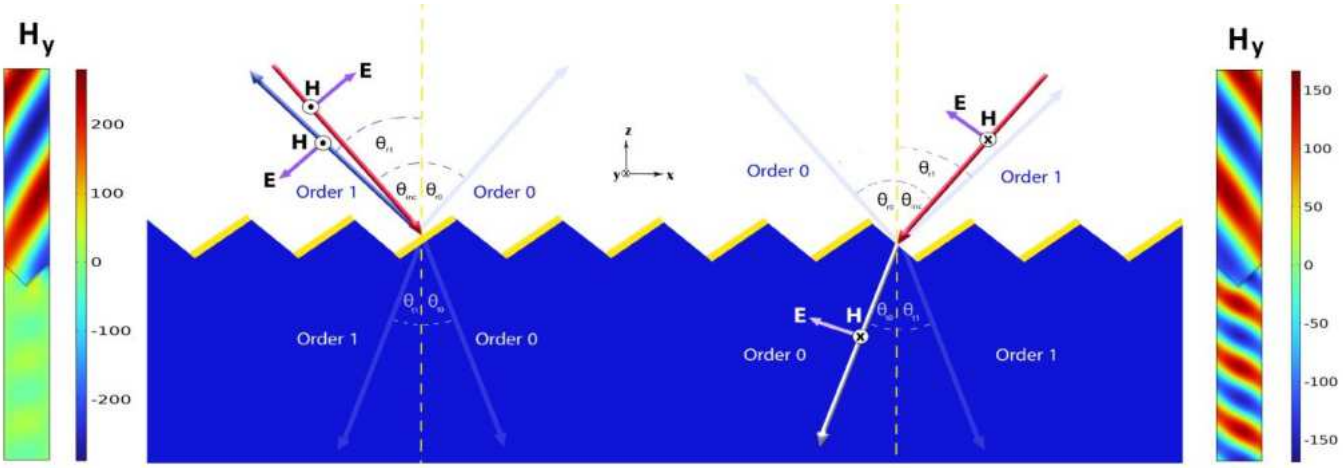

Figure 1. Schematic of the suggested meta-grating exhibiting asymmetric angular scattering.

Figure 2 (a), (b), and (c) show the 0th order, 1st order, and total transmittance, respectively, for incidence angles equal to 55° and -55°. The 0th order, 1st order, and total reflectance are also depicted in Figure 2 (d), (e), and (f), respectively. It can be noted that there is remarkable asymmetry in the total transmittance for a wavelength range starting from 0.8 to 0.95 µm. For the incidence angle (55°) where there is no transmission, the energy is rerouted to the first diffraction order in reflection as depicted in Figure 1 (e).

At the conference, we will show the response of the meta-grating in Fourier space for all three-dimensional incidence orientations. Physical insights about the inner workings of the meta-grating will be provided based

on the propagation conditions in Fourier space for each diffraction order. Moreover, two approaches for modeling and predicting the angular response of the meta-grating will be discussed. The first approach relies on the generalized sheet transition conditions [1, 2], which works only in the non-diffractive regime. The second approach is based on effective polarizabilities and Floquet expansion, which could work both in the non-diffractive and diffractive regimes. We will additionally show the fabrication process and the experimental results, which prove the asymmetric response of the transmittance. The process flow for fabrication starts with a nitride mask created on top of a silicon wafer by E-beam lithography and plasma etching. KOH is then used to create the triangular pattern since it etches the 111 plane of crystalline silicon 200 faster than the 100 plane. After that, wet thermal oxidation is applied to convert the silicon ridges to silica without deformation. Finally, oblique evaporation of gold on only one side of the ridges completes the process flow. Experimental measurements for the 0^{th} order transmittance as a function of the incidence angle and wavelength are obtained by an optical setup made of a supercontinuum light source, a polarizer, a holder, and an optical spectrum analyzer to show the angularly asymmetric response of the transmittance.

Such a meta-grating could be used for Schlieren imaging, which is typically realized by a free-space setup in which half of Fourier space is filtered. It may also be used in other applications such as angular selective thermal emission [3].

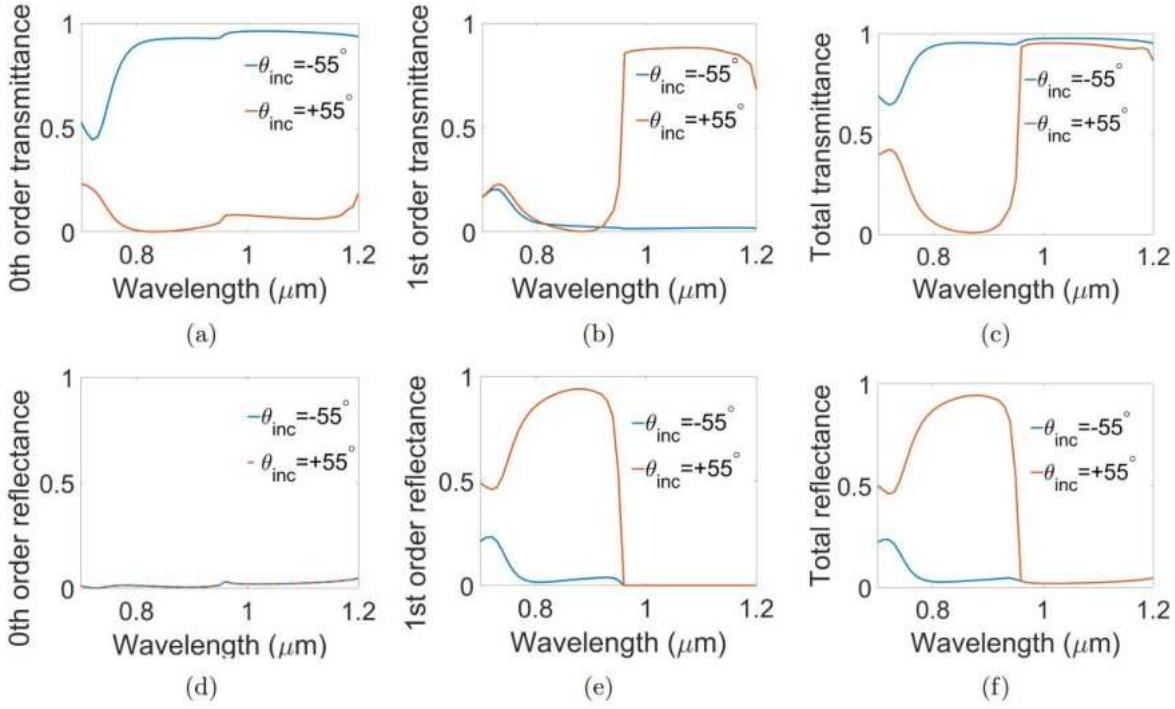

Figure 2. Full-wave simulations of the 0^{th} and 1^{st} order transmittance and reflectance as well as total transmittance and reflectance for the meta-grating in Fig. 1.

Abstract: Laser guide star wavefront sensing will be a major challenge for next generation extremely large telescopes, as Shack-Hartmann wavefront sensors will suffer from laser guide star elongation. We present the design of a meta-lenslet array which efficiently uses detector space by anamorphically rescaling the image space uniquely for each subaperture.

Laser guide star facilities for Extremely Large Telescopes (ELTs) will be crucial to correct atmospheric aberrations over a large fraction of the sky, for example the Laser Tomography Adaptive Optics (LTAO) facility for the Giant Magellan Telescope [1]. LTAO will be equipped with six laser launchers, located around the periphery of the primary mirror, to excite an asterism of artificial guide stars in the sodium layer of Earth's upper atmosphere (altitude ~95km). But the sodium layer is not infinitely thin, the 10-20km thickness of the sodium layer means a laser guide star is a vertical column of illumination rather than a point source [2]. This is particularly challenging for a Shack-Hartmann wavefront sensor (SHWFS), where each subaperture images a unique perspective elongation that is radially dependent on its off-axis position compared to the laser launcher, as depicted in Fig. 1(a). The elongation ratio for the SHWFS subapertures for ELTs varies between 1:1 and 1:10 across the aperture, see Fig. 1(b). The conventional solution is to use detectors with many pixels to adequately sample the non-elongated spots while avoiding excessive truncation of the elongated spots. But the disadvantages of using very large detectors include increased readout noise, longer readout time, decreased iteration speed, and the engineering challenges of mounting the large, heavy system on the telescope.

We present an innovative solution; a meta-lenslet array, where each meta-lenslet subaperture delivers a custom anamorphic image scale compression, allowing efficient detector packing. A SHWFS using a single layer of dielectric metalenses as the lenslet array was previously demonstrated for polarimetric beam profiling [3]. However, for our meta-lenslet array to achieve both parfocal operation and correct a broad range of elongation ratios, we developed an original design based on a metasurface bilayer configuration [4], as sketched in Fig. 1(c).

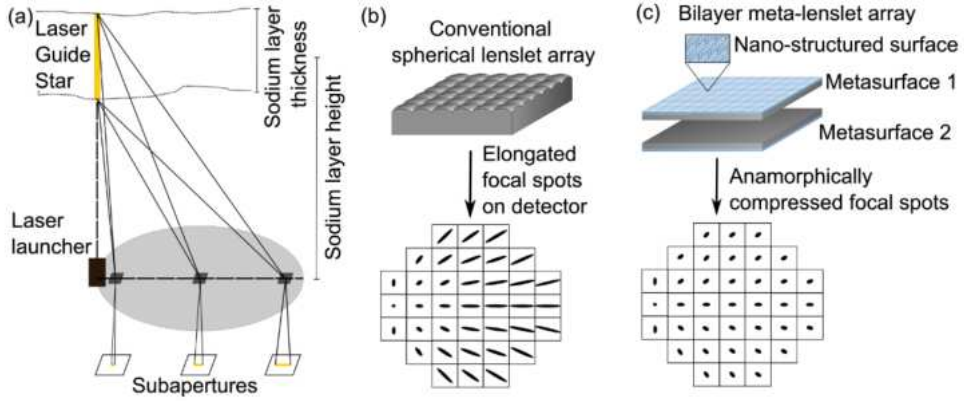

Figure 1: (a) Depiction of spot elongation due to the finite thickness of the sodium layer in the atmosphere. (b) SHWFS conventional lenslet array with variable laser guide star perspective elongation across the aperture. (c) Bilayer arrangement of the meta-lenslet, with a 6.6mm air gap between the metasurfaces.

We have designed multiple bilayer meta-lenslets with the varying the anamorphic compression ratios from 1:1 to 1:10. We matched the effective focal length of 2 mm from the LTAO design, and also investigated longer effective focal lengths up to 10mm. The Optics Studio (Zemax) simulation of our bilayer meta-lenslet and equivalent spherical lenslet showed that for f=2 mm, a 50% reduction in spot size was achieved for the most elongated spots, as seen in Fig. 2(a)-(c). For an effective focal length of f=10 mm, the spot size was completely anamorphically corrected, reducing the 104 μm spot size for the spherical lenslet to a 12 μm spot size, see Fig. 2(d)-(f). The metasurfaces can be fabricated from silicon using established research or industry facilities, or potentially titanium dioxide for increased efficiency due to a lower material absorption at the 589nm target wavelength.

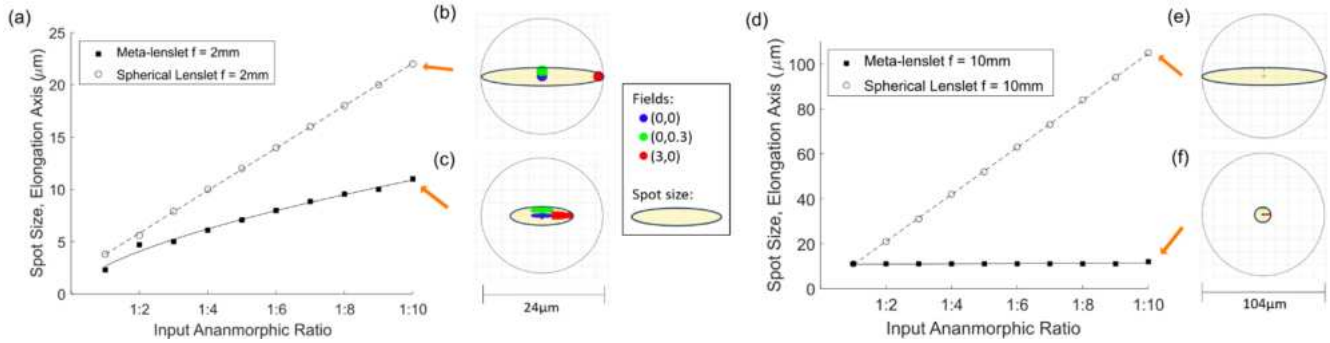

Figure 2: (a,d) Spot size versus input anamorphic ratio for a meta-lenslet and a spherical lenslet. (b,c,e,f) Focal plane field angle positions and spot size at 1:10 anamorphism for (b,e) spherical lenslet and (c,f) meta-lenslet. The effective focal lengths are (a-c) f =2 mm and (d-f) f=10 mm.

In summary, our study reveals new opportunities for anamorphic optics with meta-lenslet arrays that can find applications in telescopes and other systems requiring tailored image rescaling.

One-way excitation of normal incident light for a plasmonic grating coupler with trapezoidal dielectric gratings

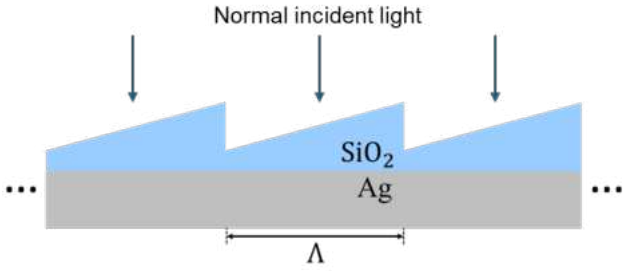
J. Shibayama[1*], H. Nakasaka[1] and K. Takeya[1]

[1]Faculty of Science and Engineering, Hosei University, Japan
[*]corresponding author: shiba@hosei.ac.jp

Abstract: We investigate the coupling problem of a plasmonic grating coupler with trapezoidal dielectric gratings. The coupler is analyzed using the frequency-dependent finite-difference time-domain method. It is shown that the normal incident light is coupled to the grating and the coupled light propagates in one direction.

When a light field is incident to gratings, the field is coupled to them provided that the phase matching condition is satisfied [1]. When gratings are used for an optical link, it is highly expected that the coupled light propagates in one direction in order to maximize the use of the incident light. Unfortunately, at normal incidence, the coupled light propagates in both directions in a plasmonic grating coupler with rectangular dielectric gratings. On the other hand, at oblique incidence, the coupled light propagates in one direction. However, it is cumbersome to precisely control the angle of incidence in a practical device.

In this article, we investigate a plasmonic grating coupler with trapezoidal dielectric gratings for one-way excitation of normal incident light. Fig. 1 shows the configuration of the plasmonic coupler, in which trapezoidal dielectric gratings made of SiO_2 are placed on an Ag substrate. The grating period Λ is set to be 1.2 μm and the lengths of the top and bottom sides of the trapezoid are determined by the conditions under which normal incident light enters the Ag substrate at the appropriate angle.



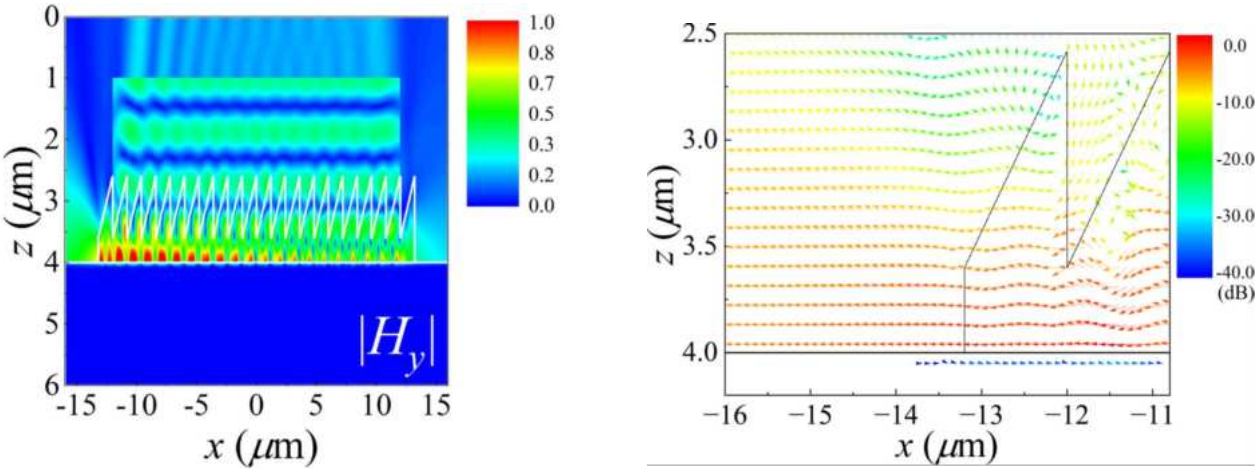


Fig. 1 Configuration of a plasmonic grating coupler with trapezoidal dielectric gratings.

To analyze a metal material using the finite-difference time-domain (FDTD) method at optical frequencies, we need to perform the frequency-dependent formulation [2]. Here, we employ the trapezoidal recursive convolution (TRC) technique [3],[4], in which only one convolution calculation is required for second-order accuracy in time. Note that the frequently used piecewise liner recursive convolution (PLRC) technique requires two convolution calculations. In the practical simulation, we apply the total-field/scattered field formulation to the FDTD method.

Figs. 2(a) and (b) show the field distribution of the H_y component at λ=1.69 μm, and the Poynting vector at

the end of the grating, respectively. In Fig. 2(a), it is found that the normal incident light is coupled to the grating, in which the field intensity is stronger on the left side of the grating. In Fig. 2(b), calculation of the Poynting vector shows that the field propagates only in the left direction, even though the field is vertically incident. It is interesting to note that the Poynting vector in the metal (blue arrows) is pointing to the right. This is because the real part of the permittivity of the metal is negative.

(a) Field distribution (b) Poynting vector

Fig. 2 Result of the plasmonic grating coupler with a 22-period grating.

In summary, we have analyzed a plasmonic grating coupler with trapezoidal dielectric gratings using the FDTD method based on the TRC technique. It is found that the coupled field propagates only in one direction, even though the field is vertically incident. Our future work is to reduce the reflected field from the gratings.

Machine-Learning Assisted Multi-User Frequency Selective Beam Steering with a Reconfigurable Intelligent Surface

Alexander Wolff[1], Lukas Mueller[1], Steffen Klingel[1], Janis Krieger[1], Lars Franke[1], Ralf Stemler[1], and Marco Rahm[1]

Abstract: We used a Machine Learning approach to design, optimize and experimentally implement a Reconfigurable Intelligent Surface (RIS) that allows simultaneous, dynamic beam steering of microwave signals at 27 GHz and 31 GHz to two users that locally move at two different locations.

In the realm of 5G and 6G mobile communication, beam obstruction caused by structures or obstacles is a significant challenge due to the utilization of higher frequency bands [1]. In this context, Reconfigurable Intelligent Surfaces (RIS) provide a remedy by redirecting radiation emitted by base stations towards obstructed regions. As shown in [2,3], continuous beam steering can be achieved within a dedicated frequency range by use of varactor diodes as tuning elements. By exploiting the frequency dependence of the S11-Parameter in such RIS, we can find tuning patterns on the unit cell level that allow us to deliberately deflect incident waves of different frequencies towards distinct directions. The determination of the required unit cell bias voltages for this task is accomplished by a semi-analytical technique that merges Kirchhoff diffraction theory with neural network algorithms. In experimental trials, we successfully demonstrate beam steering in a single plane concurrently at 27 GHz and 31 GHz, spanning deflection angles from 10° to 45°.

This research aims to enhance signal strength for two distinct users positioned at different angles relative to the normal vector of the RIS. One user operates at 27 GHz carrier frequency, while the other uses 31 GHz. Both users must receive signals simultaneously. Achieving this necessitates selecting bias voltages for the RIS varactor diodes to generate a beam lobe at the target deflection angle and frequency for each user. Yet, the voltage pattern selection is non-trivial.

For this reason, we employed a machine learning architecture, where we use the Kirchhoff diffraction formula to first analytically calculate the spatial phase distribution that is required in an ideal RIS to generate the desired spatial electromagnetic diffraction pattern at the target frequencies of 27 GHz and 31 GHz. At this point, it is important to note that the Kirchhoff formula assumes a RIS with constant, ideal reflection amplitude, which cannot be achieved in our fabricated RIS. For this reason, we pass the calculated phase pattern to a neural network that translates the phase distribution into a unit cell bias voltage distribution of the RIS with the goal to generate an identical electromagnetic diffraction pattern as previously calculated in the ideal case. As an additional constraint, the neural network is only allowed to generate bias voltages within a maximum range that is determined by the used varactor diodes in the RIS. By means of a calibration measurement that relates the applied bias voltage to the corresponding diffraction amplitude and phase from our fabricated RIS at the target

frequencies of 27 GHz and 31 GHz, we can calculate the diffractive amplitude and phase pattern of the RIS from the bias voltage matrix output of the neural network and can again use the Kirchhoff diffraction integral to calculate the resulting electromagnetic field diffraction pattern. In the training, we used a categorical cross-entropy function for the comparison between the ideal field diffraction pattern and the generated field diffraction pattern from the neural network.

With the used method, we were capable of creating bias voltage matrices for the RIS that simultaneously steered the two main lobes of the 27 GHz field pattern and the 31 GHz field pattern continuously between 10° and 45° at will.

Abstract: Computational electrodynamics is ubiquitous in nanophtonics modelling. I will describe our in-house electrodynamics software that goes beyond usual FDTD, in order to model complex light matter interactions on the nanoscale (including nonlinear and time-dependent materials) as well as our approach to the inverse design of complex light-matter interactions.

End-to-end Nanophotonic Inverse Design for Computational Imaging

Zin Lin[1*]

Abstract: We introduce end-to-end inverse design in which a nanophotonics frontend is optimized in conjunction with a computational-imaging backend to minimize reconstruction errors. We present several nanophotonics designs for snapshot multi-dimensional imaging.

Nanophotonics inverse design [1] enhances spatial, spectral and polarization sensitivities by leveraging full-wave Maxwell physics—electromagnetic interactions largely ignored by refractive or diffractive optics. Computational imaging transcends conventional optics by algorithmic reconstruction of high-fidelity information from limited optical measurements. We integrate nanophotonics inverse design and computational imaging into a holistic end-to-end framework: a single-piece nanophotonics frontend is optimized in conjunction with an image-processing backend to minimize reconstruction errors. The optics and computation are tightly coupled because the gradient of the backend error is propagated through the entire pipeline to the physical parameters of the frontend nanophotonics. In contrast to optics-only or computation-only designs, the functionality or the operating principles of the frontend optics is not prescribed *a priori* but *spontaneously* emerges during the end-to-end optimization. Unfettered by human intervention, end-to-end discovery reveals nano-structures with enhanced data-acquisition capabilities and ultra-compact form factors.

A general formulation of our end-to-end framework is described below [2,3,4]:

$$\min_{\varepsilon,\alpha} L(\tilde{u},u) \;\equiv\; \langle ||\boldsymbol{u}-\tilde{\boldsymbol{u}}||^2\rangle_{u,\eta} \tag{1a}$$

$$\tilde{u} = \mathrm{argmin}_{\mu}||\boldsymbol{G}\mu-\boldsymbol{v}||^2 + R(\mu;\alpha) \tag{1b}$$

$$v = Gu+\eta,\; G\sim|E(r_{CCD},\lambda)|^2 \tag{1c}$$

$$\nabla\times\nabla\times E(r)-\omega^2\epsilon(r)\,E(r) = i\omega\,\delta(r-r_{\mathrm{OS}})\hat{p}, \tag{1d}$$

$$\omega=\frac{2\pi}{\lambda},\; \hat{p}\in\{\hat{x},\hat{y},\hat{z}\} \tag{1e}$$

Here, the loss function L is given by the averaged reconstruction error over several training objects u and noise realizations η. For each u, the estimate $\tilde{u}$ is obtained by solving a *nested* minimization problem (commonly known as the inverse scattering problem in computational imaging); the latter seeks to recover u from a raw image v (for example, noise-corrupted readings from a CCD sensor) by minimizing the data-fitting term $\left||G\mu-v|\right|^2$ and an additional regularization function R. The measurement matrix G embodies the imaging optics and can be computed from the electric field intensities $|E|^2$ on the CCD sensor in response to a point dipole $\delta(r-r_{\mathrm{O}})\hat{p}$ at each position within the object space (OS). In our image-formation models, G can vary from convolutional kernels to full dense

matrices. In fact, the richness and complexities of G that arise from the underlying Maxwell equation differentiate our framework from traditional refractive or diffractive optics. In particular, accurate computations of G require detailed simulations of the nanophotonic permittivity $\varepsilon(r)$ as well as the gradient $\nabla_\varepsilon G$ using the full Maxwell equation and its adjoint, taking into account strong spatio-spectral and polarization dispersions. We present several examples to illustrate the capabilities of our framework [2,3,4].

Abstract: We discuss different available models of graphene conductivity, and graphene effects two main fluctuational electrodynamics effects in nanostructured systems.

We will start discussing three available models of graphene conductivity: a non-local Kubo model, a local model, and finally a non-local Quantum Field Theory based (QFT-b) model [1]. While we confirm that the local model is a proper limit of the non-local Kubo model, we find some inconsistencies in the QFT-b model as derived and used in literature. We show that the inconsistencies of QFT-b model predictions are due to a non-correct regularization-scheme which allows for the gauge invariance violation. We show how to correctly regularize the QFT-b model in order to satisfy the gauge invariance and, once also losses are correctly included, we show that the Kubo and QFT-b model exactly coincide. In the second part we will discuss the effect of graphene through its conductivity and shape on two paradigmatic fluctuation induced phenomena in periodic nanostructured graphene-based nano-systems: the Casimir forces [2] and the radiative heat transfer [3].

Abstract: Heat carried by Surface Phonon-Polaritons is investigated in thin films with contributions in the range of the one of heat conduction and of the Planck emission.

The Phonons are the quasiparticles of lattice vibrations and represent the primary heat carriers in bulk dielectric materials. The thermal conductivity of dielectric membranes is thus typically driven by acoustic phonons that is usually assimilated to a gas of particles, and generally reduces with the membrane thickness due to the increasing frequency of surface scattering events [1]. In the light of the ever-increasing miniaturization of devices with enhanced rates of operation, this reduction in the thermal conductivity causes overheating, low reliability, and reduced lifetime of electronic components [2–4]. Yet, while the thermal transport via acoustic phonons might be at the limit, the heat dissipation might be enhanced via optical phonons coupled with surface electromagnetic waves.

Over the past decade, substantial research efforts have been devoted to the study of these surface waves, because the surface effects predominate over the volumetric ones in nanostructures with high surface-to-volume ratio. Some types of surface electromagnetic waves may even carry heat [5] and thus improve the thermal performance and stability of nanoscale devices.

One type of such surface waves is the surface phonon-polaritons (SPhPs), which occurs as a hybrid of optical phonons and surface electromagnetic waves. The SPhPs are essentially evanescent waves that propagate along the surface of polar dielectric membranes [6,7].

We will first demonstrate the existence and the properties of those SPhPs in thin SiO2 films and especially uncover that the propagation lengths of those waves reach the range of hundreds of micrometers [8], which is orders of magnitude longer than the typical mean free path of acoustic phonons. Theoretical models predict that such a long propagation length enables SPhPs to conduct more thermal energy than phonons when the membrane thickness is reduced below 100 nm.

We will then corroborate the significant contribution of SPhPs to heat flux in silica membranes [9], in a restricted temperature range and also, in a wide temperature range, in silicon nitride membranes where SPhP thermal conductivity becomes predominant at 800K [10]. An additional confirmation was finally provided by showing the size dependence of thermal conductivity due to the ballistic contribution of SPhP.

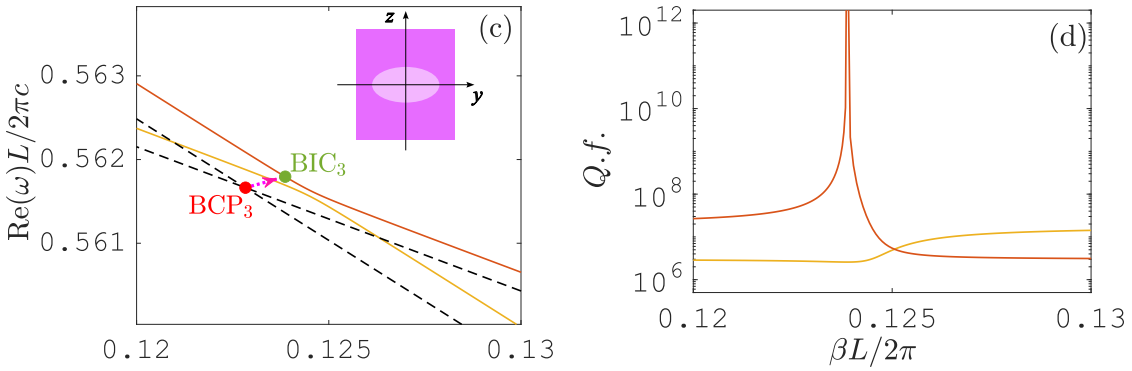
Abstract: Bound states in the continuum (BICs) have been used to improve and enhance many photonic devices, but their existence has only been justified in some special or simple cases. In this paper, we present a general existence theory for Friedrich-Wintgen BICs in a wide class of periodically perturbed slabs.

A bound state in the continuum (BIC) is guided or trapped mode with a frequency in the radiation continuum [1]. Although numerous applications of BICs have been realized, their existence is only proved for a few simple cases or special examples. The appearance of BICs in wave systems are due to a number of different physical mechanisms [1]. The so-called Friedrich-Wintgen (FW) BICs are related to the destructive interference of two resonant modes, but the original work by Friedrich and Wintgen is for a system of three 1D Schrödinger equations [2]. In a photonic system, decomposing a resonant mode as a linear combination of two independent resonant modes is not exact, and the existence of FW-BICs has not been justified rigorously in a general setting.

In this paper, we present a general existence theory for FW-BICs in periodically perturbed slabs. For simplicity, we consider the E polarization for 2D structures with a 1D periodicity. The dielectric function is given by $\epsilon(y,z) = \epsilon_*(z) + \delta F(y,z)$, where ϵ_* describes a slab of thickness $2D$ surrounded by air, F is the perturbation profile (real, periodic in y with minimum period L, even in both y and z, and $F = 0$ if $|z| > D$), and δ is the amplitude of the perturbation. A BIC of frequency ω is a Bloch mode with the x component of the electric field given by $u_{\text{bic}} = \varphi(y,z)e^{i\beta z}$, where φ is periodic in y with period L, $\varphi \to 0$ as $z \to \pm\infty$, $\beta \in [-\pi/L, \pi/L]$, $\omega > c|\beta|$, and c is the speed of light in vacuum. A guided mode of the uniform slab (i.e., $\delta = 0$) with frequency ω_0 can be written as $u_{\text{slab}} = \phi(z)e^{i\beta y} = [\phi(z)e^{i2p\pi y/L}]e^{i\beta_0 y}$, where ϕ is the mode profile (a real function of z), β is the propagation constant, p is an integer such that $\beta_0 = \beta - 2p\pi/L \in [-\pi/L, \pi/L]$. The guided modes form bands, and each band is given by a dispersion relation $\omega_0 = \hat{\omega}_{\text{slab}}(\beta) = \omega_{\text{slab}}(\beta_0; p)$. The dispersion relation for $p \neq 0$ corresponds to a folded band of the slab mode. Two folded bands may cross at a particular point (β_*, ω_*) in the β-ω plane. That is,

$$\omega_* = \omega^{(1)}_{\text{slab}}(\beta_*; p_1) = \omega^{(2)}_{\text{slab}}(\beta_*; p_2), \quad \frac{d}{d\beta_0}\omega^{(1)}_{\text{slab}}(\beta_*; p_1) \neq \frac{d}{d\beta_0}\omega^{(2)}_{\text{slab}}(\beta_*; p_2), \tag{1}$$



where the superscript (j) for $j = 1, 2$, corresponds to a slab mode with mode profile $\phi^{(j)}(z)$ and propagation constant $\beta^{(j)}$, and p_j is the related folding index. We have the following proposition: *If* (β_*, ω_*) *satisfies*

$$|\beta_*| < \pi/L, \quad |\beta_*| < \omega_*/c < 2\pi/L - |\beta_*|, \tag{2}$$

and is a crossing point of folded bands of two slab modes with the same parity in z, then for any sufficiently small δ near 0 and any perturbation profile F, the perturbed slab has a BIC $\{\varphi, \omega, \beta\}$ with frequency ω near ω_* and Bloch wavenumber β near β_*.

In the above, condition (2) ensures that there is exactly one radiation channel in the positive or negative z direction. The profile F must satisfy the conditions stated in the second paragraph above. Our result guarantees the existence of a BIC for all sufficiently small δ. The BIC depends on δ continuously and tends to a linear combination of the two slab modes at the crossing point as $\delta \to 0$. This is related to the assumptions on F and the robustness of BICs in 2D periodic structures with reflection symmetries in both y and z [3]. The robustness theory also implies that the BIC will continue its existence when $|\delta|$ is increased until (β, ω) fails to satisfy condition (2). Notice that the crossing point is only related to the slab modes and it unrelated to the perturbation profile F. For a small nonzero δ, the perturbed slab has two bands of resonant modes (near the crossing point) given by dispersion relations $\omega = \omega_{\text{res}}^{(j)}(\beta)$, $j = 1, 2$, where β is real and ω is complex. Due to the avoided crossing, $\text{Re}[\omega_{\text{res}}^{(j)}(\beta)]$ (for $j = 1$ or 2) is partially close to $\omega_{\text{slab}}^{(1)}(\beta; p_1)$ and partially close to $\omega_{\text{slab}}^{(2)}(\beta; p_2)$. Our theory implies that there is always a β near β_*, such that the imaginary part of $\omega_{\text{res}}^{(1)}(\beta)$ or $\omega_{\text{res}}^{(2)}(\beta)$ is exactly zero.

As an example, we consider a slab with $\epsilon_*(z) = 11.56$ for $|z| < D = 0.625L$ and a perturbation corresponding to a periodic array of elliptic cylinders. In the yz plane, the cross sections of the cylinders are elliptic disks with a semi-major axis $a = 0.3L$ (along the y axis) and semi-minor axis $b = 0.28618L$. The profile $F(y, z)$ equals -1 or 0, for (y, z) inside or outside the elliptic disks, respectively. In Fig. 1(c), we show two folded bands of the

uniform slab as the dashed lines and a crossing point denoted as BCP_3. For the perturbed slab with $\delta = 0.05$ (the dielectric constant of the elliptic cylinders is $\epsilon = 11.51$), We have two bands of resonant modes near the crossing point, and show $\text{Re}[\omega_{\text{res}}^{(j)}(\beta)]$ (for $j = 1, 2$) as the solid lines and a BIC denoted as BIC_3 in Fig. 1(c). The quality factors, $Q = -0.5\text{Re}[\omega_{\text{res}}^{(j)}(\beta)]/\text{Im}[\omega_{\text{res}}^{(j)}(\beta)]$, of the two bands are shown in Fig. 1(d).

Abstract: We report on the generation of second-harmonic vortices with either a uniform film or an optical metasurface, fabricated in a hybrid AlGaAs-on-sapphire platform. In the former case we demonstrate spin-to-orbital angular momentum transfer, while in the latter we generate orbital angular momentum with arbitrary topological charge via a nonlinear meta-hologram.

Calculation of surface state spectra for topological photonic and acoustic crystals

Y. X. Sha[1*], and Y. Yang[1*]

[1] Department of Physics, The University of Hong Kong, Pokfulam, Hong Kong, China
[*]corresponding author: yxsha@hku.hk; yiyg@hku.hk

Abstract: We present efficient algorithms for calculating the surface state spectra of photonic and acoustic crystals, which are highly beneficial in studying topological materials in classical systems.

In recent years, various novel topological surface effects have been experimentally observed in optical and acoustic systems. However, there is currently no ideal method available for calculating the surface state spectrum of such systems, so as to directly compare it with the results of near-field scanning experiments.

The existing method for obtaining surface states in these classical systems involves calculating the eigenvalues of a finite size supercell, which has drawbacks such as large memory consumption and high requirements for absorption boundary. In contrast, the relatively mature method of doing so in electronic systems involves calculating the surface Green's functions (i.e., surface density of states) for a semi-infinite structure, which directly highlights the surface states on a single surface in the spectrum. Moreover, various fast algorithms have been proposed for solving the surface Green's function of electronic materials, effectively reducing the consumption of computational memory. Inspired by this, here we develop various numerical algorithms for calculating the surface density of states in topological photonic and phononic crystals.

Firstly, we will introduce the relationship between the Green's functions and the local density of states (LDOS). The Green's function $\boldsymbol{G}$ for electromagnetic and acoustic waves can be defined as

$$\underbrace{\left[\boldsymbol{X}(\boldsymbol{r})-\omega^2\boldsymbol{Y}(\boldsymbol{r})\right]}_{\boldsymbol{Z}(\boldsymbol{r};\omega)}\boldsymbol{G}(\boldsymbol{r},\boldsymbol{r}';\omega)=\boldsymbol{I}\delta(\boldsymbol{r}-\boldsymbol{r}') \tag{1}$$

where $\boldsymbol{X}$ is the differential operator, $\boldsymbol{Y}$ is the material parameter and $\boldsymbol{I}$ is the unit dyad. The LDOS can be directly derived from the imaginary part of $\boldsymbol{G}$:

$$\mathrm{LDOS}\,(\boldsymbol{r};\omega)=\frac{2\omega}{\pi}\,\mathrm{Im}\left\{\mathrm{Tr}\left[\boldsymbol{Y}\,(\boldsymbol{r})\lim_{\eta\to 0^+}\boldsymbol{G}\,(\boldsymbol{r},\boldsymbol{r};\omega+j\eta)\right]\right\} \tag{2}$$

Next, we will calculate the surface Green's function for a semi-infinite photonic system. If each layer of the photonic crystal is discretized with the same finite element mesh, then the operator $\boldsymbol{Z}$ in Eq. (1) will become a semi-infinite block cyclic tridiagonal matrix, i.e., $\boldsymbol{Z}_{m,m}=\boldsymbol{Z}_{0,0}$, $\boldsymbol{Z}_{m,m+1}=\boldsymbol{Z}_{0,1}$, $\boldsymbol{Z}_{m+1,m}=\boldsymbol{Z}_{1,0}$ (the subscripts represent the layer numbers from the surface). Many efficient algorithms such as cyclic reduction method[1] and transfer matrix method[2] have been proposed to invert such a matrix. These methods deal only with one or two cells of a crystal rather than a large supercell structure, which saves lots of computational memory. They are summarized in Tab. 1 and Tab. 2 in the form of pseudocodes.

Finally, we will verify the effectiveness of our algorithms through a simple example. Fig. 1(a) is a semi-infinite acoustic crystal having two Dirac points and four helicoid surface states protected by the glide symmetries. Fig. 1(c) is the calculated surface density of states, which agrees well with those bands on a single surface in Fig. 1(b). Fig. 1(d)-1(f) are the iso-frequency cuts of the band diagram, which clearly shows the evolution of the surface states near the Dirac point.

Abstract: We present a theoretical study of the interactions between confined acoustic phonons and localized surface plasmons in metallic nanoparticles. We introduce a new physical quantity, the Raman energy density, which is a local quantity that serves as a tool for the study of Raman scattering mediated by plasmons in nanoparticles.

Most of the studies focusing on metallic nanoparticles consider them as static bodies at rest. However, localized surface plasmons (LSPs) can be temporally modulated by acoustic vibrations, also known as acoustic phonons, naturally present in the nanomaterial and surrounding environment. Very recently, there has been a renewed interest on the modulation effect of the LSPs by (opto)mechanical modes and elastic waves [1-6]. Such high-frequency (GHz-THz) modulation can be used to increase detection and sensing accuracy of nano-objects and molecules. For instance, these vibrating nanoparticles, acting as simple optomechanical nanoresonators, can be seen as nanoscale analogs to quartz crystal microbalances. Acoustic-phonons Raman scattering is a very effective, high-precision, and non-invasive technique for nanometrology. It uses the acoustic vibrations as local probes to determine sizes and distances at the nanoscale with very high accuracy. However, the effectiveness of this technique is directly related to the knowledge of the interaction mechanisms between electrons (plasmons) and phonons (acoustic vibrations). Therefore, it is necessary to know what are the vibrational modes sustained by a given nanostructure (amplitude, frequency, symmetry) and know how they interact with the LSPs to completely determine the Raman efficiencies and selection rules.

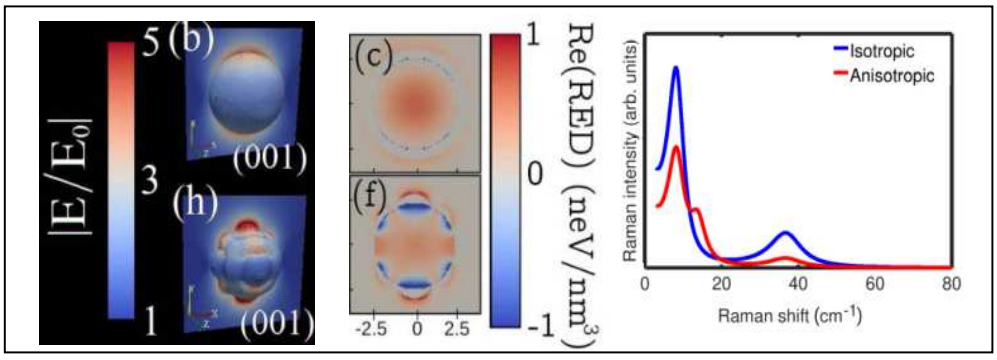

Fig. 1 Left: Isotropic (l=0) and Anisotropic (A_{1g}) breathing acoustic mode of a AuNP modulating the near electric field induced par the dipolar localized surface plasmon (LSP). **Center**: Raman energy density (RED) resulting from the interaction of the l=0 and A_{1g} vibration mode with the dipole LSP. **Right**: Calculated acoustic Raman spectra for the isotropic and anisotropic nanoparticles.

Here, we investigate the dynamic properties of metallic nanoparticles by focusing on the interaction between confined acoustic vibrations and LSPs (**Fig. 1, left**) [5, 7]. The dynamic properties of LSPs are responsible for the transient optical absorption modulation, that can be observed in time-resolved transient absorption experiments [6], and for the acoustic SERS effect [4], We describe the resonant Raman scattering process using a new approach based on a single direct acousto-plasmonic interaction process described by Fermi golden rule [7]. Within this framework, we introduce a new physical quantity, namely, the Raman energy density (RED; **Fig. 1, center**). Similarly to the Raman-Brillouin electronic density (RBED) introduced in semiconducting nanostructures [8, 9], the RED allows for studying and monitoring the acousto-plasmonic Raman scattering in the near-field. We modeled the acousto-plasmonic interaction by implementing vibrational dynamics (resonant ultrasound method, RUS), into electrodynamic calculations (discrete dipole approximation, DDA). We used this methodology to compute the acoustic Raman spectra (**Fig. 1, right**) and investigate the interaction between LSPs and (an)isotropic acoustic vibrations, thus leading to the full determination of Raman efficiencies and selection rules. We show that the RED (**Fig. 1, center**), which can be mapped in the near-field for each vibration mode, correlates the far-field Raman scattering (**Fig. 1, right**) to the local acousto-plasmonic hot spots (**Fig. 1, left**), provides a deeper understanding of the Raman scattering process (*e.g.*, Raman selection rules), and serves to study the acousto-plasmonic coupling of complex nanostructures.

Limits and opportunities for nonlinear nanophotonics

Alejandro Rodriguez*

Princeton University, USA
*arod@princeton.edu

Abstract: The ability to tailor light--matter interactions by structuring materials is crucial to a wide range of disciplines, e.g., spectroscopy and quantum communication. Advances in nanofabrication make it possible to investigate optical devices at the fundamental limits of achievable performance --- limited only by available material response and attainable feature sizes. In this talk, we review recent advances and applications of large-scale optimization techniques to nonlinear processes, including limitations on the ability of structuring to control spontaneous emission, second harmonic generation, and Raman scattering in resonant media.

Design and simulation of a metalens-based eye-tracking system

Abstract

We present a computational workflow that integrates metalens design principles into the classical optical design process. Our approach encompasses the design of phase profiles, meta-atoms, and introduces an innovative method for system-level simulation within a ray-tracing environment. As a practical application, we employ this workflow to develop a metalens-based eye-tracking system, seamlessly embedded within a VR device.

1. Introduction

Recently, an increasing interest in utilizing metalens for various optical systems has been observed due to their lightweight and compact size compared to their traditional equivalents. Some applications require integration of large-scale metalens, usually exceeding hundreds of times the wavelength, into a macro system that often includes refractive optical components. These systems are typically designed and simulated with ray-tracing methods. However, it becomes challenging to simulate metalens in this type of system. Ray-tracing is generally not suitable for simulating sub-wavelength structure, while FDTD or RCWA struggle with the large-scale system. In this paper, we will introduce a new method to simulate metalens with the ray-tracing approach to effectively simulate a metalens within a macro system. To demonstrate this new approach, we will design and demonstrate an eye-tracking system used within a VR pancake system.

2. Ray-tracing method for metalens

In this paper, we propose an innovative method for metalens design workflow where RCWA and ray-tracing are combined for an efficient way to transport nano-scale information into the mm-scale system.

This method requires a pre-calculated database of meta-atom's far field response data, amplitude and phase, for plane wave inputs in different incident angles. The pre-calculation is performed for different types of meta-atom with different geometry. For example, if the meta-atom is a cylinder, we may pre-calculate for different radius and save in the database. The response of each individual meta-atom is computed via the RCWA method with locally periodicity approximation (LPA). Another required data is a meta-atom map, which describes how meta-atom with different geometries are distributed on the metalens substrate. This meta-atom map can be derived from the meta-atom database along with an ideal phase profile that is designed in a ray-tracing process.

With the meta-atom database and a given meta-atom map, we can fully simulate a metalens in a macro system in ray-tracing process. During the ray-tracing, when a ray hits the metalens surface, we consider the ray locally as a plane wave and look up the database for the corresponding response based on the plane wave's incident angle and the corresponding meta-atom type where the ray hits. From the response data, the phase gradient of the output field at the ray position can be derived and the output ray's direction and amplitude is further calculated, as shown in Fig 1.

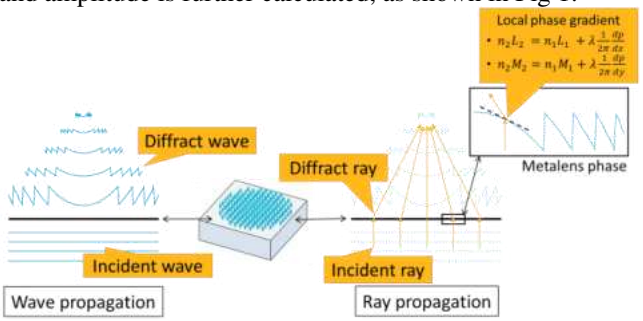

Figure 1: The left side shows how a beam passes through the metalens in viewpoint of wave propagation. The right side shows how the phase gradient data is used to decide the diffract rays. In the picture, (n1, n2) are the refractive index at two sides of the metalens. (L1,M1) and (L2,M2) are direction cosines x and y for incident and diffract rays. λ is wavelength. dp/dx and dp/dy are the phase gradient in x and y directions.

3. System design

The workflow is demonstrated with a metalens-based eye-tracking system, integrated into a compact pancake-style virtual reality (VR) device (as depicted in Fig. 2). The eye-tracking system is constructed using a glass plate with meta-surfaces on both sides (ML1 and ML2 in Fig. 2). Our specific focus lies on pancake-type VR devices, which have gained significant popularity recently. By strategically

positioning the eye-tracking system behind the VR lenses, we achieve an extended optical path, thereby able to capture image of same area around eye with smaller field of view (FOV) requirement. The tradeoff is we them have more aberration to correct because there are two traditional lenses in between the eye-tracking system and the human eye to be imaged.

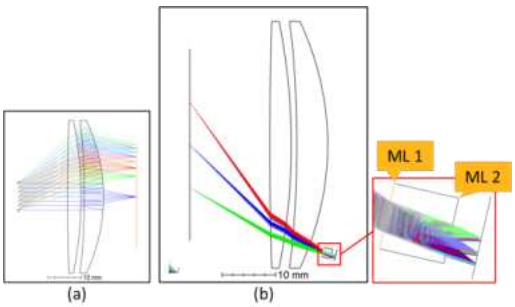

Figure 2: (a) The layout of pancake VR design. (b) The metalens based eye-tracking design embedded in pancake VR system.

The basic specifications and constraints of the system used during the design process are shown as in Table 1.

Table 1: specifications and constraints

Eye box	16 mm x 32 mm
Diameter	< 2 mm
Length	< 4 mm
Wavelength	0.85 µm
Meta-atom size	0.4 µm

3.1. Phase profile

The first step to build the system is to design the ideal phase profile in pure ray-tracing process. The phase profile on the metalens is described in the equation (1). Ai and Bi are the coefficients to be optimized for best image performance.

$$\phi = \frac{2\pi}{\lambda}\left(\sum_{i=1}^{P} A_i r^i + \sum_{i,j=1}^{N,M} B_{i,j} x^i y^j\right) \quad (1)$$

In the equation, the first part in the parentheses is rotationally symmetric phase which focuses light on the image plane and compensates most of on-axis aberrations. The second part, on the other hand, is a freeform phase, which is responsible for compensating for those aberrations caused by the off-axis nature of the system. We use the same equation for both metalenses at the two sides.

At this stage, the main goal is to optimize the coefficients Ai and Bi for the best image quality, which means the smallest spot size for sampling field of view. Note the distortion is not considered during the optimization as they can often be compensated later in the digital post-processing.

During the optimization, it is needed to constraints the phase slope not to be too large. In this design, the meta-atom size is 0.4 µm. Following the Nyquist frequency, it means there should be at least two meta-atoms in every 2π phase change, which corresponds to maximum allowed phase slope of 1/(0.4*2)=1250 mm^-1. However, in this case, the error between ideal phase and phase reproduced by meta-atom can be large. For a better quality, here we choose to constraint the maximum allowed phase slope to be <250 mm^-1, which means there are at least 10 meta-atoms in every 2π phase change on the metalens.

The optimized phase profile and its phase slope are shown in Fig 3. For first metalens, phase slope is stronger in tangential direction and works like a rotationally symmetric lens. The second metalens, on the other hand, has more phase slope in sagittal direction and works more like a freeform lens which compensates off-axis aberrations.

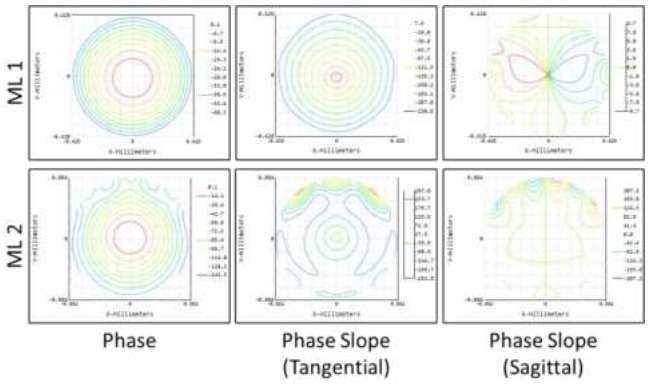

Figure 3: The optimized ideal phase and phase slope for first and second metalens in the system.

3.2. Meta-atom

The next step is to get meta-atom database by scanning the field response of the meta-atom with different incident wave and different geometry. In this design, meta-atom geometry is a simple cylinder pillar. We scan to find how phase varies with different radius and height of the cylinder as shown in Fig 4. The purpose is to find a range of radius, where the corresponding phase delay covers 0 ~ 2π range. In addition, the range of the radius is the larger the better and the minimum radius is 0.05 µm, which we assume is the minimum manufacturable size. Based on the result, we decide to fix the heigh of cylinder to 1.7357 µm and vary radius from 0.072 to 0.165 µm to include a 2π range of phase variation.

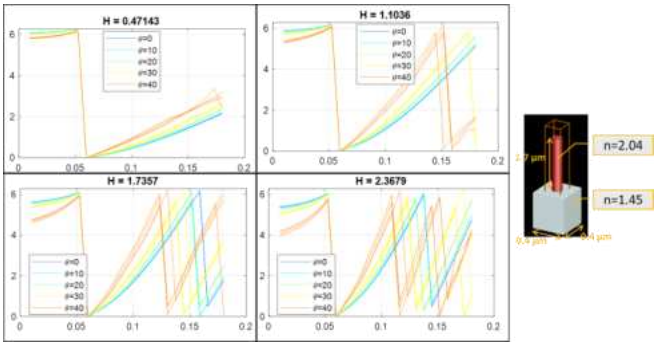

Figure 4: Phase delay introduced by the meta-atom with different cylinder radius. Different color of line corresponds to different incident polar angle, where azimuthal angle is fixed to 0 degree, as shown in the legend. Different sub plots show results with different cylinder height.

A more detailed analysis of the selected meta-atom is shown in Fig 5. where the results are shown for both phase and amplitude. The results for first and second metalens are also shown. The response of the two metalenses are different because the light is incident from different side.

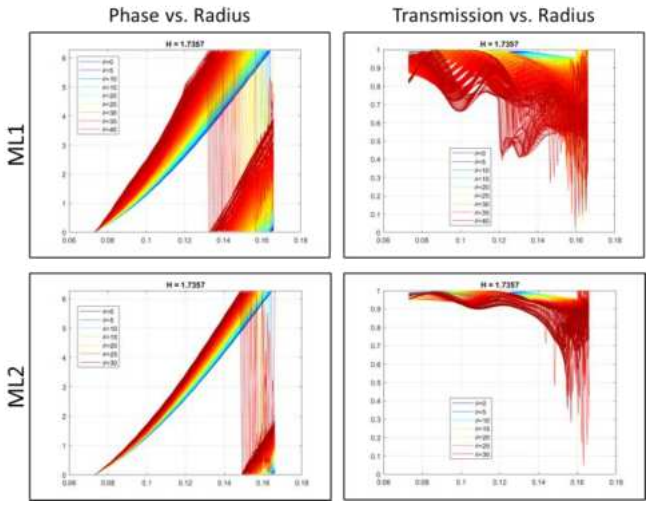

Figure 5: Phase delay and amplitude transmission introduced by the meta-atom with different cylinder radius for first and second metalens. Different color of line means different incident polar angle. For same color, there can be several lines, which correspond to different incident azimuthal angles.

It is worth mentioning that the manufacturable cylinder radius can be discrete depending on fabrication method. Thus, the generatable phase delay is also discrete. In this paper, it's assumed that the minimum phase difference between two different meta-atoms is 1 degree. This will be the source of imperfections of the metalens, as will be shown in the next section.

3.3. Macro-scale system simulation with ray-tracing method

As explained in section 2, the ideal phase created in section 3.1 and the meta-atom database generated in section 3.2 are then loaded into a ray-tracing engine by a plugin for a system-level simulation.

4. Simulation result

4.1. System performance

After applying the phase profile and the meta-atom database, the ray-tracing result shows a similar result to ideal phase but with worse performance, as shown in Fig. 6. It can also be seen that the spot size is larger with our metalens model than the result with ideal phase in Fig. 7. This is expected as the metalens cannot perfectly reproduce the designed phase, which introduces error to the diffract rays.

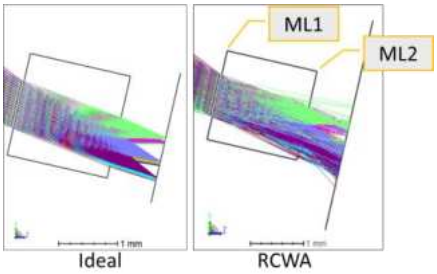

Figure 6: Layout of ray-tracing result between ideal phase and exact phase from RCWA.

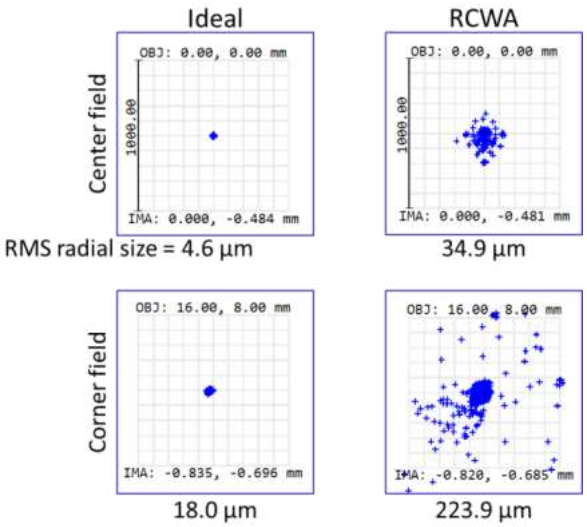

Figure 7: Spot diagram for center field and corner field with ideal and RCWA phase profile.

4.2. Image simulation

In addition to efficiency in large scale system, another benefit of ray-tracing method is the ability of doing image simulation. The result of image simulation for ideal phase and the metalens model are shown in Fig. 8. As expected, the distortion is significant because they are not considered during optimization. The image with metalens model is more blurred than image with ideal phase as the metalens doesn't perfectly reproduce the phase. It can also be seen the relative illumination is lower and the image is less sharp at the corner of the image. This is as expected because, at larger incident angle, the amplitude transmission of the meta-atom is lower and the phase error is larger.

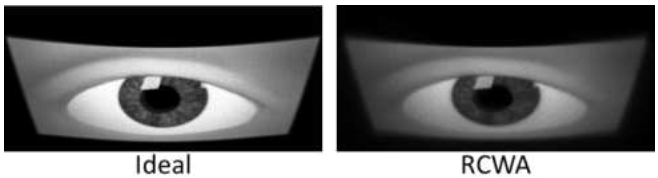

Figure 8: Image simulation result with ideal and RCWA phase profile.

5. Conclusions

We introduced a new method to simulate metalens with ray-tracing. This method requires a meta-atom database, pre-

calculated in RCWA, and a meta-atom map describing how meta-atoms are distributed on the metalens substrate. The database and the meta-atom map are loaded in ray-tracing engine to handle the metalens response. To demonstrate the method, a metalens-based eye-tracking system built in a pancake VR lens system are designed and simulated with this new method. We have compared the spot diagram and image simulation results between using ideal phase and our metalens model. It can be observed that the result with the metalens model shows similar but worse performance compared to ideal phase model, as expected.

Chiro-optical and chiral-acoustic phenomena

TiO_2 Nanoantenna Stickers for Fabricating Large-Area Twisted Metamaterials with Tunable Chiroptical Effects

Jiayang He [1], Shunsuke Murai[1*], Tienyang Lo[1], Katsuhisa Tanaka[1 *]

[1]Kyoto university, Japan
[*] murai@dipole7.kuic.kyoto-u.ac.jp

Abstract: Twisted metamaterials, created by stacking and twisting two achiral nanostructured layers exhibit chirality. We propose a simple method employing nanoantenna stickers to fabricate such metamaterials, achieving precise control of giant circular dichroism via twist angle adjustment with the largest effect at 22.5°, holding promise for chiral optics and sensing development.

1. Introduction

Chiral metamaterials, known for their chiroptical effects, exhibit asymmetric responses to left- and right-circularly polarized light, resulting in higher circular dichroism (CD) compared to natural materials[1,2]. Currently, some chiral metamaterials, exemplified by helices[3], offers inherent handedness, but their 3D nanostructure fabrication can be complex [2].

In this study, we present a novel chiral metamaterial composed of two identical achiral TiO_2 nanoantenna stickers stacked together. Its chiroptical response is precisely tunable by varying the in-plane rotation angle or twist angle between the sticker layers, yielding some CD spectra varied with the twist angle.

2. Results and discussion

The TiO_2 nanoparticles array is embedded into a transparent, flexible PDMS substrate to create stickers that are reusable and handled with ease (Fig. 1). Then we stick a pair of identical TiO_2 nanoantenna stickers with a twist angle in between (Fig. 2a-c). The transmission intensities for the right- (I_R) and left- (I_L) circularly polarized light were measured, and the CD value, defined as CD = $(I_R - I_L) / (I_R + I_L)$ was plotted as a function of incident angle (Fig. 2d, e). The flip of the sign of the CD signal is notable between the twist angles in opposite directions. The flip was further compared at normal incidence (Fig. 2f).

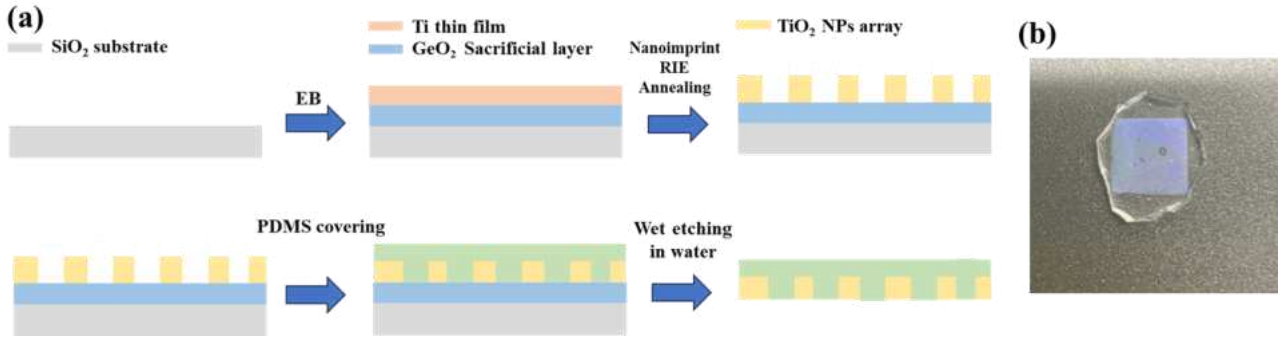

Fig. 1. (a) TiO_2 nanoantenna sticker is fabricated by nanoimprint on a sacrifice GeO_2 layer and reactive ion etching of Ti thin film followed by thermal oxidation, next, the TiO_2 array is covered with a PDMS film and transferred onto the PDMS layer by dissolving the underlying GeO_2 film in water. (b) Photograph of TiO_2

nanoantenna sticker.

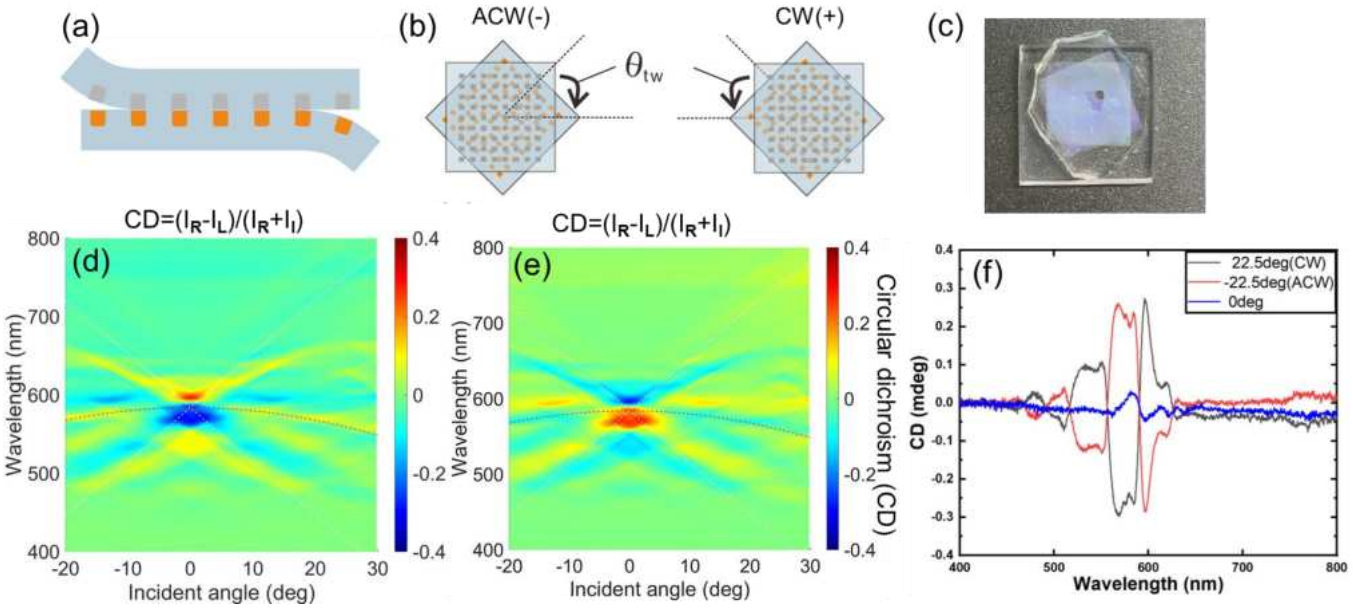

Fig. 2. (a-c) The sketch(a) and photograph (c) of the twisted metamaterial configuration composed of two identical nanoantenna stickers adhered to each other. (b) illustrates the definition of the twist angle. The incident angle dependence of the CD values at twist angles of 22.5° (d) and -22.5° (e) is depicted. CD spectra of (f) the stacked stickers with twist angles of 0 and ±22.5° at normal incidence.

3. Conclusion

The TiO_2 nanoantenna stickers embedded in PDMS were successfully fabricated through a series of treatments such as heat treatment and transfer technology and can be utilized as chiral metamaterial.

The CD results for the stacked identical stickers exhibit dependence on incident angles, revealing symmetry in CD response intensity for equal clockwise (CW) and anticlockwise (ACW) rotations.

Directional sources realized by toroidal dipoles

Junho Jung[1], Yuqiong Cheng[1], and Shubo Wang[1,2*]

[1]Depaartment of Physics, City University of Hong Kong, Tat Chee Avenue, Kowloon, Hong Kong, China
[2]City University of Hong Kong Shenzhen Research Institute, Shenzhen, Guangdong, China
[*]corresponding author: shubwang@cityu.edu.hk

Abstract: We demonstrate that toroidal dipole can be applied to realize three new types of directional sources: pseudo-circular dipole, pseudo-Huygens dipole, and pseudo-Janus dipole. These directional sources exhibit near-field directional behavior analogous to conventional directional sources, while they provide more degrees of freedom to tune the directionality.

It is well known that circularly polarized dipole, Huygens dipole, and Janus dipole can give rise to near-field directional coupling along a waveguide due to its intriguing properties associated with spin, power flow, and reactive power. [1] These directional dipole sources are composed of electric and/or magnetic dipoles. There is another type of dipole source called a toroidal dipole, which has analogous properties and the same far-field radiation pattern as an electric dipole.[2] Here, we demonstrate numerically and analytically that the toroidal dipole can replace an electric dipole component of the conventional directional dipole sources to achieve the same near-field directional coupling along a silicon waveguide. Moreover, we find that the directionality can be controlled by changing the geometric parameters of the toroidal dipole, leading to tunable asymmetric coupling between the dipole sources and the waveguide. These new types of directional sources provide more degrees of freedom to tailor the directionality compared to conventional sources. Furthermore, we demonstrate that we can optimize a toroidal dipole component of the pseudo sources to obtain the unidirectional coupling. This novel approach suggests a new way to design directional light sources and directional optical devices, which can be applied to on-chip optical routing, waveguiding, and nanophotonic communications.

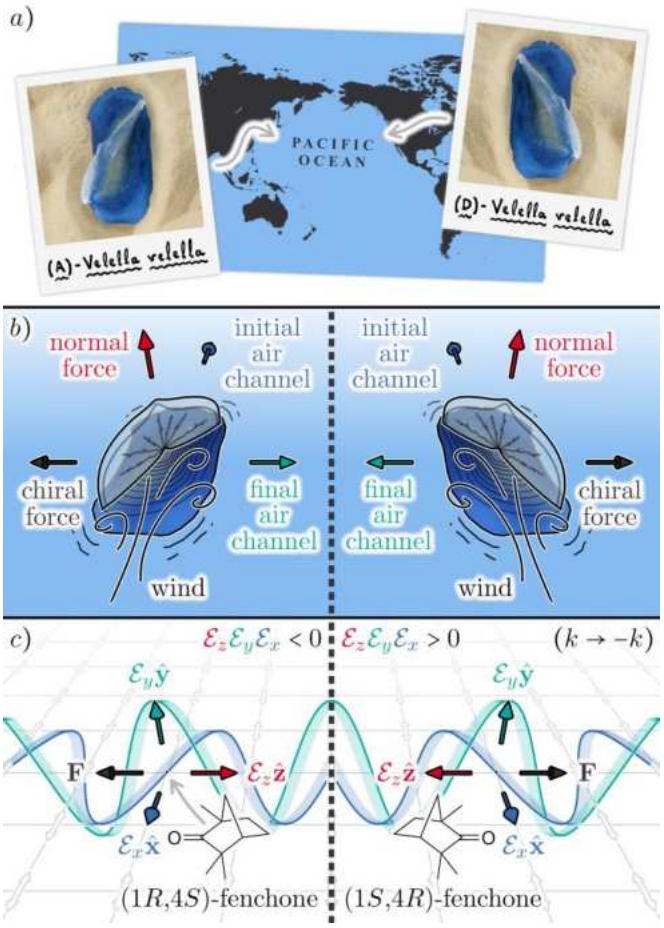
Robust chiral optical force for small chiral molecules

Robert P. Cameron[1*], Duncan McArthur[1], and Alison M. Yao[1]



[1] SUPA and Department of Physics, University of Strathclyde, Glasgow G4 0NG, United Kingdom

[*]corresponding author: robert.p.cameron@strath.ac.uk

Abstract: We draw inspiration from nature to identify a robust chiral optical force for small chiral molecules that can be several orders of magnitude stronger than other chiral optical forces proposed to date. Potential applications range from chiral molecular matter-wave interferometry to the resolution of enantiomers.

Interest is growing in the possibility of an optical force that discriminates between the enantiomers of a small chiral molecule. Such a force could find use in a wealth of potential applications, however the chiral optical forces proposed to date are extremely weak, as they rely on magnetic-dipole and electric-quadrupole interactions.

Drawing inspiration from a remarkable chiral force found in nature for the "by-the-wind sailor" *Velella velella*, we show that a static electric field combined with a linearly polarized travelling wave and a lin⊥lin standing wave can exert a chiral optical force on small chiral molecules that is several orders of magnitude stronger than other chiral optical forces proposed to date, being based on leading electric-dipole interactions rather than relying on weak magnetic-dipole and electric-quadrupole interactions.

The two distinct mirror-image forms of *Velella velella* are found on opposite sides of the Pacific a), having been separated by the wind b). Our chiral optical force is constructed by analogy c).

Our chiral optical force applies to most small chiral molecules, including isotopically chiral molecules, and does not require a specific energy-level structure. Potential applications range from chiral molecular matter-wave interferometry for precision metrology and tests of fundamental physics to the resolution of enantiomers for use in chemistry and biology.

Abstract: In this work, we report ultrafast switching of topological phases in a time-varying system both numerically and experimentally, using FDTD simulations and optical-pump terahertz-probe (OPTP) spectroscopy.

Topological phase transitions are typically observed at Dirac or Weyl points in Hermitian systems but often manifest at exceptional points (EPs) in non-Hermitian systems, where eigenvalues and eigenstates coalesce concurrently [1]. While EPs in time-invariant systems have been extensively elucidated, the characteristics of Eps in time-varying contexts remain comparatively underexplored [2-3]. In this work, we prepare a non-Hermitian metasurface on a gallium arsenide (GaAs) substrate for the observation of ultrafast topological phase switching. Through the utilization of optical pumping, we achieve instantaneous modulation of material loss, a phenomenon attributed to the photoexcited carriers in the GaAs substrate. In a time-invariant situation, where input frequency and pump power were controlled, we identify an EP where the transmission coefficient for right- to left-circularly polarized light approaches zero. By pumping the metasurface with varying input frequencies and pump-probe delay, we demonstrate ultrafast traversal past the EP on a subpicosecond scale. Our findings are corroborated through finite-difference time-domain (FDTD) simulations and optical-pump terahertz-probe (OPTP) measurements. This work not only confirms the presence of EPs but also introduces an innovative approach for ultrafast topological phase switching.

Abstract: We theoretically and experimentally construct a complete near-field directionality space by the synergy of chirality and anisotropy. An anisotropic chiral particle can serve as a directional dipole dice, achieving all types of directional dipoles via different "faces" of the particle and realizing face-multiplexed and high-dimensional routing of guided light.

Near-field optical directionality plays an essential role in almost every aspect of photonics and plasmonics. The most elemental system with this property is the class of directional dipoles, including circular dipole, Huygens dipole, and Janus dipole. Their unified realization are highly desirable for developing compact and multifunctional directional sources and switches. Here, we propose a general physical mechanism, the synergy of chirality and anisotropy, for unifying all three dipole types in one structure at the same frequency under the linearly polarized plane wave excitations. This mechanism enables a simple helix particle to generate different directional dipoles on different "faces", corresponding to a directional dipole dice (DDD). To understand the underlying physics, we apply the mode expansion analysis to reveal the origin of the DDD. The emergence of directional dipoles is attributed to the selective excitation of orthogonal chiral and achiral eigenmodes by tuning the incidence. To demonstrate the light-manipulation ability of the DDD, we employ three "faces" of the helix to realize the face-multiplexed and high-dimensional control of directional coupling to a dielectric waveguide in the infrared regime. Different dipole faces generate different types of optical directionalities in different orthogonal directions based on three degrees of freedom: spin, power flow, and reactive power. The phenomena are experimentally verified in the microwave regime using a copper helix placed near waveguides. The results can find promising applications in photonic integrated circuits, quantum information processing, and subwavelength-resolution imaging.

Abstract: We report on the peculiar behavior of waves in elastic valley-chiral phononic crystal plates, including the multi-branch topological edge states (TES) in one single devices, the transversely symmetric and antisymmetric feature of TES, the abnormal refractions, and etc. These wave behaviors provide efficient path to precisely control the wave transports.

The topological edge states (TES) have attracted great interest in optical[1], acoustic[2] and elastic[3] wave fields in recent years, due to the robustness against defects and the spin dependent wave transports. The TES with excellent features have arisen novel path to design phononic devices which possess good functionalities. Usually, the TES can be realized by mimicking the quantum Hall effect, quantum spin Hall effect, and etc. Particularly, the valley degree of freedom[1, 3] provides a convenient way to design topological devices, i.e., valley-chiral devices, however without either the complicated design of structures or the precise control of systems.

The TES in valley-chiral PC plates feature rich behaviors. For example, the valley PC plate can support multi-branch TES in one single device[4, 5], which provides multiple operating frequency bands to increase the information capacity or bandwidth of the device, and also the topological protection to enhance device stability. The valley TES also feature the transversely symmetric and antisymmetric property attributing to the valley chirality, which can tune the wave couplings and refractions[4, 6]. The transversely symmetric and antisymmetric property is efficient to control the connection between the topological PC waveguide and the external field, e.g., control the intensity of the waves coupled into the waveguide or the refraction of the outgoing waves. Besides, the valley-chiral TES can be combined with the rainbow effect, i.e., topological rainbow effect, which will benefit from both the backscattering immunity of TES and the special-spectral control of rainbow effect. The peculiar wave behaviors in valley-chiral PC plates are of great benefit to the control of wave transports, and are prospective to enrich the potential applications in wave and communication communities.

Abstract: The study demonstrates that absorption and scattering cross sections can be qualitatively different for two circular polarizations. Thus, the dominating cross section, absorption/scattering, changes with the polarization of the beam. This allows coherent phonon generation and detection by separating absorption and scattering *for the same wavelength* using the appropriate helicity.

Summary

The possibility of creating and manipulating nanostructured materials encouraged the exploration of new strategies to control electromagnetic properties. Among the most intriguing nanostructures are those that respond differently to helical polarization, i.e., exhibit chirality.[1] Circularly polarized light can be used to probe and determine the chiral nature of a plasmonic structure, which is usually reflected as quantitative differences in the values of the absorption or scattering cross-sections. However, reaching maximum absorption and minimum scattering for one helicity, and the opposite for the other is not usually found to occur at the same wavelength.[2] In the present work, we propose a simple chiral plasmonic structure based on crossed elongated bars where light-handedness defines the dominating cross-section absorption or scattering, as it identifies the two different enantiomers in a chiral structure which determine how the system interacts with its environment. The system is yet maintained simple enough to understand the actual nature of the response observed, be open to future developments, and warrant fabrication for future experimental verification [3,4]. Based on this structure, our work demonstrate that, not only through the interactions between different elements it is possible to make the absorption and scattering cross-sections radically and qualitatively different for the two circular polarizations, but also that the dominating cross-section can be switched from absorption to scattering by simply changing the polarization of the impinging beam. Also, we theoretically propose a simple pump-probe experiment using circularly polarized light. [5] In the reported structures, the generation of acoustic phonons is optimized by maximizing the absorption, while the detection is enhanced at the same wavelength -and different helicity- by engineering the scattering properties [6]. Thus, the presented results constitute one of the first steps towards harvesting chirality effects in the design and optimization of efficient and versatile acoustoplasmonic transducers.

Chiral phonon-originated nonreciprocal phenomena in magnets

Y. Nii

Institute of Materials Research, Tohoku University, Japan
*corresponding author: yoichi.nii.c1@tohoku.ac.jp

Abstract: Surface acoustic wave (SAW) devices serve a versatile platform in both classical and quantum technologies, gaining increasing prominence in modern research. This work unveils a novel facet of SAW phenomena – the manifestation of nonreciprocal responses arising from the coupling between phonon and spin angular momentum.

In media without spatial inversion symmetry, acoustic modes may adopt chirality, involving a circulating motion of the lattice [1]. Surface acoustic wave (SAW), where spatial inversion symmetry is inherently broken at the surface, stands out as the archetypal platform that provides a circular eigenmode known as the Rayleigh-wave. Owing to the superposition of the longitudinal and transverse modes, Rayleigh-SAW inherently possesses nonzero phonon angular momentum [1]. Analogous to electronic states with broken spatial inversion symmetry, the direction of phonon angular momentum varies with the SAW momentum $\boldsymbol{k}$. Consequently, various $\boldsymbol{k}$-dependent responses may emerge in SAW when coupled with magnetism.

This study presents experimental demonstrations of the $\boldsymbol{k}$-dependent, nonreciprocal phenomena of SAW using magnetoelastic devices implemented on a $LiNbO_3$ piezoelectric substrate. Initially, we show nonreciprocal propagation of SAW [2], where the transmission amplitude varies upon reversing the propagation direction. Subsequently, we elucidate the inverse effect of nonreciprocity [3], where magnetization of ferromagnetic Ni was deterministically controlled by SAW. Finally, we show nonreciprocal SAW diffraction, characterized by the asymmetric intensity of upward and downward scattered SAWs, achieved by a periodic array of magnetoelastic nanowires on a SAW device [4]. We discuss that transfer of angular momentum between phonon and spin systems is pivotal in all these phenomena. Our experimental demonstrations highlight the importance of chiral phonon states, opening avenues for further advancement of SAW-based technologies across diverse applications, including microwave communications and quantum engineering applications.

Abstract: The excitation of modes in structures depends on the spatial profile of the acoustic eigenmodes and the optics of the system. In this work we present a system that is composed of a twisted metallic propeller-like structure, that give rise to the excitation of new optical and acoustic modes.

Summary

Simple acoustoplasmonic resonators, such as nanobars and crosses, are efficient light-hypersound transducers.[1] The excitation of hypersonic modes in these structures strongly depends on the spatial profile of the acoustic and plasmonic eigenmodes and the optical properties of the system's resonances.[2] Lately, it has been made possible to selectively excite and detect phonon modes via plasmon resonances at the same frequency using chiral nanostructures and circularly polarized light.[3] In this work the structure to be analyzed is a metallic propeller-like structure, based in a three lobed perforated clover whose top face is twisted with respect to the bottom one. Only for the twisted cases the structure becomes chiral, leading to an optical response that depends on the helicity of the impinging beam. Having handedness-dependent absorption and scattering cross-sections unlocks an invaluable tool to decouple the generation and detection of coherent acoustic phonons in nanostructures. Furthermore, the plasmon-phonon transduction is an extremely useful tool for launching phonons. If the symmetry characteristics of the plasmon is transferred to the phonon launching, then the phonons to be excited in the

substrate are expected to present a chiral profile. Moreover, the presence of the twisting angle gives rise to the excitation of non-conventional phononic modes. Herewith, we will present a comprehensive theoretical analysis of the phononic and plasmonic modes alongside their surface deformation field and electromagnetic field profiles.[4]

How can planar become chiral? Maximum-chiral optics with flat metasurfaces

M.V. Gorkunov[1*], A.A. Antonov[1,2], and Y.S. Kivshar[3]

Abstract: Dielectric metasurfaces are game-changing platform for chiral optics. Designs relying on mirror symmetry breaking by variable height or elevation of meta-atoms are technologically inconvenient. We consider optical chirality of flat metasurfaces including extrinsic-chiral single-layered and intrinsic-chiral multilayered ones, and especially focus on the effects of mirror symmetry breaking by substrates.

Metasurfaces built as subwavelength arrays of meta-atoms made of highly refracting materials manifest versatile high-quality photonic resonances. Recently, it was understood that they offer a game-changing platform for chiral optics: unprecedented strong optical chirality can be realized if the resonant eigenstates are adjusted for selective interaction with circularly polarized waves. To date, the known examples of chiral eigenstate engineering rely on combinations of perturbations breaking the in-plane and out-of-plane mirror symmetries in order to isolate a particular state from waves of one circular polarization incident on one or both metasurface sides. Inconveniently for practice, most designs require variable meta-atom elevation [1] or height [2,3]. From the practical viewpoint, structures feasible for conventional lithographic processing of flat layers are much more attractive. Lithography is capable of producing precisely shaped holes and slits with vertical walls in layers of constant thickness. The resulting structures on their own, however, inevitably retain a mirror symmetry plane, and the lack of geometric chirality substantially limits the optical chirality.

There are different ways of achieving strong optical chirality using dielectric metasurfaces made of flat layers. One is to employ the phenomenon of extrinsic chirality, when the mirror symmetry plane is broken not at the structural level but by the optical setup. In such case, maximum-chiral transmission and reflection of light waves occurs if the corresponding eigenstates selectively interact with obliquely incident waves of a particular circular polarization. Remarkably, this can be achieved in meta-atoms of such simple shapes as triangular silicon particles [4].

Alternatively, the planar mirror symmetry can be lifted if flat meta-atoms are made of stacks of layers of transparent materials having different refractive indexes. Then the displacement current density of photonic quasi-bound states in the continuum becomes asymmetrically distributed within the multilayered structure. By carefully adjusting the parameters of meta-atom shape and the thickness of different layers, one can isolate a state from waves of a particular circular polarization to achieve the maximum intrinsic chirality

Finally, the planar mirror symmetry is formally broken in all lithographically cut metasurfaces supported by a substrate as long as its refractive index is different from the rest of the environment. This is rarely recognized as an important factor, as the substrate effects on metasurface optics typically remain subtle. We demonstrate, however, that it is possible to maximize the intrinsic optical chirality of a flat metasurface on substrate relying on peculiar hybridization of photonic eigenstates. In the absence of substrate, such states possess spatial parity and equally strongly contribute to the transmission and reflection of left and right circularly polarized waves. When

placed upon a substrate, the states merge into peculiar hybrids with chiral distributions of the displacement current, and, therefore, underpin sharp peaks of circular dichroism with close-to-maximum optical chirality. The metasurface remains transparent to waves of one circular polarization and resonantly blocks those of the opposite polarization.

As all discussed realizations of maximum chirality rely on selective excitation of high-quality photonic eigenstates, they can be straightforwardly employed for various chiral light transformations desired for emerging applications. For example, the extrinsic chiral metasurface stacked with an ordinary metal mirror forms an optical cavity selectively coupled to obliquely incident circularly polarized waves, which can serve as an ultracompact source of chiral light [4]. Reciprocally, maximum chiral structures made of emerging optoelectronic materials can be used in sensitive detectors of chiral light. As the excitation of high-quality chiral eigenstates is accompanied by enhancement of near-fields by orders of magnitude, they pave the way for numerous nonlinear-optical chiral light transformations including the harmonic generation [5].

Circularly-Polarized Light for Probing and Controlling Spins and Magnetization in Atomically-Thin Materials

M. H. D. Guimaraes[1*]

[1]Zernike Institute for Advanced Materials, University of Groningen, The Netherlands
[*]corresponding author: m.h.guimaraes@rug.nl

Abstract:
Two-dimensional materials provide an exciting platform for studying spin-dependent (chiral) light-matter interaction. In this talk I will show how (chiral) light can be used to control the spin accumulation and magnetization in two-dimensional magnets and semiconductors.

Summary:
Van der Waals (vdW) materials are ideal systems to probe how spins and magnetism behave in low dimensions since they maintain their excellent optical, magnetic and electronic properties down to the atomically-thin limit. Because of their low dimensionality, these materials possess another exciting property, they are extremely sensitive to external stimuli, such as light and electric fields.

In this talk, I will give a brief introduction to vdW two-dimensional semiconductors and magnets, particularly focusing on their (chiral) light-matter interaction. I will also show how we can use time-resolved magneto-optical Kerr effect (TR-MOKE), a technique able to detect the differences in the index of refraction for the two helicities of light, to probe the spin and magnetization dynamics in these materials.

I will then present our recent results which show how (ultrashort) circularly-polarized light pulses can be used to excite a spin accumulation in two-dimensional semiconductors [1,2], and how we can use magnetic fields to control the dynamics of this spin accumulation [3]. I will also show examples on how the magnetization of vdW magnets can be similarly controlled and probed using ultrashort laser pulses [4]. Particularly, I will focus on the material $Cr_2Ge_2Te_6$, for which we demonstrated that linearly-polarized light pulses can be used to apply a magnetic torque on the magnetization [5]. These light-induced magnetic torques can be effectively controlled using electric fields and be turned on and off at will through electrostatic gates.

Our studies illustrate the potential of vdW materials for combining optics, spintronics and magnetism, making them appealing for new opto-spintronic and opto-magnetic device architectures for future integrated photonic systems.

Far-field and near-field chirality in plasmonic metamolecules

T. Aoudjit[1], F. Lamaze[1], J. Béal[1], A. Hmima[1], W. d'Orsonnens[1], T. Maurer[1], J. Plain[1], J. Proust[1], D. Gérard[1*]

[*]corresponding author: davy.gerard@utt.fr

Abstract: We study metamolecules consisting of coupled metallic nanoparticles. We show that the local field dissymmetry under left- and right-handed circular polarization can be directly imaged using a photopolymer. Then, we show experimentally that both the far- and near-field chirality can be controlled by fabricating the metamolecules onto a stretchable substrate.

Although optical chirality is generally studied in the far field, many interesting chiral effects occur in the near field. For example, in plasmonic metamolecules (i.e., complex nanostructures using metal nanoparticles as elementary building blocks), chirality can appear due to the complex interplay between the coupled nanoparticles. This leads to the existence of "hidden chirality" in otherwise achiral nanostructures [1] and to the appearance of "chiral hot spots", which can be switched on and off depending on the handedness of the exciting light [2]. Near-field characterization of chiral plasmonic nanostructures is however more difficult, and relies on advanced tools such as near-field microscopy or cathodoluminescence. Here, we take advantage of a photochemical imaging technique allowing us to directly probe the dissymmetry of the electromagnetic near-field around chiral nanostructures. Our approach is demonstrated using coupled gold nanorods as a simple chiral metamolecule [2].

Then, using a more complex chiral geometry, we show that chirality can be engineered by fabricating the metamolecule onto a stretchable substrate. Under the application of strain, the metamolecule undergoes deformation, leading to a significant change in its chiroptical response. This mechanically-induced changes are experimentally tracked both in the far-field (using circular dichroism measurements) and in the near-field (using photochemical imaging)

1D and 2D topological solitons in nanoelectromechanical resonator arrays

Hiroshi Yamaguchi[1*], Daiki Hatanaka[1], Motoki Asano[1], and Samer Houri[1#]

[1]NTT Basic Research Laboratories, NTT Corporation, Kanagawa 243-0198, Japan
[*]corresponding author: hrsh.yamaguchi@ntt.com

Abstract: We theoretically and numerically demonstrate 1D and 2D coupled parametric resonator arrays generating a topological soliton in its rotating-frame phase space. The topological soliton can be implemented by using electromechanical resonators in both 1D and 2D systems providing a fully controlled on-chip test bed for the study of a topological soliton.

Topological soliton is a commonly observed stable excitation in various nonlinear dynamical systems. In a one-dimensional (1D) system, for example that described by Sine-Gordon equation [1], the topological soliton is the boundary between two identical, but topologically distinguished phase domains, generated as a zero-mass Goldstone mode by the spontaneous breaking of translational symmetry. Its annihilation requires an energy to overcome the phase rotation and the existence is energetically protected by the topological properties. As has been widely demonstrated in the system of topological insulators, importing the concept of topology into artificial 2D lattice systems, such as photonics, microwave, and acoustics structures, is promising to open up new directions in device and material technologies based on the topologically robust properties. In this invited talk, we present our theoretical and numerical works that demonstrate 1D and 2D topological solitons using the arrays of parametric resonators. The key idea is to use quadrature variables, i.e. the sine and cosine oscillation amplitudes, in parametric oscillation to define the phase of dynamical variables. In 1D system, the boundary between 0-phase and π-phase parametric oscillation shows the feature of topological solitons and the motion can be driven by the electromechanical harmonic actuation of resonators [2]. In 2D system, four quadrature components in the square array of doubly degenerate circular membrane resonators play as the similar role as magnetic moments in ferromagnetic systems and the numerical simulation shows that the texture of skyrmion, which is one of the most important 2D topological solitons, can be generated by the parametric excitation. We performed a FEM calculation to prove the feasibility using realistic device designs [3]. In both 1D and 2D cases, we also discuss the robustness against the frequency fluctuation of resonator arrays.

Abstract: We investigate propagation characteristics of microwave phonon waves in valley topological ring and waveguide coupled systems. The coupled system sustains valley polarization of phonons so that we successfully excite resonant vibrations in wavelength-scale micro-rings without significant backscattering. The results indicate capability of the topological technology to finely manipulate phonons.

Phonons are elementary excitations of lattice vibrations in solids and are being recognized for their capability as one of the next generation information carriers. In particular, acoustic phonons at microwave frequencies (> 0.3 GHz) possess short wavelength and radiation-free structures compared with electromagnetic waves at similar frequencies [1]. Therefore, establishing their control technology and understanding their propagation dynamics can lead to development of miniaturized and high-performance microwave devices for application of wireless communications and quantum technologies [2]. However, they are susceptible to micro and nanoscale structural disturbance and defects which induce backscattering, thus generating undesired spatial and spectral wave localization and hampering their stable operations.

We utilize topological technology to operate wavelength-scale fundamental circuits composed of phononic ring and waveguide [3]. Ultrahigh frequency phonon waves propagate in a boundary between two phononic crystals with different valley Hall phases and the valley pseudospin polarized waves are immune to backscattering due to time-reversal symmetry. As results, we successfully observe resonant oscillations in tiny phononic rings by their spectral response and spatial mapping measurements. Furthermore, the valley preserved ring circulations interfere to phonons with the same valley propagating in the evanescently coupled waveguide, which enables the phonon transmission efficiency to be regulated by the ring resonator. Our findings provide a proof of the capability of topological technology for dealing with microwave phonons and constructing their integrated systems, which are useful for microwave information processing applications.

Abstract: We demonstrate a high degree of non-reciprocity for surface acoustic waves (SAWs) at GHz frequencies propagating in an epitaxial ferromagnetic layer. The non-reciprocal behavior depends on the relative chirality between the SAW strain field (phonons) and spin waves (magnons) in the ferromagnetic film.

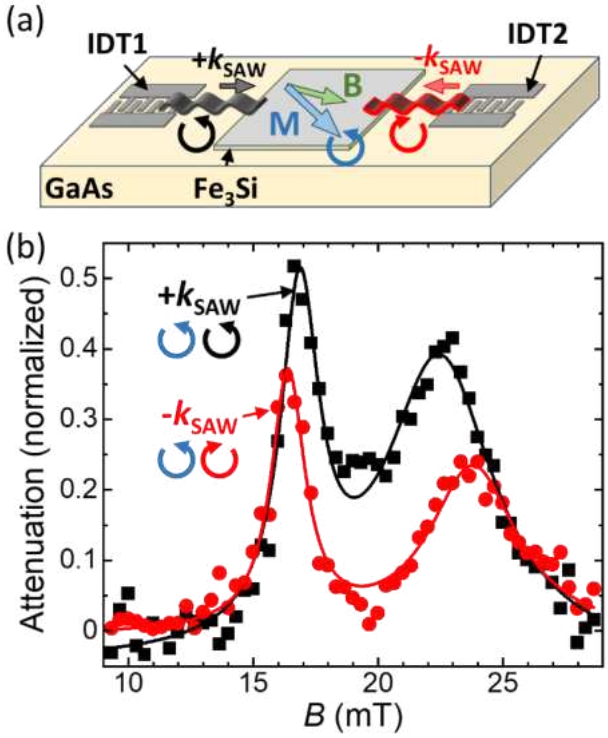

Figure 1. (a) Schematics of the magneto-acoustic system. Interdigital transducers (IDTs) at opposite ends of a ferromagnetic Fe_3Si film launch and detect SAWs with opposite wave vectors, $\pm k_{SAW}$, and chiralities. (b) SAW attenuation as a function of an external in-plane magnetic field, B. The magneto-acoustic resonances cause stronger SAW attenuation for $+k_{SAW}$ than for $-k_{SAW}$.

In the last years, there has been an increasing interest in non-reciprocal systems for the efficient manipulation of sound. Especially appealing for applications are surface acoustic waves (SAWs) [1]. Due to their efficient piezoelectric generation and detection, and their low propagation velocities, SAWs are ideally suited for controlling and interfacing elementary excitations in the solid state [2].

One way to achieve non-reciprocal SAW propagation is to break time-inversion symmetry by coupling the strain field of the SAW (phonons) to spin waves (magnons) [3]. The non-reciprocity arises from the chiral nature of both the SAW and the spin wave. In this contribution, we demonstrate non-reciprocal transmission of high-frequency SAWs (3.4 GHz) traveling along a hybrid structure consisting of a ferromagnetic Fe_3Si thin film epitaxially grown on a GaAs substrate [4]. When the SAW and the spin wave have the same frequency and wave vector, then the magneto-elastic and magneto-rotational coupling transfer energy from the acoustic to the magnetic system, resulting in SAW attenuation, see Fig. 1. The efficiency of this coupling depends on the relative chirality of the SAW and spin wave, which is determined by the orientation of the magnetization with respect to the SAW wave vector and can be controlled with an external magnetic field. The resulting transmission non-reciprocity, defined as the difference between the transmitted acoustic power for forward and backward SAW propagation, reaches values up to 20% under magneto-acoustic resonance.

Abstract: Beams carrying Orbital Angular Momentum are produced from multilayered structures upon excitation of surface modes. Such structures are axially-symmetric and exhibit a high Local Density of States to facilitate radiation coupling from localized, possibly individual emitters located on the surface, such as q-dots or defected 2D materials.

In the perspective of mitigating the forthcoming issue of the “capacity crunch” in optical communications, the use of spatial degrees of freedom of light has been proposed, in addition to wavelength and polarization, for information coding. Vortex beams (VBs) are structured electromagnetic paraxial modes characterized by a phase singularity along the optical axis, surrounded by a helical wavefront. A convenient way to describe such axis-symmetric VBs is by means of Laguerre-Gauss functions. In 1992, Allen and co-workers demonstrated that the topological charge m appearing in the L-G representation of a VB unveils the existence of an Orbital Angular Momentum (OAM) associated thereto [1]. Most of the previous-art approach for generating OAM beams rely on the conversion of an incoming radiation into specifically controlled vortex beams. This is done with planar devices based on Liquid Crystals (LC) technology and anisotropic media, holographic or diffractive optical elements (DOEs) and more recently, meta-surfaces (MSs). The large majority of these solutions lead to very energy-efficient mode-converters. The coherence properties required to a VB are inherited from the input beam, which is usually extracted out of a laser source. In an attempt to increase the level of integration, sometimes, MSs or DOEs have been directly inserted within laser cavities, on a more macroscopic scale. However, according to this previous art, the source device is functionally separated from the LC/DOE/hologram/MS element producing VBs. Hence, the resulting VB is obtained upon manipulation of a far-field radiation. When single emitters are concerned, approaches based on MS or holographic/DOE are hardly suitable for a single, localized source integrated therein. In fact, since the beam conversion through DOE/MS relies on a spatial-dependent phase transformation, an emitter located in a specific position on a MS would be insensitive to the overall geometry of the MS itself. Instead, the emission will be only affected by the local MS optical properties, unless some collective modes are intervening.

In this work we propose all-dielectric structures based on planar multilayers that are suitable for integration with single emitters. More specifically, a stack of dielectric materials, such as TiO_2 and SiO_2 or Al_2O_3 carrying Bloch Surface Waves (BSW) in a specific wavelength range, is decorated with axially-symmetric resonant and diffractive structures on the top surface, such that the outcoupled radiation can carry OAM.

In a first implementation, a multilayer supporting TE-polarized BSW is considered, wherein the top surface is patterned with spiral gratings with different topological charge. In order to couple BSW, a rotating dipole laying on the stack top plane is emulated by focusing a circularly polarized optical beam at high Numerical Aperture (NA=1.49) through oil-immersion optics. Different OAM for right- and left- circularly polarized light (RHC and LHC respectively) are observed, according to the conservation of total momentum [2].

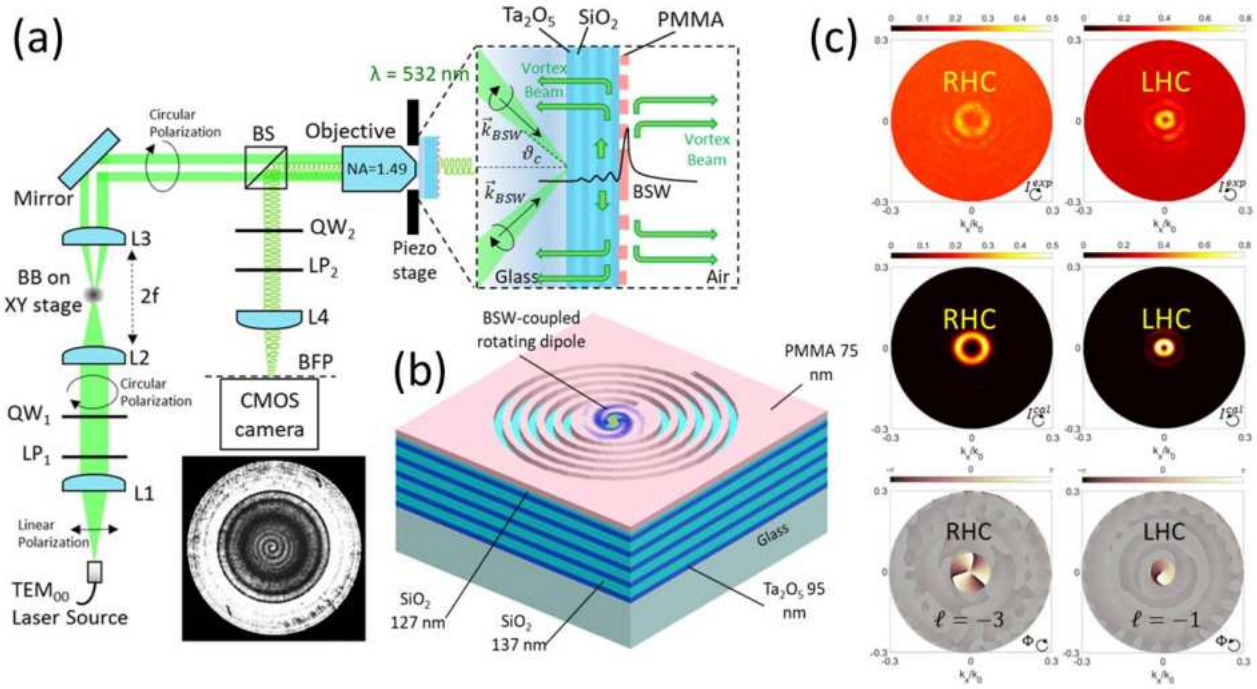

Figure 1. (a) Experimental setup for BSW coupling and diffraction with OAM imparted by spiral gratings; (b) sketch of the sample, with the source being a rotating in-plane electric dipole emulated by a focused circularly polarized light; (c) illustrative examples of diffracted beams carrying OAM for RHC and LHC light.

In a second implementation, a multilayer sustaining TM-polarized BSW is used. Here, the wavefront of the coupled BSW is circular. In addition, space-variant patterns are used to provide different diffraction efficiencies for RHC and LHC radiation, so that separation of two perpendicular polarization states is facilitated thanks to anomalous diffraction effects.

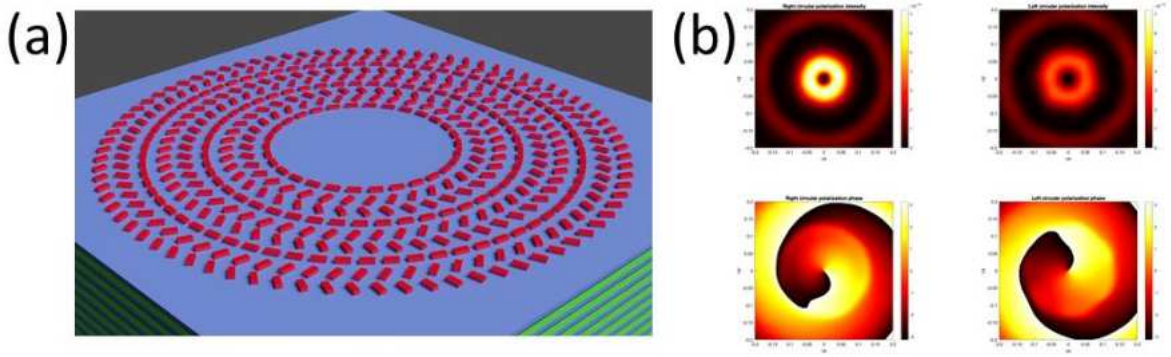

Figure 2. (a) Sketch of the multilayer, carrying a null topological charge metasurface; (b) calculated intensity and phase of RHC and LHC components of the diffracted radiation upon BSW coupling.

Angular momentum addition for flexural waves using transformation approach

Pengfei Zhao[1+], **Xiaofan Wang**[2+], **Liyou Luo**[1+], **Jensen Li** [1*] **and Huanyang Chen** [2*]

Abstract: We propose to add flexural wave angular momentum on the plate with tailor-made thickness profile using transformation approach. The experimental result illustrates that two vortexes with same topological charge l located at different positions in space appear like a new single vortex with topological charge $2l$ in the near field.

In the past three decades, orbital angular momentum (OAM) has become a rapidly emerging field of research, in both classical and quantum systems, which deepened the understating of the wave-matter interaction [1]. It also has facilitated distinctive applications across various domains including communications, metrology, tweezers, and nanophotonics. Recently, the OAM in elastics has been theoretically studied [2] and experimentally realized [3]. The transverse OAM [4], described by a transverse spirally azimuthal phase $\exp(-il\phi)$ with l as the topologic charge (TC) and ϕ the azimuthal angle, draws much attention and has been experimentally verified in elastic waves by metamaterials [5]. When considering the flexural wave on the thin plate, we can utilize thickness profile to manipulate flexural wave by transformation approach [6]. Therefore, we can simply use the thickness profile of the plate to investigate the OAM in elastics instead of complex metamaterials. By designing a proper thickness profile through transformation approach, two OAM with the same TC can appear like a single vortex source with added TC in the near field. The experimental result confirms the TC addition and shows the evolution of wavefronts over distance.

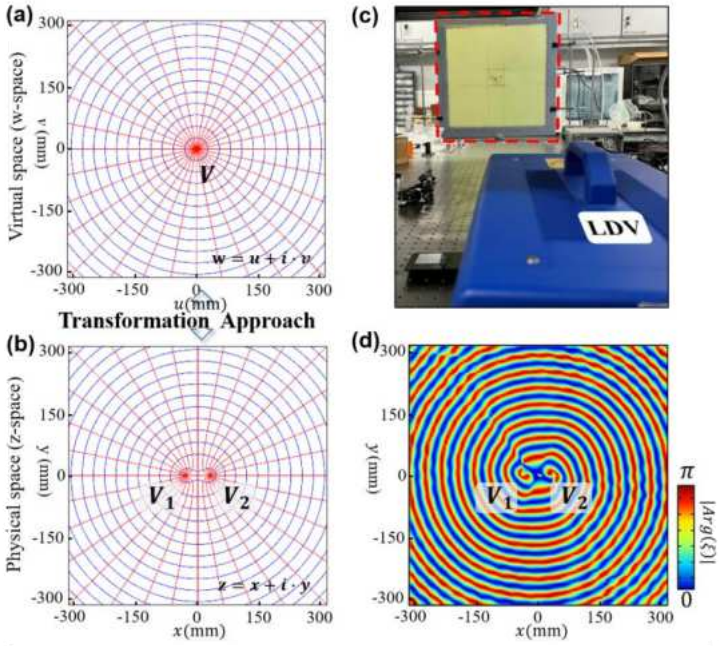

Figure 1. Transformation approach between (a) virtual space (w-space) and (b) physical space (z-space). (c) The experimental setup including Laser Doppler Vibrometer (marked as LDV) and curved plate with tailor-made thickness profile with Blu tack on the boundaries (red dashed box). (d) Experimental measurement (phase of out-of-plane velocity field) obtained for the two vortexes , with the vortex realizing $1 + 1 = 2$ at 6kHz.

We introduce one kind of conformal mapping $w = f(z)$ between physical space defined by coordinates (x, y) and virtual space defined by coordinates (u, v). Fig. 1(a) shows the virtual space with polar coordinates, where the blue and red lines indicate contours of the magnitude $|w|$ and argument $\mathrm{Arg}(w)$. Here, we choose two centers (V_1, V_2) in the physical space from the mapping. Then, contours of magnitude $|f(z)|$ in blue and argument $\mathrm{Arg}(f(z))$ in red in Fig. 1(b) will share the similar distributions away from the origins in physical space. Now we consider flexural wave propagation on a thin plate. Once a flat plate in virtual space is set as h_0, the corresponding inhomogeneous thickness profile h in physical space is obtained. In this case, our target is that the customized thickness profile h enables flexural vortex waves from V_1 and V_2 to act as a single vortex at V in a plate with constant thickness h_0. In order to produce a vortex source for various topological charges in elastics, we typically use an array of transducers with different phases. Here, we excite two vortex sources with the same topological charge $l_{1,2} = 1$ at V_1 and V_2 in physical space with the same amplitude. Certain significant optimizations are required for the real sample for available thickness range. Fig. 1(c) shows the experimental setup including a Laser Doppler Vibrometer (LDV) as a sensor and our experimental sample bounded by Blu tack strips. As we can see, in Fig. 1(d), the measured $|\mathrm{Arg}(\xi)|$ on the tailor-made thickness profile remains original TC as 1 around V_1 and V_2 which we also plot in the Fig. 1(c). The flexural waves gradually superpose when the flexural wave travels several wavelengths away from the V_1 and V_2, showing that the total TC becomes 2 from a virtual vortex located at V. We will also discuss other possible additions of TC for the OAM in the talk.

In conclusion, we demonstrate adding angular momentum with tailor-made thickness profile which is calculated by the transformation approach. Generally speaking, the two vortexes share the same TCs will interfere to each other and observer can easily distinguish them by scattering fields. In our design, by simply adding the tailor made thickness profile near the sources, the observer will see only one vortex source at the origin. Furthermore, the total TC of the field will appear as 2. Our experimental result verifies this vortex illusion effect by employing two vortex sources ($\mathrm{TC} = 1$) at two different positions and then achieving desired vortex image ($\mathrm{TC} = 2$) at the origin. The developed transformation approach for manipulating the vortex waves will be useful for studying vibration control and wavefront shaping in theory. Understanding how angular momentums are added or combined can provide insights into the manipulation of the TCs in other classical waves and has potential to achieve applications such as signal isolation and signal detector.

Abstract: We construct a two-dimensional mechanical wave machine based on a hexagonal lattice to investigate low-frequency flexural plate waves whose propagation mimics a topological quantum valley Hall system. Imaging experiments, backed up by simulations, reveal the presence of boundary modes along a topological interface.

Concepts in topological physics, which have been utilized in condensed matter physics, have recently been extended to classical physical systems. Topological boundary modes arising at interfaces of different topological phases have garnered attention in the control of classical wave fields due to their robustness and low energy loss, representing a localized phenomenon in both photonics [1] and phononics [2]. Quantum Valley Hall (QVH) systems, known for their compatibility with photonic/phononic crystals, can be realized by breaking the spatial inversion (*P*) symmetry of the unit cell. While QVH phononic crystals have been extensively studied from kilohertz to gigahertz frequencies, they face challenges in the observation of the motion of mechanical vibrational modes with small displacements, which are beyond the capability of conventional cameras. Although a low-frequency experimental study on a mechanical QVH system at ~10 Hz based on magnetically coupled spinners has been reported, observing the motion of modes with a high degree of freedom, such as those involving chiral phonons, is not feasible with such a system that exhibits a single degree of freedom for each lattice point [3].

In this study, we construct a two-phase mechanical hexagonal-lattice model to elucidate the behavior of a phononic QVH-like system for low-frequency flexural plate waves [4]. Figure 1 shows photographs of the constructed two-dimensional structure consisting of stainless-steel thin plates, plastic hollow rods, and brass weights, measuring overall 1300 mm on each side, and oriented in a vertical plane. The rods and weights enhance the moment of inertia, lowering the eigenfrequencies of the lowest modes to ~1 Hz. To break *P*-symmetry and

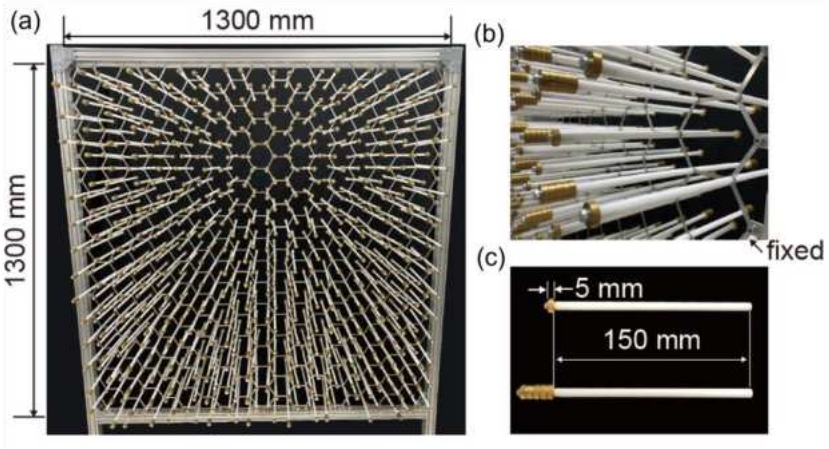

Fig. 1 (a) Photograph of the constructed model. (b) Close-up view of some unit cells. One site rods are loaded with 5 weight, and the other site rods are loaded with a single weight. (c) Close-up view of the polyoxymethylene plastic rods.

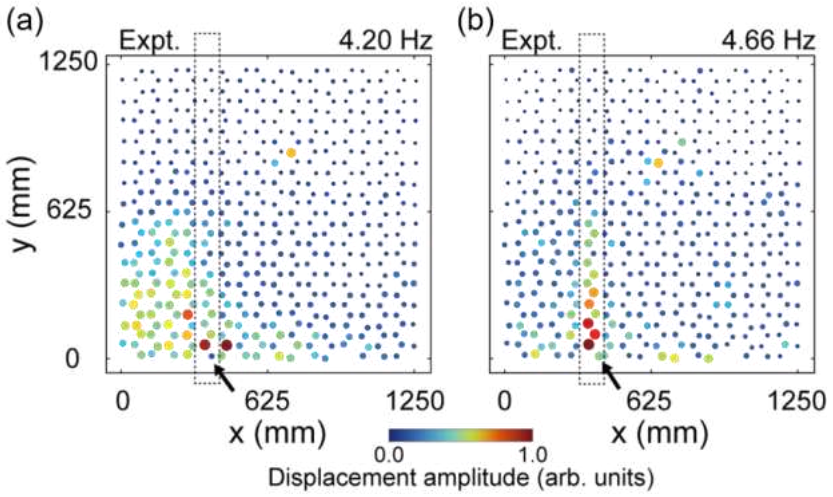

Fig. 2 Displacement fields in the experiment: (a) Bulk mode at 4.20 Hz. (b) Topological boundary mode at 4.66 Hz. The dotted box and arrow indicate the topological interface and excitation point. The point size reflects the normalized displacement amplitude.

induce valley polarization, we adjust the brass weights within each unit cell. In the lefthand 1/3 of the structure, A-site rods are loaded with 5 weights and B-site rods with a single weight. In order to produce a region with a second topological phase, in the center 1/3 of the structure A-site rods are loaded with a single weight and B-site rods with 5 weights. The vertical boundary of the left-hand and central regions consists of a bearded boundary composing single-weight rods forming a zigzag ribbon.

We measured the dynamics of this system. Single-frequency in-plane mechanical vibration was applied to a rod at the lowest position of the interface using an electrodynamic shaker. The motion of each cell was monitored with a motion capture system. The experimental vibration maps based on displacement amplitude are shown in Figs. 2(a) and 2(b), which correspond to bulk and topological boundary modes at 4.20 and 4.66 Hz, respectively.

In future, it would be interesting to vary the structure, for example by changing the dimensions, material or lattice of the cellular plate, in order to investigate the effect on the topological phononics and waveguiding. In addition, our approach should be applicable to metamaterials, including reconfigurable and active systems.

Some three-dimensional acoustic flat bands

Baile Zhang[1,2]

[1]Division of Physics and Applied Physics, School of Physical and Mathematical Sciences,

corresponding authors: ‡blzhang@ntu.edu.sg

Abstract: Flat bands are momentum-independent energy levels, whose history can be traced back to the Landau levels introduced in 1930. Here we discuss the construction of 3D flat Landau levels in an acoustic crystal. We also discuss the construction of highly degenerate 3D flat bands with acoustic waves.

Flat bands are of broad interest in multiple fields of physics since their high density of states provides access to strong-interaction regimes. The first concept of flat bands might be Landau levels introduced by Landau in 1930, which refer to the quantized energy levels of 2D electrons exposed to perpendicular strong magnetic fields. Related to 3D flatbands, we will discuss two works. One is that the construction of 3D flat Landau levels. The other is the construction of highly degenerate flatbands.

In the first part, we design and demonstrate a 3D lattice exhibiting Landau levels that are flat in all three directions. This is accomplished with an acoustic crystal (Fig. 1a) that incorporates an inhomogeneous structural distortion. In the absence of the distortion, the band structure contains a circular nodal ring (i.e., a ring in momentum space along which two bands touch). The introduction of the distortion generates a pseudo magnetic vector potential pointing radially from the nodal ring's center in momentum space, as well as varying in real space. The nodal ring spectrum hence splits into 3D flat bands, in a manner analogous to the formation of 2D Landau levels from Dirac points. In presence of a speaker at the center of the crystal, we can measure the acoustic response, and observe multiple peaks that correspond to different orders of Landau levels in the 3D crystal (Fig. 1b).

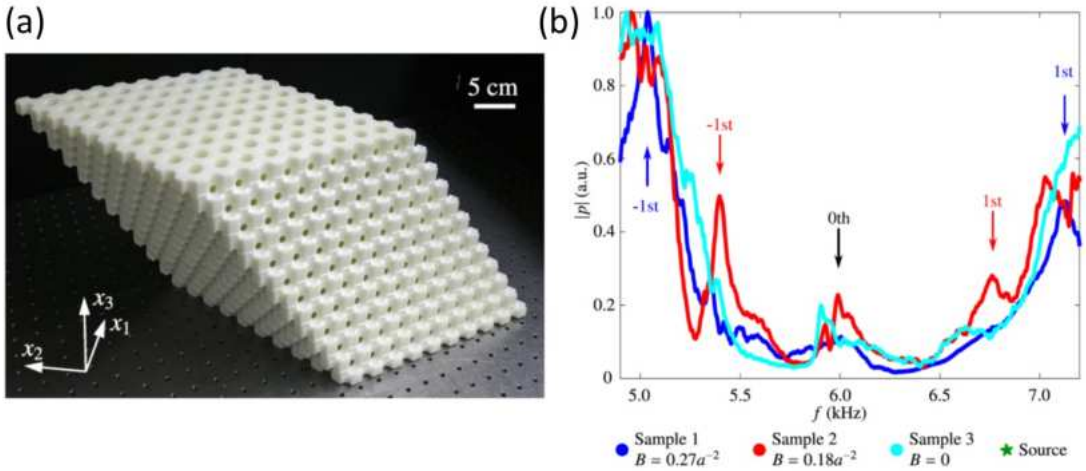

Figure 1 Construction of acoustic Landau levels. (a) The inhomogeneous acoustic crystal. (b) Measured acoustic response when a speaker is placed at the center of the crystal

In the second part, we design and construct an acoustic crystal that exhibits 3D flat bands that are highly degenerate. We start with 1D structures that exhibit bound states in the continuum (BIC), and then stack them up to form 2D and 3D structures. The resultant 3D structure can exhibit 12-fold degeneracy, and thus allow the localization of vortices in 3D spaces.

Jet formation induced by sub-nanosecond optical vortex optical pulses

Abstract: The jet formation was induced by a 120-ps optical vortex pulse irradiation with a topological charge of 1. The generated jet was monitored by a snapshot imaging system and its speed was evaluated to be about 40 m/s.

Laser-induced forward transfer (LIFT) is one of the direct writing techniques and offers us flexible maskless fine prototyping for printed electronics/photonics structure, bioprinting as well as screen-printing. Since LIFT does not require any nozzles for droplet ejection unlike inkjet technology, it is free from clogging problems [1]. Therefore, it is applicable to a wide variety of donor materials such as high-viscosity fluids, solid, dielectric particles.

When optical vortex pulses are utilized as laser sources, their orbital angular momentum (OAM) causes the generated “jets” or the ejected droplets to rotate. This is called ‘spin jet’ phenomena, which makes patterning possible with high resolution and long working distance [2]. Although such “spin” jet formation occurs basically in the microsecond regime, the light-matter interaction takes place only within pulse duration (typically, few nanoseconds) of irradiated pulses. The questions of why the OAM influences trajectory of donor materials despite the significant different time scales has not been investigated in detail. In previous works, only nanosecond optical vortex pulses have been utilized so far for driving laser source in all the cases. To clarify the mechanism of “spin jet” formation, we focus on the interaction time between light waves and (donor) materials, namely, pulse duration. In this paper, we present jet formation induced by 120-ps optical vortex pulses.

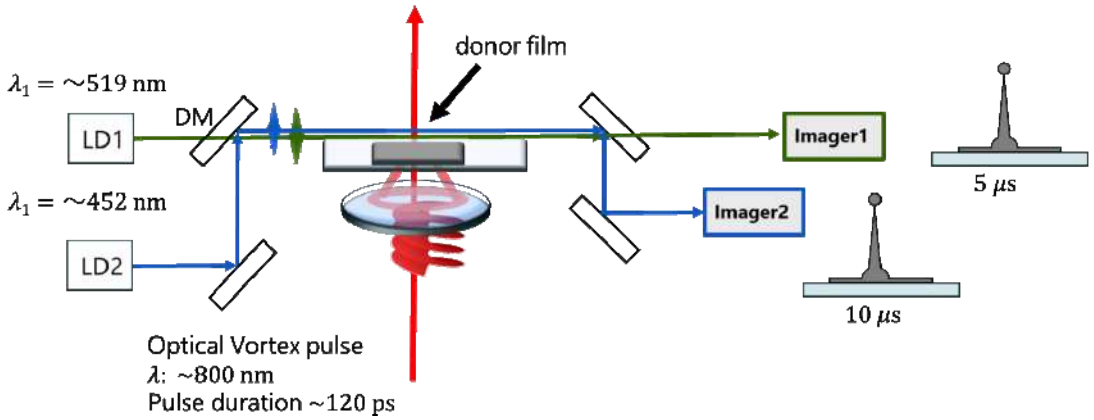

Fig. 1 Schematic of experimental setup. DM: dichroic mirror. Imager1,2: CMOS cameras with imaging lenses.

The schematic of experimental setup is shown in Fig.1. A 120-ps optical pulse from a Ti:Sa multipass amplifier (repetition rate of 1 kHz, center wavelength of ~800 nm) was converted into a linearly-polarized optical

vortex pulse with topological charge of 1 by using a *q*-plate, and focused onto a 40-μm-thick donor film by using a lens with a focal length of 40 mm. The donor film was made of a black ink (SAILOR, Kiwaguro) diluted 100 times with glycerol, and formed on a borosilicate glass substrate. The jet formation was monitored by a snapshot imaging system consisting of two directly modulated laser diodes with pulses durations of 60 ns and two CMOS cameras. Figure 2 shows the snapshot images at 5 μs and 10 μs after sub-nanosecond optical vortex pulse irradiation. The input pulse energy was 14 μJ, and the beam diameter on the donor film was about 40 μm. As clearly seen in Fig. 2, the long stable jet was successfully generated by even sub-nanosecond pulse irradiation, and its speed was evaluated to be about 40 m/s. In addition, we have verified that 23-ps optical vortex pulse irradiation also induced "jet formation".

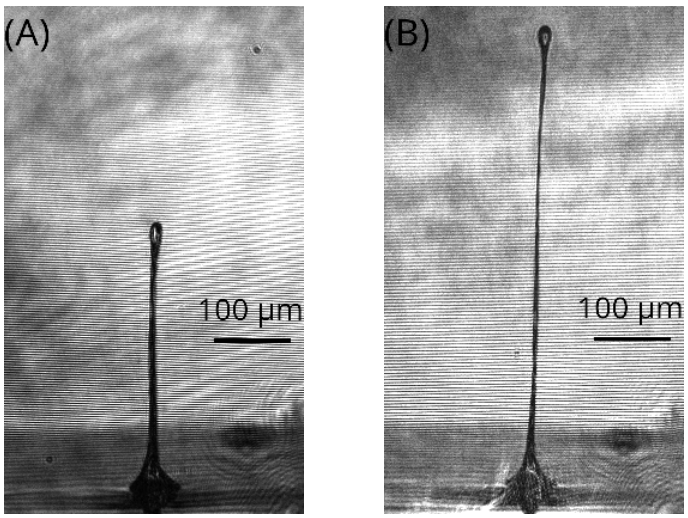

Fig. 2 Snapshot images of jet formation (A) 5 μs and (B) 100 μs after optical vortex irradiation.

Control of Circular Polarization Using Nonlinear Optical Effect in Dielectric Membrane Nanostructures

K. Konishi

Institute for Photon Science and Technology, The University of Tokyo, Japan
*corresponding author: kkonishi@ipst.s.u-tokyo.ac.jp

Abstract: Circular polarization is crucial for exploring chiro-optical effects. However, in the vacuum ultraviolet region, generating and controlling circular polarization proves difficult. We discovered that the nonlinear optical effect of nanostructures fabricated on free-standing films with a sub-micron thickness enables the generation and control of circular polarization in such short-wavelength region**s.**

Circular polarization is essential in exploring the chiro-optical effect. However, absorption is high for many materials in the short wavelength region below the ultraviolet. Therefore, the materials needed for circular polarization control elements are limited, and unlike in the visible light region, it is difficult to obtain high-performance circular polarization control optics. Recently, polarization control technology using plasmonic metasurfaces has also been developed. Still, polarization control utilizing plasmonics is also difficult because metal plasmon resonance does not occur in the vacuum ultraviolet region. As a result, it is also challenging to generate and control circular polarization even with nanostructures. We have recently discovered that the nonlinear optical response of nano-periodic structures fabricated on freestanding thin films (nanomembrane) several hundred nanometers thick enables generating and controlling circular polarization in such an ultra-short wavelength region [1,2]. We have succeeded for the first time in generating circularly polarized light in the vacuum ultraviolet region directly from nanostructured materials by the third harmonic generation of a circularly polarized visible femtosecond laser. Recently, we have also succeeded in fabricating such dielectric membrane nanostructures using a more versatile material, SiO2. In this presentation, I will introduce our new approach.

Abstract: We designed three-dimensional acoustic/elastic waveguides based on higher-order topological modes in stacked layer phononic crystals. A hierarchical property of phononic bandgaps was utilized for designing two-dimensional edge modes and one-dimensional hinge modes. The elastic-wave propagation normal to the layers is demonstrated numerically and experimentally in a layered Kagome lattice.

As the demand for higher integration of information processing increases, elastic and/or acoustic devices are also required to have a higher degree of freedom in their propagation paths. Conventional elastic devices are implemented in 2-dimensional substrates, which prevent additional devices mounted on top of the device. Thus 3-dimensional elastic devices have advantages in developing multichannel and multifunctionality, however, there is an obstacle in making a waveguide perpendicular to a substrate without energy loss.

Topological phononic crystals (PnCs) are artificial acoustic/elastic structures to realize efficient acoustic-/elastic-wave propagations. Topological insulators have robust boundary states against bend, disorder, and defects [1]. Recently, new topological material, named higher order (HO) topological insulator, has been proposed [2]. This material has topological state at boundary of a lower dimension. Especially, a second order topological insulator has a localized hinge state, leading to wave transport perpendicular to substrates.

In this study, we investigate topological boundary modes in stacked layer lattices, aiming to develop an efficient multichannel waveguide through the topological band design. Starting from highly degenerate Dirac band in stacked layer PnCs, it is shown theoretically and numerically that the degeneracies can be split into several distinct modes that exhibit 1st and 2nd order topological states by changing intra- and inter-layer bonds.

To engineer this controllability of the HO modes, we design a topological elastic waveguide based on a 3-dimensional phononic crystal with stacked Kagome lattices. Topological corner modes are shown to be elaborated by changing the intracell- and intercell-bonds. We demonstrate numerically and experimentally that such topological corner modes can be extended to one-dimensional hinge mode [3].

Abstract: This presentation introduces a novel method for computing the band structure of nonperiodic crystals using Fourier-based techniques and plane wave expansion. It discusses applications to Moiré lattices, cut-and-project quasicrystals, and incommensurable modulated crystals. The method is broadly applicable to wave systems like photonic, acoustic, and phononic quasicrystals.

In this presentation, we introduce an analytical approach for computing the band structure of quasicrystalline materials using Fourier-based methods. Departing from traditional periodic crystal analyses, our method offers a novel perspective on understanding the properties of nonperiodic structures.

Through an examination of plane wave expansion and Fourier space characteristics, we unveil a set of mathematical expressions capable of accurately determining the band structure and phase space diagrams of modulated potentials within Schrödinger's equation. Notably, our method transcends the limitations of conventional analyses by accommodating various incommensurable structures.

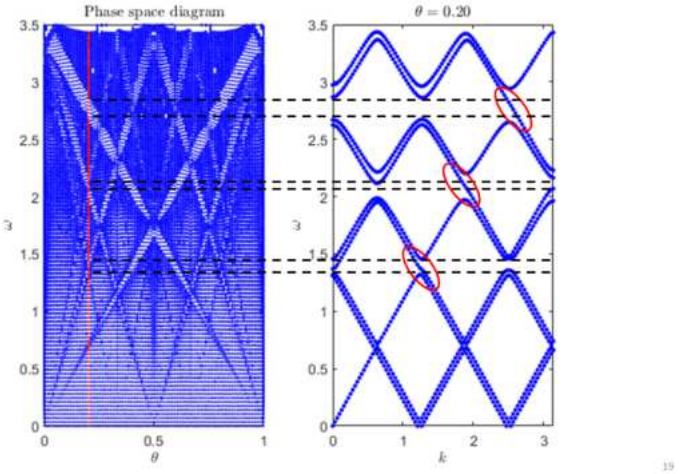

Figure 1 Example of dispersion relation calculation for modulated 1-D quasi crystals as a function of the modulation parameter (left panel) and the wave vector (right panel)

Throughout the discourse, we illustrate the versatility of our approach by exploring three distinct examples: the incommensurate superposition of periodic lattices, exemplified by Moiré lattices; cut-and-project

quasicrystals; and incommensurable modulated crystals. Importantly, while our investigation primarily revolves around the Schrödinger's equation framework, the applicability of our findings extends to diverse wave systems, encompassing photonic, acoustic, and phononic quasicrystals.

Our numerical simulations yield profound insights into the behavior of quasicrystalline materials, revealing the emergence of stop bands with chiral states in accordance with the Cantor spectrum properties inherent to quasicrystals. Furthermore, we elucidate that essential band structure information can be gleaned from the projection of modes aligned with the anticipated diffraction directions dictated by the structure's geometry.

To validate the robustness of our computational predictions, we complement our numerical analyses with rigorous time-domain simulations, thus reinforcing the reliability and accuracy of our methodology. Through this comprehensive investigation, we not only advance the understanding of quasicrystalline band structures but also pave the way for future applications in several wave-based systems.

Acoustic Spin and Phonon Spin

Jie Ren[1]

[1] Center for Phononics and Thermal Energy Science, China-EU Joint Lab on Nanophononics, Shanghai Key Laboratory of Special Artificial Microstructure Materials and Technology, School of Physics Science and Engineering, Tongji University, Shanghai 200092, China

Abstract: Spin angular momentum is an inherent property of classical waves. It was believed that only circularly polarized transverse waves carry spin, while longitudinal waves lack spin structures. However, recent progress has challenged this understanding. Here, I'll share recent progress on acoustic and phonon spin, along with spin related chiral phenomena.

1) SAM of elastic wave and acoustic wave

Elastic waves, which refer to vibrations in elastic media, can be described by the displacement field $\boldsymbol{u}(\boldsymbol{r},t) = \boldsymbol{u}_0(\boldsymbol{r})e^{i(\boldsymbol{k}\cdot\boldsymbol{r}-\omega t)}$. The SAM density carried by elastic waves can be expressed as [1,2]: $\boldsymbol{S} = \frac{\rho\omega}{2}\mathrm{Im}[\boldsymbol{u}^* \times \boldsymbol{u}]$

Taking into account that air acoustic waves are a special case where the $\nabla \times \boldsymbol{u}$ is zero, Eq. (1) is also applicable to acoustics waves. Experimentally, we can utilize absorbers that absorb acoustic waves to actually measure the torque induced by SAM of acoustics and verify its existence [3].

2) Spin related chirality in acoustic meta waveguides

The chiral phenomena associated with the spin of air acoustics can be harnessed as a tool for manipulating acoustic waves. For example, by disrupting the symmetry of an acoustic waveguide, we can establish a fixed chiral relationship among SAM, wave vector, and the waveguide's structure [4]. Leveraging this relationship, we can tailor specific propagation paths for acoustic waves, as demonstrated in Figure 1a. Furthermore, by exploiting the chiral relation between spin, energy flow, and reactive power in surface waves [5], we can achieve selective excitation of acoustic waves [6], as exemplified in Figures 1b and 1c.

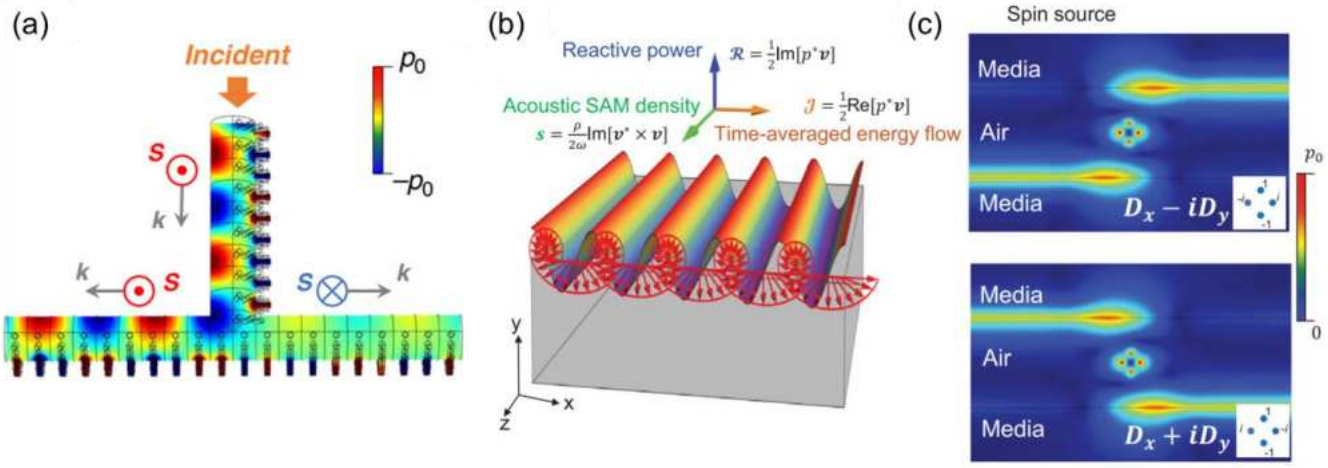

Figure 1. (a) A metasurface waveguide for sound carrying non-zero acoustic spin with tight spin-momentum coupling can be achieved by imposing an effective soft boundary. Assuming that the direction vector from the soft boundary to the hard boundary is denoted as $\boldsymbol{n}$, we can obtain the right-handed chirality as $\boldsymbol{s}\cdot(\boldsymbol{n}\times\boldsymbol{k}) > 0$. The acoustic wave will selectively propagate along one side due to the SAM match when facing multiple channels. (b) The evanescent wave can be supported on the interface between conducting (air in the acoustic case) and insulating media (gray block). We can obtain the right-handed chirality as $\boldsymbol{s}\cdot(\boldsymbol{\mathcal{J}}\times\boldsymbol{\mathcal{R}}) > 0$. (c) Selective excitation according to the spin-related symmetry.

3) Hybrid Spin in elastic waves

Electromagnetic waves belong to the category of transverse waves. In a vacuum devoid of free charges, the electric field's divergence vanishes, mathematically expressed as $\nabla \cdot \boldsymbol{E}$. Longitudinal waves, such as those found in air acoustics, exhibit a velocity field with zero vorticity due to the inability of ideal fluids to transmit shear forces, resulting in $\nabla \times \boldsymbol{v}$. Elastic waves, however, stand apart from both of these types, display both divergence-free and cure-free parts. Their displacement field can be represented by $\boldsymbol{u} = \boldsymbol{u_l} + \boldsymbol{u_t}$, satisfying $\nabla \times \boldsymbol{u}_l = 0$ and $\nabla \cdot \boldsymbol{u}_t = 0$. The spin of elastic waves is expressed as $\boldsymbol{S} = \frac{\rho\omega}{2}\mathrm{Im}[\boldsymbol{u}^* \times \boldsymbol{u}] = \frac{\rho\omega}{2}(\mathrm{Im}[\boldsymbol{u}_l^* \times \boldsymbol{u}_l] + \mathrm{Im}[\boldsymbol{u}_t^* \times \boldsymbol{u}_t] + \mathrm{Im}[\boldsymbol{u}_l^* \times \boldsymbol{u}_t] + \mathrm{Im}[\boldsymbol{u}_t^* \times \boldsymbol{u}_l])$, which possess the hybrid parts $\boldsymbol{u}_l^* \times \boldsymbol{u}_t$ and $\boldsymbol{u}_l^* \times \boldsymbol{u}_t$ [1,2,7]. Therefore, even within similar systems, the spin distribution of elastic waves may vary significantly, as illustrated in Figure 2. This uniqueness endows elastic waves with manipulation techniques that are unparalleled in other systems.

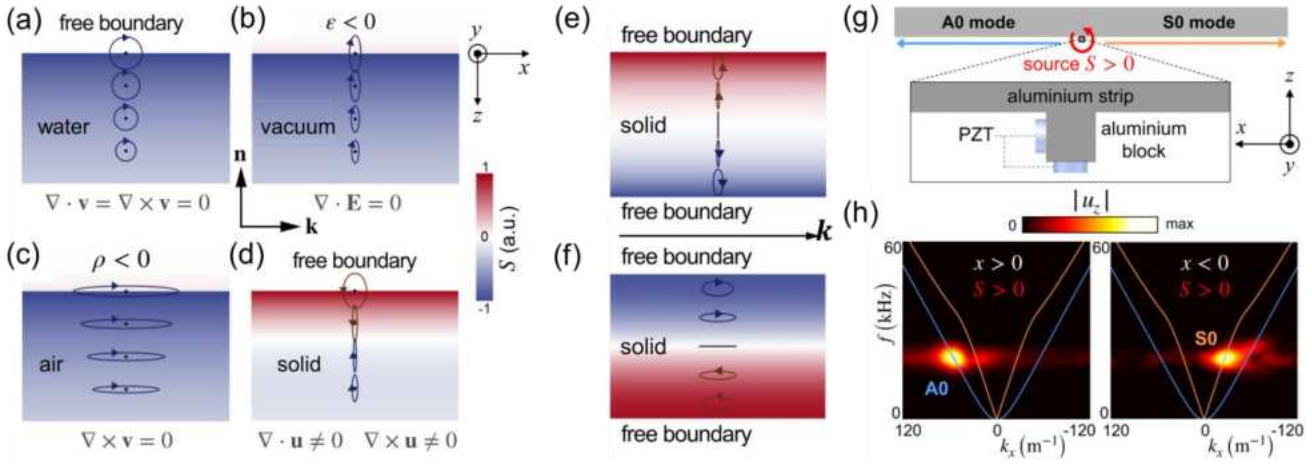

Figure 2. Anomalous spin-momentum locking in elastic waves. Transverse spin density in surface water (a), electromagnetic (plasmon-polariton) (b), acoustic (c), and elastic Rayleigh (d) waves. The spin-normal-momentum triad is right-handed in (a), (b) and (c) as $\boldsymbol{s} \cdot (\boldsymbol{n} \times \boldsymbol{k}) > 0$ and left-handed near the surface for Rayleigh waves as $\boldsymbol{s} \cdot (\boldsymbol{n} \times \boldsymbol{k}) < 0$. In Lamb wave, the A0 mode (e) has a reversed spin sign with S0 mode (f). As such, a spin source will induce the spin-induced directional excitation of the Lamb modes, as shown in (g) and (h).

[*]corresponding author: clivia.sotomayor@inl.int

Abstract: We present simulations of phononic crystals supporting interface modes in the GHz range, which are treated as waveguides. Under certain conditions chiral phononic modes are predicted. The sensitivity to critical dimensions variability is discussed.

Phononic waveguides could eventually become an alternative to in-chip interconnects if their losses are minimal. This leads to consider the concept of topological protection of phonons in a waveguide as a legitimate aim to explore phononic waveguides formed at the interface between two phononic crystals with different phases.

We have already demonstrated the presence of waveguide modes in a mechanical phononic structure realized in silicon-on-insulator, exhibiting a gap of 5.3 GHz centered at 8.4 GHz where the frequencies of the waveguide modes were found to be 5.7 and 7.1 GHz at room temperature [1]. The simulations were successfully compared to data from Brillouin scattering to obtain the dispersion relations of phonons in the phononic waveguide by solving the full 3-dimensional elastic wave equation by FEM simulation in COMSOL Multiphysics.

Here we will present simulations of selected phononic crystal structures with an interface waveguide between phononic crystals with similar but not identical geometry and a distinct variation of mass density in the unit cell. We will discuss the dramatic impact of a few nm variability in critical dimensions on dispersion relation, on a topological invariance and on the topological waveguide modes. The cases where chiral modes are expected will be illustrated [2].

Tunable spiraling metamaterial as a platform for controlling sound waves, electromagnetic waves, and enhancing optomechanical coupling

Osama R. Bilal[1*]

[1]Department of Mechanical, Aerospace, and Manufacturing engineering, University of Connecticut, Storrs, Connecticut 06269, USA Affiliation, Country

Abstract: In this work we present a platform for designing phononic and photonic materials utilizing a periodic tessellation of Archimedean spirals. Such tessellations are capable of opening band gaps for both sound and electromagnetic waves and enhancing opto-mechanical coupling in a programmable manner.

Metamaterials are repeating geometric patterns in space that construct artificial lattices. Such lattices can be utilized as platforms to realize peculiar behavior for both electromagnetic and sound waves. The design approaches for engineering such lattices are vastly different (from material layering and holes, pillar coatings and heavy inclusions to hinged mechanisms [1-6]). In this work, we present a generic platform, based on Archimedean spirals, to engineer a wide spectrum of wave manipulation capabilities by varying the spirals' geometry [7-10]. These spiraling materials can be easily manufactured using either additive or subtractive manufacturing technologies and can be easily programmed in a reversible manner. In addition to the realization of the different band gap physics through the proposed platform, we capitalize on the internal unit cell symmetry creating partial propagating bands within full band gaps. Such symmetry breaking allows for the demonstration of two cases of wave beaming. Moreover, we modify the packing symmetry of the spiraling unit cells to create topologically protected wave behavior. Our demonstrations show the potential of coupling various wave phenomena within unified and easy-to-design and fabricate building blocks, enabling the design of novel phononic and photonic materials for different applications. The presented advances highlight the versatility of spirals-based metamaterials.

Acoustic Metasurface in a Nano-Opto-Electro-Mechanical Device for High Optomechanical Coupling Rate

A. Guedidda, Y. Pennec[1*], L. Carpentier[1], G. Lévêque and B. Djafari-Rouhani[2]

Abstract: We theoretically investigate a phoXonic nanobeam for optomechanical coupling. Our focus lies to explore high-frequency (10 GHz) phonons trapped inside tapered or topologic high-Q cavities. To reach this objective, we propose the design of a metasurface to focus the acoustic wave into the nanobeam.

The Nano-Opto-Electro-Mechanical device comprises an optomechanical (OM) cavity housed within a phoXonic nanobeam. It is connected with two sets of inter-digitated transducers (IDT) at its input and output, facilitating the excitation and detection of acoustic waves. The optical modes within the OM cavity are stimulated by an external optical waveguide, which terminates with a Bragg mirror constructed from tapered holes. A scheme of the device is presented in Figure 1(a).

The phoXonic cavity is constructed with a periodic arrangement of holes and stubs, which concurrently generate an acoustic bandgap within the GHz range and an optical bandgap around 1550 nm for telecommunications. Our research has showcased[1,2] different cavity designs that sustain both acoustic modes spanning from 2 to 4 GHz and optical modes characterized by high-quality factors. Moreover, these cavities exhibit a substantial optomechanical coupling rate, denoted as g, on the order of MHz. Additionally, we explored the feasibility of exciting the phononic cavity modes using a set of inter-digitated transducers positioned in front of the nanobeam[3].

An acoustic metasurface, made of an array of sub-wavelength resonant pillars is tailored to concentrate the elastic wave emanating from the IDTs towards the nanobeam entrance. We proposed to obtain the focalization functionality by using elliptical pillars[4,5] with a constant height but a gradient in their ellipticity, which is suitable for the microfabrication technologies. We demonstrated that the proposed metasurface allows to focus the incident flexural waves into a focal spot with an intensity six times that of the incident wave with a full width at half maximum (FWHM) of the focal spot equal to $0.39\times\lambda$ (Figure 1(b)).

We then explored high-frequency acoustic cavities operating within the 6-10 GHz range. The design of OM cavities that support phonon localized modes in the range of 10 GHz while the optical cavity modes need to have both a high-quality factor and a strong OM coupling rate. In some of our previous works[1,2], we proposed tapered cavities where the sizes of the holes and stubs in the center of the cavity were increased (resp. decreased) with respect to the phoxonic crystal parameters in order to decrease (resp. increase) the cavity phonon frequency in the range of 2-4 GHz. In contrast, to go to 10 GHz frequencies, we adopted here an opposite solution, namely putting a long length stub at the center and relying on its high frequency second order breathing mode to compresse the holes and create the conditions for strong OM coupling. Different tapered cavities are under

investigation and some promising solutions are expected. One example is presented in Figure 1(c) where we show the acoustic and optical fields of the cavity with a coupling rate of g = 5 MHz.

In parallel, we are exploring the possibility of using simultaneous localized acoustic and optical modes at the interface between two topologically different phoXonic crystals. The principle is based on the analogy with the Su-Schrieffer-Heeger (SSH) model by making a pairing of the pillars and constructing a unit cell with two sub-units. Both photonic and phononic topological interface modes have been obtained by this approach.

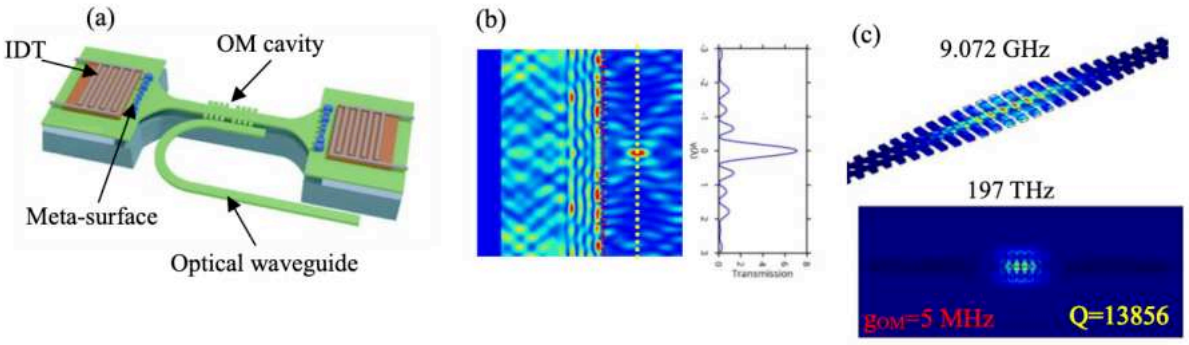

Figure 1: Schematic view of the opto-electromechanical device. (b) Elastic wave focusing effect of the metasurface. The blue curve represents the transverse intensity evaluated along the yellow line crossing the focal spot. (c) An example of phononic and photonic cavity modes providing high OM coupling rate g_{OM}.

Abstract: Burgeoning study on the spin angular momentum (SAM) of phonons has advanced profound understanding of fundamentals of SAM, from its classical to quantum aspects, and also envisioned intriguing applications of SAM in controlling elementary particles (e.g., photons, magnons, and electrons) via the spin–orbit interaction. Notwithstanding, prevailing studies on SAM of phonons are restricted to isotropic media in a frequency domain up to megahertz, in part due to the challenges in acquiring the full-field information of phonons using interferometry at a gigahertz (GHz) frequency. The present work is dedicated to gaining insight into the SAM of GHz evanescent acoustic phonons (EAP) in the lattice of monocrystalline materials, in which the temporally averaged Poynting vector of EAP is zero along specific directions. Theoretical modelling on lattice dynamics reveals that the EAP carries intrinsic three-dimensional (3-D) SAM – a trait that the bulk acoustic phonons do not manifest. A femtosecond-laser pump-probe set-up with the assembly of a knife-cutting-interferometer is configurated, to optoacoustically generate GHz surface acoustic phonons (SAP) -- a typical type of EAP, and measure the corresponding 3-D SAM. Experiment results evidence the detectability of the knife-cutting-interferometry to the in-plane components of atomic velocity of EAP, on which basis the 3-D SAM is imaged for intuitive observation. Experimental observation corroborates the 3-D intrinsic nature of the SAM carried by EAP as predicted using the theoretical modelling. The 3-D intrinsic SAM of EAP displays spin-momentum locking and omnidirectional conservation. We also reveal that the propagation of EAP along specific orientations can lead to the orthogonalization of SAM. Results of this study accentuate an application prospect of navigating elementary particles based on the conservation and transfer of angular momentum.

[#]presenting author: grazia.salerno@aalto.fi

Abstract: Multiparticle unit cells of nanoparticle arrays are a promising concept for realizing quasi-BIC modes whose darkness in the far-field is topologically protected against imperfections. By combining theory with polarization-resolved measurements of the emission, we show that the lasing emission from a plasmonic quadrumer array has a topological charge.

Metal nanoparticle arrays exhibit surface lattice resonances (SLRs), creating plasmonic-photonic modes with controllable dispersion. When combined with a gain medium, SLRs provide light-matter interaction, resulting in various phenomena such as lasing and Bose-Einstein condensation [1,2]. Thus far, simple unit cells of only one or two particles have been studied extensively, while the potential of complex unit cells with many particles is only starting to be explored. Our work focuses on a quadrumer nanoparticle arrays, and we show the unique characteristics of the multiparticle unit cell enables unique lasing characteristics [3].

We study lasing from a bound-state-in-continuum (BIC) mode, arising from the quadrupolar nature enforced by the quadrumer unit cell. BICs are localized states decoupled from the extended modes of the continuum, and are appealing for applications in lasing, filtering, or sensing [4-5]. They possess a quantized topological charge and are dark in outgoing radiation [6]. Our work combines a two-dimensional SLR lattice with a gain medium, observing emission primarily at sample edges and

corners. Under optical pumping, we experimentally observe the strongest emission at the corners and edges of the sample. By theoretical analysis of the isolated quadrumer, combined with numerical analysis of the electromagnetic fields both in finite and infinite systems, we identify BIC modes in an infinite lattice, and quasi-BIC in a finite one. Comparison of polarization-resolved lasing images to the numerical calculations reveals the lasing occurs in a quasi-BIC mode. The mechanism of coupling the BIC light to far field is in our system provided by the edges of the sample. We observe a nontrivial winding of the polarization field both in the experiments and simulations, indicating a nonzero topological charge.

The lasing BIC mode exhibits a high Q-factor (Q ~ 1400), surpassing typical SLR modes (Q ~ 300) [7]. The potential of nanoparticle complexes in designing topologically protected high-Q modes for lasing is demonstrated, with implications for understanding loss-dependent momentum dependence of the Q-factor. This study showcases lasing in a system with complex unit cells, highlighting the role of structure in determining mode characteristics and the potential of sample edges as leakage mechanisms for quasi-BICs, where losses significantly impact the quasi-BIC mode [8].

Abstract: We utilise a fully quantum-mechanical theory without perturbative approximations to investigate non-contact friction between two metallic bodies in relative motion, employing modified fluctuation-dissipation relations.

We demonstrate that when the metallic slabs are engaged in relative motion (Figure 1), low-frequency waves can undergo amplification, fundamentally altering the fluctuation-dissipation relation. Thereby, the metallic slabs can behave as gain media. This amplification, tailored by the Doppler effect, occurs in a directionally selective manner. By incorporating the modified fluctuation-dissipation relations for gain media, we rediscover the formula for frictional force previously postulated by Pendry et al. [1-3]. The directionally selective wave amplification results in the frictional force.

Moreover, the strength of interaction between the two slabs, their relative velocity, and the degree of dissipation jointly determine the stability of the system. In an unstable scenario, the modes of the system may experience exponential growth, culminating in the divergence of the frictional force. This shift from stability to instability is governed by the poles of Green's function. When one of the poles traverses the real frequency axis and enters the upper half of the complex frequency plane, the associated mode undergoes time growth rather than damping. Consequently, above the instability threshold, the quantum friction process is not stationary in time.

Furthermore, our study establishes a link between the quantum friction between two metal sheets and the classical Kelvin-Helmholtz instability (KHI). In the quasistatic limit, the equations of motion of the electromagnetic problem coincide with those governing KHI. Consequently, the instability in our quantum system emerges as a quantum electromagnetic analogue of the well-known Kelvin-Helmholtz instability, providing new insights into non-contact friction physics.

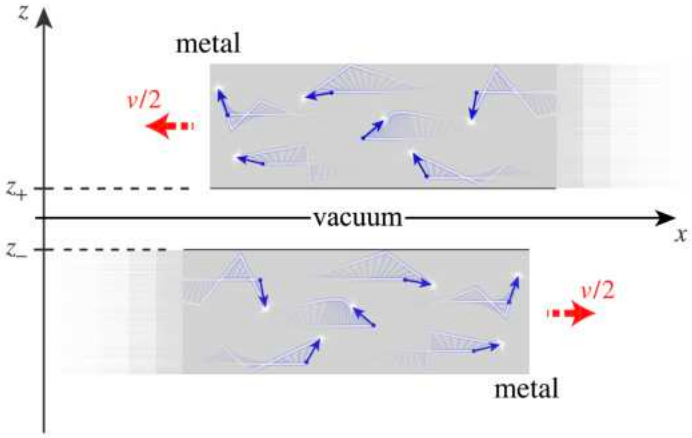

Figure 1. Schematic of the system analysed in this work: two metal sheets in a shear motion separated by a vacuum gap. The metallic medium is subject to finite damping, which implies the existence of noise currents in the medium (indicated by blue arrows).

On-Chip Metaphotonics Empowered Single-Photon Emission

Yinhui Kan[1*], Xujing Liu[1], and Sergey I. Bozhevolnyi[1*]

Abstract: We present a new avenue by introducing array of subwavelength nanostructures to on-chip couple with quantum emitters (QEs), which can efficiently outcouple the QEs-excited nonradiative surface plasmon polaritons to photon emission encoded with desired properties, i.e., directionality, specific spin and orbital angular momenta.

Generation of single photon beams with desired directionality, polarizations, and phase fronts is at the cornerstone of both classical and quantum optics.[1] However, conventional approaches for molding single-photon emission, relying on external bulky devices, such as polarization filters and spiral phase plates, decrease not only the compactness of single-photon configurations but also their efficiency and brightness. Efficient integration of quantum emitters (QEs) with beam shaping and polarization encoding functionalities has always been on the agenda but heretofore remained elusive.

Here, we present a new avenue by introducing metasurfaces to on-chip couple with QEs, which can efficiently outcouple the QEs-excited nonradiative surface plasmon polaritons to photon emission encoded with specific spin and orbital angular momenta (SAM and OAM), respectively.[2-4] We have also realized independent manipulation of the single-photon SAM and OAM states by using metasurface dimers of orthogonal nanobricks that generate (by scattering) high purity SAM (98% for S3 > 0.9).[5] By arranging the nanobrick dimers along different metasurface trajectories controlling OAM, high-purity SAM states are superimposed with OAM states corresponding to different phase-front helicities, for example, l = 0, 1, and 2. Furthermore, we have demonstrated the generation of high-purity linearly polarized (LP) single-photon vortex beams. Remarkably, the design strategy enables simultaneous generation of high-purity orthogonal LP single-photon beams with arbitrary different OAMs, meeting thereby growing demands for increasing the quantum information channel capacity.[6] Thus, by selectively covering azimuthally different metasurface areas with differently arranged nanobricks, we realize multiplexing of single-photon emission channels with orthogonal LPs carrying different topological charges (OAMs) and confirm their entanglement.

Moreover, we develop the vectorial scattering holography approach, as an inverse design method, with both single-channel and multiple-channel regimes for flexibly designing versatile on-chip QE-coupled metasurfaces.[7-9] Based on the proposed approach, we design, fabricate, and characterize on-chip quantum light sources of two well-collimated single-photon beams propagating along different off-normal directions with orthogonal linear polarizations.[8] Furthermore, we experimentally demonstrate on-chip generation of multichannel quantum emission encoded with different SAMs and OAMs in each channel.[9] The multichannel holography approach is further extended for tempering the strength of QE emission into a particular channel. The holography-based inverse design approach developed and demonstrated on-chip quantum light sources with multiple degrees of freedoms enable thereby a powerful platform for quantum nanophotonics, especially relevant for advanced quantum photonic applications, e.g., high-dimensional quantum information processing.

Dual-Band Control of Bound States in the Continuum with Pairwise Positioning of Singularities in Metasurfaces

Chloe F. Doiron[1]

[1]Sandia National Laboratories, USA
*corresponding author: cfdoiro@sandia.gov

Abstract: Applications of metasurfaces in classical and quantum optics are driving the need for polarization control of nearly-degenerate, high quality-factor (Q) modes. To address this need, we developed and experimentally demonstrated a design paradigm for controlling the Q-factors, mode splittings, and polarization responses of pairs of high-Q modes in dielectric metasurfaces.

Controlling the quality (Q) factor and far-field polarization response of a metasurface is critical for many applications in classical and quantum optics with new applications driving the creation of increasingly sophisticated devices that require multi-dimensional control. In particular, one emerging need is the ability to robustly create and control nearly-degenerate pairs of high-Q modes while shaping the frequency splitting, Q-factors, and polarization responses across two bands simultaneously. Achieving such comprehensive control would create pathways for enhancing metasurfaces in applications ranging from sensing to generating entangled photon-pairs, as well as enhancing non-linear mixing.

Here, we present and experimentally demonstrate a paradigm rooted in group theory for creating and choreographing guaranteed pairs of bound states in the continuum (BICs) — modes that are completely decoupled from the radiation continuum and therefore have infinite Q-factors [1]. By starting with guaranteed pairs of symmetry-protected BICs found in triangular lattices with six-fold rotational symmetry, symmetry breaking operations can independently control the frequency splitting and Q-factor with two-fold rotational symmetry breaking controlling Q-factors and three-fold rotational symmetry breaking controlling mode splitting (Figure 1) [2].

Moreover, the presence of BICs results in the formations of polarization singularities (points where the major axis of the polarization ellipse orientation is ill-defined). Because the variation of polarization away from these singularities is smooth and predictable, the positioning of these singularities can control the polarization response of the entire band. We will show pairwise generation, annihilation, and positioning of polarization singularities,

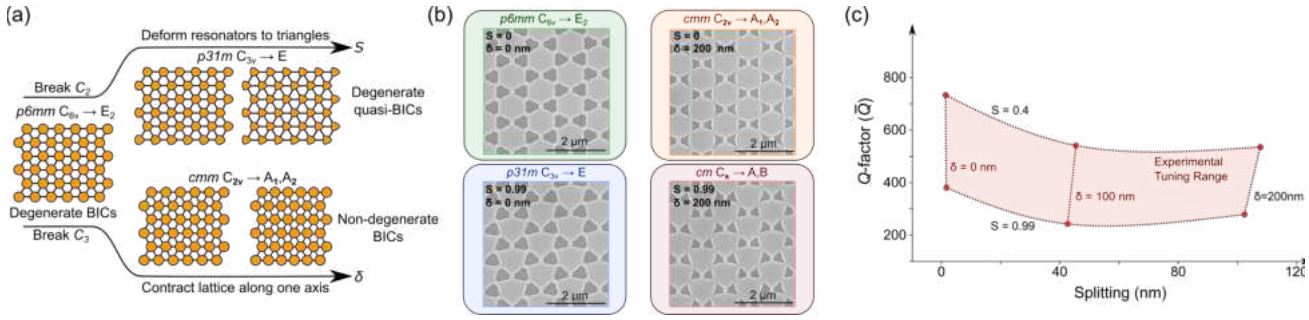

Figure 1: (a) By deforming the circular resonators into triangles, two-fold rotational symmetry (C_2) can be broken. Correspondingly, three-fold rotational symmetry (C_3) can be broken by contracting the lattice along one axis. (b) Scanning electron micrographs of silicon metasurfaces in all four symmetry phases. (c) Experimentally measured Q-factors and mode splitting for silicon metasurfaces with three-fold symmetry breaking (δ) controlling splitting and two-fold rotational symmetry breaking (S) controlling Q-factors.

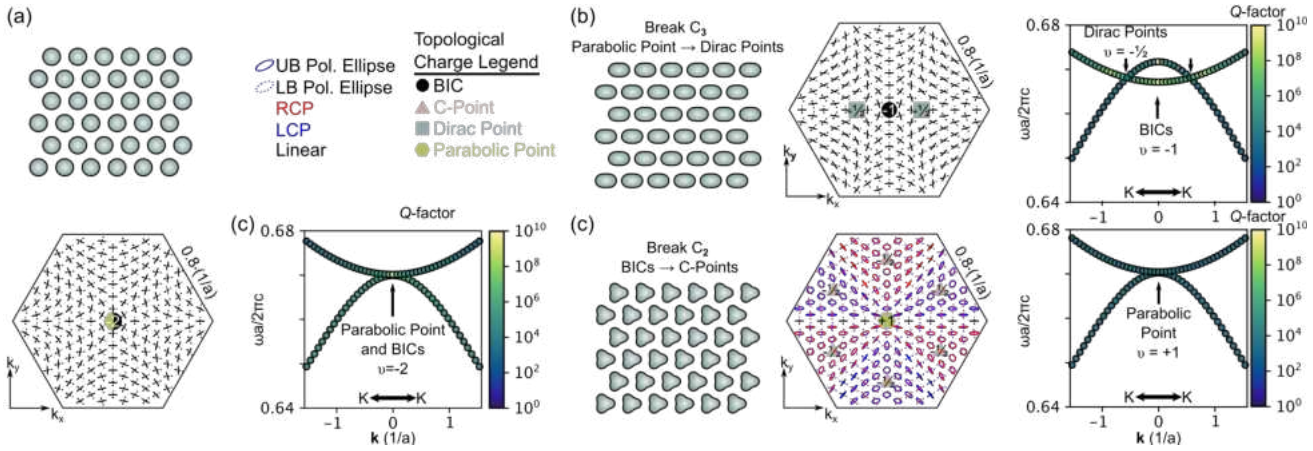

Figure 2: (a) When all symmetries of the triangular lattice are preserved, symmetry-guaranteed pairs of symmetry-protected BICs can form. Looking at the eigenpolarization near the **Γ**-point, a topological singularity exists at the **Γ**-point with topological charge (-2) arising from the presence of BICs and a parabolic degeneracy. (b) When a C_3 symmetry breaking deformation is applied to the resonators in the triangular lattice, the degeneracy is lifted resulting in the creation of two Dirac-points, but two symmetry-protected BICs remain. (c) Correspondingly, when a C_2 symmetry breaking deformation is applied, the parabolic degeneracy is preserved but the symmetry-protected BICs are converted to quasi-BICs resulting in the creation of 6 C-points per band.

derived from symmetry-guaranteed pairs of symmetry-protected bound states in the continuum in silicon metasurfaces (Figure 2) [3]. Building upon these demonstrations, we will conclude by presenting a design methodology for narrowband wavefront shaping without deeply sub-wavelength features.

Abstract: We develop, for the first time, an ultrathin source of two-photon polarization Bell states based on an InGaP nonlinear metasurface. The metasurface facilitates a local optical resonance with a tailored angular dispersion, enabling the all-optical tuning of polarization entanglement.

Nonlinear dielectric metasurfaces incorporating subwavelength nanostructures are emerging as promising platforms for generating versatile and highly flexible miniaturized photon pair sources via spontaneous parametric down-conversion (SPDC) [1]. Unlike conventional nonlinear crystals, metasurfaces can enhance and customize SPDC by leveraging optical resonances in the nanostructures. Recent experiments demonstrated strongly enhanced generation of spatially [2] and spectrally [3] entangled photon pairs, as well as counterpropagating emission [4]. While polarization entanglement was proposed in a multiplexed metasurface [5] and was demonstrated in Transition Metal Dichalcogenide thin film [6], the generation in metasurfaces remained an open challenge.

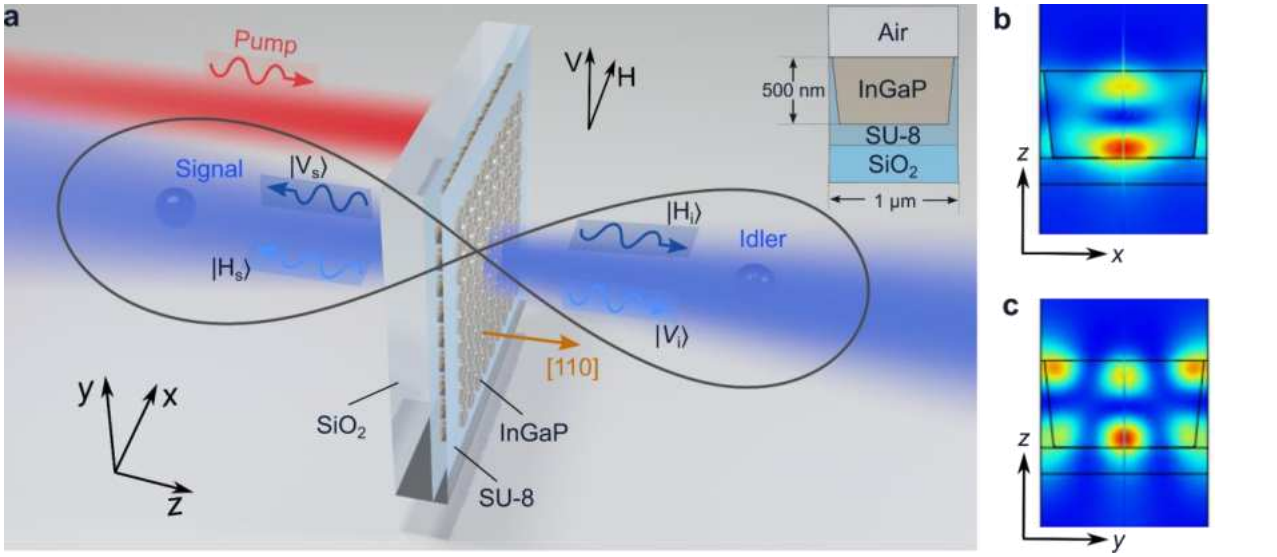

Figure 1 Concept. a. Polarization entanglement from an InGaP nonlinear metasurface. The metasurface incorporating nanostructured <110> InGaP film emit a pair of counter-propagating photons with crossed polarization. The polarization of each photon is uncertain before performing measurements, producing biphoton polarization entanglement. The inset presents the cross-section of a unit cell of the metasurface. **b-c.** Optical mode profile of the metasurface. The metasurface manifests an optical resonance at ~1571 nm, where the optical field inside the InGaP nanostructures is enhanced. The resonance enables enhanced and tailored generation of polarization entanglement.

Here we reveal, for the first time to our knowledge, that enhanced and tailored generation of polarization Bell state can be realized with an InGaP nonlinear metasurface through the SPDC process. The metasurface incorporates nanostructured InGaP film of 500 nm thickness and supports a local optical resonance at 1571 nm, as shown in Fig. 1. The resonance reveals strong field enhancement within the nanostructure (Fig. 1**b-c**), allowing enhanced generation of counterpropagating photon pairs. The InGaP material exhibits low fluorescence and a notably high

second-order susceptibility of 110 pm/V and the selected crystal orientation [110] offers a specific nonlinear tensor for generating cross-polarized photon pairs. Our experiments, displayed in Fig. 2, show that photon-pair rate is enhanced by 25 times in comparison to unstructured film (Fig. 2**a**). The density matrix reconstructed using maximum likelihood estimation confirms the generation of the polarization-entangled state, manifesting a concurrence of 0.92 and fidelity of 95% with the Bell state $|\psi^-\rangle = \frac{1}{\sqrt{2}}(|H_s V_i\rangle - |V_s H_i\rangle)$ (Fig. 2**c-d**). More importantly, we observe that the amplitude α of polarization entanglement $|\psi\rangle = \frac{1}{\sqrt{\alpha^2+1}}(|H_s V_i\rangle - \alpha|V_s H_i\rangle)$ is optically tunable via pump wavelength (Fig. 2**b**) due to nanostructure asymmetry along the light propagation, which is a unique feature unattainable with unstructured nonlinear films. The results will establish the first metasurface-based source of tunable polarization entanglement and manifest an important step closer to quantum communications with quantum light sources from metasurfaces.

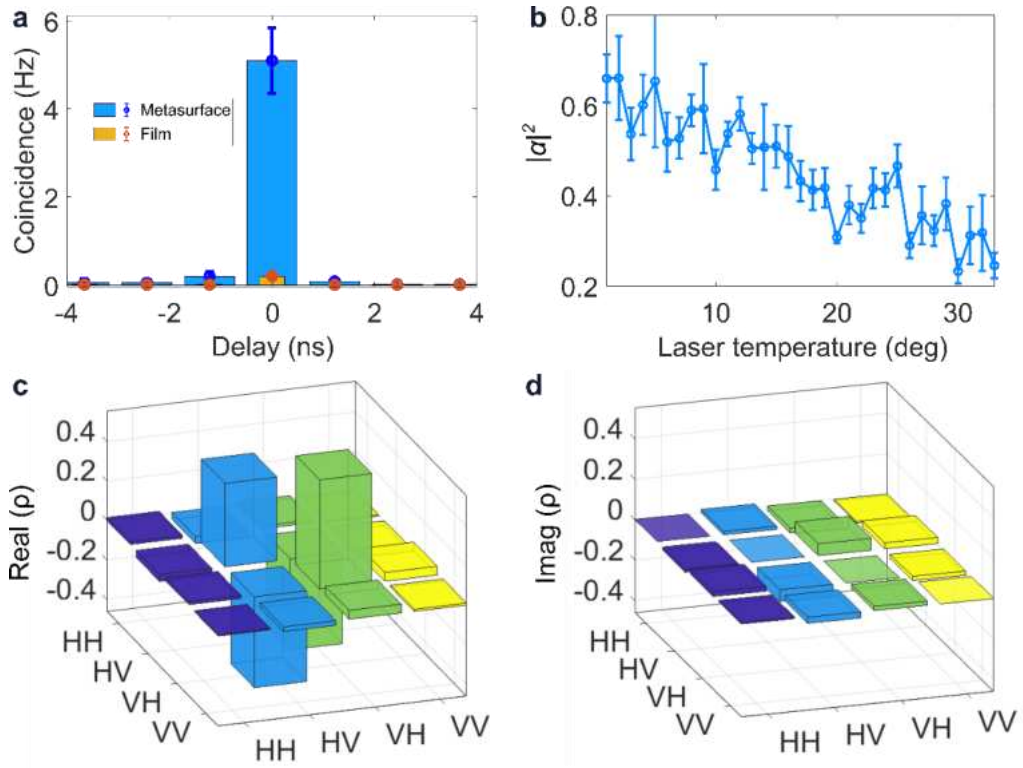

Figure 2 Experimental characterization of tunable polarization entanglement. a. Enhanced SPDC rate with metasurface. The generation rate and coincidence-to-accidental ratio of photon pairs from metasurfaces are both enhanced by ~25 times, as compared to unstructured thin film. **b. All-optical tuning of polarization entanglement.** The amplitude $|\alpha|^2$ of the polarization entanglement is tunable via pump wavelength, which is controlled by the laser temperature in our experiment. **c-d. Quantum tomography of polarization entanglement.** The reconstructed density matrix reveals the generation of a polarization-entangled state, having a concurrence of 0.92 and fidelity of 95% with Bell state. The pump wavelength considered here is ~782 nm.

Abstract: Our theoretical study explores using L-shaped gold metal nanoparticles with intrinsic plasmonic second-order nonlinearity for spontaneous parametric downconversion. Through quantum optical modeling parameterized by FDTD simulations, it demonstrates the MNPs' potential as probabilistic quantum photon sources suitable for applications as building units of quantum metasurface.

Metal nanoparticles (MNPs) exhibiting plasmonic resonances can serve as essential building blocks of quantum metasurfaces[1]. When paired with semiconductor quantum emitters, they can be used to control quantum light properties, particularly in quantum photon sources. Here, we present a theoretical study of the effect of spontaneous parametric downconversion (SPDC) carried out by the plasmonic MNPs. Leveraging our prior investigation[2], which involved the classical effect of difference-frequency generation within an array of L-shaped Au-MNPs, along with a semiclassical analysis of the SPDC, we now focus on quantum calculations of the SPDC energy conversion rate. The novelty of this research lies in harnessing the intrinsic plasmonic second-order nonlinearity exhibited by the L-shaped MNPs. This property of the MNPs eliminates using quantum emitters or additional nonlinear media as the source of nonlinearity.

As depicted in Fig. 1(a), we examine a 1D array of noninteracting L-shaped MNPs with arms l= 130 nm in length and w=40 nm in width. The thickness, d, of the MNPs is a variable parameter. The array is subject to incident pump pulse of frequency ω_p and intensity I_p polarized in the plane of the MNP array and tuned to the second harmonic frequency of the MNP plasmonic resonance, i.e., $\omega_p = 2\omega_{sp}$. The second-order susceptibility, $\chi^2(\omega_p;\omega,\omega_p-\omega)$, attributed to the MNP plasmonic nonlinearity, facilitates the SPDC of the pump pulse into the signal and idler photon pair of frequencies ω and $\omega_p-\omega$, respectivly. Our quantum optical model provides the following expression for the energy conversion yield, i.e., the ratio of the total plasmon energy of the signal and idler normalized per energy due to the pump photons

$$\eta = \frac{2\hbar}{A\pi\varepsilon_o c^5\left|1+n(\omega_p)\right|^2}\int d\omega\,\omega^3\left[\omega_p-\omega\right]^2\left\{\left|\chi^{(2)}(\omega_p;\omega,\omega_p-\omega)\right|^2+\left|\chi^{(2)}(\omega_p;\omega_p-\omega,\omega)\right|^2\right. \quad (1)$$

$$\left.+2\,\mathrm{Re}\left[\chi^{(2)*}(\omega_p;\omega,\omega_p-\omega)\chi^{(2)}(\omega_p;\omega_p-\omega,\omega)\right]\right\}\iint d^3r d^3r'\,\mathrm{Im}[G(r,r';\omega)]\,\mathrm{Im}\left[G(r,r';\omega_p-\omega)\right].$$

Here, A is the MNP area exposed to the pump, ε_o is the vacuum permittivity, c the speed of light in vacuum, and $n(\omega)$ is the refractive index accounting for the plasmon resonance. $G(r,r';\omega)$ is the MNP Green function defining the signal and idler joint density of states in Eq. (1), represented using the plasmon pole approximation

$$G(r,r';\omega) = \frac{e^{ik(\omega_{sp})(z-z')}}{V(\omega_{sp})\left[\partial(\omega n(\omega))^2/\partial\omega\right]_{\omega=\omega_{sp}}(\omega-\omega_{sp}-i\gamma_{sp})}. \quad (2)$$

In Eq. (2), $k(\omega_{sp}) = n(\omega_{sp})\omega_{sp}/c$ and $V(\omega_{sp}) = \int d^3r\, n(\omega_{sp}, r) e^{2Im[k(\omega_{sp})]z}$ is the surface plasmon mode volume. For comparison, we also consider the semiclassical expression for the idler photon energy yield[2]

$$\kappa = \frac{\hbar d^2}{2\varepsilon_o c^4}\left|\frac{[1+n(\omega_p)]}{1+n(\omega_p-\omega)}\right|^2 \int d\omega\omega^2\left[\omega_p-\omega\right]^2 \left|\chi^{(2)}(\omega_p;\omega,\omega_p-\omega)\right|^2 \mathrm{Im}\left[G(0,0;\omega_p-\omega)\right] \quad (3)$$

$$\times \left|\frac{\sin([k(\omega_p-(\omega_p-\omega)+k(\omega)]d/2)}{[k(\omega_p-(\omega_p-\omega)+k(\omega)]d/2}\right|^2 e^{-\mathrm{Im}[k(\omega_p-\omega)+k(\omega)]d}.$$

To parameterize Eqs. (1)-(3), we consider the Au MNPs. We performed FDTD simulations of the linear and nonlinear plasmonic response using the hydrodynamic model for the conduction electrons coupled with the Maxwell equations for the electromagnetic field. Using the approach developed in Refs.[2,3], we have extracted the linear response, *n(ω)*, characterized by the plasmon energy $\hbar\omega_{sp}$= 1.23eV, linewidth $\hbar\gamma_{sp}$= 0.077eV, and transition dipole p_{sp}= 4.75 10^3D. The nonlinear susceptibility was fit to the anharmonic response model with $|\chi^{(2)}| = 4$ pm/V at the second harmonic energy of the plasmon resonance.[2]

The calculated quantum and semiclassical energy conversion yields are shown in Fig. 1(b) as a function of the MNP thickness *d*. According to the plot, the total energy conversion rate of the signal photons to the signal and idler plasmon quanta is $\eta \sim 10^{-10}$. The energy yield for converting the pump photons to the outgoing idler photons saturates at $\kappa \sim 10^{-11}$. For comparison $\kappa \sim 10^{-12}$ is typical for SPDC process in 1mm thick BBO crystal, suggesting superior performants of the considered MNP of the sizes allowing their incorporation into metasurfaces. It is noteworthy that the difference between η and κ yields can be associated with the nonradiative plasmonic losses. The inset to Fig. 1(b) presents the yield energy distributions peaked at the surface plasmon energy resulting from the plasmon-enhanced SPDC processes.

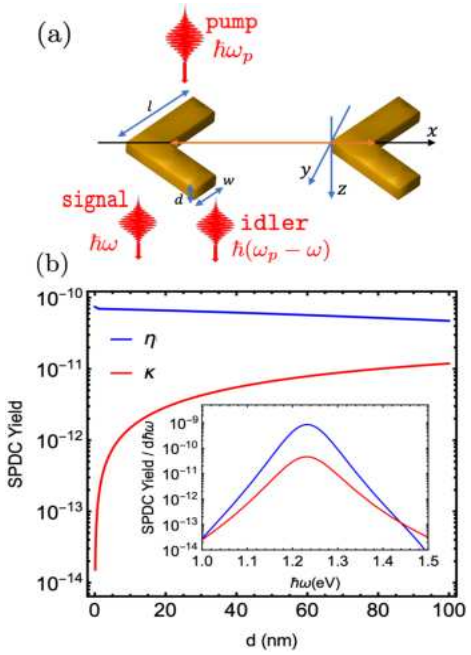

Figure 1 (a) Geometry of MNP subject to incident pump pulse and outgoing signal and idler photon pair. (b) Calculated energy yields vs. MNP thickness *d*. The inset shows yield energy distributions $d\eta/d\hbar\omega$ & $d\kappa/d\hbar\omega$ at *d* = 30 nm.

Quantum light-matter interfaces with arrays of trapped atoms

E. Shahmoon[1,*]

[1]Department of Chemical & Biological Physics, Weizmann Institute of Science, Rehovot 7610001, Israel
[*]corresponding author: ephraim.shahmoon@weizmann.ac.il

Abstract: We develop a general framework for the design of efficient atom-array quantum interfaces. Our approach relies on the mapping of realistic, collective atomic systems to a generic 1D model of a quantum interface, characterized by a reflectivity parameter. This gives a universal relation between a simple measurable quantity – the reflectivity – and various desired quantum tasks, from quantum memories to entanglement generation.

Arrays of laser-trapped atoms, such as optical lattices or tweezer arrays, form some of the most prominent quantum platforms, with applications in quantum simulations, metrology and computation. Recent studies highlighted that they may also couple strongly to light, as evident by their strong reflectivity [1-3]. For spatially ordered arrays, this strong coupling results from the combination between spatial order and the collective response to light, established by photon-mediated dipole-dipole interactions between the atoms. Subsequent studies found that this strong coupling is also useful in various quantum tasks such as quantum memories [4] and entanglement generation between photons [5-7]. This motivates a systematic study of atomic arrays as a new type of quantum interfaces which rely on collective effects to enable the efficient transfer of quantum information from propagating photons to atoms, crucial for a variety of quantum tasks.

To this end, we develop a universal approach for the analysis of two-sided quantum interfaces in collective atomic systems, relying on the mapping to a generic 1D scattering model characterized by a reflectivity [8]. This entails two important consequences: (i) the efficiency of the quantum interface in performing various quantum tasks is characterized by a measurement or a simple classical calculation of a reflectivity; (ii) we show how the reflectivity, and hence the efficiency, can be greatly enhanced by a properly designed photon mode which spatially matches the collective eigenmodes of the array structure.

Our methodology consists of two parts: (i) 1D model of a quantum interface and its characterization by a reflectivity; (ii) procedure for the mapping of a collective atom-photon system to the 1D model. Beginning with the former, we consider a minimal 1D model for a two-sided atom-photon interface: a collective mode of atomic dipoles P is coupled to a 1D-propagating ``target" photon mode E, while also scattering to other modes considered as loss. Denoting the ratio of these couplings by the cooperativity $C=\Gamma/\gamma_{\rm loss}$, we find that the on-resonance reflectivity of the target mode, given by $r_0=C/(C+1)$, fully characterizes atom-photon coupling. In particular, r_0 is equal to the efficiency of energy conversion between the dipole P and the target mode E and hence emerges as a universal figure of merit of quantum tasks. This can be demonstrated for efficiencies of quantum memory and entanglement generation [8].

The second part is to identify the mapping of given atom-photon systems to the two-sided 1D model. We consider a general collection of atoms interacting with a paraxial target photon mode in free space, accounting for collective dipole-dipole interactions between the atoms. For atoms on a single plane, we find that the mapping is possible if the transverse profile of the target mode E spatially matches an eigenmode P of the dipole-dipole interaction kernel whose eigenvalue is denoted by D_0. While P can decay to both the target mode E and to other photon modes at a total rate $\Gamma_0 = 2\mathrm{Im}[D_0]$, we find a general formula for its coupling rate to the target mode $\Gamma<\Gamma_0$, yielding the mapping parameters Γ and $\gamma_{\rm loss} = \Gamma_0 - \Gamma$ [9]. For multiple planar atomic layers, the mapping is possible when the inter-layer distance is an

integer multiple of half of the wavelength, yielding Γ that increases linearly with the number of layers.

We apply our approach for the description and design of realistic atom-array interfaces [8]:

2D and 3D lattice arrays: We derive analytical expressions for typical cases of ordered arrays considering their finite size and position disorder. The mapping to the 1D model is established, showing that a target photon mode in a typical Gaussian-beam shape matches an approximate eigenmode of the dipole-dipole interaction, whereas deviations due to imperfections are accounted for by the loss parameter γ_{loss}. Analytical results for r_0 derived from the mapping theory agree with numerical results of both the reflectivity and the efficiency of a quantum memory protocol.

Beyond lattice symmetry: Considering a 2D ordered array with a finite filling fraction, we show how the reflectivity can be greatly enhanced if we go beyond the typical case of a Gaussian-beam target mode. Choosing a target mode that matches a dipole eigenmode, we obtain efficiencies of r_0=0.99 and r_0=0.94 for filling fractions as low as 85% and 70%, instead of much lower efficiencies with a typical Gaussian-beam target mode. Analytical results agree with numerical ones, showing that the mapping is valid so that enhancement of r_0 implies enhanced efficiencies of quantum tasks. We also consider a circular array, again demonstrating efficient coupling of corresponding paraxial dipole eigenmodes.

Going forward, this approach opens the prospect for a unified treatment of more applications and platforms, as demonstrated by our subsequent works. First, considering quantum tasks beyond those discussed here, e.g. the dissipative transfer of squeezing correlations [9]; Second, considering atom-array interfaces beyond the geometries discussed above, e.g. using tweezer atom arrays [10,11].

Lattice Resonances in Periodic Arrays with Multiparticle Unit Cells

A. Manjavacas[1*]

[1]Instituto de Óptica (IO-CSIC) Consejo Superior de Investigaciones Científicas, Spain
[*]corresponding author: a.manjavacas@csic.es

Abstract: We explore novel functionalities provided by the lattice resonances supported by periodic arrays of nanostructures with multiparticle unit cells.

Two-dimensional periodic arrays of metallic nanostructures can support collective optical modes known as lattice resonances. These excitations occur at wavelengths commensurate with the periodicity of the array and give rise to very strong and spectrally narrow optical responses. Thanks to these exceptional properties, periodic arrays are being exploited in a wide variety of applications [1]. In this contribution, we will discuss some recent theoretical advances on the topic of lattice resonances. In particular, we will analyze the response of arrays with multi-particle unit cells using an analytical approach based on hybridization theory [2], which provides a simple and efficient way to design periodic arrays with engineered properties [3,4]. Furthermore, we will explore how the response of a periodic array is affected by the characteristics of the source used to excite it [5-7]. Finally, we will analyze different array geometries that support lattice resonances with extraordinary properties such as perfect circular dichroism [8] and perfect absorption [9].

Controlling quantum states and quantum noise with nonlinear photonics

Nicholas Rivera[1]

[1]Department of Physics, Harvard University, Cambridge MA 02138
[*]corresponding author: nrivera@fas.harvard.edu

Abstract: We present recent theoretical and experimental results on using engineered nonlinear interactions to generate elusive quantum states of light and control quantum noise of electromagnetic fields.

The quantum mechanical nature of electromagnetic fields has a variety of important consequences for fields such as sensing, microscopy, laser physics, communications, and quantum information processing. There are several bottlenecks in realizing broad application of quantum states of light. One is that it is currently challenging to deterministically produce an important class of quantum light states called non-Gaussian quantum states, even given powerful resources like single and few-photon nonlinearities realizable in cavity quantum electrodynamics and excitonic systems. The other bottleneck is that many applications, even those that rely on Gaussian states (e.g., squeezed states), require control over highly multimode systems, where quantum noise dynamics are not well-understood. With respect to the first bottleneck, we present a new approach which enables deterministic generation of important non-Gaussian states. The approach is based on combining few-photon nonlinearities with engineered loss and/or gain to create nonlinear loss and gain that promotes the creation of these states. As an example, we will show how certain types of nonlinear cavities and beamsplitters can enable creation of Fock and Schrodinger cat states from simple coherent-state inputs [1-4]. Along the lines of controlling highly multimode quantum systems, we present a new theoretical approach called quantum sensitivity analysis that enables prediction of quantum noise dynamics in highly multimode nonlinear systems [5]. Guided by this theoretical framework, we experimentally demonstrated new low-noise correlated states in the phenomenon of supercontinuum generation [5], as well as quantum correlated states in highly multimode nonlinear fibers [6].

Abstract: In this talk, I will discuss the generation of photon pairs driven by quasi bound states in the continuum resonances in metasurfaces made of gallium arsenide of two different crystallographic orientations, and how these resonances can shape the polarisation state of the emitted photons.

Metasurfaces hold a big potential for the engineering of the quantum state of photon pairs. Indeed, since the first demonstration of photon pair generation from metasurfaces via Mie-type resonances [1] in 2021, it was clear that metasurfaces could shape the emission of photon pairs in different degrees of freedom such as frequency, direction of emission, and polarisation.

We generate photon pairs via spontaneous parametric down-conversion (SPDC) in metasurfaces made of GaAs wafers. SPDC is a quantum process where a higher-energy pump photon is split into two lower-energy photons after interacting with a second-order nonlinear material (e.g. a GaAs metasurface). The metasurfaces studied here feature quasi bound states in the continuum (qBIC) resonances of relatively high quality factors ($300 < Q < 1600$) at multiple wavelengths in the telecom range. The mechanism of photon pair generation is the following. The qBIC resonance enhances the zero-point vacuum fluctuations at a particular wavelength. Then, when a pump photon interacts with the metasurface, its energy is split into two photons, one of them being emitted by the qBIC mode which is driving the nonlinear interaction, forcing the emission of the other (conjugate) photon at the wavelength that conserves the energy. The resonance not only fixes the wavelengths of emission but also enhances the conversion efficiency. Using qBIC resonances, it was possible to demonstrate the spatially-entangled emission of photon pairs [2], and the frequency-multiplexed emission of photon pairs [3] using multiple qBIC resonances. More complex scenarios have been demonstrated too, such as bidirectional and collinear emission of frequency non-degenerate photon pairs [4], and the more general case of photon pairs being emitted in opposite directions at complementary angles, where the angle of emission can be tuned via the pump wavelength [5].

Most studies have focused on the spectral and emission direction degrees of freedom, but polarisation, which is essential in quantum information applications, remains practically unexplored. A recent work [6] characterized the polarisation state of photon pairs emitted in nonlocal metasurfaces and suggested a configuration for the generation of Bell states.

In this work, we performed a complete polarisation tomography of photon pairs emitted by qBIC resonances in metasurfaces made of (001)-oriented GaAs [3]. By carrying out two-photon polarisation tomography measurements of frequency-nondegenerate photon pairs, we reconstructed the density matrix and calculated the

purity of the photons. Here, the nondegenerate emission was driven by a single resonance, that is, one photon is emitted at the resonance wavelength, and the conjugate photon is emitted at the wavelength that conserves energy according to the pump laser wavelength. The two-photon tomography results show that the polarisation state is mixed with no sign of polarisation entanglement. To understand the origin of the mixedness, we carried out further polarisation tomography measurements on each photon of the pair. The results show that photons within the same pair are in different polarisation states. Moreover, photons emitted by the resonance have higher purity (> 0.9) than their conjugates, indicating that the mixedness of the two-photon quantum state might be a consequence of the conjugate photon populating more than one eigenmode of the metasurface.

A drawback of metasurfaces for SPDC is the low conversion efficiency, which is a consequence of their ultrathin profile. Despite featuring relatively large quality factors ($300< Q \leq 1600$) and one of the largest second-order susceptibilities ($\chi^{(2)} \sim 240$ pm/V), the emission rate of SPDC in (001)-oriented GaAs metasurfaces does not surpass 8 Hz/W, which is low for practical quantum applications. In an effort to improve the generation rate, we fabricated metasurfaces using (110)-oriented GaAs wafers using the same design and target wavelengths as in our (001)-oriented GaAs metasurfaces [3]. The advantage of this crystallographic orientation is a direct access to the components of the second-order susceptibility tensor. Our preliminary results show that the rate is improved by a factor of 20x when compared to its (100) counterpart [3], and the enhancement (10^3) with respect to an unpatterned film of the same thickness is maintained. We believe that the rate can be further improved by adjusting the in-plane orientation of the nanoresonators, which is subject of current investigation.

Applications of Spacetime Quantum Metasurfaces to Simulating Hawking Radiation

Patrick Brown[1,2], Wilton J. M. Kort-Kamp[3], Gerald Cleaver[1,2], and Diego Dalvit[3]

The Dynamical Casimir Effect (DCE) was first theorized by Gerald T. Morre in 1970 where he demonstrated that a moving mirror would create excitations in the quantum vacuum resulting in the production of real photons. This photon production effect arose from the fluctuations in the quantum vacuum caused by the time dependent boundary conditions created by the moving mirror. It was later shown that this effect could be enhanced if the mirror was instead made to oscillate at one end of a closed cavity at roughly twice the cavity's resonant frequency. Many detailed analyses of closed and open cavity systems have been conducted as well as detailed studies of single oscillating mirror systems. These studies have included the use of $\delta - \delta'$ b mirrors to analyze not only the time dependent boundary conditions, but also the presence and consequences of asymmetry (Silva et. al. and Gorban et. al.). However, it has been shown that in all scenarios involving mechanical oscillation of the mirror, it would need to be oscillating at a sizable percentage of the speed of light posing an obvious problem for experimental application. Yablonovich, however, showed that the DCE could be modeled by modulating the optical properties of a material. This was first theorized to be possible in a nonlinear optical medium whose index of refraction was rapidly oscillating in time, which Yablonovich chose to be a rapidly growing plasma. It was quickly shown that this effect was not limited to plasmas, but was in fact possible with nonlinear materials through the rapid oscillations of their optical properties. Since then much research has been devoted to designing new materials and systems to produce the DCE through optical modulation. The first successful observation of DCE photons was performed through the use of a wave guide terminated by a SQUID (Wilson et. al). There are, however, limitations to the use of SQUID systems including the very low temperatures at which SQUIDs must be operated and the low DCE photon generation rate that this system produces. It is then necessary to look for new systems capable of much higher DCE photon generation rates.

In recent years, Spacetime Quantum Metasurfaces (STQMs) have garnered a lot of interest due to their unique quantum and optical properties through the use of both spatial and temporal modulation (Wilton et. al.). These include the application of electrical bias for the creation of metalenses by modulating their index of refraction, magnetic field modulation taking advantage of the near instantaneous response of metasurfaces and metamaterials to magnetic fields, temperature modulation through the use the thermo-optic effect, optical modulation through their ultra-fast responses to photon interactions, and of course mechanical modulations. The most attractive feature of STQMs is the enhancement of their response to these modulations by combining two or more of these modulation schemes in conjunction with each other. This allows for the generation of unique physical phenomena including on demand control of entanglement among all degrees of freedom of a single photon, encoding quantum information into high-dimensional color qudits, higher degrees of control of multispectral and multispatial modes in spontaneous emission, and the generation of steered and vortex photon pairs out of the

vacuum. For this talk we will be solely interested in STQMs ability to create real photons from vacuum fluctuations (DCE) and the applications therein. One such application is the analysis of the quantum aspects of curved spacetime, specifically Hawking Radiation.

In 1975, Hawking first theorized that black holes could indeed evaporate, or decrease in size, through the emission of real photons. He demonstrated that this emission of photons came from the excitation of the quantum vacuum near the event horizon of a black hole. Specifically, he demonstrated that the difference in the creation and annihilation operators of both the quantized scalar and electromagnetic fields near the event horizon and past null infinity are realized as the creation of real photons from vacuum excitations. It was then shown by Davies and Fulling that this process could be simulated by a moving mirror. They demonstrated that if the mirror was made to move on an asymptotically null trajectory that the emission of particles from the vacuum would model the same mechanism of particle production predicted by Hawking for black holes. Since the Dynamical Casimir Effect is characterized by the emission of real photons from the vacuum, it was proposed that Hawking radiation could be simulated by modulating the optical properties of a material. Since then much work has been done to analyze these so-called “optical event horizons.” Nation et. al. proposed the use of a superconducting transmission line though the use of SQUIDs. The biasing of such a circuit with a space-time varying flux creates the necessary effective metric and “analogue” horizon. Horsley and Pendry, however, proposed the use of diffraction gratings synthetically moving at trans-luminal velocities. Here it is the creation of vacuum excitations when the grating and wave velocities are equal which create the “optical” event horizons.

STQMs allow for the engineering of not only spatial and temporal modulations of the material, but also allow for the steering and control over the quantum properties of the output photons. These features could provide methods for not only the emission of Hawking photons but also the use of such emissions to probe much deeper into the quantum aspects of curved spacetime. In this talk I discuss how these unique quantum properties of STQMs could provide a novel and unique platform for the simulation of Hawking radiation and other quantum effects predicted in curved spacetimes.

Space-Time Quantum Metasurfaces

Diego Alejandro Roberto Dalvit

Los Alamos National Lab., USA
*corresponding author: dalvit@lanl.gov

Abstract: Metasurfaces have recently entered the realm of quantum photonics, enabling manipulation of quantum light using a compact nanophotonic platform. Realizing the full potentential of metasurfaces at the deepest quantum level requires the ability to tune coherent light-matter interactions continuously in space and time. Here, we introduce the concept of space-time quantum metasurfaces for arbitrary control of the spectral, spatial, and spin properties of nonclassical light using a compact photonic platform. We show that space-time quantum metasurfaces allow on-demand tailoring of entanglement among all degrees of freedom of a single photon. We also show that spatiotemporal modulation induces asymmetry at the fundamental level of quantum fluctuations, resulting in the generation of steered and vortex photon pairs out of vacuum. Space-time quantum metasurfaces have the potential to enable novel photonic functionalities, such as encoding quantum information into high-dimensional color qudits using designer modulation protocols, sculpting multispectral and multispatial modes in spontaneous emission, and generating reconfigurable hyperentanglement for high-capacity quantum communications.

Analog of Quantum Bit Empowered by A Novel Electromagnetic Metasurface

Abstract

Current metamaterial research mainly focuses on the classical bit as the fundamental unit of information. To overcome the limitations of classical information capacity, we recently have proposed a new electromagnetic metasurface to implement analog quantum bit. This presentation would summarize our recent works in the field of analog quantum metasurfaces.

1. Introduction

Information transmission has ancient roots, dating back 5,000 years with fire signals and drumming for distance communication. In 2014, Cui et al. pioneered the digital coding metamaterials concept [1], marking a significant leap in the integration of information technology with material science. These metamaterials serve as intermediaries between the physical and digital worlds [2][3], acting as a bridge that enables the seamless exchange of data across domains. Presently, the focus in metamaterials research is on leveraging the classical bits for information processing [5][6]. For instance, electromagnetic (EM) metamaterials can be designed to enhance wireless communication signals and develop stealth technologies for cloaking objects [7][8]. Our research has shown that quantum-inspired information metamaterials have the potential to go beyond the limitations of classical information capacity, and this has been reported [9]. By drawing inspiration from quantum mechanics, these metamaterials can exhibit properties such as superposition, which are not found in classical systems.

In this paper, we summarize and report the latest research results achieved by our team in the field of quantum-inspired metasurfaces [9][12]. Specifically, we have successfully created an analog quantum information metasurface, which is different from another representative of analog quantum metasurfaces (topological metasurfaces) and from real quantum metasurfaces, please refer to Ref. [9]. Our work is progressively bridging the gap between classical and quantum systems, paving new paths for the realization of quantum-inspired information metamaterials.

2. Results and discussion

2.1. Principle

This section introduces a novel concept, the analog quantum bit (qubit), inspired by the qubit.

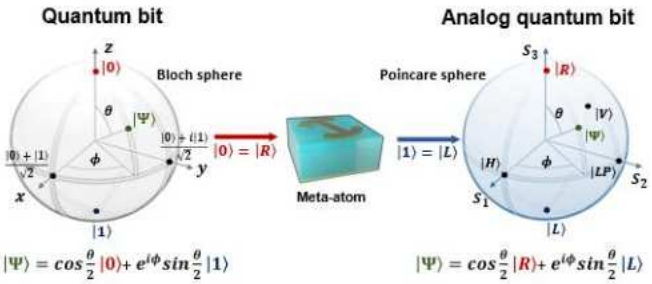

Figure 1: The concept of quantum bit and analog quantum bit.

As is well-known, the state of a qubit $|\Psi\rangle$ can be mathematically represented as a linear superposition of two orthogonal states, that is $|\Psi\rangle = cos\frac{\theta}{2}|0\rangle + e^{i\phi}sin\frac{\theta}{2}|1\rangle$, with the sum of their squared amplitudes equaling one, in accordance with probabilistic constraints. Furthermore, the state of a qubit can be visualized geometrically using the Bloch sphere. This superposition property significantly surpasses the binary nature of classical bits. Based on these principles, we propose the concept of an analog qubit and demonstrate its physical realization using a Pancharatnam-Berry (PB) phase metasurface, as illustrated in Fig. 1. In the design and analysis of the metasurface, we focus on the transformation of the Jones matrix, successfully achieving the analysis of conversion between linear and circular polarizations and deriving the corresponding mathematical representations.

$$\begin{cases} |r_{RR}| = \sqrt{\frac{|r_{uu}|^2[1+\cos(\theta_{vv}-\theta_{uu})]}{2+|r_{uu}||r_{uv}|[sin(\theta_{vv}-\theta_{uv})+sin(\theta_{uv}-\theta_{uu})]}} \\ |r_{LR}| = \sqrt{\frac{2+|r_{uu}||r_{uv}|[sin(\theta_{vv}-\theta_{uv})+sin(\theta_{uv}-\theta_{uu})]-|r_{uu}|^2[1+\cos(\theta_{vv}-\theta_{uu})]}{2+|r_{uu}||r_{uv}|[sin(\theta_{vv}-\theta_{uv})+sin(\theta_{uv}-\theta_{uu})]}} \end{cases} \quad (1)$$

$$\begin{cases} \phi_{RR} = arg(r_{uu}+r_{vv}) \\ \phi_{LR} = 2\alpha + arg([(r_{uu}-r_{vv})-i(r_{uv}+r_{vu})]) \end{cases} \quad (2)$$

where r_{ij} denotes the reflection coefficient from the j-th incident wave to the i-th reflected wave, with i, j belonging to the sets $\{u, v\}$ for linear polarization and $\{R, L\}$ for circular polarization. It should be noted that the aforementioned expressions are valid under the excitation of a right-hand circularly polarized (RCP) incident wave. In this case, we can further derive the mathematical representation of the analog qubit.

$$|\Psi\rangle = cos\frac{\theta}{2}|R\rangle + e^{i\phi}sin\frac{\theta}{2}|L\rangle \quad (3)$$

$$\begin{cases} \theta = 2arccos\left(\sqrt{\frac{|r_{uu}|^2[1+\cos(\theta_{vv}-\theta_{uu})]}{2+|r_{uu}||r_{uv}|[sin(\theta_{vv}-\theta_{uv})+sin(\theta_{uv}-\theta_{uu})]}}\right) \\ \phi = 2\alpha + arg([(r_{uu}-r_{vv})-i(r_{uv}+r_{vu})]) - arg(r_{uu}+r_{vv}) - \pi \end{cases} \quad (4)$$

Based on this mathematical representation, we can geometrically visualize the qubit-like states using the Poincaré sphere, where RCP and LCP are represented as two orthogonal vector states (i.e., $|R\rangle$ and $|L\rangle$). For more details on the principle, please refer to Ref. [9].

2.2. Verification of the mathematical representation

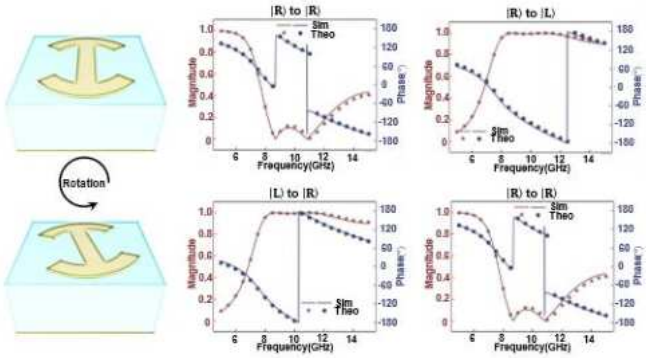

Figure 2: Mathematical representation verification of the analog qubit.

We have developed a PB phase metasurface to physically validate the mathematical representation of the proposed analog qubit. Specific details on the dimensions of the meta-atoms can be found in Ref. [9]. By rotating any structured meta-atom to arbitrary angles, the theoretical predictions of circularly polarized reflection coefficients can be derived from the linearly polarized reflection coefficients using equations (1) and (2). As depicted in Fig. 2, one set of examples (i.e., $\gamma = 105°$, $\kappa = 105°$, and $\alpha = 15°$) illustrates that the theoretical predictions of the magnitudes and phases of the four circularly polarized reflection coefficients are in high agreement with the numerical simulations. This agreement confirms the correctness of our theory and, by extension, the mathematical representation of the analog qubit. It is also noteworthy that this theory is not only applicable to the symmetrical structures (as shown in Fig. 2) but also to anisotropic structures.

2.3. Verification of the geometrical representation

We further validated the geometric representation of the analog qubit within PB phase metasurfaces. To study the polarization evolution paths on the Poincaré sphere, we employed Stokes parameters $\{S_0, S_1, S_2, S_3\}$to evaluate the positions of the electric field polarization states at different locations in the incident and reflection regions. Figure 3 illustrates the polarization evolution path when excited by an RCP wave for a specific metasurface structure. In the incident region, the polarization state remains unchanged due to the absence of interaction; conversely, in the reflected region, the RCP state gradually transitions into various other polarization states, eventually stabilizing as the far-field polarization state. We marked the numerically simulated state on the Poincaré sphere with green dots and calculated the theoretical predictions using equations (3) and (4), represented by red dots. The high overlap between these points confirms the accuracy of the geometric representation of the analog qubit. Additionally, we conducted broadband validation, further enhancing the reliability and robustness of our findings (refer to [9]).

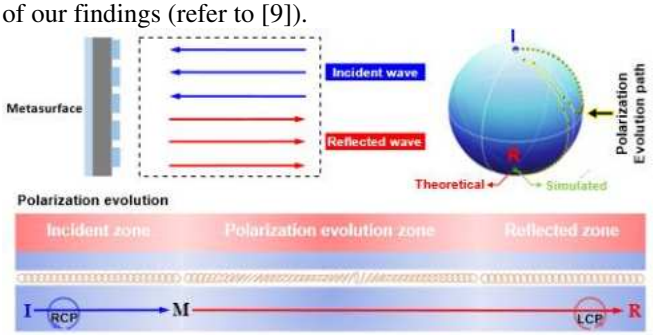

Figure 3: Geometrical representation verification of the analog qubit.

2.4. Demonstration of the analog quantum bits

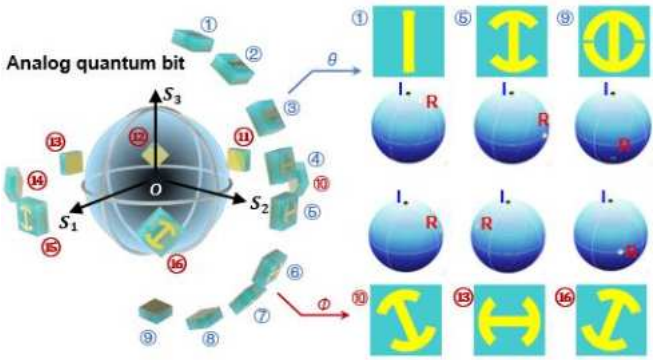

Figure 4: Modulation of the realization of the analog quantum bit.

To achieve the superposition state characterization property of the analog qubit, and considering that these superposition states are governed by two degrees of freedom on the (θ and ϕ) Poincaré sphere, we have proposed a feasible scheme.

As shown in Fig. 4, the latitude angle is primarily influenced by the magnitude of the reflection coefficient. By maintaining a constant rotation angle for the meta-atom and varying the lengths of two equal arcs, we can achieve a full coverage of magnitudes from 0 to 1, thereby enabling precise control of the latitude angle across any meridian. Since the meta-atom adheres to the PB phase, by keeping the arc length constant and rotating around the central z-axis, we can induce a twofold change in the longitude angle, thus enabling precise control over the longitude angle along any latitude.

To quantitatively demonstrate our control strategy, theoretical predictions and numerical simulations are presented in Tables 1 and 2, further validating the correctness of our approach. More detailed results are available in Ref. [9]. The high degree of overlap between the numerical simulations and theoretical predictions

verifies our comprehensive coverage of polarization states across the Poincaré sphere.

Table 1: Quantitative analysis of the modulation of the latitude angle θ.

No.	$\gamma = \kappa[^\circ]$	Theoretical	Simulated
1	20	90.01	89.80
5	105	89.99	89.75
9	175	90.05	88.96

Table 2: Quantitative analysis of the modulation of the longitude angle ϕ.

No.	$\alpha[^\circ]$	Theoretical	Simulated
10	22.5	134.99	127.91
13	90	269.99	269.89
16	157.5	44.99	51.59

2.5. Experimental Verification

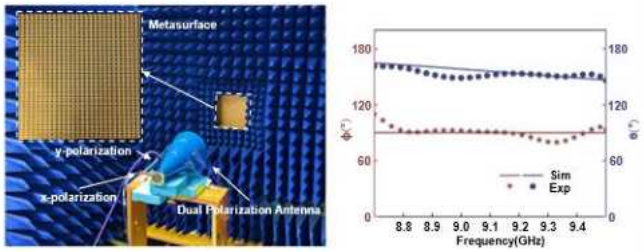

Figure 5: Experimental setup and results.

We constructed a small anechoic chamber experimental platform to verify the accuracy of our theoretical predictions, as illustrated in Fig. 5. By interfacing a dual-polarized horn antenna with a vector network analyzer (VNA), we measured the four linear polarization complex reflection coefficients ($\{r_{uu}, r_{vu}, r_{uv}, r_{vv}\}$). This enabled us to obtain experimental results for the two components of the analog qubit at corresponding positions on the Poincaré sphere. The high degree of consistency between the experimental results and numerical simulations further validates the feasibility of using the proposed analog qubit to emulate quantum bits.

3. Conclusions

In summary, this paper presents our recent advancements in the field of quantum-inspired metasurfaces, with a particular focus on introducing the concept of the analog qubit. We developed a feasible metasurface-based physical platform, which has been validated through mathematical and geometrical representations. Additionally, we conducted relevant experiments to verify the effectiveness of this concept. It should be noted that this study is still limited to passive metasurfaces. Our team is currently working on extending this research to tunable and even active metasurfaces, aiming to advance the development of analog qubit and create new opportunities for the fields of information science and quantum science.

Integrated metasurfaces/metamaterials on photonic platform

Observation of momentum-gap topology of light

Y. Yang[1*]

[1]Zhejiang University, Hangzhou 310027, China
[*]corresponding author: yangyihao@zju.edu.cn

Abstract: Topological phases have prevailed across diverse disciplines. Hitherto, the understanding of these phases has centered on frequency bandstructures, showcasing topological boundary states at spatial interfaces. Here, we report the experimental observation of momentum-gap topology of light, manifesting as topological boundary states at temporal interfaces between systems with distinct momentum-gap topology.

Topological phases, which are pivotal in the fields of electronics, photonics, and acoustics, have traditionally been centered on the study of energy bandstructures and the exploration of spatial topological boundary states. Yet, recent advancements have led to the discovery of a novel class of bandstructures characterized by momentum bandgaps, or 'k gaps', particularly prominent in photonic time crystals. This seminal development heralds a diverse array of topological phases within momentum bands, alongside numerous topological boundary states in the temporal domain. In this talk, we will present the experimental observation of k-gap topology within an optical temporal synthetic lattice, demonstrating temporal topological boundary states. These states manifest at the temporal interfaces between two subsystems, each characterized by distinct k-gap topologies. Our findings present a novel perspective in the study of k gaps, temporal topological states, and the dynamics of time-varying physical systems, thus catalyzing further research and exploration in this burgeoning field.

Approaching unity quantum coupling of free electrons and photons using nanophotonic structures

Yuval Adiv[1]

[1] Department of Electrical and Computer Engineering, Technion-Israel Institute of Technology, 32000 Haifa, Israel
*corresponding author: yuvalad@campus.technion.ac.il

Abstract: Using a dispersion-engineered nanophotonic structure we achieve a unity quantum coupling strength between free electrons and 2D photons. This record coupling strength enables the first observation of 2D Cherenkov radiation and provides insights into the quantum nature of free-electron radiation.

The quantum coupling strength between free electrons and photons is a unitless measure reflecting the average number of photons emitted by a single electron when interacting with an optical medium. Typically, free-electron radiation phenomena, like Cherenkov and Smith-Purcell radiation, exhibit relatively weak coupling, on the order of 10^{-4} to 10^{-2}. Intriguingly, the dimensionality of the medium into which the radiation is emitted can fundamentally change the radiation properties such as its spectrum, intensity, directionality, and polarization. The manipulation of these properties can potentially lead to an enhancement of the quantum coupling strength by orders of magnitude.

This is particularly true for Cherenkov radiation (CR). The CR first observed and explained over 80 years ago as an electromagnetic shockwave emitted by a charged particle when it exceeds the phase velocity of light in a medium [1]. Since then, CR has been mostly conceived as a 3D phenomenon where the radiation creates a cone around the emitting particle. Theory papers predicted two-dimensional CR (2D-CR) to have a sharper bandwidth emitted into longitudinal modes [2], but, until this work, only phenomena analogous to it were demonstrated experimentally [3,4], and such radiation has yet to be observed.

In this work, we present the first observation of 2D-CR, which we generate in a transmission electron microscope (TEM) by aligning an electron beam to propagate close and parallel to a dispersion-engineered multi-layered structure. We tune the electron velocity and observe a corresponding shift in the electron energy loss spectrum (EELS) that follows the Cherenkov (phase-matching) condition and matches the dispersion of the surface photonic mode. The reduced dimensionality leads to sharp EELS characteristics, allowing us to unveil the quantum-optical nature of CR emission. The EELS data shows up to three quantized emission events by each electron – the first such observation in any process of coherent free-electron radiation (i.e., coherent cathodoluminescence). Most importantly, a thorough analysis of our measurements reveals a quantum coupling strength of unity between the free electron and the photon it emits, indicating, for the first time, on the single-electron–single-photon interaction regime.

This experiment arises from theory papers and a scientific debate on the quantum state of radiation emitted by free electrons, which recently led to a paradigm shift: For many years, radiation emitted by a free electron was considered as classical light (i.e. a Glauber coherent state). However, recent theoretical works showed this to be generally incorrect [5-7]. Instead, the electrons can become entangled with the photons they emit – changing the quantum state of the emitted photons. Our work provides experimental support to this paradigm shift.

Time Edge States Protected by Chiral Symmetry

Hao Hu[1*]

[1]National Key Laboratory of Microwave Photonics, Nanjing University of Aeronautics and Astronautics, Nanjing, China
[*]corresponding author: hao.hu@nuaa.edu.cn

Abstract: This talk will introduce a novel type of edge states that are localized in the time domain. As protected by the chiral symmetry, the time edge states are proven to be robust against the external perturbations.

Time photonic crystals whose electromagnetic parameters are modulated periodically in time, are of paramount significance, owing to their promising applications in non-resonant laser, reconfigurable intelligence surfaces, and particle accelerators. Inspired from recent advances in space photonic crystals, the topological band theory has been transferred to the time photonic crystals whose unit cells preserve time-reversal symmetry, enabling the temporal version of topological edge states. However, disorders will readily break the time-reversal symmetry, hence heavily impacting the behaviors of corresponding edge states. To this end, we propose a novel type of time photonic crystals that respect the chiral symmetry, only if the temporal duration over the refractive index for each layer is a constant. The chiral symmetry of time photonic crystals gives rise to the quantized winding number (i.e., 0 or 1) that is defined in the Bloch frequency. Contacting time photonic crystals with different winding number results in the emergence of chiral-symmetry protected edge states localized at the temporal domain wall and spectrally manifested as sharp dips in the momentum gap. Importantly, the chiral symmetry remains unbroken even if the applied disorders are sufficiently strong. This remarkable property favorably enhances the robustness of behaviors (e.g., the resonant frequencies and field patterns) of topological edge states in time photonic crystals.

Thin film lithium niobate double notch filter

Songyan Hou[1*]

[1]Xidian University, China
[*]corresponding author: housongyan@xidian.edu.cn

Abstract: We propose a tunable double notch filter on thin-film lithium niobate using dual micro-ring architecture. This unique integrated filter is essential for complex photonic integrated circuits, along with multiple channels and various frequency spacing.

Integrated optical filter is one of fundamental building blocks in many optical applications, notably in the context of wavelength division multiplexing (WDM) networks[1, 2]. To meet the flexibility requirements of the wavelength selection in the forthcoming highly functional optical circuits, the optical filter featuring continuous tunability has attracted increasing attention. To realize the tunable optical filter, widely adopted approaches are implemented based on silicon photonics. For example, arrayed waveguide grating[3] and cascaded micro-ring filter[4] on silicon platform have been demonstrated a wide tunability. However, the lack of intrinsic electro-optic effect in silicon photonics makes the optical filter suffer from extra optical transmission losses and high power consumption when the functionality is achieved by the means of carriers doping and thermal tunning, prompting the exploration of alternative materials with robust Pockels electro-optic coefficient, such as lithium niobate (LN)[5-10].

Here, a tunable double notch filter is proposed and experimentally demonstrated on thin-film LN. The design consists of two cascaded microring resonators, whose electric filed are revised by one external voltage. The frequency spacing of the filter is tunable by reversely tuning the resonances of the two microrings. A wide separation tunability range from 16.1 GHz to 89.9 GHz is demonstrated, and the separation can be increased to free spectral range (FSR) of 423 GHz when further increase the voltage. With an ultracompact footprint of 0.0248 mm2, the device provides a frequency separation tunability of 0.82 GHz/V with a contrast of 10~16 dB.

The Proposal of the Substrate-inverted Multi-Material Technology (SuMMIT) for Scalable Heterogeneously-Integrated Photonics

Jia Xu Brian Sia[1,2]

[1]School of Electrical and Electronic Engineering, Nanyang Technological University, 50 Nanyang Avenue, 639798, Singapore
[2]Department of Material Science & Engineering, Massachusetts Institute of Technology, Cambridge, M.A., USA
[*]corresponding author: jiaxubrian.sia@ntu.edu.sg

Abstract: Current silicon photonic heterogeneous integration has displayed challenges with contemporary foundry-compatible, wafer-scale silicon photonics. Through the integration of industrial foundry-level silicon photonics and hybrid Cu bonding technologies, the SuMMIT platform is proposed, where heterogeneous photonic integration can be realized in a scalable fashion.

The silicon photonic platform possesses significant limitations, arising from the material limitations of Group IV materials. The abovementioned has led to a distinct split in the development of the silicon photonics between industry and academia. Firstly, there is the development of foundry-driven, wafer-level silicon photonics consisting of complex back-end-of-line (BEOL) layers which facilitates the realization of high-speed silicon modulators and germanium-based photodetectors, widely adopted by industry [1]. Heterogeneous silicon photonics, on the other hand, has attracted considerable interest from the academic front, where functional materials (i.e., III-V gain medium [2], Ce:YIG [3]) have been integrated close to the silicon waveguide core to extend the suite of functionalities possible within the platform. However, heterogeneous material integration in silicon photonics could lead to a reduction in scalability.

To that effect, the SuMMIT platform is proposed, illustrated in Fig. 1(a); the detailed fabrication process flow is elucidated in [4]. A 200 mm silicon foundry-manufactured silicon photonic wafer is shown at the inset of Fig. 1(a). The SuMMIT platform can be categorized into 4 technology layers: 1.) CMOS electronics, 2.) Through-glass/silicon via (TGV/TSV), silicon photonics, and multi-material integration layer. The substrate removal of the silicon photonic wafer (silicon substrate and buried oxide) results in the formation of a surface at the backside of the silicon waveguides with low rms values (< 0.5 nm). This results in compatibility with multi-material integration via techniques such as hydrophilic bonding, and material deposition.

An example of material integration on SuMMIT is shown in Fig. 1(b), where the back-end-of-line (BEOL) layers, preserved by the SuMMIT vertical architectures enables the electrothermal control of the Sb_2Se_3, a phase change material used for non-volatile photonic memory [4]. A 30 nm thick, and 5 μm long Sb_2Se_3 strip is integrated on a straight PIN junction, embedded within a silicon racetrack resonator. The silicon waveguide has a width of 500 nm. The PIN junction, which makes use of a rib waveguide has a rib height of 130 nm, where the rest of the racetrack resonator comprises of strip waveguides, with height of 220 nm. The N++ and P++ regions of the PIN junction are spaced 250 nm from the edge of the rib waveguide (intrinsic) to prevent optical loss due to carrier absorption. The electrothermal characteristics of the PIN junction, simulated via the IV curve of the PIN junction shows a thermal time constant of 248 ns (1/e from peak temperature). This is commensurate for

Sb_2Se_3 to bypass crystallization. The non-volatile photonic memory of the Sb_2Se_3-integrated racetrack resonator is shown in Fig. 1(c) and (d), via the through and drop port, where a large contrast can be seen between the crystalline and amorphous states. By fixing a laser wavelength a $\lambda_{res.}$, a non-volatile photonic transmission states can be addressed via electrothermal switching.

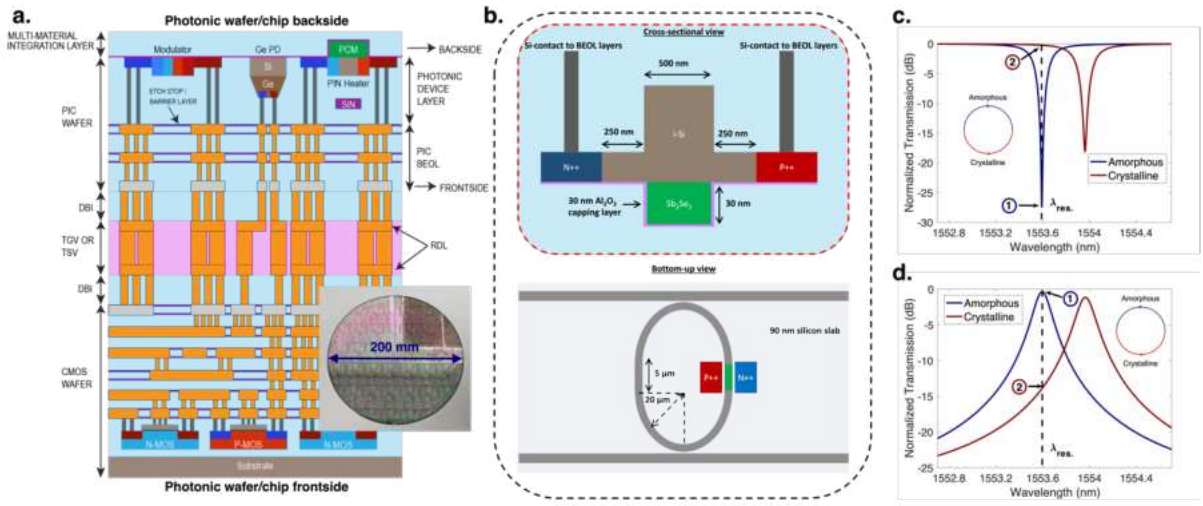

Fig. 1. (a) Illustration of the SuMMIT technology platform. The photograph of the 200 mm silicon photonic wafer is shown at the inset. (b) Sb_2Se_3-integated racetrack resonator via the SuMMIT platform, facilitating the on-chip non-volatile photonic memory. The (c) through, and (d) drop port of the Sb_2Se_3-integated racetrack resonator when the Sb_2Se_3 is switched to a crystalline and amorphous state via electrothermal switching of the PIN junction.

SuMMIT will provide a high-scalable approach for heterogeneous integration of various optical materials. Via the innovative architecture, the preservation of the BEOL layers within the silicon photonic wafer can facilitate light-matter control.

Extending the bandwidth of nonlinear optics

Yu Luo[1*], Chunyu Huang[2], and Hui Liu[2]

[1] National Key Laboratory of Microwave Photonics, Nanjing University of Aeronautics and Astronautics, Nanjing 211106, China

[2] Collaborative Innovation Center of Advanced Microstructures National Laboratory of Solid State Microstructures，School of Physics Nanjing University Nanjing Jiangsu 210093 China

[*]corresponding author: yu.luo@nuaa.edu.cn

Abstract: Integrated nonlinear optical devices play an important role in modern optical communications. However, the realization of efficient nonlinear optical conversion on chip over a broadband frequency range is widely acknowledged as a challenging task. In the first part of my talk, I will present a universal strategy based on the theory of transformation optics to design broadband nonlinear optical devices on chip [1]. In the second part of this talk, I will show how stacked perfect-electric-conductor (PEC) and epsilon-near-zero (ENZ) metamaterial consisting of nonlinear varactors can be used for strong second harmonic generation over a wide range of illumination angles.

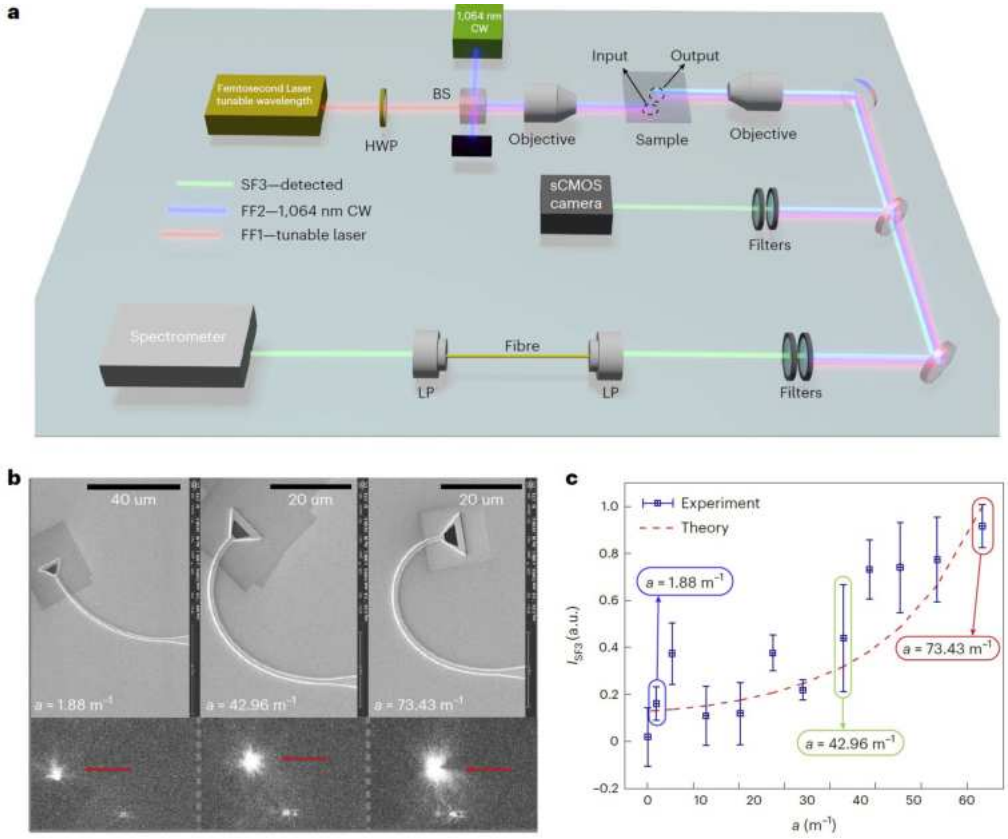

Figure 1: **Experimental demonstration of enhanced SFG.** (a) Schematic of the experimental setup. The wavelength-tunable femtosecond laser and the steady-state light source are used at the fundamental frequency. (b) The electron microscope images of the accelerated waveguides with different gradient curvatures and the corresponding CMOS images. The three sub-figures clearly demonstrate that the larger the acceleration, the

higher the light intensity. (c) The intensity of the sum-frequency light as a function of the acceleration. The red line represents the theoretical calculation, the blue points correspond to the experimental mean values, and the vertical error bars denote the range of standard deviation, respectively.

We will first demonstrate from the theoretical point of view that accelerating waveguides with gradient curvatures provide a powerful platform to extend the bandwidth of various nonlinear optical processes on chip. As an experimental proof, we will show how this method can be applied to boost the efficiency of sum-frequency generations for infrared signal upconversion (SFG-ISU) in curved accelerating waveguides (CAWs) made of LiNbO3, as shown in Fig. 1. Especially, we will discuss the relationship of the gradient of the waveguide curvature (i.e. the acceleration) and the bandwidth of the SFG process. Such a broadband SFG process offers a promising method in the long wavelength detection and imaging in the mid/far-infrared [1].

The conformal transformation approach presented in this talk is general and can be extended to other nonlinear optical processes at any wavelength range. It can also be realized with various nonlinear optical materials. Besides, our scheme does not require complicated fabrications or accurate designs. It is mass producible and compatible with the CMOS process.

Spoof Plasmonic Skyrmions and Sensing Application

Liangliang Liu
National Key Laboratory of Microwave Photonics, Nanjing University of Aeronautics and Astronautics, Nanjing, 211106, China
corresponding author: llliu@nuaa.edu.cn

Abstract: Recent concept of spoof plasmonic skyrmions (SPSs) has attracted much attention for their topologically robust and multiple equidistance sharp resonances. However, highly-efficient excitation and its application for broadband sensing still remain elusive. Here, we developed an ultracompact and topologically robust sensor based on SPSs for characterizing dielectric materials in a wideband with ultrahigh sensitivity. Moreover, a shape-immuned hybridization model with SPSs is proposed to offer remarkable field enhancement. Simulation and experimental results show that SPSs sensor features highly sensitive (>4.82%) and extremely accurate (≈99.99%) sensing performance against continuous shape deformations. These results open up an avenue for multiple resonant measurements of dielectric materials in broadband and provide a very versatile platform for the design and fabrication of ultracompact, highly sensitive and topologically robust plasmonic sensors.

Abstract: Special beams, exemplified by the Airy beam since 2007, exhibit intriguing properties. However, their behavior in hyperbolic media remains poorly explored. We propose a method to convert half Bessel beams in isotropic media into self-focusing special beams in hyperbolic media, expanding avenues for advanced beam manipulation.

Special beam is a beam family typical of non-diffracting main lope. The first found special beam is Airy beam which originates from the special solution to Schrodinger equation and was introduced to optical system in 2007 [1]. The most striking property is that the main lope always remains its energy without diverging into other directions. It can remain the beam shape when propagating and the main lope trajectory follows a parabola in the paraxial range. After that, people have been trying to push the special beam into non-paraxial regime with different main lope trajectories and a series of special beams are proposed. The main lope of Half Bessel beam [2] follows a circle and Weber beam [3] follows an parabola while Mathieu beam [3] follows an ellipse. They can overcome the paraxial limit and the beam can bend to nearly 90°.

However, all these special beams are derived in the isotropic media such as in free space and it also requires complicated derivation. How to build up a special beam with one simple design principle that can be applied to all kinds of media, including isotropic, ellipse and even hyperbolic media, remains unexplored. Regarding this blankness, this work reports a general design principle which can be applied to all kinds of media.

Based on this design method, we can realize special beams in elliptical media and even hyperbolic media. Especially, in the hyperbolic media we realize non-diffracting special beams with unique properties, which are transformed from the half Bessel beams in isotropic media. Compared with the original half Bessel beam, the transformed beams have the following new properties:

1. Finite aperture
2. Self-focusing
3. Longer propagation length

Moreover, two different self-focusing mechanisms are realized. The beam in Figure1(a) shows only one focal point when the main lope meets the asymptote. While the beam in Figure1(b) illustrates multi-focusing effect each time when side lopes meet the asymptote.

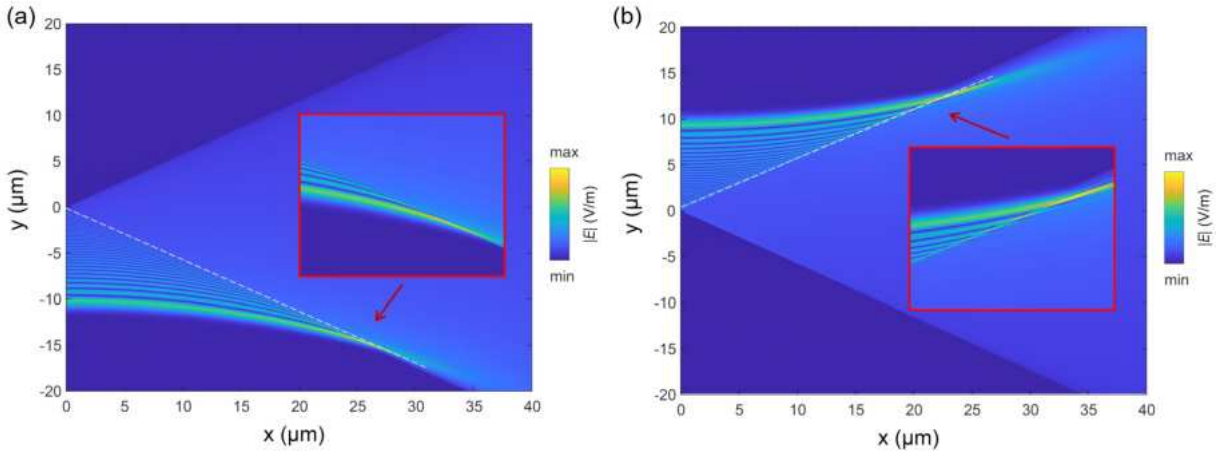

Figure1 The field distribution of two different self-focusing beams in hyperbolic media. (a) Focusing will only happen when the main lope meets the asymptote. (b) Focusing will happen multi-times when each side lopes meet the asymptote. The insets show the detailed light behavior along the asymptote.

Meta-optics for imaging, microscopy and information processing

The Multi-angle Beam Bender with Transformation Materials

Wen-xiu Dong[1,2], **Yun-yun Lai** [1,2], **and Jin Hu**[1,2 *]

[1] Beijing Institute of Technology, China

Abstract: In contrast to the usual bender that can only bending fixed angle of the beam path no matter what the incidence angle is, a new bender that can guiding the beam path to wide range bending angles is proposed, which can adjust the path directions according to the incidence angles.

The beam bender is a useful device that can control the wave propagation path along the predefined direction with no limitation such as cut-off frequency as the waveguide tube has [1]. The usual bender is fixed by its bending angle no matter what the incidence angle is, as shown in Fig.1. This means if one wants to adjust the wave path bending angle then the corresponding bender must be replaced to fit the new angle, such situation limits the flexibility of the bender applications.

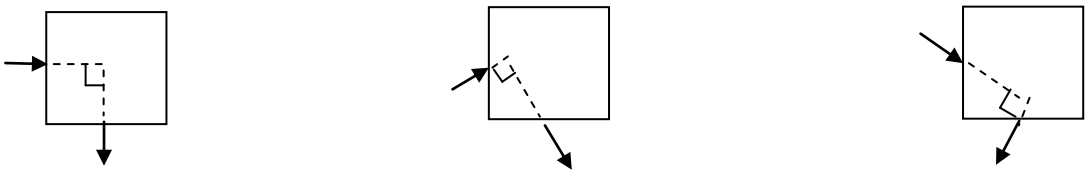

Figure 1. The conventional bender can only turn the beam path at fixed angle no matter what the incidence angle is; here is 90 degree as an example.

In this study, we propose a new kind of beam bender that can tailor the input wave path to different bending angle using the same device, provided the incidence angle is set to an appropriate one. The proposed bender is transformed from the circular Eaton lens based on transformation optics (TO) [2], with planar input and output surfaces. As a characteristic of the Eaton lens, the incident angle of the ray equals to its emergence angle on the boundaries; therefore, when transformed to rectangle, this feature turns to be an arbitrary angle bender that the turning angle of the ray path is controlled by the incident-angle. The space mapping and this bending-control principle are shown in Fig.2.

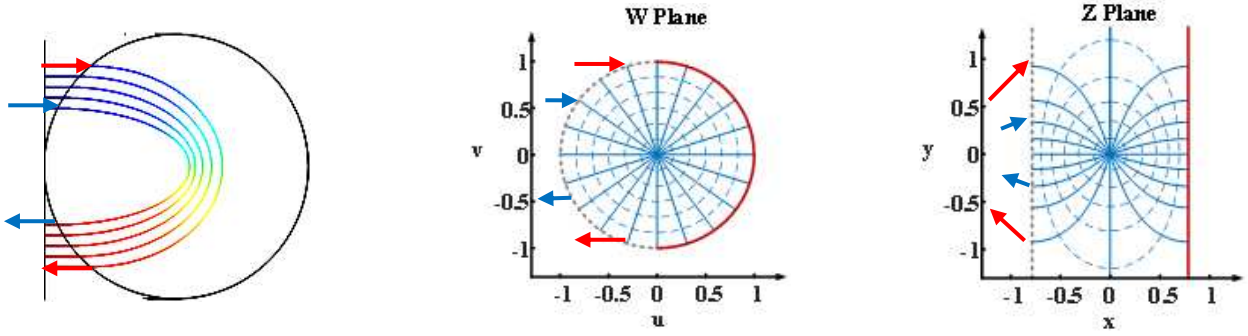

Figure 2. The multi-angle bending control principle. Left: the ray path in the circular Eaton lens; mid: the original space before the mapping; right: the transformation space after the mapping, where, as a result, different incident angle will have different emergence angle on the boundaries.

The effectiveness of the bender is verified by numerical simulations, as shown in Fig.3, which clearly shows that the same device can provide quite wide range of beam bending angles, even can greater than 180 degree. Such a multi-angle angle beam bender may greatly improve the flexibility and conveniences of wave path manipulation.

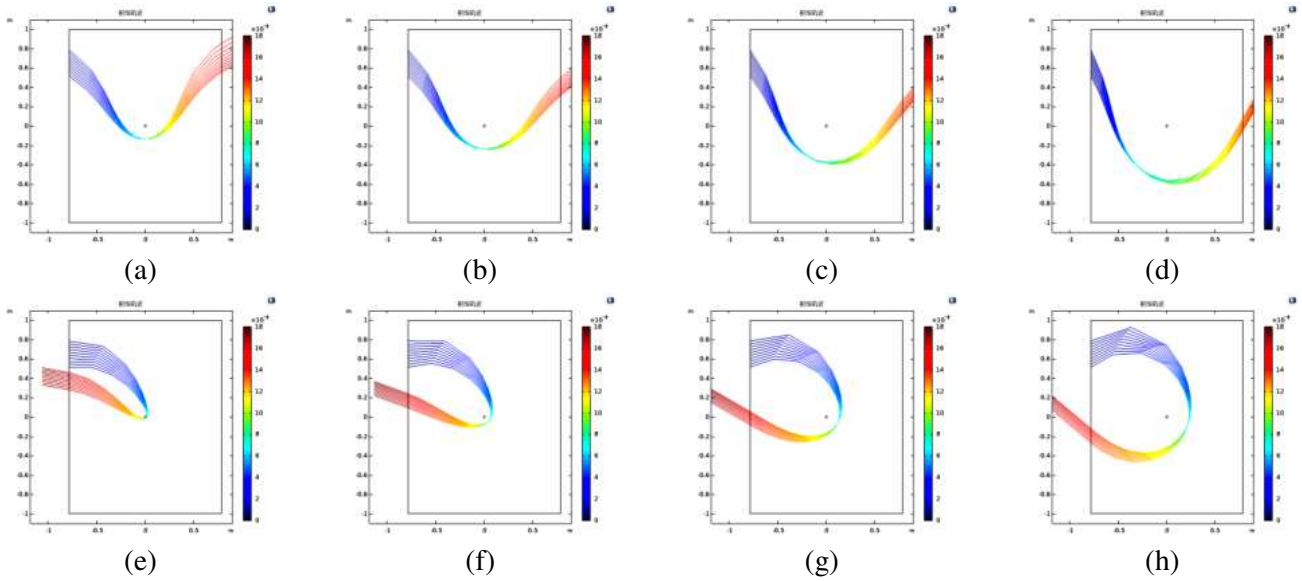

Figure 3. The simulation results of the wide range angle beam bender. (a) 60 degree bending with incident and emergence angles are 30 degree; (b) 80 degree bending with incident and emergence angles are 40 degree; (c) 100 degree bending with incident and emergence angles are 50 degree; (c) 120 degree bending with incident and emergence angles are 60 degree;(e) 200 degree bending with incident and emergence angles are 100 degree; (f) 220 degree bending with incident and emergence angles are 110 degree; (g)240 degree bending with incident and emergence angles are 120 degree; (h) 260 degree bending with incident and emergence angles are 130 degree.

Computer-generated holography and its applications to metasurfaces

Kexuan Liu[1], Yunhui Gao[1], Jiachen Wu[1], Zehao He[1], and Liangcai Cao[1*]

Abstract: Optical metasurfaces offer unprecedented light manipulation capabilities for various applications including holography. In this talk, we introduce the general inverse problem approach for computer-generated holography and discuss its potential applications with the emerging field of optical metasurfaces.

Computer-generated holography (CGH), as a powerful means of light field control, has important applications in computational display and imaging with the help of diffractive optical elements and metasurfaces. Typically, the hologram for optical reconstruction is obtained by solving an ill-posed inverse problem. The reconstruction quality of CGH is greatly limited by the accuracy of the forward model and the reliability of the inverse solver. Currently, realizing high-speed and high-quality hologram generation remains a key challenge, and iterative optimization algorithms and deep learning algorithms provide promising solutions.

In this talk, we present a general inverse problem approach for CGH. CGH algorithms based on numerical optimization and deep learning will be briefly introduced and analyzed. Specifically, model-based deep learning methods, which combine the unique advantages of both model-based methods and deep learning methods, will be highlighted and discussed in detail. [1] We demonstrate the realization of high-speed, high-quality 4K hologram generation with the recently proposed 4K-DMDNet.[2]

While conventional CGH has primarily been realized using liquid-crystal spatial light modulators (SLMs), optical metasurfaces offer unique light manipulation capabilities that are favorable in holographic applications. This talk will conclude with a discussion on the potential application of metasurfaces in the field of holography, particularly towards higher dimensions and higher information capacity.[3]

Super-Resolution Exciton Imaging of Nanodefects in 2D Semiconductors

Jia-Tai Huang[1], **Benfeng Bai**[1*]

[1]State Key Laboratory of Precision Measurement Technology and Instruments, Department of Precision Instrument, Tsinghua University, Beijing 100084, China
[*]corresponding author: baibenfeng@tsinghua.edu.cn

Abstract: The nanodefects in Two-dimensional (2D) semiconductors rise during growth and transfer inevitably and may significantly alter the optoelectronic properties of composed devices. We provide a near-field nanophotoluminescence method that can investigate their impact on local excitonic properties of 2D semiconductors with a very high spatial resolution of 10 nm.

2D semiconductors, such as transition metal dichalcogenides, have emerged as important candidate materials for next-generation chip-scale optoelectronic devices with the development of large-scale production techniques, such as chemical vapor deposition (CVD). However, 2D materials need to be transferred to other target substrates after growth, during which various micro- and nanoscale defects, such as nanobubbles, are inevitably generated. These nanodefects not only influence the uniformity of 2D semiconductors but also may significantly alter the local optoelectronic properties of the composed devices. Hence, super-resolution discrimination and characterization of nanodefects are highly demanded. Here, we report a near-field nanophotoluminescence (nano-PL) microscope that can quickly screen nanobubbles and investigate their impact on local excitonic properties of 2D semiconductors by directly visualize the PL emission distribution with a very high spatial resolution of ~10 nm, far below the optical diffraction limit, and a high speed of 10 ms/point under ambient conditions.

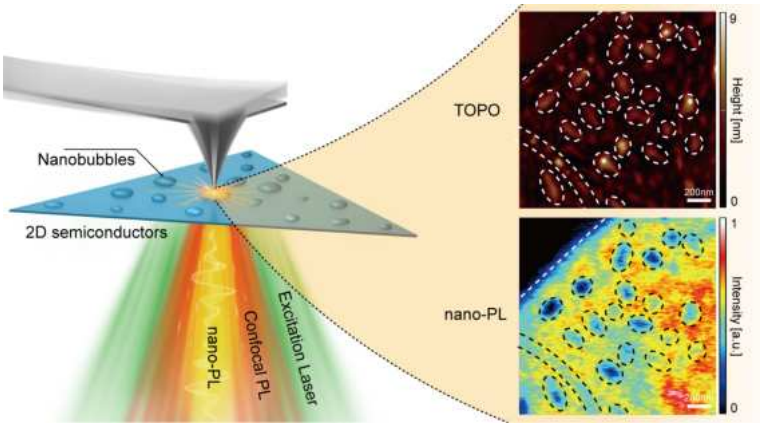

Figure 1. Left: Schematic illustration of the working principle of the nano-PL method. Right: Topography and nano-PL mapping images of the 1L-WS2 sample obtained with the nano-PL system simultaneously.

By using nano-PL microscopy to map the exciton and trion emission intensity distributions in transferred CVD-grown monolayer tungsten disulfide (1L-WS2) flakes, it is found that the PL intensity decreases by 13.4% as the height of the nanobubble increases by every nanometer, which is mainly caused by the suppression of trion emission due to the strong doping effect from the substrate. In addition to the nanobubbles, other types of nanodefects, such as cracks, stacks, and grain boundaries, can also be characterized. The nano-PL method is

proven to be a powerful tool for the nondestructive quality inspection of nanodefects as well as the super-resolution exploration of local optoelectronic properties of 2D materials.

Abstract: An abstract section (limited to 50 words max) should appear on the top of the page, after the names of the authors and the contact information of the corresponding author.

In epsilon-near-zero (ENZ) materials, second-harmonic generation (SHG) is significantly enhanced but the oblique incidence is required to address nonlinearity. We show that Au meta-atoms on an indium-tin-oxide (ITO) layer provide an approximately 10^4-fold experimentally measured SHG enhancement at normal incidence at the fundamental wavelength near the ENZ condition of ITO.

Abstract: We demonstrated a compact metasurface array-based spectroscopic ellipsometry system that allows single-shot spectropolarimetric detection and accurate determination of thin film properties without any mechanical movement.

Spectroscopic ellipsometry is widely adopted in semiconductor processing, such as in the manufacturing of integrated circuits, flat display panels, and solar cells. However, a conventional spectroscopic ellipsometer, as shown in Fig.1a, typically modulates the polarization state via mechanical rotation of the compensator or analyzer[1-2]. For spectral detection, it either requires wavelength scanning or the use of a multi-channel spectrometer[3-4]. The resulting system is often bulky, complex, and require multiple measurements.

Here, we proposed and experimentally demonstrated a compact metasurface array-based system for single-shot spectroscopic ellipsometry measurement, as shown in Fig.1b. The proposed system utilizes a silicon-based metasurface array to encode the full Stokes polarization spectrum of light reflected from the thin film. Subsequently, the polarization and spectral information is decoded based on the intensity signals collected by a CMOS sensor using convex optimization algorithms. It can reconstruct the full Stokes polarization spectrum of the thin film, which then further allow the determination of film thickness and refractive index. This approach significantly simplifies conventional spectroscopic ellipsometry systems and enables single-shot thin film parameter measurements.

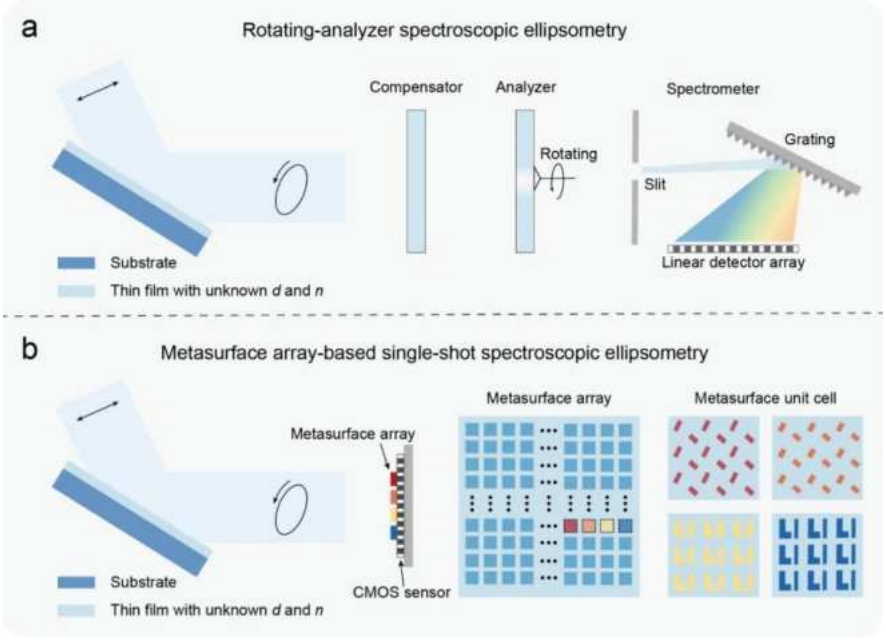

Figure 1. Comparison between conventional (a) and metasurface array-based (b) spectroscopic ellipsometry. a,

Schematics of a conventional spectroscopic ellipsometry system. b, Schematics of a metasurface array-based single-shot spectroscopic ellipsometry system.

The spectropolarimetric detection section of the ellipsometer is composed of a metasurface array integrated onto a commercial CMOS sensor, resulting in an extremely compact system. The metasurface array consists of 20 × 20 optimized elements designed to support anisotropic and spectrally-diverse response, ensuring accurate reconstruction of the full Stokes polarization spectrum. In this work, five SiO_2 thin films with thicknesses ranging from 100 nm to 1000 nm deposited on a silicon substrate were selected as samples for testing. The fitted thicknesses and refractive index dispersions of the tested thin films closely matched the ground truth obtained from a commercial spectroscopic ellipsometer, with errors of only 2.16% and 0.84% for thickness and refractive index measurements, respectively.

The metasurface array also holds promise for spectropolarimetric imaging[5-7], which may further allow the non-destructive characterization of spatially-inhomogeneous thin films. Our approach opens up a new pathway towards a compact and robust spectroscopic ellipsometry system for the high throughput measurement of thin film properties.

Abstract: In this talk, I will introduce metasurface-enabled advanced imaging techniques: (1) Electrically tunable varifocal metalens and point cloud generating metasurface for 3D depth imaging, (2) Dual-mode metalens for switchable bright-field and edge-enhanced imaging (3) Multifunctional metalens for photoacoustic microscopy

Metamaterials or metasurfaces – materials that are engineered to have properties that are not found in natural materials – allow us to overcome physical limitations. Metasurface science is further not only expanding field of optics and photonics by providing ultra-compact and multifunctional flat optical devices, also resolves challenging problems in diverse sectors like healthcare, optical display, imaging, and military affairs.

In this talk, I will introduce metasurface-enabled wavefront engineering applications, especially advanced imaging technologies. First, I will explain an electrically tunable varifocal metalens that operates at visible wavelengths and a point cloud generating metasurface for advanced 3D depth imaging or LiDAR applications [1,2]. The electrically tunable varifocal metalens will enable solid-state zoom tuning camera. The point cloud generating metasurface is able to spread 10K dots over 2π full space with over 80% diffraction efficiency, which is promising for scanning-free LiDAR technology. Second, I will show a dual-mode metalens integrated with a liquid crystal cell that can be electrically switched between bright-field and edge-enhanced imaging on the millisecond scale [3]. We demonstrate the focusing and vortex generation ability of the metalens under different states of circular polarization and prove its use for biological imaging. Third, we will introduce metasurface-enhanced photoacoustic microscopy for label-free biomedical imaging. We design an achromatic transmissive lens for 266 and 532 nm wavelength with NA of 0.8 for multispectral photoacoustic microscopy [4]. Also, we demonstrate a diffraction-limited needle beam generating metasurface with an aspect ratio of 260 (along the beam propagation direction) for deep tissue photoacoustic imaging.

Monocular polarimetric metalens for ultracompact snapshot stereo-imaging

Shuming Wang[1]

[1] National Laboratory of Solid State Microstructures, School of Physics, Nanjing University, Nanjing 210093, China

[*]corresponding author: wangshuming@nju.edu.cn

Abstract: We propose a non-interfering, all-Stokes imaging polarimeter based on a single-layer metasurface to demonstrate the stereo-imaging in an ultracompact size.

Polarization, as an optical degree of freedom, provides spatially varying information that can be detected through polarization imaging. Analyzing the polarized reflection information of objects represents a rapid, passive, and interference-resistant monocular three-dimensional (3D) depth recovery method. Metasurfaces, as subwavelength-scale 2D arrays, offer versatile control over the wavefront and polarization of light. In this paper, we propose a non-interfering, all-Stokes imaging polarimeter based on a single-layer metasurface. This polarimeter achieves compact snapshot coverage of the entire Poincaré sphere for full polarization information acquisition, overcoming the inherent limitations of 50% efficiency in conventional polarizers. We explore a matching algorithm for 3D reconstruction, providing a comprehensive technical roadmap for monocular detection. The achievable minimum pixel accuracy of our system is 5 μm, paving the way for high-resolution polarization cameras. Innovatively introducing circular polarization information into the 3D reconstruction system enhances surface detail and texture information, especially for miniature and circular objects. This breakthrough provides an ultra-compact depth perception platform for applications such as face recognition and visual systems for automotive robots.

Towards thinner imaging systems with Huygens' spaceplates

F. J. Díaz-Fernández[1,2], L. M. Máñez-Espina[1], A. Díaz-Rubio[1], and V. Asadchy[2,*]

[1]Universitat Politècnica de València, Camí de Vera s/n, Valencia 46022, Spain

Abstract: Spaceplates are designed to replace free-space gaps in optical systems. We show that by leveraging Huygens'-type condition in a photonic crystal slab supporting two resonance modes it is possible to strongly enhance spaceplates characteristics and make it transparent across a wide frequency range, laying the foundation for multicolor spaceplate systems.

The advent of spaceplates marks a significant development in non-local metasurfaces, enabling the compression of the optical path in systems between the detector and the lens. Unlike traditional optics advancements that focused on miniaturizing lenses and sensors, spaceplates manipulate the intervening space [1,2]. They reduce the optical system's free space, effectively decreasing its size by the factor called reduction ratio $h_{\text{eff}}/h_{\text{s}}$, where h_{s} and h_{eff} are the actual spaceplate thickness and the thickness of an air slab it can emulate, respectively (see illustration in Figure 1). Primarily, spaceplates aim to compact optical systems, benefiting devices from smartphone cameras to medical instruments, potentially fostering new human body study techniques. Recently, the spaceplates have been achieved based on the Fano resonances in photonic crystal slabs [2] and Fabry-Perot resonances in multilayer films [3,4]. In both cases, the required properties have been produced with a single resonance or by cascading structures with the same-type (with even or odd symmetry) resonances.

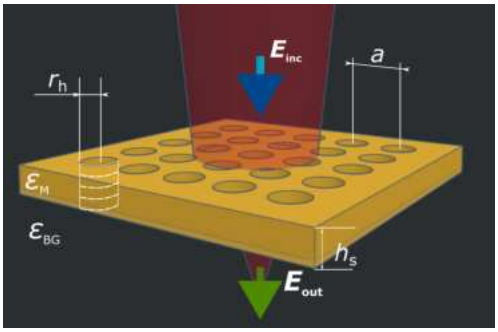

Figure 1. Spaceplate concept. The spaceplate slab with thickness h_{s} emulates an air slab of thickness h_{eff}. The spaceplate allows for a decrease in the air distance between any optical component. For example, in the figure, the convergence of an optical beam is enhanced through interaction with the spaceplate.

In this study, we study the performance limits of spaceplates with two spectrally overlapped even and odd (orthogonal) resonances and demonstrate strong enhancement of the reduction ratio. The spectral overlap of resonances with opposite mode symmetries, fulfilling the so-called Huygens' condition, has been utilized over the past decade through Huygens' metasurfaces [5]. Very recently, a similar idea of combining two resonances in spaceplates was suggested in [6] based on the susceptibility model, however, the model is recognized for its complexity in application to optical designs, and no feasible geometry has been presented. Our results

demonstrate that the overlap of two orthogonal resonances in a spaceplate not only doubles its reduction ratio $h_{\text{eff}}/h_{\text{s}}$, but also drastically expands its operational bandwidth and transparency window. Additionally, we explore the use of nearly overlapping resonances, examining their performance beyond the Huygens' configuration.

Figure 2 compares the conventional (single-resonance) and proposed Huygens' (double-resonance) spaceplates. The notations used in the figure are explained in its caption. From the second raw of plots, one can observe the double enhancement of the reduction ratio $\Phi \sim h_{\text{eff}}/h_{\text{s}}$ and full-transparency regime for large range of frequencies and incident angles available only in Huygens'-type spaceplates.

In the presentation, we will show the developed temporal coupled-mode theory for such Huygens'-type spaceplates and several realistic designs of them implemented based on a photonic-crystal-slab geometry [7].

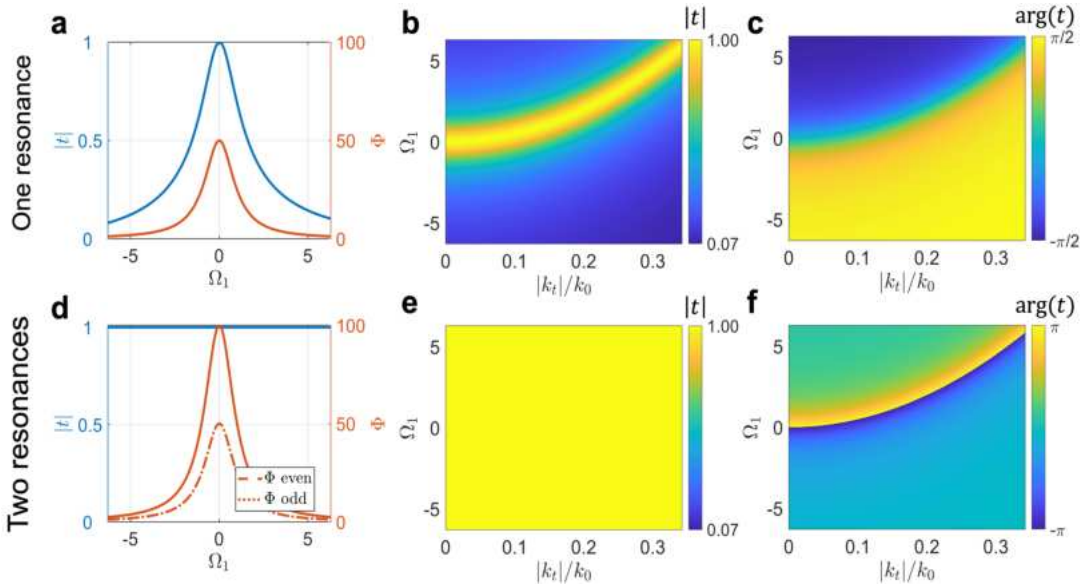

Figure 2. Comparison of conventional (a-c) and Huygens'-type (d-f) spaceplates. For the latter, the electric and magnetic resonances share the same frequency. (a,d) Transmission coefficient for normally incident light (blue) and compression parameter Φ proportional to $h_{\text{eff}}/h_{\text{s}}$ for the conventional (top) and Huygens'-type (bottom) spaceplate. Ω_1 is the frequency shift with respect to the resonance frequency of the spaceplate and normalized by the resonance width. (b,e) Transmission coefficient amplitude and (c,f) phase of the spaceplate versus frequency and the incident angle defined as asin($|k_t|/k_0$).

Abstract: Meta-device is a new type of flat optical device composed of artificial nanostructures that can manipulate the incident electromagnetic wave. We developed varifocal meta-lenses to manipulate the focusing spot for bioimaging and 6G communication from 1D to 3D.

Introduction

The manipulation of focused light beams is widely used in our lives, such as camera lenses and signal transmission. Although there are traditional lenses that realize off-axis focusing, the requirements of tilting need extra space, and the tilting stage hinders its compact integration. These disadvantages hinder the development of device miniaturization or increased construction complexity. Meta-devices composed of artificial nanostructures can manipulate the incident electromagnetic wave's phase, polarization, and amplitude. Here, we demonstrate Moire meta-devices for focal length tuning in the z-axis (1 dimensional, 1D), focal spots manipulation in the x-y plane (2 dimensional, 2D), and x-y-z axis (3 dimensional, 3D).

Results and Discussion

Following the Moiré technique, a variable focus dielectric meta-device in 1D is designed and implemented for high-contrast optical sectioning fluorescence microscopy at the visible spectral region in Fig 1(A). Fig.1(B) shows the designed phase, and the SEM images. Measured focus beam profiles of the varifocal meta-devices along the propagation direction under different rotation angles (θ = 180-350°) in a step of 30° are shown in Fig.1(C). The focal length can be tuned from 20 mm to 10 mm, which is a function of rotation angle (θ) and decreases with the increasing relative rotation angles of the metasurfaces. We demonstrated telecentric imaging equipped with variable focus meta-lens, which performs high-contrast multi-plane fluorescence imaging for mouse intestine tissue samples, as shown in Fig.1(D).

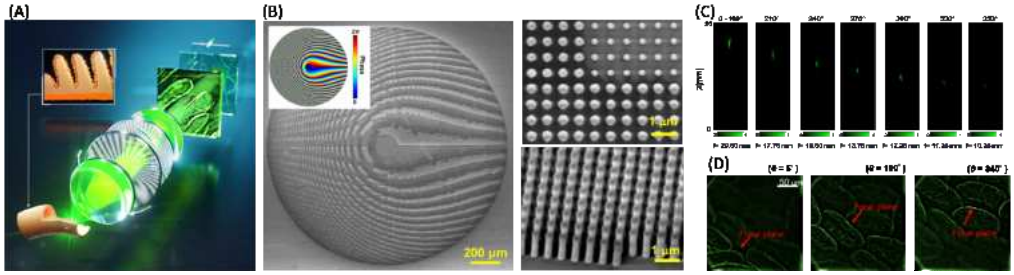

Fig. 1. Varifocal meta-devices for 1D. (A) 1D varifocal for bio-imaging. (B) SEM images of meta-devices. Insert image is the designed phase. (C) focusing profile of varifocal in the z-axis with various rotation angles. (D) Bio-imaging of mouse intestine tissue with different focus depths by this meta-device.

The synthetic phase design of rotary doublet Airy beam and triplet Gaussian beam varifocal meta-devices to fully control the 300GHz beam's propagation direction and coverage area are shown in Fig.2(A-B) and (D-E), respectively. The focusing spot can be delivered to arbitrary positions in a two-dimensional plane or a three-dimensional space, as shown in Fig.2(C) and (F), respectively. The highly concentrated signal can be delivered to a specific position, and the transmission direction can be adjusted freely to enable secure, flexible, and high-directivity 6G communication systems. This metasurface technology avoids the high costs associated with extensive use of active components (e.g., pin diodes and varactor diodes). 6G communication systems, wireless power transfer, zoom imaging, and remote sensing will benefit from the large-scale adoption of such a technology.

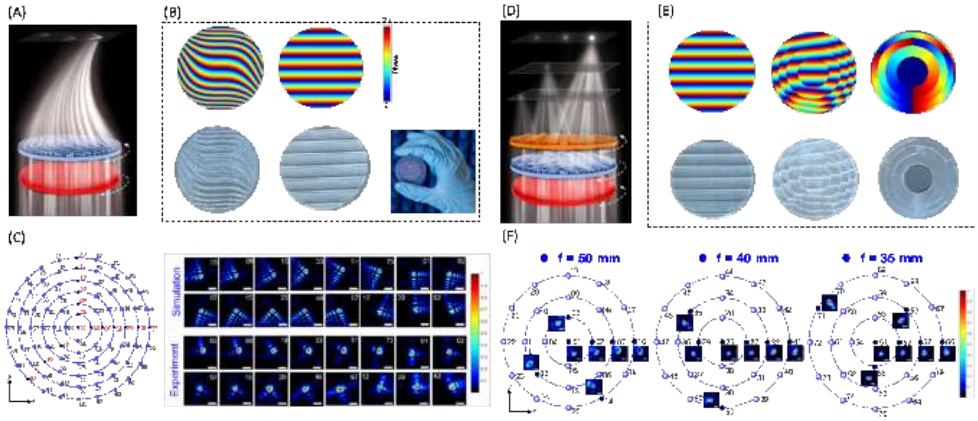

Fig. 2. (A) Varifocal meta-devices for 2D manipulation. (B&E) Designed phase and fabrication sample by 3D printing. (C) Varifocal focusing map in 2D. (D) Varifocal meta-devices for 3D manipulation. (F) Varifocal focusing map in 3D.

Summary

We demonstrate Moire meta-devices for the focal spot tuning in 1D, focal spots manipulation in 2D and 3D. The varifocal meta-devices are used for bio-imaging and 6G signal transmission. We show the telecentric imaging equipped with variable focus meta-lens, which performs high-contrast multi-plane fluorescence imaging for mouse intestine tissue samples. The sixth-generation (6G) communication technology is being developed in full swing and is expected to be faster and better than the fifth generation.

Subnanometer-matter's Farfield Optical Fingerprints and Metrology Applications

Xue-Wen Chen[1,2*]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, China.
[2]Wuhan Institute of Quantum Technology, Wuhan, China.
[*]Corresponding author: xuewen_chen@hust.edu.cn

Abstract: We report that subnanometer-dielectric surface undulations feature deterministic and pronounced speckles in the farfield via interference scattering microscopy. We show they could serve as the optical fingerprints of the dielectric substrate surface. Consequently, we demonstrate their applications for marker-free position identification and displacement sensing with sub-nanometer precisions.

Interferometric scattering microscopy, as an ultrasensitive fluorescence-free imaging modality, has recently gained enormous attention and has been rapidly developing from demonstration of principle to quantitative sensing and bioanalytics. A substrate, such as a coverslip or wafer, is an indispensable component of any modern optical microscope. The interaction between the substrate and sample naturally imprints the substrate's signatures into the observations, in particular, for interferometric scattering microscopy, where the image directly relies on the interference between the reflected/transmitted field from the substrate surface and scattering of the sample. Thus, typical microscope substrates used in the laboratory, such as glass coverslips, have been made extremely at, often with surface roughness well below 0.5 nm. However, even employing such flat substrates, images obtained in interferometric scattering microscopy still exhibit seemingly mysterious “random" speckle patterns, which have been speculated to originate from combined effects of uncontrollable imperfections including uneven illumination, glass inhomogeneity, surface roughness, dust, or stray light in the setup. The speckles set a lower limit for the size of detectable scatterers.

In this talk, we report that substrates commonly used in the laboratory feature deterministic speckle patterns in interference microscopy, which originate, counterintuitively, from the sub-nanometer surface roughness [1]. We show they serve as the optical fingerprints of the substrate surface. We demonstrate their applications for marker-free position identification and displacement detection with sub-nanometer precisions, which are essential for many modern technologies, including positioning of wafers in the semiconductor industry and accurate localizations of single-molecule labels in super-resolution microscopies. We also discuss approaches to remove the speckle pattern [2].

We acknowledge partial financial support from the National Natural Science Foundation of China (Grants No. 92150111 and No. 62235006).

Photothermal inspection of optoelectronic chips

Xiangping Li

Institute of Photonics Technology, Jinan University, P.R.China
*corresponding author: xiangpingli@jnu.edu.cn

Abstract: In this paper, we report the microscopic excitation and imaging of dielectric Mie resonators. The interaction of tightly focused vector beams with dielectric nanoparticles leads to exotic phenomena including multipolar excitation by displacement resonances, directional scattering, as well as superresolution imaging.

The studies of Mie scattering in dielectric nanostructures reveal strong electro-magnetic multipolar resonances, laying foundation for emerging nanophotonic applications [1]. Canonically, the morphology-sensitive resonances hinge on excitations under plane wave illuminations. The tight focusing condition under microscope, a typical scenario of nanophotonics, leads to a plethora of freedom in manipulation of light-matter interactions. In this talk, we show that the confocal microscopic imaging of silicon nanostructures exhibits distinctive patterns of the scattering point spread functions, which manifests the excitation of higher-order multipolar modes associated to displacement resonance by tight focusing. In addition, the manipulation of focal field component of vector beams can lead to directional scattering of dielectric dimer structures by judicious configuring the multipolar excitations. Moreover, the strong multipolar electro-magnetic resonance by microscopic excitations empowers pronounced photothermal heating effect. At a mild light irradiance on the order of MW/cm2, it enables a giant nonlinear modulation of the confocal reflection intensity from dielectric nanostructures and their imaging patterns [2]. Thereby, it opens up an entirely new paradigm for label-free sub-diffraction imaging with a demonstrated ~λ/7 feature size [3].

Optical Information Processing on Thin Film Lithium Niobate

Mengjie Yu

Department of Electrical and Computer Engineering, University of Southern California, Los Angeles, CA 90089, United States
E-mail: mengjiey@usc.edu

Abstract:

Lithium niobate (LN) is an excellent nonlinear photonic material due to its large electro-optic (EO) coefficient, second order ($\chi^{(2)}$) and Kerr ($\chi^{(3)}$) nonlinearity, along with a wide optical transparency window. Thanks to the recent advances in nanofabrication technology, monolithic LN waveguides with high optical confinement and ultralow linear loss has been achieved, which was critical to the success of the silicon-based platform in the past decade. Highly efficient and controllable light-matter interactions can be achieved using optical, electrical, or mechanical waves at extremely compact footprints. In this talk, I will review our recent developments of generation and measurement of ultrafast optical waveforms, optical modulation for free space communication and optical neutral network on thin-film LN nonlinear platform.

Quantum metamaterials for artificial intelligence

Analyzing qubit arrays via a multiresolution approach

M. Bidarvand[1*], A. Sowa[1]

[1]University of Saskatchewan, Canada
[*]corresponding author: mab867@usask.ca

Abstract: Utilizing a multiresolution approach, we analyze the properties of infinite qubit arrays. Our method merges the classical Borel isomorphism and the Haar basis, connecting the qubit system's Hilbert space to $L_2(0,1]$. This furnishes a geometric representation of fundamental operators and reveals an unexpected integration of classical calculus in this structure.

Introduction: Qubit arrays are a type of quantum metamaterial that interact with a mode of the electromagnetic field in a manner that depends on its quantum state. The fundamental problem is the solvability of mathematical models describing such systems. A systematic investigation originated in the physics literature [2, 5, 6]. Solvability of the model, with a certain choice of constituent parameters, was demonstrated in [3]. We further refine the mathematical methods introduced therein. Specifically, we use the multiresolution methods to rigorously establish a correspondence between $L_2(0,1]$ and the Hilbert space of an array of qubits, which may be finite or infinite.

The Model: We adopt the generalized Jaynes-Cummings model, which describes a system consisting of n qubits and a quantum harmonic oscillator, which represents a single mode of the electromagnetic field. In this model the Hamiltonian consists of three components, which capture the qubits, the field, and the interaction between them. The interaction part is the most important, [3]. It assumes the form

$$\mathcal{H}_I = C_x^{(n)} \otimes (\hat{a} + \hat{a}^\dagger), \tag{1}$$

with $\hat{a}$ and $\hat{a}^\dagger$ being the harmonic oscillator's annihilation and creation operators, respectively, while

$$C_x^{(n)} = \sum_{k=1}^{n} \lambda_k \, \sigma_x^k, \qquad \sigma_x^k = I \otimes \ldots I \otimes \sigma_x \otimes I \ldots \ (\sigma_x \text{ in k-th place}) \tag{2}$$

where σ_x is the Pauli matrix. Here, we provide rigorous interpretation for the limit $n \to \infty$, for a specific choice of the weights λ_k. We also discuss what happens when σ_x is replaced by, say, σ_y, which in the case of an infinite array is deeply nontrivial.

Let $\mathbb{H}_Q = \text{span}\{|0\rangle, |1\rangle\}$, so that the Hilbert space of an n-tuple of qubits is $\bigotimes_{j=1}^{n} \mathbb{H}_Q$. Naturally, one envisions the state space of an infinite array to be $\bigotimes_{j=1}^{\infty} \mathbb{H}_Q$. Viewing $\mathbb{H}_Q$ as the space of functions on $\mathbb{Z}_2$, the infinite tensor product of such spaces should embody functions on the infinite Cartesian product $\mathbb{Z}_2 \times \mathbb{Z}_2 \times \mathbb{Z}_2 \times \ldots$. The latter can be correlated with the interval $(0,1]$ through binary expansion. Moreover, the Haar basis and its associated multiresolution enable the representation of quantum states via square-integrable functions on the interval $(0,1]$. Furthermore, operations on states can be represented through integral operators, typically with distributional kernels. This structural setup simplifies the characterization of the spectral properties of the central operators. A key example is C_x (i.e., the $n \to \infty$ limit of $C_x^{(n)}$), which takes on the form

$$C_x[\Phi](x) = \sum_k \frac{1}{2^k} \Phi\left(x + \frac{(1)^{\epsilon_k(x)}}{2^k}\right) \quad x \in (0,1], \tag{3}$$

for a continuous function Φ. Note that $\epsilon_k(x) \in \{0,1\}$ denotes, the k-th digit in the dyadic expansion of $x \in (0,1]$, i.e.

$$x = \sum_{k=1}^{\infty} \frac{\epsilon_k(x)}{2^k}.$$

As it turns out, the Haar transform reduces the operator (4) to a block matrix with consecutive diagonal blocks increasing in size, see Fig. (1) . This is sufficient to characterize the spectrum of C_x. Perturbing the entire array along the Bloch sphere, we are led to consider

$$C_y[\Phi](x) = \sum_k \frac{(-1)^{\epsilon_k(x)} i}{2^k} \Phi\left(x + \frac{(-1)^{\epsilon_k(x)}}{2^k}\right) \quad x \in (0,1]. \tag{4}$$

At first glance, one might expect a similar scenario for C_y as for C_x, given the unitary equivalence between σ_x and σ_y. However, the situation is more intricate: the Haar transform fails to convert C_y into a block matrix. Instead, C_y emerges as the combination of such an operator and a compact operator.

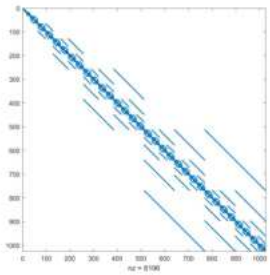

Figure 1: The block matrix representing C_x in the Haar basis.

The block structure remains the same for C_x and C_y (with different numerical entries). The aforementioned necessary compact correction, denoted K, is defined as follows:

$$K = i(L' - L), \qquad L[u](x) = \int_0^x u(y)dy, \tag{5}$$

where L'represents the adjoint of L. Defining operators

$$C_- = \sum_{k=1}^{\infty} \frac{1}{2^k}\, \sigma_-^k, \quad C_+ = \sum_{k=1}^{\infty} \frac{1}{2^k}\, \sigma_+^k, \tag{6}$$

where $\sigma_\pm$ are the raising/lowering operators, we obtain

$$C_y = i((C_+ + L') - (C_- + L)) - K. \tag{7}$$

The first two terms turn into block matrices when represented by the Haar transform.

Conclusion: As is well known, due to the exponential dependence of the underlying Hilbert space dimension on the number of qubits, generic classical simulations of quantum systems have scaling limitations. Furthermore, the standard approaches to quantum many-body theory often ignore real quantum effects in favor of roughly factorized quantum states. Quantum engineering has great potential due to the fact that it can harness the quantum correlations seen in non-factorized states, [4]. The explicitly solvable quantum models, like the ones discussed here, provide unique insight that could not be obtained via simulation. The conceptual framework presented here amounts to an alternative, scale-based, model of quantum information. While it is equivalent to the canonical one, it provides advantage in certain types of analysis. In particular, it enables rigorous analysis of systems that comprise an infinite number of qubits.

Effects of Strong Capacitive Coupling Between Meta-Atoms in Three-Dimensional rf SQUID Superconducting Metamaterials

Jingnan Cai[1], Yilin Li[1], and Steven M. Anlage[1*]

[1] Quantum Materials Center, Physics Department, University of Maryland, College Park, MD 20742-4111 USA
[*]corresponding author: anlage@umd.edu

Abstract: We model and measure a nonlinear three-dimensional superconducting metamaterial with qualitatively new properties enabled by strong capacitive coupling between the meta-atoms. The new form of coupling creates a multitude of resonant modes. The model is verified with rf current images produced by laser scanning microscopy of the operating metamaterial.

Superconducting macroscopic quantum metamaterials have been of interest since the first experimental demonstration in 2005 [1-4]. We consider, for the first time, the effects of strong capacitive and inductive coupling between radio frequency Superconducting Quantum Interference Devices (rf SQUIDs) in a three-dimensional overlapping metamaterial geometry when driven by rf flux at and near their self-resonant frequencies [5]. The equations of motion containing the gauge-invariant phases on the Josephson junctions in each SQUID are set up and solved which include the high-frequency displacement currents through capacitive overlap between the wiring of SQUID loops. We begin by modeling two overlapping SQUIDs and studying the response in both the linear and nonlinear high-frequency driving limits. By exploring a sequence of more and more complicated arrays, the formalism is eventually extended to the $N \times N \times 2$ overlapping metamaterial array, where we develop an understanding of the many $(8N^2 - 8N + 3)$ resulting resonant modes in terms of three classes of resonances. The capacitive coupling gives rise to qualitatively new self-resonant response of rf SQUID metamaterials, and is demonstrated through analytical theory, numerical modeling, and experiment in the 10-30 GHz range on capacitively and inductively coupled rf SQUID metamaterials [5]. To further investigate the predictions of the theory, we image the rf current distributions in the SQUID metamaterial while it is under rf magnetic flux illumination in the superconducting state, by means of laser scanning microscopy [6]. We also discuss the use of machine learning to design structured light perturbations to bring the rf SQUID metamaterial into coherent oscillation.

Point defect-based material solutions for quantum sensing and quantum reservoir computing

V. Ivády[1,2,3,*]

Abstract: Point defects with controllable electron and nuclear spin states provide a versatile toolbox for developing quantum applications in the fields of sensing, information processing, and computation. My talk outlines the physics of point defect quantum bits and discusses recent advances in light of sensing and quantum reservoir computing.

Quantum applications are about to revolutionize several key areas of science and technology, including but not limited to computation, communication, and sensing. Quantum bits (qubits) realized by point defects in semiconductors are the building blocks for several of these developing applications. For example, the unprecedented properties of point defect qubits have opened new horizons for nano-scale sensing in material science and biology. Point defect qubits are complex atomic-scale structural imperfections in wide-bandgap semiconductors that can be comprehensively characterized by measurements and first-principles calculations.

Point defect qubits that utilize both the optical and the spin degree of freedoms exhibit extraordinary controllability and long coherence time. Their most prominent representative is the NV center in diamond1, which can be read out by electrical and optical means, remain coherent as long as 1.8 ms at room temperature, and operate at high temperatures up to 1000 K. Besides the NV center, the divacancy in silicon carbide [1] (SiC) and the silicon vacancy in SiC [2] have recently gained considerable interest in the field of quantum sensing and quantum computation, respectively. In particular, 64 ms coherence time, 30% room temperature read-out contrast, emission at the edge of the O-band (~1100 nm) with lifetime limited linewidth, and spin-to-photon conversion are only the most recent demonstrations in SiC that underline the potential of this material for advanced quantum technologies.

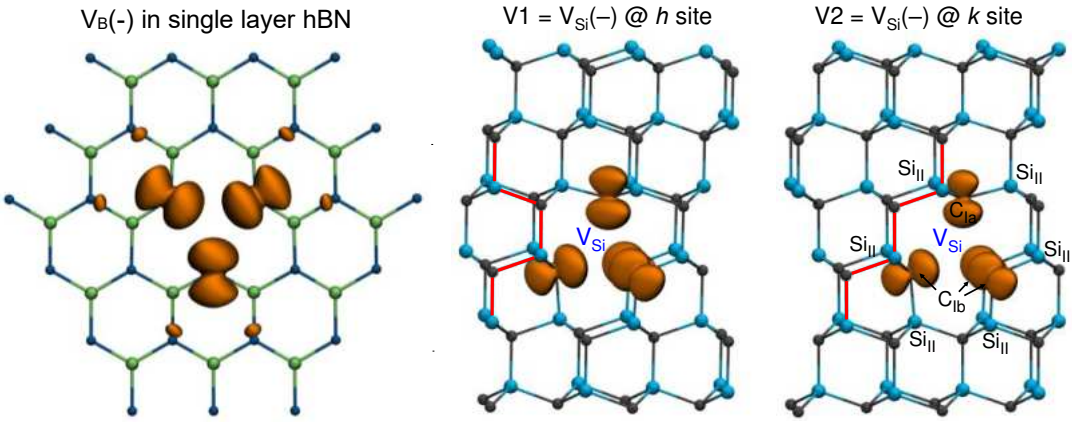

Fig. 1. The spin density of a) the boron vacancy in single-layer hexagonal boron nitride and b), c) the silicon vacancy in the 4H polytype of silicon carbide. b) and c) the so-called *h* and *k* site of the defect in 4H-SiC.

It is worth noting, however, that there are countless qubit candidates in diamond, SiC, and other wide-bandgap semiconducting materials. Very recently, two-dimensional semiconductor hosts have gained considerable attention due to their rich physics with potential technological advantages over their bulk counterparts. The negatively charged boron vacancy ($V_B(-)$) [3] is among the first color centers in hexagonal boron nitride (hBN), whose spin could be initialized, coherently manipulated, and read out.[4] The possibility of exfoliation of hBN and the creation of vacancy centers close to the surface open new horizons for quantum sensing.[5]

In my talk, I briefly introduce the most relevant features of point defect quantum bits in wide band-gap semiconductors. In particular, I will discuss the boron vacancy in hBN and the silicon vacancy in 4H-SiC, see Fig. 1. I will discuss the properties and use of the high spin ground state of the defect in light low dimensional sensing applications and quantum reservoir computing.

An infinite array of boson sites—a rigorous approach

Artur Sowa[1]∗**, Jonas Fransson**[2]**,**

[1]Department of Mathematics and Statistics, University of Saskatchewan, Saskatoon, Canada
[2]Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden
*corresponding author, E-mail: sowa@math.usask.ca

Abstract: We demonstrate how to analyze an infinite array of boson sites with the use of the Dirichlet series. The results apply to the Bose-Hubbard model, which is of relevance to various types of physics, including anisotropic magnetism. Our approach leads to the construction of coherent states in the Fock space.

Our strategy to tackle the case of an infinite array of boson sites relies on a known device, perhaps first explored in [1] and [2]. Namely, we label the sites by primes rather than by consecutive integers. This has the effect of revealing the structure of the Fock space as that of $\ell_2(\mathbb{N})$ with a major role to play by the multiplicative number theory. In particular, some techniques of the analytic number theory become indispensable and, indeed, enable a rigorous theoretical approach to a system with infinitely many degrees of freedom. This framework emphasizes the role of the multiplicative group of positive rationals $\mathbb{Q}_+$, which was investigated in depth in [3]. While the generalized Fourier transform on $\mathbb{Q}_+$ has been part of the abstract harmonic analysis expositions, e.g., [4], it has not been applied in quantum theory before.

One of the main developments is the construction of a new type of coherent states. We refer to them as nonlocal coherent states (NCS), as indeed they are distributed over the entirety of the infinite array of sites. The NCS are structurally akin to the Dirichlet series. In particular, we discover yet another representation of the Fock space that is imprinted on a set of the Dirichlet series. This representation may be viewed as a many-body analogue of the Bargmann-Segal representation of the single-particle Hilbert space. The main technical result consists of a demonstration that NCS arise from the vacuum state via an application of a suitably defined displacement operator, an effect analogous to that known in the context of the canonical coherent states. We also obtain a suitable resolution-of-the-identity formula, based on the NCS. Furthermore, we demonstrate how the NCS lead to explicit formulas for the expectation of certain types of Hamiltonians. We also discuss additional physical insights that can be derived from the proposed mathematical approach.

The 1985 compendium, [5], features a historical introduction which states that already at that point there were over 1000 publications on the subject. Contemporarily, the 'mathscinet' displays a steady stream of mathematics publications involving CS in over half a century, with the total of over 1500 papers. A search on the 'arxiv' reveals over 5600 papers that involve the CS or the related squeezed states. However, to our best knowledge, none of the preexisting work refers in any way to the Dirichlet series which, in a way, are the centerpiece of this work.

Abstract: We report a Bloch transistor for the emerging platform of quantum electronics. The fully quantum device facilitates precise control of electronic current in quantum circuits. The transistor maintains the source-drain current at quantized values, $I=2efn$, through four controls: the gate or bias voltage and the frequency or amplitude of the microwave.

The emerging new quantum paradigm necessitates devices with functionalities that differ from their classical counterparts. The envisaged applications of these devices are quantum calculations, sensing, and imaging. We report one of these devices, the Bloch transistor (BT). It can deliver the precisely controlled quantized current $I=2efn$ (e is the charge of an electron, f is the microwave driving frequency, and n is the integer). The transistor operation is based on the manipulation of two quantum conjugates, the charge and phase in a superconducting circuit [1]. The BT operates at a bias voltage of a few microvolts and can deliver quantized current up to 10 nA. The amplitude of the quantized current is adjustable through four controls: the gate or bias voltage and the frequency or amplitude of the microwave. The design of the BT is shown in the left panel of Fig. 1. Inductances, L1 and L2 are made of TiN thin film with L_{sq}~2 nH [2]. They turn to a superconducting state at ~1.5 K. The Pd resistors R have a value ~10 kΩ. When the JJ are biased with V_b and the microwave drive is applied the quantized current steps are developed, see right panel of Fig. 1. They correspond to n =1, 2, 3. The width of the step can

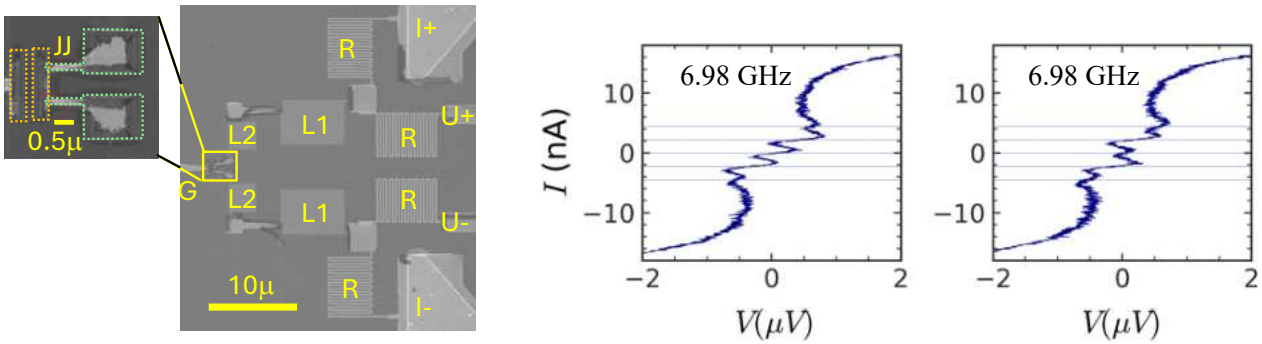

Fig. 1 Left: SEM photo of the Bloch transistor (BT). There are two JJs (blow-up) embedded in a circuit with inductances (L1, L2) and resistances (R). A gate electrode (G) serves also as the feeding line for the MW. BT needs five electrodes for operation (V+, V-, I+, I-, G). Right: Current quantization with f = 6.91GHz and two MW amplitudes, $I_{ac}/2ef$=1.44, 1.76. BT is kept at T=15 mK.

be as large as ~1 μV. One can change the width of the step and even dissolve the current steps by changing the amplitude of the drive MW. Similarly, one can change the quantized current from one to another value by changing the bias voltage. The gate control of the quantized current is shown in Fig. 2. The peaks in the intensity

plot of dV/dI correspond to the quantized current. By changing the gate voltage V_g one can change the current from the quantized value to zero and back. The last control of the BT is the frequency of the MW. By varying the MW frequency, the amplitude and position of the current can be continuously varied. In this work, we discuss the operation of the BT and explain its limits and applications.

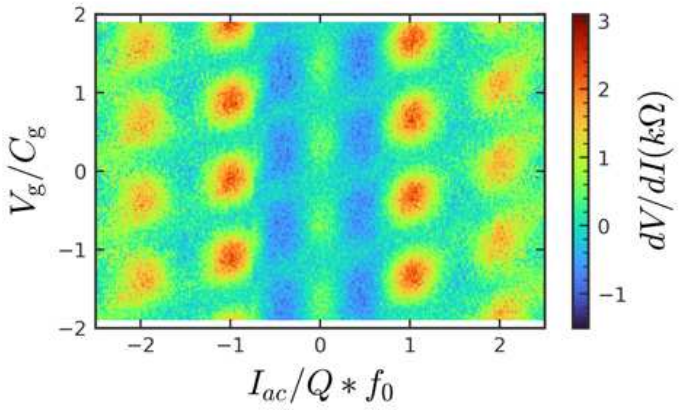

Fig. 2 Intensity plot of dV/dI in coordinates of MW amplitude and induced charge V_g/C_g. The peaks correspond to the quantized current.

Abstract: We experimentally demonstrate a driving protocol in which, in addition to the conventional AC gate drive, we also apply an AC bias drive. This improves the single-electron current accuracy by one order of magnitude and allows accurate single-electron current generation even at zero DC bias.

Hybrid turnstiles have proven to generate accurate single-electron currents that underpin electric current metrology.[1] A hybrid turnstile, nicknamed SINIS, consists of a normal-metal island tunnel coupled to two superconducting electrodes, and the island potential is controlled by the nearby gate, as shown schematically in Fig.1(a). The usual turnstile operation involves setting the working point of the device by adjusting the DC bias, V_{0b}, and gate, V_{0g}, voltages, and application of an AC harmonic signal to the gate, $V_g \sin \omega t$.[2] This corresponds to the straight pumping trajectory on the SINIS stability diagram, that links two charge states differing by one electron, as shown by the horizontal magenta line in Fig.1(b). Ideally, one electron is transferred through the device per pumping cycle resulting in the well-defined current plateaus in the transport characteristics. However, the accuracy of charge pumping at high operation frequencies is limited by the so-called back-tunnelling events when electrons tunnel in the direction against the applied bias.[3] The increase of the barrier transparency between the island and the superconducting electrodes as well as the source-drain bias suppresses these events but leads

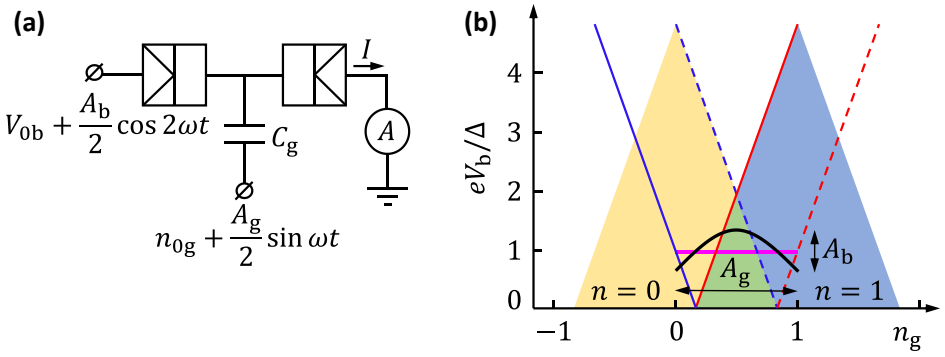

Figure 1. (a) Schematic diagram of the SINIS turnstile and measurement circuitry. (b) Stability diagram of a SINIS turnstile with two identical tunnel junctions for positive bias and gate voltages, showing two charge states (Coulomb diamonds) $n = 0$ and $n = 1$. Ideally, no current flows in the DC regime inside the Coulomb diamonds. The blue and red lines are tunneling thresholds: blue (red) corresponds to the right (left) junction, continuous (dashed) lines correspond to tunneling into (out of) the island. Crossing the line adds or removes one electron to or from the island. The horizontal magenta line is a pumping trajectory when AC signal is applied to the gate only. The black parabola is a pumping trajectory when AC signals are applied to both the gate and the bias.

to some additional errors.

We experimentally demonstrate a novel driving protocol that suppresses back-tunnelling, thus extending the range of frequencies for generating accurate single-electron currents. The main feature of this approach is an additional AC harmonic signal applied to the bias with frequency twice that applied to the gate electrode.[4] This allows additional modulation of the island chemical potential and improves the single-electron current accuracy by one order of magnitude. This can be seen in Fig.2 in which the current plateau at zero AC bias deviates strongly from the expected magnitude indicated by the dashed red line. However, the agreement becomes better when AC drive is applied to the bias. We also show that accurate single-electron currents can be generated at zero average bias voltage by applying only AC drive to the bias.[5] Furthermore, we show that within this protocol, the current direction can be reversed by shifting the phase of the source signal. Besides metrology, this novel drive method can find applications in quantum sensing and quantum computing.

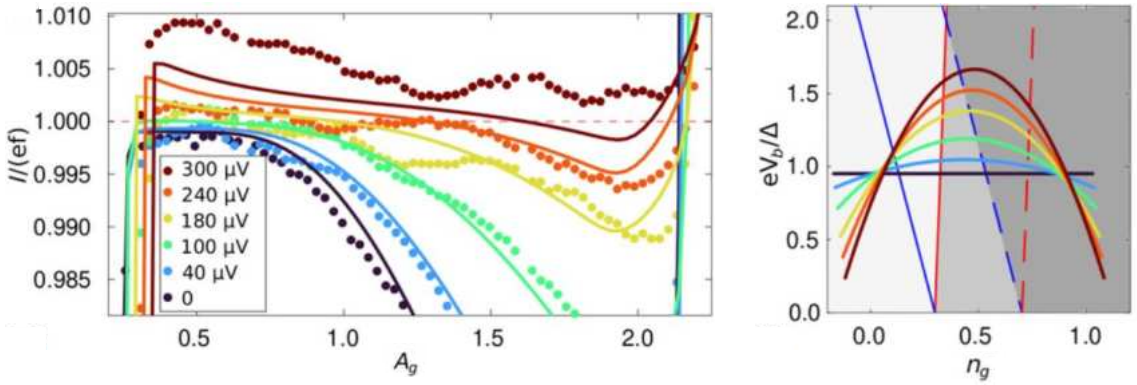

Figure 2. (a) Current plateaus using parabolic driving at $f = 5$ MHz and $V_{0b} = 200$ μV; the legend designates the peak-to-peak bias amplitude used. Dots represent measurements, solid lines simulations based on the semiclassical theory of charge tunnelling. The right panel shows the corresponding pumping trajectories.

Recent Advances in Metamaterials and their Applications

Optoelectronic metasurface based on photodiodes

Y. L. Sun[1*]

[1] State Key Laboratory of Millimeter Waves, Southeast University, Nanjing, China
[*]corresponding author: huolunyou@163.com

Abstract: We present an optoelectronic metasurface that can realize direct and efficient optical-microwave interactions in free space. This metasurface is realized by integrating microwave resonant meta-structure with photoresponsive materials. We construct an optoelectronic metasurface based on photodiodes, in which the phase of output microwave can be tuned by input laser intensity.

Interactions between light and matter are fundamental to both contemporary classical and quantum physics [1]. An enormous amount of work has been focused on how to improve and manage the interactions between matter and electromagnetic (EM) waves in various spectrum [2]. Traditionally, these kinds of interactions in the optical and microwave bands have included distinct mechanisms and approaches that are developed in parallel. However, a significant convergence is occurring at the interface between material science and information technology, due to the fast expansion of both sciences, giving rise to other emergent fields, such as lightwave electronics [3] and microwave photonics [4]. Among them, the convergence of the optical and microwave domains forms the basis for several appealing applications, including coherent quantum transduction, electro-optic modulation, microwave-to-optical conversion [5], and optically-controlled microwave transmission [6]. Many physical platforms have been built recently in order to carry out the multi-physics field coupling. Nevertheless, it is challenging for the already proven metasurfaces to react to optical and microwave simultaneously.

Here, we present and realize an optoelectronic metasurface that is able to interact with the incident optical and microwave fields simultaneously, thus generating optical-microwave coupling effects. This metasurface is achieved by integrating photosensitive materials into microwave metasurface. The hybrid integration involves a relationship between the input optical intensity and the output microwave phase. This optoelectronic metasurface is theoretically simulated and experimentally verified by a manufactured photodiode-based metasurface sample. In Figure. 1, we show the specific design of optoelectronic metasurface by employing photodiodes as the photosensitive materials integrated into metasurface units. When light and microwave irradiated on this optoelectronic metasurface concurrently, the impedance of photodiode varies by light absorption, thus leading to different microwave reflected phases. The output microwave reflected phases depend on the input light intensity. Therefore, we realize the efficient free-space interaction between the optical intensity and microwave phase. This spatial optical-microwave interaction offers a compelling foundation for a variety of applications in signal processing, energy conversion, wave manipulation, photoelectric sensing, and nonlinear microwaves.

Smart Electromagnetic Manipulation Based on Programmable Metasurfaces with Space Sensing

Yuanke Liu[1*]

[1*]Southeast University, China

Abstract: We introduce a programmable metasurface with smart control system that can detect multiple parameters of environment such as the orientation, distance and shape of an external target. Based on the detected information, electromagnetic manipulation is realized in a non-contact and self-adaptive way.

Digital coding and programmable metasurfaces develop a new way of realizing more different functions in real time. However, most programmable metasurfaces could only be triggered artificially to perform the predefined functions[1-3]. How to realize the intelligent or cognitive metasurfaces that can work without hunman intervetion are the directions of future development. Compare to the conventional control method with field-programmable gate array (FPGA), intelligent control provides an automatic way to manipulate the electromagnetic (EM) waves without human intervention[4]. In this study, we introduce a programmable metasurface with smart control system, through which non-contact electromagnetic manipulation is realized.

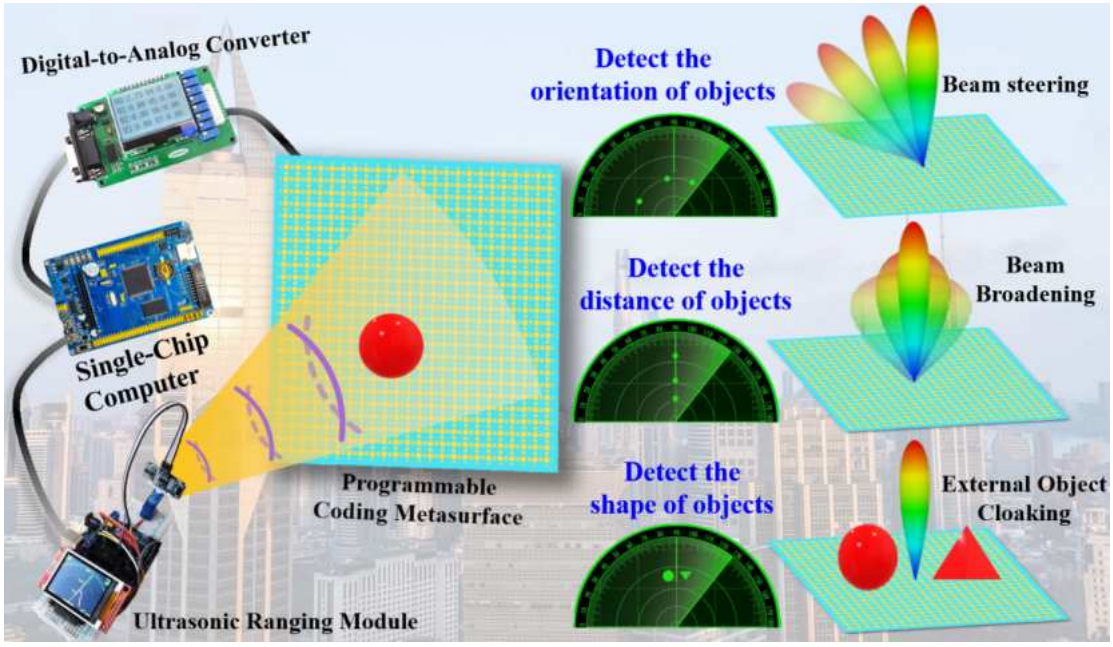

Figure 1. Schematic of the proposed self-adaptively metasurface based on ultrasonic ranging.

As shown in Figure 1, the high intelligent metasurface platform based on ultrasonic ranging that can detect multiple parameters such as the orientation, distance and shape of an external object. We integrate a broadband and full polarizations programmable metasurface a with ultrasonic ranging module, a single-chip computer and several digital-to-analog converters (DACs). By alternating the bias voltage supplied to varactor diodes

embedded on metasurface, 3-bit reflection states are achieved and each super unit cell can be controlled independently. The bias voltage sequences generated by DACs are changed according to the positional data of object captured by ultrasonic ranging module. Therefore, a non-connect and remote control of metasurface is accomplished without the intervention of human beings.

This study sets up a new paradigm for intelligent and cognitive metasurface, which is expected to find extensive applications in advanced EM device and communication system.

Abstract: We design and demonstrate topological metamaterials with an arbitrary auxiliary orbital DOF by applying continuous generalized Kekulé modulations in honeycomb surface-wave metamaterials. Three kinds of photonic platforms are constructed . The perfect electrical conductor boundaries in finite structures, the interface of the two topological metamaterials and a band-notch line-defect waveguide.

Photonic topological insulators have unique advantages as regards ensuring lossless transmission and realizing stable energy locality of electromagnetic waves. More complex requirements to manipulate discrete degrees of freedom of photons, such as orbital degree of freedom (DOF), show a great foresight. With the development of topological band theory for electromagnetics, photonics and acoustics, topological insulators can be realized by resorting to spin,[1] polarizations,[2] or valley-pseudospin DOF.[3,4] Recently, an emerging type of Nano mechanical topological systems with auxiliary orbital DOF has been introduced in integrated circuits accommodating distinct topological edge channels.[5] Similar to spin DOF, orbital DOF constitutes another fundamental attribute of Bloch waves that describes the spatial distribution of wave functions inside the unit cell of crystals. Exploration of additional DOF, particularly orbital DOF provides a powerful approach to investigate novel topological insulators. However, nanoscale platform requires a higher vacuum environment with considerable Nano membrane air damping, limiting its practical value. By adopting additional spatial [6] or temporal [7] DOF, adiabatic topological transition has been realized. However, it is difficult to apply to on-chip two-dimensional (2D) topological circuits. It will be undoubtedly promising that optimizing topological photonic circuits with the control of orbital states is achieved by using a simple solid metamaterial structure. Moreover, it is rare to report topological photonic insulators with an arbitrary auxiliary orbital DOF. Based on surface wave metamaterial microstructure, the physical mechanism to achieve additional DOF also needs to be demonstrated clearly in the domain of synthetic dimensions. [8]

To this end, we explore a more generic type of topological photonic insulator with arbitrary orbital DOF, and demonstrate the mechanism of multiple platforms carrying photonic topological states. It is expected that the present results can become an alternative means to manipulate topological phase transition, and provide a underlying platform for exploration of additional DOF. The novelty of the work is shown as follows:

1. By applying continuous generalized Kekulé modulations in honeycomb surface-wave metamaterial

lattice, translational symmetry and mirror symmetry are broken, we explore a more generic type of topological photonic insulator with arbitrary orbital DOF.

2. By setting different boundary conditions in finite structure, we construct three kinds of photonic platforms carrying abundant topological phenomena, including the perfect electrical conductor boundaries of finite topological phase structure, the domain wall interface consisting of two topological phase structures, and the line-defect channels.
3. We investigate 1D edge states and 0D corner states with auxiliary orbital DOF at perfect electrical conductor boundaries of finite topological metamaterial. At the interface of two topological metamaterials, we obtained helical edge states with arbitrary auxiliary orbital DOF and demonstrated adiabatic waveguide states transition. By adjusting structure defect, we design a curved waveguide path of 90°.

Abstract: Experimental fluid dynamics is mainly studied using PIV, but traditional methods need complex optical system. Binocular meta-lens PIV, utilizing polarization-independent GaN meta-lenses and CMOS sensors, offers a compact solution for obtaining three-dimensional velocity fields. Measurement error of 1.3% on vortex ring shows promise for space-constrained applications.

Our speech will present a particle image velocimetry (PIV) system employing a binocular meta-lens based on GaN[1]. The performance of the binocular meta-lens PIV system was verified and evaluated through a typical vortex ring experiment [2]. Experimental setup of binocular meta-lens PIV is performed in Figure 1(a), (b), and (c). The system demonstrated the capability to capture high-quality particle images (as shown in Figure 1(d)) and provide two-dimensional three-component (2D-3C) velocity fields.

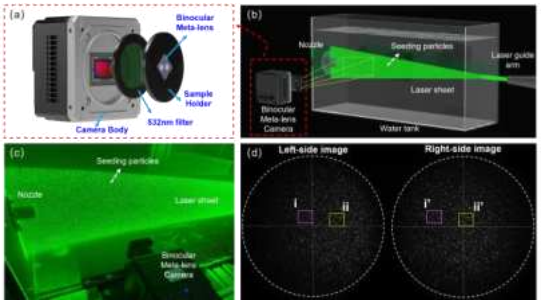

Figure 1. Binocular meta-lens camera and experimental setup of binocular meta-lens PIV.

We assembled the compact custom-built binocular meta-lens camera utilizing a single high-speed CMOS sensor, a 532nm filter, and two thin, light-weight, high-quality meta-lenses with a diameter of 2.6mm and 4mm distance apart. The binocular meta-lens is fabricated with GaN cylindrical nanopillars on a sapphire substrate. Scanning electron microscope (SEM) image of fabricated meta-lens are shown in Figure 2(b), (c). Efficiency and phase response of nanopillars with different radius has been simulated and presented in Figure 2(d). Characterizations show successful fabrication with varying diameter nanopillars and high aspect ratio. Experimental results demonstrate close-to-diffraction-limited focusing performance with a full-width at half-maximum (FWHM) of 2.2 μm in Figure 2(e), (f). Additionally, the system's binocular vision allows for depth perception in a range of 6 to 45 cm in accordance with Figure 2(g).

For the calibration and data processing of the binocular meta-lens PIV system, calibration images were captured with a calibration board placed inside the water tank. The acquired calibration images and particle images underwent data processing. The direct linear transformation (DLT) method based on the pinhole model was utilized to compute mapping matrices between pixels and world coordinates for each sub-lens. A self-calibration process based on particle images iteratively updated these mapping matrices. Standard

two-dimensional two-component (2D-2C) velocity fields (as illustrated in Figure 3(a)) were obtained through cross-correlation analysis of segmented left and right images, followed by the reconstruction of 2D-3C velocity fields using Soloff 's method (as shown in Figure 3(b)). The 2D cross correlation is performed upon an interrogation window and an interrogation grid. Mark the 1st and 2nd images as f_1 and f_2, then the cross-correlation can be expressed as [3]:

$$\Phi(m,n)|_{(i,j)} = \sum_{i}^{i+M-1} \sum_{j}^{j+N-1} f_1(i,j) \cdot f_2(i+m, j+n), \left(|m| \leq \frac{M_g - M}{2}, |n| \leq \frac{N_g - N}{2} \right) \quad (1)$$

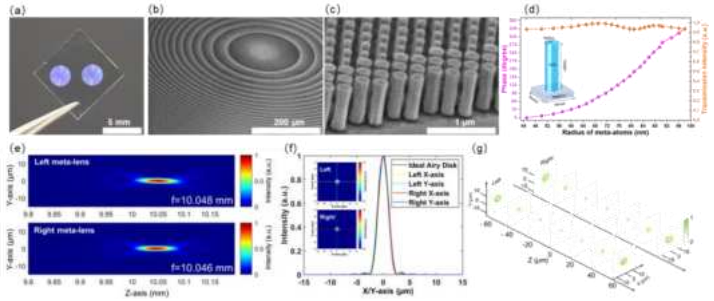

Figure 2. The optical characterization of the binocular meta-lens.

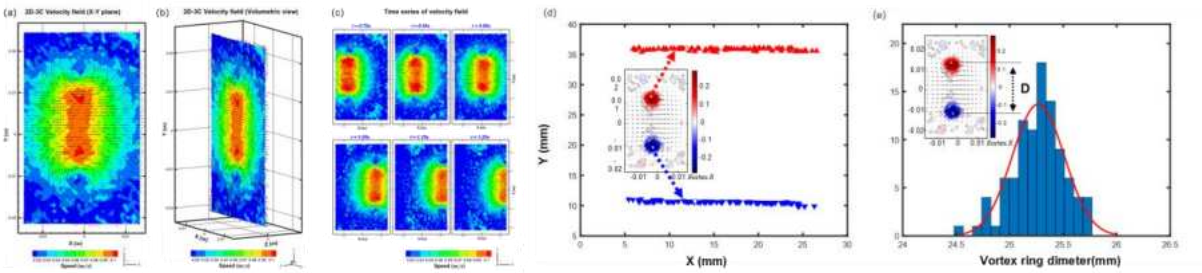

Figure 3. Results of the phase-averaged 2D-3C velocity field at the central plane of the vortex ring (Reynolds number = 2000) obtained using our binocular meta-lens PIV system.

The diameter of the vortex ring (core-to-core diameter) can be determined directly by measuring the distance between the two vortex cores. Figures 3(d) and (e) illustrate the diameter distribution between t = 0.75s and t = 1.25s in Figure 3(c), with the red line representing the normal distribution curve fit. The peak value of the fitted line is D' = 25.27 mm, with a standard deviation (STD) of σ = 0.24 mm. Additionally, the theoretical diameter value can be calculated as D_{ideal} = $1.18D(L/D)^{1/5}$~ 25.59 mm, indicating that the measured uncertainty in the vortex ring diameter is 1.25%.

In conclusion, the binocular meta-lens PIV system provides a reliable and accurate method for capturing and analyzing flow fields, with potential for improved depth direction performance through modifications in the setup configuration.

Reflective Moiré Metasurfaces: A Paradigm of Innovation and Challenge

Shuo Liu[1*], Lei Zhang[1], and Xiaoqing Chen[1]

[1]State Key Laboratory of Millimeter Waves, Southeast University, Nanjing 210096, China
[*]corresponding author: liushuo.china@seu.edu.cn

Abstract: Reflective moiré metasurface offers a cost-effective solution for dynamic beamforming in RIS applications and importantly, paves new ways for synthesizing far-field scattering using tightly stacked ultrathin metallic patterns of varying plane symmetries. This innovation is expected to have widespread impact across the fields of electromagnetics, antenna development, and wireless communication.

Dynamic beamforming plays a pivotal role in various technological applications, including radar systems, holographic imaging, and the development of reconfigurable intelligent surfaces (RIS).[1-3] Traditional methods for achieving this dynamic control rely heavily on active electronic components, such as pin-diodes and varactor diodes. This reliance significantly escalates costs for large-scale implementations, a challenge that becomes even more pronounced at millimeter-wave and sub-terahertz frequencies where these components are notably costly or may not be readily available.

Recently, the fascinating physical properties of moiré patterns created by overlaying two differently twisted two-dimensional (2D) materials have drawn renewed attention. In this context, we introduce a novel approach for dynamic beam steering using two closely attached metasurfaces. By adjusting the in-plane rotation of these two metasurfaces relative to each other, we can continuously manipulate the direction of reflected beams [4], as demonstrated in **Figure 1**. This method allows for a variety of beam configurations, directions, and paths by varying the twist angle and designing different patterns for each metasurface layer. In this work, we design and experimentally demonstrate two different moiré metasurfaces, the chessboard-type and triangular-type, which produce four-beam and six-beam radiations, respectively. Remarkably, the beam efficiency achieved by our moiré metasurfaces is even greater than the conventional metasurface designed with super unit cell configuration. Note that the design of moiré metasurfaces is fundamentally different from all previously reported moiré metasurfaces, in which the separation between the two metasurfaces is designed large enough to ensure linear combination of the functionality of each individual layer.

Our design offers a cost-effective solution for dynamic beamforming in RIS applications and unveils a novel approach to exploring new physics in programmable metasurfaces. Their compact profile makes them highly adaptable for use in a variety of applications, effortlessly blending into indoor environments as part of walls, ceilings, and decorative art, as well as enhancing outdoor infrastructures like building facades, streetlights, and advertising boards to extend signal reach. Beyond the cost-saving advantage, our fully passive reflective moiré metasurface architecture boasts several remarkable features, including zero static power consumption, no receiver noise, and a high capacity for handling power, showcasing its vast potential for applications in RIS and electronic warfare.

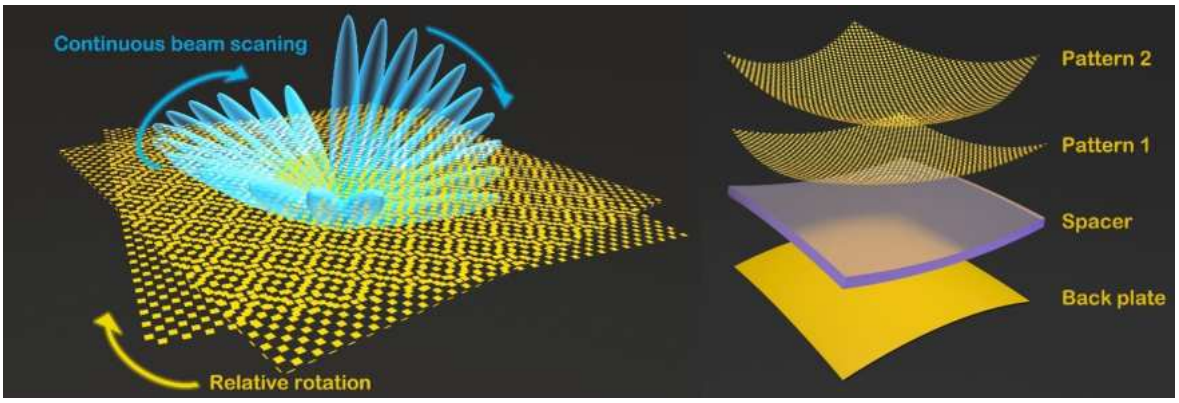

Figure 1 Schematic illustration and composition of a moiré metasurface.

However, the exploration of reflective moiré metasurfaces presents unique challenges and issues across various aspects, diverging significantly from the traditional design paradigms of conventional metasurfaces. Unlike their conventional counterparts, which rely on the repetitive nature of unit cells with locally periodic boundary conditions, reflective moiré metasurfaces cannot be described using a similar approach. This is because the moiré patterns, although periodically perceivable by the human eye under most conditions, do not exhibit true two-dimensional crystallinity except at certain discrete twist angles where the overlaid grid lattices of the two patterns align exactly.

Further complicating the design and understanding of moiré metasurfaces is their inherent high anisotropy. Traditional metasurface designs often leverage straightforward geometric shapes arranged in square or hexagonal lattices, resulting in predictable electromagnetic (EM) responses. Reflective moiré metasurfaces, however, introduce an additional layer of complexity due to the complex moiré pattern that changes with the twist angle. The moiré pattern not only complicates the polarization state of reflected waves, which may contain both co-polarized and cross-polarized components, but also leads to a shift in moiré periodicity across various lattice types as the twist angle changes. Such changes significantly affect the radiation pattern, making the design process more intricate.

Our research paves the way for novel methods of engineering far-field scattering by closely aligning ultra-thin metal patterns from different symmetry groups, a breakthrough with significant theoretical and practical implications. This innovation is expected to have widespread impact across the fields of electromagnetics, antenna development, and wireless communication, marking a significant step forward in these disciplines.

Metasurface-enabled light-to-microwave hybrid wireless communications

Xin Ge Zhang, Ya Lun Sun, and Wei Xiang Jiang*

State Key Laboratory of Millimeter Waves, Southeast University, Nanjing 210096, China
*corresponding author: wxjiang81@seu.edu.cn

Abstract: We will introduce an optically-controlled programmable metasurface for remote microwave control and hybrid light/microwave signal processing. A hybrid wireless communication system that allows dual-channel data transmissions in a light-to-microwave link is demonstrated, and the experimental results show that two different videos can be transmitted and received simultaneously and independently.

Metasurfaces are ultrathin array structures consisting of artificial subwavelength elements arranged on a specific two-dimensional surface, and have shown great capabilities to manipulate phase, amplitude, frequency, and polarization features of electromagnetic (EM) waves flexibly. Recently, programmable metasurface with real-time EM control and digital information processing capabilities has been a hot topic in the EM and communication communities[1,2].

In this talk, we will introduce an optically-controlled programmable metasurface for remote microwave control and hybrid light/microwave signal processing. First, we present the design and realization of the spatial-domain optically-controlled programmable metasurface that can manipulate microwave scatterings by light, achieving different EM functions including beam tuning, external cloaking, and vortex beam generation. The unique advantage of optically-controlled programmable metasurface is that it can avoid effectively complex bias network design and adverse DC-EM signal crosstalk. Then, we present the design and implementation of a time-domain optically-controlled programmable metasurface that can tailor microwave spectra by time-varying light signals. Next, we will show how the time-domain optically-controlled programmable metasurface is used to construct a light-to-microwave hybrid wireless communication system that can convert light signal to microwave signal directly, without using down-conversion process to baseband. More importantly, one designed light signal channel can carry two independent original information that can be encoded onto two microwave carriers with different incidence frequencies by using the dispersion characteristic of the metasurface. As an attractive example, we realize a dual-channel light-to-microwave hybrid wireless communication system that can transmit simultaneously two different videos with the aid of frequency division multiplexing scheme. Different from the microwave photonics technologies typically target fiber and on-chip methods, the optically-controlled programmable metasurface can realize hybrid signal processing based on wave modulations, which could stimulate attractive information-oriented applications.

Abstract: An approach for digital image correlation (DIC) measurement using a single camera is reported in this work, utilizing the polarization-independent GaN binocular meta-lens to measure the displacement of the flat-plate. Finally, the depth and displacement of the cylinder are measured through binocular imaging, validating the feasibility of the proposed approach.

Digital Image Correlation (DIC) is a non-interferometric optical technique used to measure full-field displacements and strains on the surface of an object [1]. This study introduces a digital image correlation (DIC) system utilizing a binocular meta-lens based on GaN. The basic principle of DIC is shown in Figure 1. In this system, binocular meta-lens is employed to image the specimen, replacing traditional lens. The binocular meta-lens is shown in Figure 1(a). We demonstrate the setup image for the flat plate displacement experiment of meta-lens DIC in Figure 1(b). Generally, the implementation of DIC involves the following steps [2]: (1) specimen preparation;(2) image capture before and after deformation;(3) calculation of the displacement field and strain field. We illustrate a high-quality speckle pattern on a flat plate specimen in Figure 1(c) [3]. Subsequently, speckle patterns before and after deformation, as shown in Figure 1(d) and Figure 1(e), can be captured using the camera.

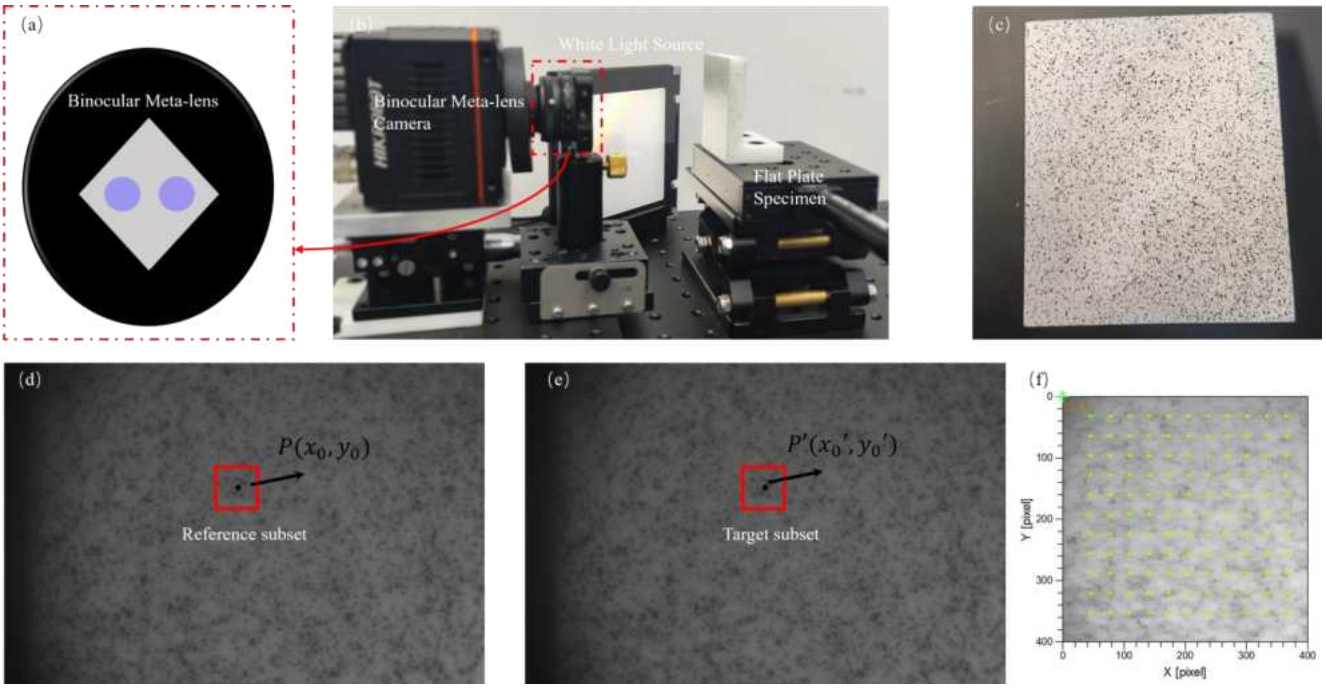

Figure 1 Schematic image of Meta-lens DIC. (a)binocular meta-lens; (b) experimental setup image of meta-lens DIC; (c)specimen preparation; (d)schematic illustration of a reference square subset before deformation; (e)schematic illustration of a target subset after deformation; (f)calculated displacement field.

In implementation of the DIC method, the region of interest (ROI) should be defined at first similar to the region outlined by the red lines in Figure 1(d). The ROI region is generally a (2M+1) * (2M+1) area centered at the point $P(x_0, y_0)$. Then, we calculate the correlation criterion to find where reference subset has moved to after deformation. As shown in Figure 1(f), the reference subset has moved to the target subset, and the point $P(x_0, y_0)$ has moved to the point $P'(x_0', y_0')$.Finally, we can calculate the displacement corresponding to each subset, thereby obtaining the displacement field.

We initially validated the feasibility of this system through the in-plane displacement experimental, the experimental setup is shown in the Figure 1(b). The pixel size of this image is 0.08 mm/pixel. We conducted 30 sets of displacement experiments with a step size of 0.1 pixels [4]. We conducted 2D-DIC in-plane experiments using the right eye of the binocular meta-lens. The images we obtained before and after deformation are shown in the Figure 1(d) and Figure 1(e). We use the cross-correlation (CC) to evaluate the similarity degree between the reference subset and the deformed subset. Then, we use the inverse compositional Gauss-Newton (IC-GN) algorithm as a sub-pixel displacement registration algorithm to calculate the precise sub-pixel displacement of each subset [5]. Ultimately, we obtain the displacement field as shown in Figure 1(f).

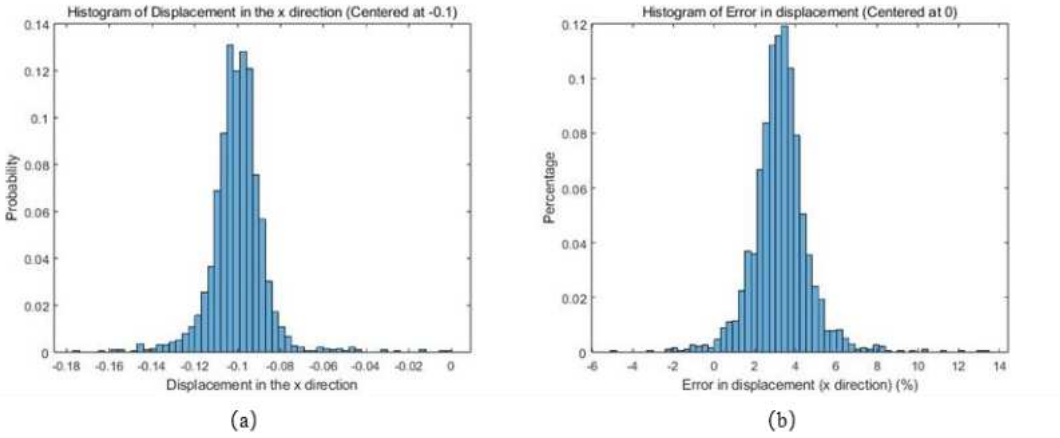

Figure 2. Histogram of in-plane displacement and error. (a) Histogram of in-plane displacement. (b) Histogram of in-plane displacement error.

We conducted a statistical analysis of the calculated sub-pixel displacements, as shown in Figure 2(a). Figure 2(b) illustrates the errors between these displacement values and the ground truth. The majority of displacement errors fall between 1.8% and 5%. However, due to edge distortion of the meta-lens, approximately around 10% of the displacement errors increase.

Combinatorial Optimization of Electromagnetic Devices using metamaterial Function Units

Guoyan Dong*

Center of Materials Science and Optoelectronics Engineering, School of Optoelectronics, University of Chinese Academy of Sciences, Beijing 100049, China
*corresponding author: gydong@ucas.ac.cn

Abstract: Periodic or aperiodic spatial arrangements of metamaterial resonant elements can not only enhance and extend the resonant characteristics through mutual coupling resonance effects but also design and optimize the performance of devices according to specific application requirements. These designs have significant applications in light modulation and performance enhancement.

Keywords: Metamaterials, Functional element, Photonic crystal, Device Engineering, Mie resonance.

The scattering properties of periodic or aperiodic structural materials empower them to efficiently manipulate electromagnetic wave (EMW) propagation by adjusting their characteristics. For instance, by altering the alignment and percentage of different materials inside the periodic structure, the location and breadth of the band gap can be changed to achieve the limiting or transmission of electromagnetic waves in a given frequency range [1]. Changes in structural parameters can regulate the effective permittivity and permeability. These synthetic functional units are arranged and integrated in a way that allows them to display unusual electromagnetic properties lacking in natural materials. The versatile design of electromagnetic metamaterials provides more potential for the development of resonant devices.

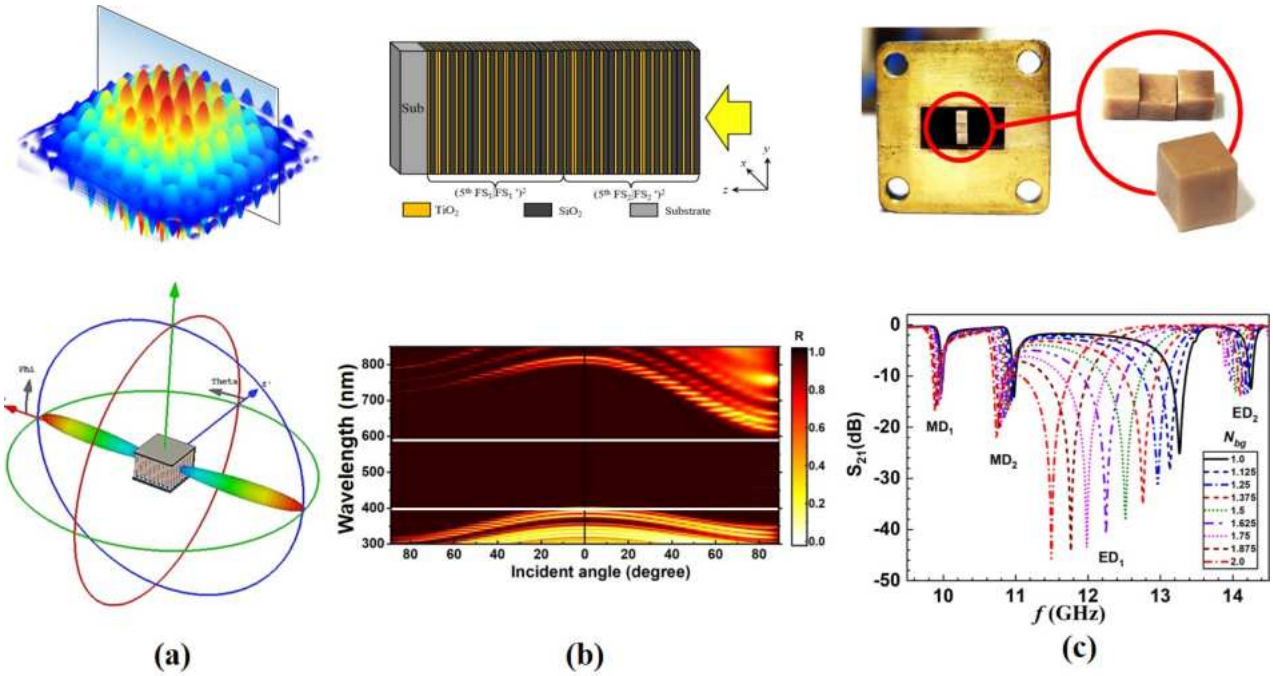

Figure 1. (a) Resonance and radiation pattern of PhC-antenna, (b) Structure and reflectivity spectra of dielectric-reversal quasicrystal sequence, (c) Dielectric-particle trimer and measured spectra detecting on ambinent refractive index changes.

First, metamaterials are used to create functional elements that have characteristics not found in nature. These elements then work as platforms for creating useful devices. Employing the near-zero effective refractive index of photonic crystal (PhC) at the center of the first Brillouin zone (FBZ), as shown in Fig. 1(a), we develop a PhC antenna composed of dielectric cylinders for splitting and directional radiation [2]. Microwave simulation and tests have confirmed that the space incident light may be redirected orthogonally and radiated symmetrically with high directional gain by inducing the PhC array resonance near the band edge scope [3]. Compared with traditional directional antennas, this PhC array antenna has the advantages of compact size, simple structure, economical cost, high coupling efficiency, and directivity.

Second, metamaterial components of diverse properties are devised and ingeniously integrated to create unique functional devices. In Fig. 1(b), we proposed a dielectric-reversal quasicrystal sequence to expand the bandgap while eliminating its inherent defects for impeccable omnidirectional reflection with fewer dielectric layers [4]. Although defects can be mitigated, it is challenging to entirely eliminate transmission flaws in quasicrystal sequences. Consequently, through the ingenious design of the central wavelength, we integrate it with periodic sequences or other quasi-periodic sequences, resulting in an omnidirectional high reflectance function surpassing 98% in the visible light band spanning approximately 150nm.

Thirdly, resonance coupling between structural units is exploited to amplify and optimize the functional features of metamaterials. The Mie resonant interactions of rectangular particles can serve as the foundation to enhance anisotropic light-matter interactions and enable increased sensitivity towards particular spectral regions. The coupled Mie resonances in a symmetrical linear rectangular-particle trimer (Fig. 1c) ensure the enhancement of electric dipole and magnetic dipole resonances. The symmetrical nature of the trimer overcomes the split dipolar resonance challenge presented in earlier designs and shows the potential for advanced sensing devices.

In summary, modifying the structure of electromagnetic metamaterials has expanded their functionality by inducing specific resonance, integrating different sequences, and coupling Mie resonances. This research introduces a promising method for broadening metamaterial functions and may pave the way for next generation metamaterial devices.

Abstract: Based on the phase-change materials, we propose a storage technology capable of writing and erasing the functions of metasurfaces. By constructing phase storage units using phase-change materials, the phase of pixels can be written and erased with a laser.

Metasurfaces have contributed to many hotspots in the optical field over the past decade, with their powerful capability to modulate light fields, becoming the darling of researchers and technologists in various optical scenarios and interdisciplinary fields. However, most existing metasurfaces are static, which means that their functionalities cannot be changed once the sample fabrication is completed. This limitation significantly constrains the practicality of metasurfaces in scenarios oriented towards storage, display, encryption, and the like.

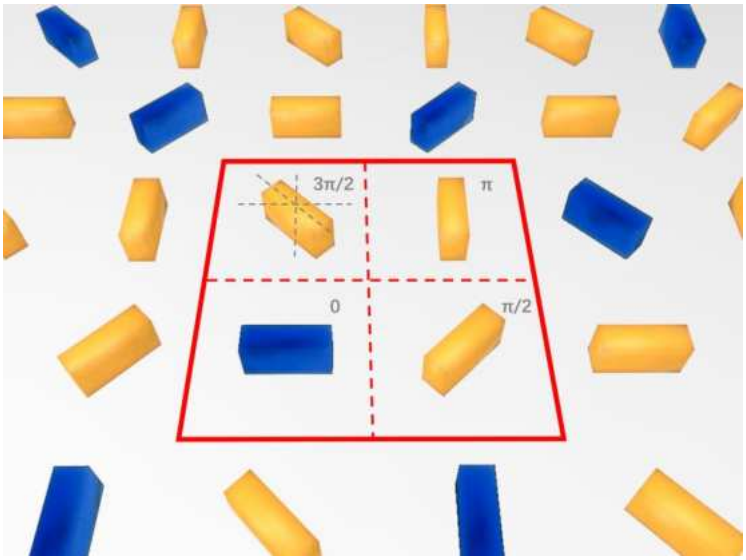

Fig.1 Schematic diagrams of designed the rewritable metasurface

The emergence of phase-change materials has provided a new approach to addressing this issue. Here, we utilize the phase-change material GST ($Ge_2Se_2Te_5$) [1] to construct rewritable metasurface phase storage units. The basic configuration is illustrated in Fig. 1, where four units form a storage pixel according to the geometric phase. The specific units within each pixel are irradiated with a focused laser to induce a phase change in the material, resulting in a reduced polarization conversion efficiency [2]. Meanwhile, the efficiency of the non-irradiated units remains high, determining the phase state of that pixel. As a result, the functionality of the metasurface can be defined.Owing to the non-volatile nature of the phase transition of GST, its functionality can

be preserved for an extended period. To erase the functionality, it is only necessary to anneal the metasurface at high temperature, which resets the phase state of each unit, thus allowing new functions to be written.

Abstract: We present an innovative method for achieving spin switchable electromagnetic camouflage and target identification functionalities using an irregular chiral meta-coder. This meta-coder is designed by combining chiral meta-atoms with an irregular phase encoding method. It could potentially open up new avenues for applications in the field of information security.

Electromagnetic camouflage, which is crucial for concealing an object's physical identity from external electromagnetic detection, has been extensively researched in recent years. While metamaterial advances have introduced transformative solutions, such as cloaking devices enabled by transformation optics, they often suffer from limitations due to bulky or static materials [1]. The emergence of metasurfaces has revolutionized our control over the propagation of electromagnetic waves [2]. By precisely arranging meta-atoms over curved surfaces, metasurfaces can mimic flat mirrors, effectively rendering objects invisible [3]. Advances in metasurfaces have led to significant advances in skin cloaking technology, with spin decoupled metasurfaces enabling cloaking under arbitrary polarization states, and tunable metasurfaces facilitating dynamic switching for reconfigurable camouflage [4,5]. The reported metasurface cloaking strategy relies on a conformal approach, requiring a metasurface equivalent to the volume of the cloaked object. However, this approach has limitations for larger objects and introduces manufacturing complexities due to conformal design requirements. A seamless transition between camouflage and visualization functions is critical. Addressing these challenges, including concealing objects while ensuring secure communication, has been the focus of extensive research and development efforts.

In this paper, we present an innovative chiral meta-coder to achieve spin switchable electromagnetic camouflage and target identification. By integrating chiral meta-atoms with an irregular phase encoding method, our approach eliminates the need for complex conformal designs and experimental operations on metasurfaces, providing a more efficient strategy. The core concept involves the dense arrangement of meta-atoms around a target object, coupled with the encoding of appropriate phase sequences for wavefront shaping and camouflage. At the same time, the target object can be identified by modulating the helical state of the incident wave based on the chiral resonance property of the meta-atoms. To validate our approach, we have provided a proof of concept through the design and experimental demonstration of a chiral meta-coder applied to a camouflaging "A" shaped target object. For contrast, Figure 1(a) shows a single "A" target without meta-atoms. When an electromagnetic wave hits an "A" shaped object, reconnaissance systems can easily decipher the target from the far-field scattering pattern. For the target object surrounded by meta-atoms, as shown in Figure 1(b), our results indicate that by encoding an appropriate sequence of meta-atoms, these meta-atoms can adapt the wavefront to effectively conceal target information when exposed to right circularly polarized (RCP) waves. The resulting camouflage pattern exhibits diffuse scattering in the far field and three focal patterns in the near field. Conversely, under the excitation of left-circularly polarized (LCP) waves, these meta-atoms transform into a

wave-absorbing configuration, facilitating the precise identification of target information, as shown in Fig. 1(c). We believe that this innovative strategy may have promising applications in the fields of data security, privacy, and communication.

Abstract: We present a novel technique for transferring a polymer membrane incorporating monocrystalline silicon (c-Si) nanoparticle arrays (NPAs) onto diverse support substrates. Leveraging the collective resonances of the c-Si NPAs, this device exhibits efficient capabilities for beaming the fluorescence of μ-LED color-converters, serving as an étendue reducer for wireless optical detection, and enhancing light outcoupling in scintillators for low-dose X-ray imaging.

Luminescent films, demonstrating fundamental absorption and re-emission phenomena, are versatile in applications, spanning traditional white light emitting diodes and displays. They also play a crucial role in down-converting optoelectronics for detecting propagating light and high-energy particles from free space. This innovative technique broadens the detection range beyond commercially available silicon-based detectors, finding utility in luminescent solar concentrators, information storage, fluorescence anti-counterfeiting, scintillators for ionizing radiation detection, and wireless optical communications. The effectiveness of these down-converters hinges on factors like absorption, internal quantum yield, and external out-coupling efficiency. Despite design strategies, the high refractive index of the emitter matrix limits the external efficiency of luminescent slabs due to total internal reflection. This results in the majority of luminescent photons leaking into the substrate and being guided to the side where detectors are positioned, significantly constraining the integration of the optoelectronic system.

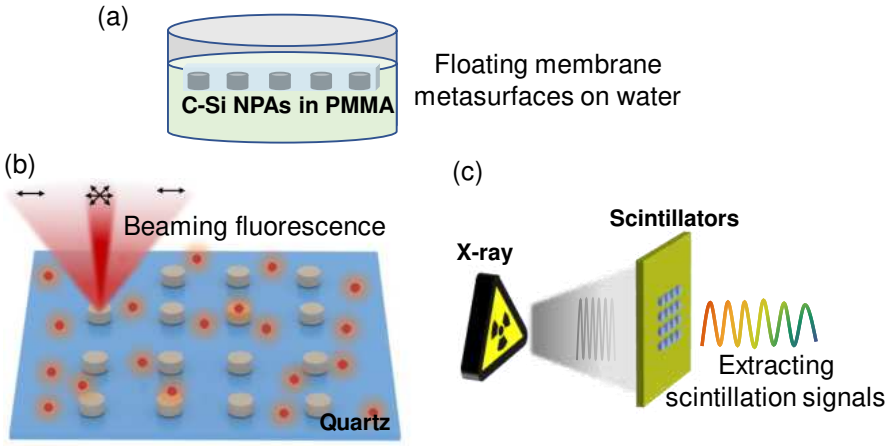

Figure 1. Floating membrane metasurfaces on water (a) can be transferred onto target substrates for beaming the fluorescent emission and act as an étendue reducer (b) or extracting the scintillation light from the crystals.

To overcome inherent limitations, optical metasurfaces emerge as a promising solution. These ultra-thin, lightweight two-dimensional elements integrate seamlessly onto down-converters due to their flat structure and natural alignment with detectors. Leveraging metallic or dielectric nanoparticle arrays (NPAs), these metasurfaces position luminescent materials within the strong near-field range of nanoantenna resonances, forming light-emitting metasurfaces. Various configurations include coating emitters on top of NPAs, depositing NPAs on luminescent slabs, or embedding emitters inside NPAs.

In Figure 1, we successfully crafted a metasurface using c-Si, known for its low loss and high refractive indices in the visible light range.[1-3] This metasurface, designed to enhance the directional emission of fluorescence layers, was transferred onto a quartz or scintillator substrate using the 'floating off' technique. It was securely affixed to quartz through dangling bonding at the interface between c-Si and substrates. We present an adaptive approach to enhance quasi-BIC emission from a resonant monocrystalline silicon (c-Si) metasurface through lattice and multipolar engineering. Dual-BICs, originating from electric quadrupoles (EQ) and out-of-plane magnetic dipoles, are identified. EQ quasi-BICs concentrate near-fields near c-Si nanodisks, enhancing fractional radiative local density of states and promoting efficient out-coupling. Coupling EQ quasi-BICs with Rayleigh anomalies enhances directional emission intensity, revealing inherent opposite topological charges in multipolar-controlled dual-BICs. Our work paves the way for fundamental research in strong light-matter interactions, the design of highly efficient light-emitting metasurfaces, and other relevant optoelectronic devices.

Abstract: Plasmonic nanoparticle clusters are reliably fabricated with a modified electron-beam lithography method using self-assembly superlattices, where the interparticle separations is less than 5 nm, the non-radiative losses can be suppressed, and the fabrication processes are simplified compared with conventional top-down approaches.

Plasmonic nanoparticle clusters have gained considerable attentions due to their versatile collective optical responses, and the interparticle separations have to be reduced as far as possible to enhance the plasmon coupling, which is hard to achieve with conventional top-down approaches (e.g., electron-beam lithography).[1, 2] This study proposes and demonstrates that using self-assembly nanoparticle superlattices, plasmonic nanoparticle clusters are reliably fabricated with a two-step lithography method (electron-beam exposure and washing process). Since the nanoparticles are separated with the coated polymer molecules. the interparticle separations are less than 5 nm (Figure 1). Besides that, the non-radiative losses of the metallic material can also be effectively suppressed due to the good crystallization for the nanoparticles fabricated with the wet-chemistry method.

Optomechanical metasurfaces based on kirigami technology

Nanzhong Deng[1,2], Ashish Pandey[1,3], Gregory Roberts[1,3], Haogang Cai[1,2,3*]

[1]Tech4Health Institute, NYU Langone Health, New York, USA

Abstract: As inspired by the Japanese art of paper cutting, kirigami technology has been used to create mechanical and optical metamaterials. Based on our recent nano-kirigami actuators whose tilting angle can be predefined by the geometry, we demonstrated deformable mirrors, dynamic tunable optical metasurfaces and photonics crystals with broad applications.

As inspired by the Japanese art of paper folding and cutting, “origami” and “kirigami” technologies provide a unique solution to create three-dimensional (3D) complex architectures and metamaterials with predefined two-dimensional (2D) geometry of creases and hinges (Fig. 1a) [1]. Through various processes of cutting, folding, bending, twisting, 2D thin films could pop up with a “nonlinear” expansion in 3D space by several orders of magnitude, adding an extra degree of freedom in 3D nanofabrication and actuation beyond the design possibilities through conventional approaches [2]. In particular, kirigami leverage existing 2D lithographic techniques, enabling a high compatibility with standard semiconductor manufacturing processes. The buckling-induced deformation mechanism is universal across many size scales (Fig. 1b, c) and can be applied to a broad range of materials, from conventional silicon-based materials, 2D materials, to soft and biomaterials. Therefore, kirigami is not only widely utilized in micro-electromechanical systems (MEMS) [3], but also suitable for biomimetic design of robotic, biomedical, and consumer devices [4].

Recently, kirigami technology has been used to create chiral and reconfigurable metasurfaces [5, 6]. Here, we adopted a simple kirigami design using only perpendicular cuts in a thin membrane. Two suspended panels are connected through hinged regions in the middle (Fig. 1a). When a tensile stress is applied to the membrane, kirigami panels are tilted by buckling-induced out-of-plane deformation. By changing the geometric parameters of hinge size h and cut width c, we obtained distinct deformation configurations, which are referred to as “symmetric” and “asymmetric” tilting modes [1]. The actuation of a kirigami results in a panel tilting angle θ (Fig. 1c) under a tensile stress $\sigma_{xx} = N_{xx}/t$, where N_{xx} is the load per unit length, t is the membrane thickness. We investigated the relationship of θ vs. σ_{xx} or strain ε (Fig. 1d), which is determined by the geometric parameters. Each kirigami actuator could work as a meta-atom to build novel optomechanical metasurfaces. Since the kirigami tilting angle can be predefined by its geometry, kirigami with different angles can be arranged in an array to form deformable mirrors with desired topographic profiles. Moreover, kirigami provides an ultra-compact thin-film mechanical actuation platform for dynamic tunable optical metasurfaces and photonics crystals. As an example, a photonic crystal film was integrated on top of a kirigami array, by self-assembly of a monolayer of polystyrene spheres, displaying structural colors at a given view angle [7]. The kirigami pixels can be engineered to encode different colors for optical information display, encryption and anti-counterfeiting.

Multiband and broadband acoustic topological metamaterial

C. L. Ding[1*], Y. Sun[1], and X. P. Zhao[1]

[1]Smart Materials Laboratory, School of Physical Science and Technology, Northwestern Polytechnical University, Xi'an 710129, People's Republic of China
[*]corresponding author: dingchanglin@nwpu.edu.cn

Abstract: We firstly present a dual-band acoustic high-ordered topological metamaterial (AHOTM) composed of meta-atoms and meta-molecules with edge states and corner states in two frequency regions. And then the dual-band negative refraction, valley-locked topological transport and local enhancement are investigated. At last, we realize broadband AHOTM with topological edge states.

Acoustic topology is a hot spot in recent year, because Acoustic topological insulator presents topological transport with defect immunity, backscattering immunity, and robust edge states.[1-4] Although some ATIs have been achieved by phononic crystals based on Bragg scattering, the narrow work frequency band related to the lattice constant limits their applications.[5-8] Acoustic metamaterials (AMs)[7-10] based on local resonance are another kind of candidate for the design of ATIs.[11]

In this paper, we propose a dual-band and broadband composite acoustic higher-order topological metamaterial (AHOTM)[12] based on the concepts of local resonance and weak interaction. The dual-band AHOTM is composed of meta-atoms of hollow tubes (HTs) and meta-molecules of opened-hole hollow tubes (OHTs) arrayed as a regular triangle in a hexagonal lattice with C3v symmetry. The two edge states and corner states can be separately tuned by the geometry sizes of HTs and OHTs because of their local resonances and weak interactions. The dual-band AHOTM also presents frequency-selective topological transport of edge states and higher-order corner states by rotating one structure and can sustain the topologically robust edge states against some defects. By designing three kinds of arrays A, B and C with different rotated angles of -30 ˚, 0 ˚, 30 ˚, respectively, the topological transport of edge states occurs in the wide region of array B in two bands. The AHOTM also present other dual-band acoustic effects, such as negative refraction, valley-locked topological transport and local enhancement. The concept of the dual-band AHOTM can be extended to design multiband and broadband acoustic topological insulators for their flexible manipulation of sound waves with broadband topological edge states.

The Design, Control and Optimization of Cavity-based Metamaterials for Miniature Spectrometer Application

Ruonan Ji[1*], Qingquan Liu[1], and Shaowei Wang[1]

[1] State Key Laboratory of Infrared Physics, Shanghai Institute of Technical Physics, Chinese Academy of Sciences, China
[*]corresponding author: jiruonan@mail.sitp.ac.cn

Abstract: Spectrometers are vital for diverse applications but face limitations like size and cost. This paper focuses on developing compact, integrated miniature spectrometers using dielectric cavity-based metamaterials, enhancing portability and performance through innovative spectrometric metamaterials and advanced reconstruction algorithm. This research contributes to the ongoing progress in miniaturized optical sensing systems.

Spectrometers are indispensable tools in a wide range of applications, including environmental monitoring, biomedical diagnostics, food quality analysis, agriculture, and industrial process control. However, traditional spectrometers often suffer from limitations such as large size, high cost, and limited mobility, restricting their usability in many real-world scenarios, including real-time analysis, in situ measurements, space and field-deployable capabilities. To overcome these limitations and meet the demands of diverse applications, the development of miniature spectrometers has gained significant attention[1]. The all-dielectric optical microcavity, featuring exceedingly low losses, can confine light within a very small volume, significantly enhancing the interaction between light and matter. This enhancement leads to improved performance of photonic devices. Moreover, its simple fabrication process and ease of integration provide an excellent platform for developing photonic spectroscopic devices suitable for miniaturized spectrometers. This paper presents various applications of all-dielectric microcavity-based metamaterials in miniaturized spectrometers and how spectral super-resolution reconstruction techniques can be used to enhance spectral resolution, addressing the challenges of size, cost, and spectral resolution faced by miniaturized spectrometers.

A short-wave infrared broad-spectrum detection chip based on an F-P (Fabry-Perot) microcavity array is proposed. Using ultraviolet laser direct writing grayscale lithography, the F-P microcavity array is rapidly fabricated directly on the InGaAs focal plane detector. Combined with spectral reconstruction methods, this allows for a very wide spectral detection range with few spectral channels, covering 900 to 1700 nm in the short-wave infrared range, and achieving a spectral resolution of 2 nm[2]. Furthermore, by integrating a two-dimensional metasurface with an all-dielectric optical microcavity, a novel optical metainterface device capable of simultaneous polarization and spectral splitting is proposed[3]. This device achieves simultaneously polarization extinction ratio(PER) of 800 and a spectral resolution power (SRP, $\lambda/\Delta\lambda$) of 113 with a very thin metal grating, and its fabrication process is simple and easy to manufacture. Moreover, it can break the limitation of diffraction and achieve much higher polarization extinction ratio with limited size gratings. This research contributes to the ongoing progress in miniaturized optical sensing systems, opening up possibilities for advancements in diverse application domains.

Overlapped Bandgap and Ultrabroadband Transmission in a Valley Photonic Insulator Based on Dendritic Structure

Yahong Liu[1,2*], Meize Li[1,2], Peng Li[1], Liyun Tao[1,2], Lianlian Du[1]

[1] School of Physical Science and Technology, Northwestern Polytechnical University, Xi'an 710129, China

*corresponding author: yhliu@nwpu.edu.cn

Abstract: Exploring multi-dimensional manipulation waves will greatly promote the development of physical systems. In topological insulators[1-2], overlapped bandgap with nontrivial topology has never been reported. Besides, it is urgent to improve the bandwidth of topological transmission[3-4]. In this work, overlapped bandgap and ultrabroadband transmission are realized in dendritic valley photonic insulator.

Keywords: overlapped bandgap, edge states, corner states, valley photonic insulator, ultrabroadband, dendritic Structure.

Topological insulators have attracted considerable attention due to their strong backscatter immune transmission. A higher-order valley photonic insulator composed of arrays of dendritic structure is designed. As in any uniaxial structure, eigenmodes propagating can be classified as TE mode and TM mode. As shown in Fig.1, based on the two modes of dendritic structure, overlapped bandgap and ultrabroadband valley transmission are realized, respectively.

Firstly, we discuss TM mode. The band structure shows an overlapped bandgap is observed, and the overlapped bandgap divides the band structure to three bandgaps. The evolution of the overlapped bandgap is investigated by changing the geometric parameters and increasing fractal to break the C_{3v} symmetry drastically. Besides, it is notable that the band structure of the proposed valley photonic insulator is flat bands. It is demonstrated that undistorted transmission can be observed as a plane electromagnetic wave transmits through the proposed valley photonic insulator. The interface consisting of two valley photonic structures with distinct topological nontrivial phases is constructed. Edge states and corner states with strong energy localization are obtained in multi-band frequencies. Remarkably, two triangular structures with different Wannier center configurations both have corner states in the same bandgap, which does not obey the valley selectivity. The phenomenon is caused by the weak valley locking property due to the overlapped bandgap.

Secondly, we discuss TE mode. The valley photonic crystal composed of dendritic structure can realize valley transmission with a relative bandwidth up to 59.65%. Theoretical analysis, numerical simulation and experimental measurement all confirm flexible manipulation of electromagnetic

wave propagation paths. Ultrabroadband topological waveguides with the zigzag and armchair interface are demonstrated, which can achieve experimentally 58.71% and 36.78% relative bandwidth, respectively. Several topological channel intersections are designed, and two types of corner states with topological switchability and valley selectivity are demonstrated.

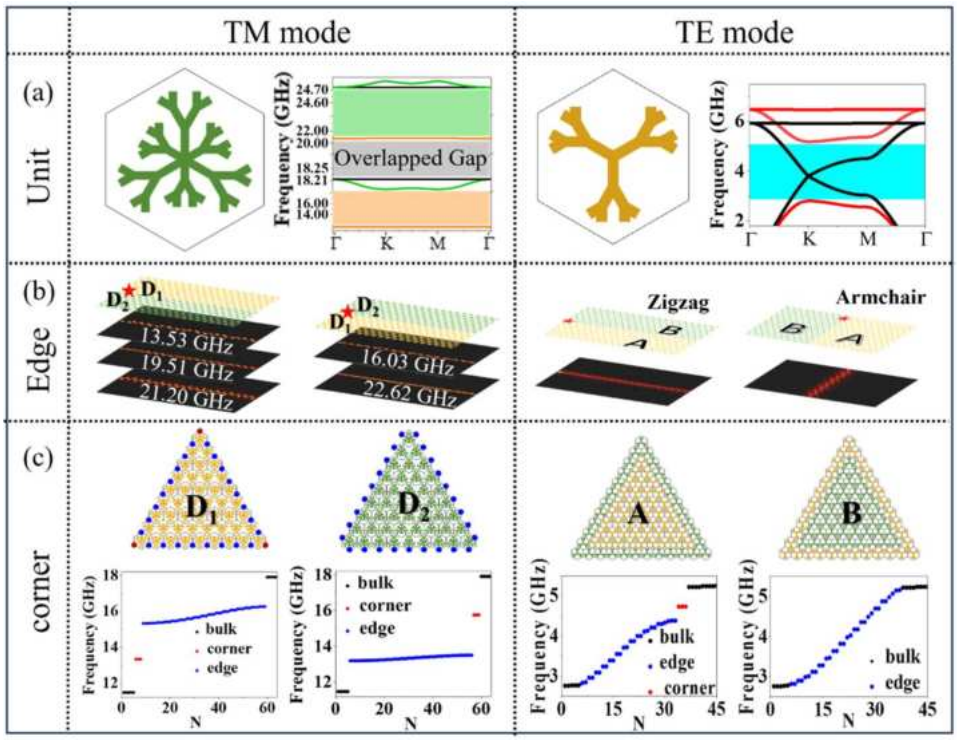

Figure 1. (a) Schematics and the band structures. (b) Schematic and electric field distributions for waveguides. (c) Schematic and eigenspectral for corner structures.

Perovskite Photovoltaics: Light-Matter Interaction

Subcell Characterization Platforms for Emerging Tandems

J. Y. Kim[1*]

[1]Department of Materials Science and Engineering, Seoul National University, Seoul 08826, Republic of Korea
[*]corresponding author: jykim.mse@snu.ac.kr

Abstract: We report comprehensive electrical characterization methods based on either 2-terminal or 3-terminal platform that can accurately and easily analyze the subcells of monolithic emerging tandems. In addition to the current-voltage and external quantum efficiency measurements, advanced characterization for subcells such as impedance spectroscopy and thermal admittance spectroscopy will be demonstrated.

Introduction

The efficiencies of emerging tandems are rapidly increasing in recent years. Among them, the perovskite/Si tandem solar cells (PVSK/Si TSCs) are particularly attracting interest from both of academia and industry, because its highest certified efficiency (33.9%) has already surpassed the efficiency limit of the single junction solar cells.[1] Despite this extensive improvement in device performance, subcells are relatively poorly understood because of the limited availability of their characterization methods. Optical methods such as photoluminescence and electroluminescence have been reported as possible tools for characterizing subcells; however, they can only provide indirect information regarding the device performance. Moreover, a few facile electrical characterization methodologies have been reported, but their applications for PVSK/Si TSCs have not been fully investigated. Indeed, most of the electrical characterization methods that have been developed for single-junction solar cells are inadequate for probing the subcells of monolithic TSCs. Given that the performance optimization of PVSK/Si TSCs is currently mostly realized through the independent characterization of single-junction cells, this lack of tools for characterizing subcells represents a severe obstacle to further enhance the device performance. In this study, we report a comprehensive methodoloty based on either 2-terminal or 3-terminal characterization platform. Examples of subcell characterizations such as the current density-voltage (J-V) curves, external quantum efficiency (EQE) curves, impedance spectroscopy (IS), transient photovoltage decay (TPVD), and thermal admittance spectroscopy (TAS) will be presented based on highly efficient PVSK/Si TSCs.

Contents

A. Subcell Characterization Methods using the 3-Terminal Platform[2]

The 3-terminal platform utilizes the internal recombination layer as an auxiliary contact for the subcell characterization. We will present the examples of subcell characterization using 3-terminal platform, where accurate current density-voltage (J-V) and external quantum efficiency (EQE) curves of each subcell can be obtained without any additional light bias. Further studies such as the electron dynamics study of subcells and the current-mismatch effect on the fill factor will also be presented.

B. 2-Terminal Characterization Protocols based on Subcell-selective Illumination[3]

Unlike the 3-terminal platform, the 2-terminal platform is based on subcell-selective illumination, and can be applied to general 2-terminal monolithic TSCs without the auxiliary contact. The way how we can obtain subcell characteristics and examples of the accurate characterization of the subcells will also be presented for highly

efficient PVSK/Si TSCs.

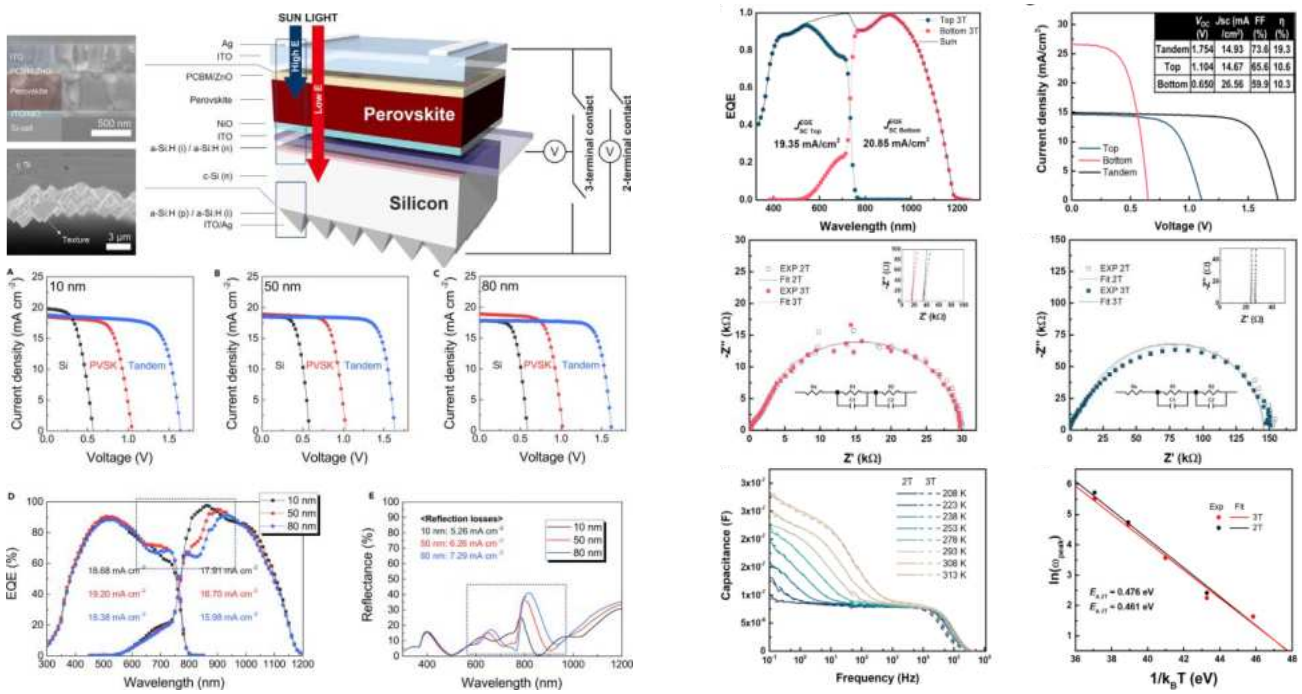

Fig. 1. (Left) Structure of 3-terminal characterization platform and example of subcell characteristics.
Fig. 2. (Right) Example of subcell characterization using the 2-terminal protocol.

Summary

We present 2-terminal and 3-terminal characterization platforms for accurate subcell characterization of emerging tandem solar cells using a model system of highly efficient perovskite/Si tandem solar cells. The 3-terminal platform utilizes the internal recombination layer as an auxiliary contact for the subcell characterization, whereas the 2-terminal platform is based on subcell-selective illumination, which can be applied to general 2-terminal monolithic TSCs without the auxiliary contact. The presented protocols for the accurate subcell characterization of monolithic tandem cells will be beneficial to the further development of high efficiency tandem cells and their successful commercialization.[4-6]

Nano-photonics as a route to enhance the open circuit voltage from perovskite and organic photovoltaic cells

Jordi Martorell

ICFO-The Institute of Photonic Sciences, The Barcelona Institute of Science and Technology, 08860 Castelldefels, Barcelona Spain.
Departament de Física Universitat Politécnica de Catalunya, Terrassa 08222, Spain.

Abstract
A nanophotonic structuration of perovskite and organic solar cell architectures is considered for enhancing the open-circuit voltage (Voc). Numerical and experimental results to limit Boltzmann losses and set the path to push the efficiency from planar geometry single junction cells from 33% to levels exceeding 41% will be presented.

Summary
While existing light management strategies predominantly target an effective sunlight absorption and short-circuit current density enhancement, optical approaches to reduce Voc losses in solar cells are seldom explored. In the current work we take a radical shift for enhancing the efficiency of perovskite and organic solar cells, with a specific focus on improving the open-circuit voltage (Voc) by considering the incorporation of a nanophotonic structuration designed to serve as angular restrictor for the emission photons in thin film solar cells.

We will present different nanophotonic structures which primary objective is to mitigate losses associated with bimolecular radiative recombination, specifically Boltzmann losses, without the reliance on sunlight concentration. This approach aims to preserve the advantages inherent from a planar configuration in solar cells. We will discuss numerical and experimental results where light emission and quasi-Fermi level splitting in perovskite and organic solar cells is modified by the incorporation of different nanophotonic structures. We will also discuss how the nanophotonic structuration can control the Voc to open paths for surpassing the planar geometry single junction solar cell power conversion efficiency limit and push it from 33% to reaching levels exceeding 41%. Through such unconventional approach we aim at taking planar geometry single junction solar cells to reach the high efficiencies obtained by sunlight concentration in simple and commercially viable photovoltaic configurations.

Interface study for Sn-Pb mixed perovskite solar cells

D. H. Kim[1*]

[1] Department of Materials Science and Engineering, Korea University, Republic of Korea
[*]corresponding author: donghoekim@korea.ac.kr

Abstract: Most studies of Sn-Pb perovskite have focused mainly on itself. In this presentation, I introduce our diverse works on the interfaces between Sn-Pb perovskite and charge transport layers to improve the electrical and physical properties on the device.

The perovskites are an attractive choice as ideal light absorbing materials for next generation solar cells due to their unique bandgap tunability and excellent optoelectrical properties. As a result, various perovskite-based solar cells have shown many outstanding performances, such as the highest certified efficiency in thin-film criteria (26.1%) and in silicon-based dual-junction tandem device (33.9%).[1]

Among the various types of perovskites, those with a mix of tin (Sn) and lead (Pb) in the B-site have a narrow bandgap. This allows them to absorb light up to the near-infrared region. Theoretically, this means they could be used to create higher-efficiency single-junction solar cells than that of Pb-based perovskite solar cells. Moreover, they could be part of tandem solar cells that surpass 30% efficiency. As a result, narrow bandgap perovskites have gained importance in perovskite solar cell research. To tap into the potential of Sn-Pb perovskites, researchers have explored various aspects such as composition, morphology, and how to prevent Sn^{2+} from oxidizing.[2] So far, the efficiency of Sn-Pb perovskite solar cells has reached up to 23.8%.[3] However, most studies have focused mainly on the Sn-Pb perovskite itself. For further breakthroughs, it's crucial to look at the interface between materials.

For example, from the beginning, poly[3,4-ethylene dioxythiophene]-poly[styrene sulfonate] (PEDOT:PSS) has been commonly used as the hole transport layer because it matches the energy levels well. But, the PEDOT:PSS layer has several downsides. First, its acidic nature; second, its sensitivity to moisture; and third, its lower electrical conductivity for moving charges because the PEDOT is encased in PSS. These issues mainly cause defects at the interface between PEDOT:PSS and the perovskite, making it less stable compared to Pb-based perovskites. Despite these disadvantages, it is still in use because the interface with PEDOT:PSS has not been changed or replaced by a new HTL material.

In this talk, I will introduce how we enhanced the electrical properties of the interface between the electron transport layer and Sn-Pb mixed perovskite through additives and introduced molecular engineering on the PEDOT:PSS surface to improve the electrical and physical junction properties of the PEDOT:PSS/perovskite interface. I believe that the results of these surface studies will provide some insights to open the next chapter of Sn-Pb perovskite research.

Crystal Growth and Composition Engineering for Reproducible Fabrication of High-Performance Perovskite Solar Cells

Jin-Wook Lee *

Department of Nano Science and Technology and Department of Nanoengineering, SKKU Advanced Institute of Nanotechnology (SAINT), Sungkyunkwan University, Suwon 16419, Republic of Korea.
SKKU Institute of Energy Science & Technology (SIEST), Sungkyunkwan University, Suwon, 16419, Republic of Korea

Metal halide perovskite solar cells (PSCs) have been spotlighted as a promising next-generation photovoltaic technology. Recently, there has been a surge of efforts in the commercialization of PSCs in academia and industries worldwide with record power conversion efficiencies over 26% for both n-i-p and p-i-n structured devices. Nevertheless, their subpar operational durability, module scalability, and material toxicity are challenges often brought up as the major barriers hindering practical commercialization. The poor reproducibility of PSCs has been relatively overlooked, but negatively impacts institutional research laboratories, start-up companies, and large established corporations all alike. Reproducible fabrication of PSCs is a critical consideration for market viability and practical commercialization. In this work, I will discuss the critical functions of atmospheric humidity to regulate the crystallization and stabilization of formamidinium lead triiodide ($FAPbI_3$) perovskites. We demonstrate that the humidity content during processing underlies profound variations in perovskite stoichiometry, thermodynamic stability, optoelectronic quality and thus reproducibility of PSCs. In second part of the presentation, I will discuss the interplay between composition of perovskite, and performance and stability of inverted PSCs. We rationalize the difference in widely used perovskite compositions in n-i-p and p-i-n PSCs.

Vacuum-Processed Additive: A Novel Approach for Controlling Growth of Perovskite Crystals in All Vacuum Processed Perovskite Solar Cell

K. Lee[1], and K. Kim[1]

[1] Department of Chemistry and Nano Science, Ewha Womans University, Seoul 03760, Republic of Korea
*corresponding author: kimkk@ewha.ac.kr

Abstract: We present a novel method for controlling the growth of perovskite crystals in a vacuum thermal evaporation process by utilizing a vacuum-processable additive, propylene urea (PU). Co-evaporating of perovskite precursors and PU retards the direct reaction between the perovskite precursors. This facilitates larger domain size and reduced defect density.

In this study, we present a novel method for controlling the growth of perovskite crystals in a vacuum thermal evaporation process by utilizing a vacuum-processable additive, propylene urea (PU). By co-evaporating perovskite precursors with PU to form the perovskite layer (Figure1), PU, acting as a Lewis base additive, retards the direct reaction between the perovskite precursors. This facilitates larger domain size and reduced defect density (Figure 2). Following the removal of the residual additive, the perovskite layer, exhibiting improved crystallinity, demonstrates reduced charge recombination, as confirmed by time-resolved microwave conductivity analysis. Consequently, there is a notable enhancement in open-circuit voltage and power conversion efficiency, increasing from 1.05 V to 1.15 V and from 17.17% to 18.31%, respectively. The incorporation of a vacuum-processable and removable Lewis's base additive into the fabrication of vacuum-processed perovskite solar cells offers new avenues for optimizing these devices.

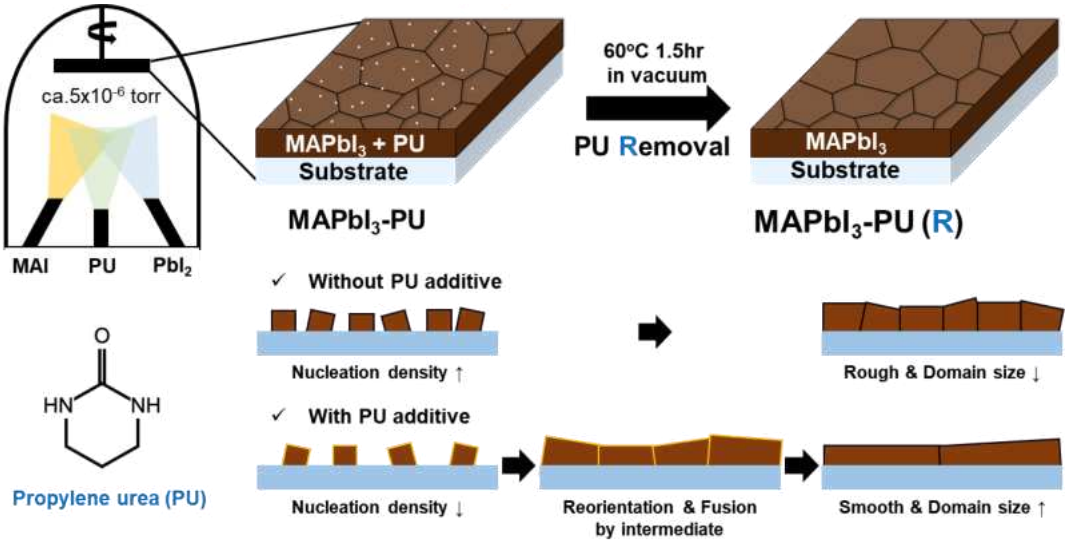

Figure 1. Schematic diagram of the vacuum-processed perovskite fabrication process with a vacuum-processable propylene urea (PU) additive and subsequent removal step for residual PU additive. Schematic representation of perovskite crystal formation without and with PU additive and corresponding chemical structure of PU are also shown.

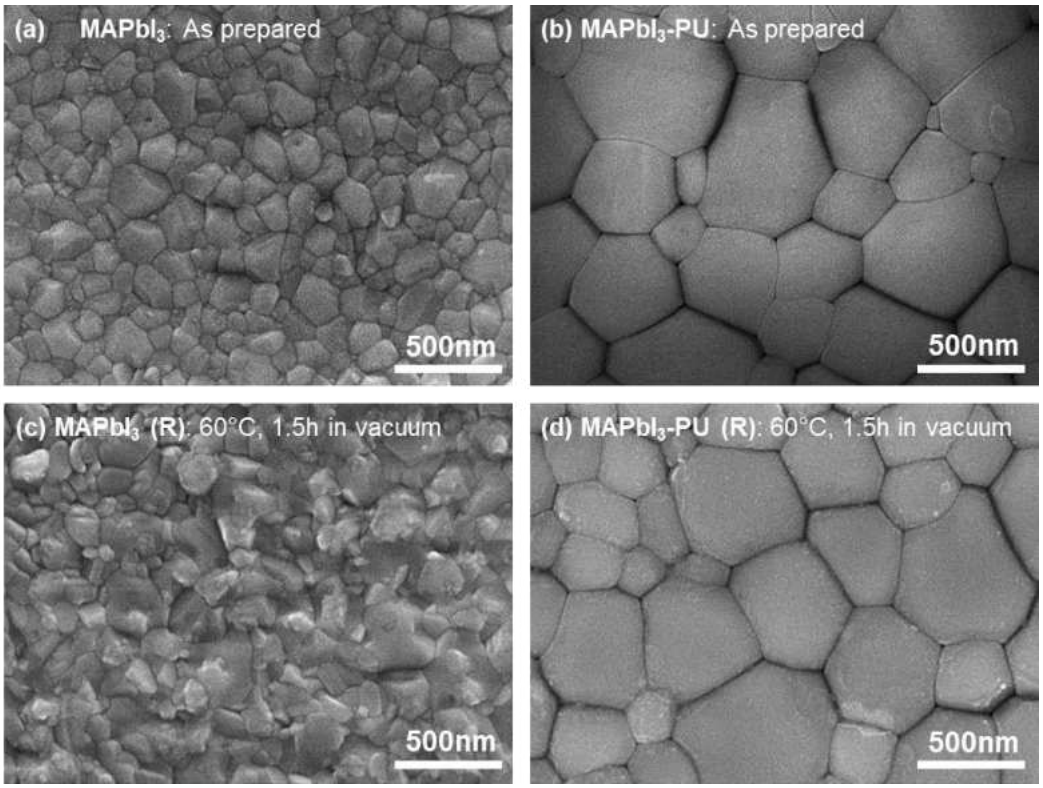

Figure 2. Top view scanning electron microscopy (SEM) images of vacuum-processed $MAPbI_3$ film with different fabrication condition. (a) $MAPbI_3$ film without PU additive and (b) with PU additive before the subsequent annealing step and (c) $MAPbI_3$ film without PU additive and (d) with PU additive after the subsequent annealing step.

Performance-limiting processes in $Cs_2AgBiBr_6$ double perovskite solar cells

Wolfgang Tress*

Institute of Computational Physics, Zurich University of Applied Sciences, 8400 Winterthur, Switzerland

*corresponding author: wolfgang.tress@zhaw.ch

Abstract: $Cs_2AgBiBr_6$ double perovskite solar cells are one of the sister devices of the lead-based perovskites. However, their photophysics is highly distinct posing various open questions. Some of those are addressed by photo and electro-luminescence spectroscopy and sensitive spectral response measurements, all performed on working devices and temperature-dependent.

Highly-efficient perovskite solar cells contain the heavy metal lead. One way to avoid lead consists of employing double perovskite materials. One of the most common representatives in photovoltaics research is $Cs_2AgBiBr_6$, so far commonly yielding power-conversion efficiencies below 5%. Although the potential of this material as an absorber in solar cells is limited due to an absorption onset above 2 eV, it is a highly interesting optoelectronic material. Understanding its properties might contribute to pave the way for the development of further lead-free perovskite(-similar) materials.

In this contribution, the performance-limiting factors in $Cs_2AgBiBr_6$ solar cells are discussed based on a temperature-dependent study of the optoelectronic properties. The findings are very distinct from the lead-halide perovskites, which can be described as a semiconductor, where e.g. the common reciprocity relations are applicable.

The large Stokes shift between absorption (peak at 2.8 eV) and emission (peak at 2.0 eV) of $Cs_2AgBiBr_6$ and the broad emission were early observations that gave rise to still ongoing debates. We find that it is indeed not straight-forward to employ reciprocity relations to deduce radiative open-circuit voltage (Voc) limits from sensitive measurements of the photocurrent onset. Fitting a Gaussian allows to calculate a radiative Voc limit of 1.95 V and roughly reproducing the photoluminescence (PL) spectra.[1] However, using an exponential fit, a strongly temperature dependent Urbach energy with a value of ca. 50 meV at room temperature can be found. Furthermore, the PL, which increases by two to three orders of magnitude when decreasing the temperature to 100 K, can be separated into two peaks: One (630 nm), whose shape is hardly affected by temperature similarly to the absorption peak and a second one further in the red (670 nm) that shows a stronger temperature dependence. The first confirms earlier suggestions of a rather localized excitonic transition in contrast to a transition between a valence and conduction band of the crystal. Since the absorption peak remains mainly unaffected by temperature as well, this indicates the same origin of absorption and PL despite the large shift. From impedance spectroscopy, we deduce a dielectric constant of 21, which indicates efficient charge screening. Analyzing light- and temperature dependent open circuit voltage data in the range above 250 K allows for a linear extrapolation to values at 0 K, yielding a value of around 2 V. The open-circuit voltage is limited by non-radiative recombination as electroluminescence yields of 1e-8 show, where interestingly the EL spectrum is further redshifted compared to the PL. One part of the rather low Voc of 1.1 V can be explained by poor contact selectivity as voltage-dependent external quantum efficiency measurements indicate. Also scan-rate dependent current-voltage curves unravel slow processes that counteract efficient charge collection. Adding a 2D perovskite layer on top of the 3D one could slightly attenuate these losses.[2]

Functions of Porous Carbon in Multi-Porous-Layered-Electrode Perovskite Solar Cells (MPLE-PSCs)

S. Ito[1]

[1]University of Hyogo, Japan
corresponding author: userid@institution.edu

Abstract: Information of carbon materials (carbon black and graphite) for fully-printed carbon-based perovskite solar cells has been disclosed. TEM images and conductivity variation with the mixing ratio are shown. And, the hole extraction ability has been discussed with the results of J-V curves by inversed-structured multi-porous- layered-electrode perovskite solar cells (MPLE-PSCs).

For commercialization of perovskite solar cells, utilization of carbon back contact is quite important, because of the reasons below:

[1] Printability (without vacuum deposition)
[2] Low sheet resistance (small resistibility as TCO in solar cells)
[3] Chemical stability (stable against iodide)
[4] Hole extraction
[5] Moisture blocking with perovskite crystal
[6] Water adsorption (as activated charcoal)

If solar cells will be fabricated via vacuum deposition, the system cost must be larger than printing one. Moreover, printing procedure is faster than vacuum deposition, which is important to fabricate cost-effective solar cells. And, the printed carbon layer can be a good conducting film. The sheet resistance of printed-carbon layer is as low as transparent conducting oxide (TCO) [8 - 10 Ω/sq.]. We have used conducting carbon black (about 30 nm diameter) (Figure 1) and graphite (about 1 - 30 μm) (Figure 2). Specially, combination of carbon black and graphite is quite important (Figure 3). The standard materials in perovskite solar cells for used back contact electrodes are gold and/or silver, which can react with iodin in perovskite solar cells. For the long-time stability, elimination of Au and Ag is quite important about perovskite solar cells.

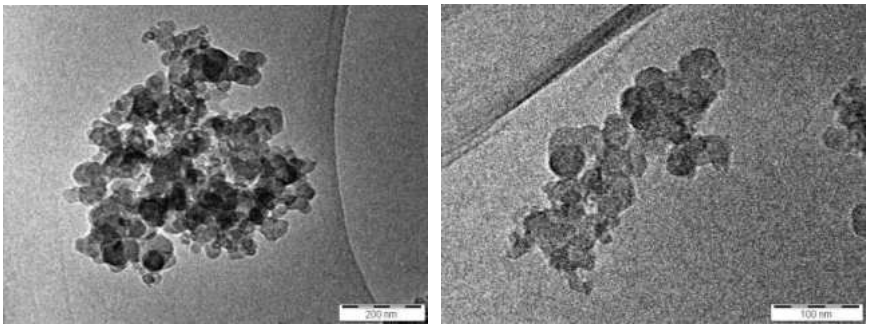

Figure 1. TEM images of carbon black for MPLE-PSCs; left: large view; light magnified view.

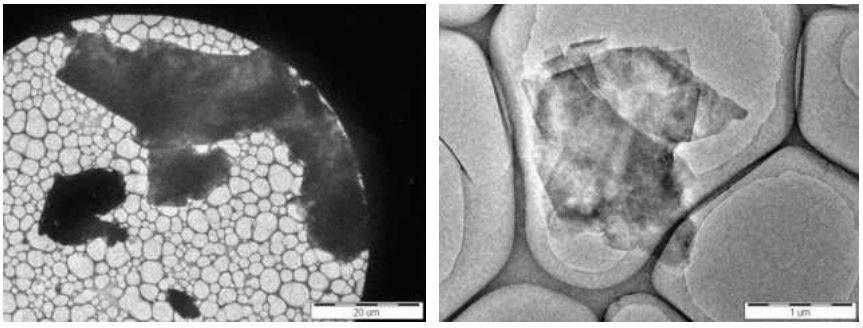

Figure 2. TEM images of graphite for MPLE-PSCs; left: large view; light magnified view.

The conducting carbon layer has the function of hole extraction. In order to confirm it, we have compared J-V curves of inversed-structured multi-porous-layered-electrode perovskite solar cells (MPLE-PSCs) of <porous carbon/porous In-Zn-O(IZO)/porous ZrO_2/compact NiO/FTO/glass> and <Ag/BCP/porous In-Zn-O(IZO)/porous ZrO_2/compact NiO/FTO/glass> (Figure 4). The porous layers were filled with organo-lead-iodide perovskite crystal ($(5\text{-AVA})_{0.05}MA_{0.95}PbI_3$). Since Nickel oxide and carbon compete for holes, the Voc of "carbon electrode" became quite smaller than that of "Ag electrode". Hence, we have confirmed that caron has strong ability to extract holes in perovskite crystal.

Moreover, the porous carbon layer has the ability of moisture blocking with filled perovskite crystal in the pore. And, water can be adsorbed like activated charcoal, which can work as getter material in solar cells. The details would ne In the conference, the details will be discussed.

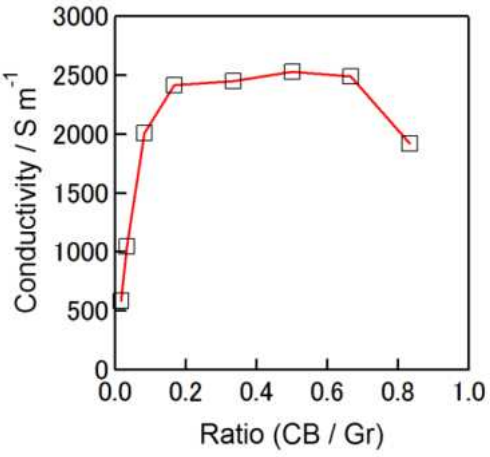

Figure 3. Variation of conductivity with the mixing ratio of carbon black (CB) and graphite (Gr.)

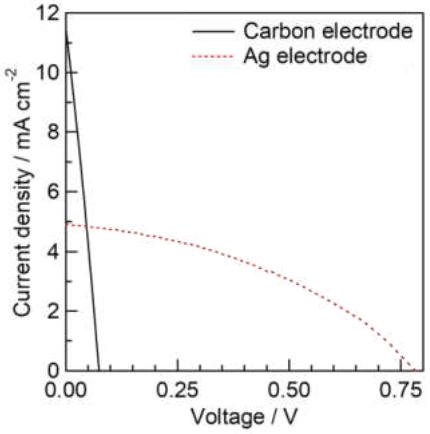

Figure 4. J-V curves of inversed-structured multi-porous-layered-electrode perovskite solar cells (MPLE-PSCs) of <porous carbon/porous In-Zn-O(IZO)/porous ZrO_2/compact NiO/FTO/glass> (as "Carbon electrode" in figure) and <Ag /BCP /porous In-Zn-O(IZO) /porous ZrO_2/compact NiO /FTO /glass> (as "Ag electrode" in figure).

Halide Interfacial Layers for Perovskite Solar Cells

Jun Hong Noh[1*]

[1]School of Civil, Environmental & Architectural Engineering, KoreaUniversity,

Seoul, South Korea

[*]corresponding author: junhnoh@korea.ac.kr

Abstract: Halide perovskite solar cells have a thin-film device architecture including interfaces between hetero-materials such as oxides, halides, and organic materials. Here, the wide-band gap halide interfacial layers will be discussed to ensure compatibility with the light absorbing halide perovskite layer for achieving high photovoltaic performance.

The light absorbing halide perovskite layer with narrow band gap of ~ 1.5 eV is used in perovskite solar cells. The interface between the light absorbing layer and charge transporting layers such as Spiro-OMeTAD, P3HT, and SnO_2 is a crucial location where non-radiative recombination sites are predominantly formed, and it serves as a key site where charge transfer must take place. The articles show wide band gap halide perovskite layers that do not only successfully passivate the interfacial trap sites but also design the interfacial electric field.

Abstract: Perovskite solar cells are emerging as a game-changer in photovoltaics, offering a path to highly efficient solar energy conversion.[1–3] Surface modification of perovskite layer is crucial to improve device performance and durability. In this talk, we will present recent progress on the development of charge collecting materials and surface modification with dipole strategy.

Tripodal Triazatruxene Derivative as a Face-On Oriented Hole-Collecting Monolayer for Efficient and Stable Inverted Perovskite Solar Cells[1]

Hole-collecting monolayers have drawn attention in perovskite solar cell research due to their ease of processing, high performance, and good durability. Since molecules in the hole-collecting monolayer are typically composed of functionalized π-conjugated structures, hole extraction is expected to be more efficient when the π-cores are oriented face-on with respect to the adjacent surfaces. However, strategies for reliably controlling the molecular orientation in monolayers remain elusive. In this work, multiple phosphonic acid anchoring groups were used to control the molecular orientation of a series of triazatruxene derivatives chemisorbed on a transparent conducting oxide electrode surface. Using infrared reflection absorption spectroscopy and metastable atom electron spectroscopy, we found that multipodal derivatives align face-on to the electrode surface, while the monopodal counterpart adopts a more tilted configuration. The face-on orientation was found to facilitate hole extraction, leading to inverted perovskite solar cells with enhanced stability and high-power conversion efficiencies up to 23.0%.[4]

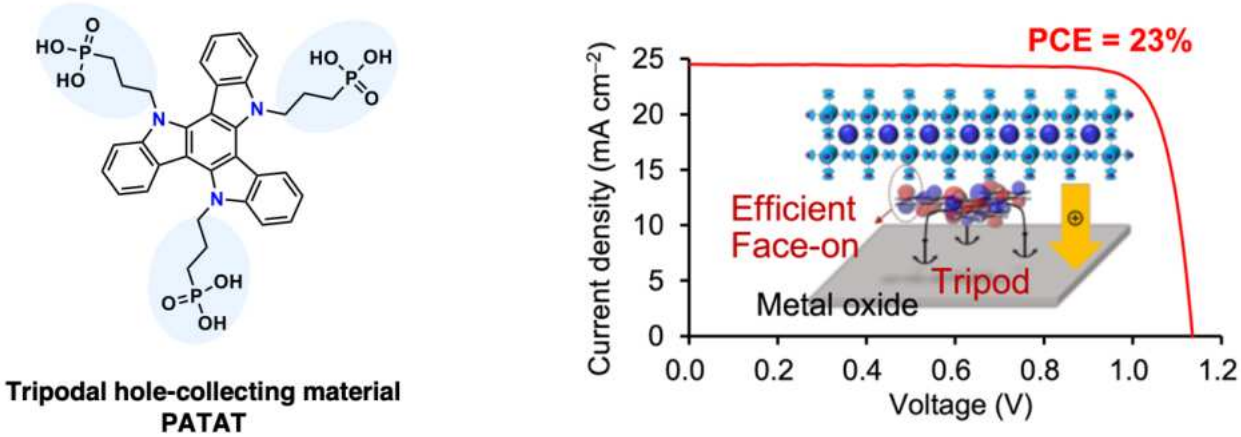

Fig. 1. Triazatruxene-based tripodal hole collecting monolayer for inverted perovskite solar cells.

Optimized Carrier Extraction at Interfaces for Efficient Perovskite Solar Cells[5–7]

Carrier extraction in mixed tin–lead perovskite solar cells is improved by modifying the top and bottom perovskite surfaces with ethylenediammonium diiodide and glycine hydrochloride, respectively. Trap densities in the perovskite layers are reduced as a result of surface passivation effects and an increase in film crystallinity.

In addition, the orientated aggregation of the ethylenediammonium and glycinium cations at the charge collection interfaces result in the formation of surface dipoles, which facilitate charge extraction. As a result, the treated mixed tin–lead perovskite solar cells showed improved performance, with a fill factor of 0.82 and a power conversion efficiency up to 23.6%. The unencapsulated device also shows improved stability under AM1.5G, retaining over 80% of the initial efficiency after 200 h continuous operation in inert atmosphere. Our strategy is also successfully applied to centimeter-scale devices, with efficiencies up to 21.0%.[5]

New Class of Semiconducting Organic-Inorganic Metal Halides for Photovoltaic Devices

Hyunjung Shin*

Department of Energy Science, Department of Future Energy Engineering, SKKU Institute of Energy Science and Engineering, Sungkyunkwan University, Suwon, Korea

*corresponding author: hshin@skku.edu

Abstract: Organic-inorganic hybrid metal halides are now emerging as new class of semiconductors. It shows "Perovskite" crystal structure and is used as a main light absorber in photovoltaic cells, known as 'Perovskite Solar Cell (PSC)'. The notable examples are $MAPbI_3$ (methyl ammonium lead triiodides) and $FAPbI_3$ (formamidinium lead triiodides). The PSC now shows a remarkable power conversion efficiency (PCE) of 26.1%. These halides are truly unique semiconducting materials showing excellent optoelectronic properties, even their preparation methods are simple like spin coatings of precursor solution with a low temperature annealing. Unlike monocrystalline Si, and GaAs, these halides contain lot of defects, which are potentially non-radiative recombination centers. Defect tolerating in these halides is now under debating and thus defect engineering is the key to increase further the PCE. In this talk, the unique semiconducting properties studied are summarized and understanding of the materials' structure-properties relationship will be discussed. Further, we examined the crystallization process of MACl, as higher concentration of MACl induces slower crystallization kinetics. Microscopic observations, such as electron back-scattered diffraction (EBSD), confocal photoluminescence (PL), time-resolved photoluminescence (TRPL) mapping, and conductive atomic force microscopy (C-AFM), were conducted to examine the optoelectronic properties of [001] preferentially oriented grains. Reduction in the non-radiative recombination, a longer lifetime of charge carriers and less photocurrent deviation between each grain induce higher short-circuit current density (J_{sc}) and fill factor (FF) in α-$FAPbI_3$ based PSCs with MACl40%.
It highlights the importance of crystallization kinetics resulting in desirable microstructures for device engineerin g.

Orientation control of perovskites using asymmetric amines

Y. Takeoka[1*], H. Kobayashi[1], D. Hishida[1], Masahiro Yoshizawa-Fujita[1], and M. Rikukawa[1]

[1]Sophia University, Japan
[*]corresponding author: y-tabuch@sophia.ac.jp

Abstract: q-2D organic-inorganic perovskites are expected as solar cell materials due to their high stability. Because the orientation q-2D perovskites affets carrier transport properties, the orientation is important. In this study, we focused on the orientation control of q-2D perovskites prepared from asymmetric diamines and evaluated their solar cell performance.

Lead halide-based perovskite compounds have attracted significant attention since their initial application to photovoltaic devices by Miyasaka *et al*. in 2009.[1] As research into perovskite solar cells (PSCs) has progressed over the last several years, the power conversion efficiency (PCE) values of PSCs have increased from 3.8% to more than 25%, that reaches the level of practical application. Among the lead halide-based PSCs, three-dimensional (3D) perovskites have been mainly used. However, they are easily affected by moisture, oxygen, and heat, and are susceptible to degradation by water. To address this issue, two-dimensional (2D) perovskites have attracted much attention because of their excellent stability against moisture. Because 2D perovskites possess an organic ammonium layer that acts as an insulator and the $[PbX_6]^{4-}$ (X: halogen) layers are connected two-dimensionally, the diffusion of photo-generated carriers is limited. Therefore, quasi two-dimensional (q-2D) organic-inorganic perovskite compounds which are intermediate compounds of 2D and 3D perovskites show potential to solve the stability issue of PSCs. In solar cells, the direction of carrier transport is perpendicular to a substrate. However, q-2D perovskites have a strong tendency to orient parallel to a substrate and this trend renders the migration of transport carriers in the vertical direction difficult. As a result, the power generation performance of PSCs based on q-2D perovskites is significantly reduced. Our group has reported the orientation control of 2D and q-2D perovskites which has one or more inorganic sheets by changing organic ammoniums with various film preparation methods.[2-4] As a result of these considerations, although the verticality of the inorganic layer improved, it was not possible to achieve a completely single crystal orientation.

In this study, we focused on the structural orientation and improvement of crystallinity brought about by the asymmetry of diamine and aromatic ring-containing organic ammonium. We investigated the structure, optical properties, and crystal morphology of q-2D perovskites using asymmetric phenyleneammonium and its counterpart of asymmetric alkylammonium.

By introducing a rigid aromatic ring to the asymmetric diammonium, a q-2D perovskite compound with a controlled orientation of certain angle was obtained. It was suggested that carrier transport is possible because the inorganic layer forms a structure that is oriented out of plane with respect to the substrate. In addition, by changing the self-organization, a thin film containing many large-n phases was obtained, the band edge was red-shifted, and the crystallinity was improved. A q-2D perovskite compound using asymmetric phenylene diammonium was suggested to be a promising material for solar cells.

Abstract: Organic-inorganic hybrid perovskites have emerged in recent years as one of the most promising materials for solution-processed electronics and optoelectronics. We showed that through a full precursor technology option, it is possible to access a wider cation library for these capping layers.

Organic-inorganic hybrid perovskites have emerged in recent years as one of the most promising materials for solution-processed electronics and optoelectronics including solar cells, light-emitting diodes (LED) and field-effect transistors (FET). There is an active exploration of different organic molecules contribution to the materials behaviour and also the use of novel interfacial layer and their functions to improve the performance of the devices. The key to the successful implementation of any materials systems depends very much on the how facile is the methodology. In this presentation, two examples will be shown on how the understanding of the materials can lead to simple solution with good outcome. In solar cells application, there are two critical performance indicators – efficiency and stability. Two layers combination making up of three-dimensional (3D) perovskite capped with low-dimensional (LD) perovskites materials have shown be an effective strategy in resolving the compromise that we have to live with for hybrid perovskites – compromise between photovoltaic efficiency and operational stability. In the study, instead of the conventional LD capping layers containing Pb2+ or Sn2+, we showed that through a full precursor technology option, it is possible to access a wider cation library for these capping layers.[1] Through this method, high efficiency cells can be achieved. Hybrid perovskites also have shown to have great potential to be used as emitters with tunable emission, high color purity and good ease of fabrication. A lot of studies have so far been focused on three-dimensional (3D) perovskites, such as CH3NH3PbBr3 and CH3NH3PbI3 for green and infrared emission. The organic molecules used in these systems can be varied and it can give rise to different optical behaviour. I will also share some work that we have done with active cations which of energy levels that can be made use of to encourage the harvesting of triplets and this opens up a very interesting optoelectronic behavior[2,3].

Tailoring Charge Transport in Mixed-Valence Coordination Polymers for Emerging Molecular Devices

M. Freitag
Newcastle University, UK
*corresponding author: Marina.Freitag@newcastle.ac.uk

Abstract: Coordination polymers offer exceptional tunability and sustainability as charge transport materials for emerging technologies, including photovoltaics, batteries, and sensors. This comprehensive study elucidates their structure-function relationships, charge transport mechanisms, and applications, showcasing their potential to outperform conventional charge extracting materials. Tailoring mixed-valence copper polymers yielded high efficiencies and stability in hybrid solar cells.

The relentless pursuit of sustainable energy solutions has spurred the development of emerging technologies, including photovoltaics, batteries, and sensors. However, their widespread adoption has been hindered by the lack of efficient, stable, and tuneable charge transport materials. Coordination polymers (CPs), comprising metal centres bridged by organic or inorganic ligands, present an unprecedented opportunity to address this challenge. This comprehensive study delves into the intricate structure-function relationships governing charge transport in CPs and their applications in cutting-edge molecular devices.

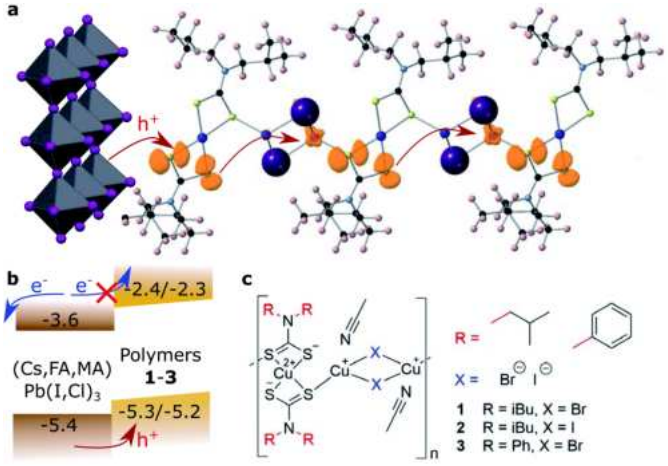

Figure 1 Copper coordination polymers as hole conducting materials. (a) Polarons hop along a computational model of a coordination polymer chain. (b) Energetic position of the frontier orbitals in relation to the halide perovskite valence and conduction band edges. (c) General structure of the coordination polymers presented in this work

Through a synergistic approach combining experimental and theoretical methods, the charge transport mechanism in a series of mixed-valence $Cu^{(II/I)}$ coordination polymers is elucidated. Electrochemical analysis, Raman spectroscopy, and X-ray diffraction techniques are employed to unravel the electronic and structural properties of these materials. Density functional theory calculations reveal that the bridging halide ligands play a pivotal role in modulating the electronic conductivity. The iodide-bridged polymer exhibits superior transport characteristics, with a conductivity of 1 mS cm^-1 and a hole mobility of 5.8×10^{-4} cm^2 $(V\ s)^{-1}$ at room

temperature, attributed to the enhanced orbital conjugation between copper ions facilitated by the more polarizable iodide anions.

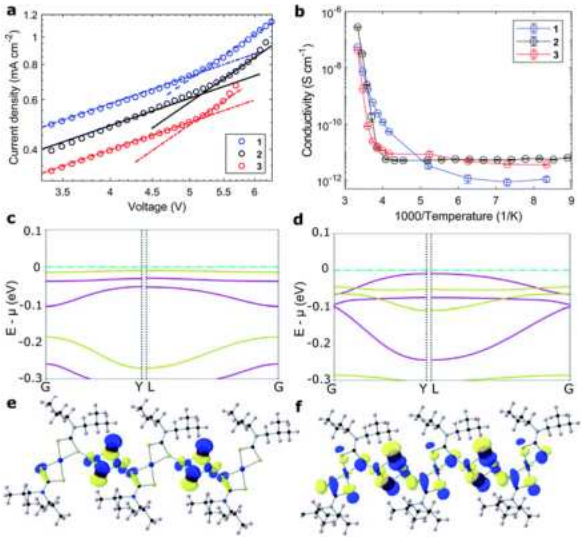

Figure 2 Charge transport in the coordination polymers. (a) Space-charge limited current hole mobility and (b) temperature-dependent conductivity of coordination polymers 1–3. (c and d) Band structure around the valence band of polymers 1 and 2 along high symmetry paths. (e and f) Orbital projections of the top of the valence band for 1 and 2.

The exceptional charge transport properties of CPs are harnessed in the development of perovskite solar cells. Picosecond photoluminescence spectroscopy confirms the rapid charge extraction from halide perovskite films by the CP hole-conducting layers. Remarkably, carbon-based perovskite solar cells incorporating the iodide-bridged CP achieve high power conversion efficiency with carbon electrodes outperforming state-of-the-art organic hole conductors and exhibiting improved long-term stability, retaining stability over months.

This comprehensive study underscores the pivotal role of coordination polymers as sustainable, high-performing charge transport materials for emerging molecular devices. By elucidating the structure-function relationships and charge transport mechanisms, researchers can harness the unique advantages of CPs, such as their exceptional tunability through molecular design. The ability to fine-tune the electrical and structural properties paves the way for the development of environmentally friendly and efficient technologies, addressing the pressing need for sustainable energy solutions.

Plasmonics: Fundamentals and Applications

Plasmon-based chiroptical sensing

S. Liu, R.-Y. Wang *

School of Physics, Beijing Institute of Technology, Beijing 100081, China.
*corresponding author: wangry@bit.edu.cn

Abstract: In this talk, we report a chiral plasmonic nanosensor capable of transforming molecularly enantioselective recognition into asymmetrically amplified plasmonic circular dichroism (CD) readouts. This chiral nanosensor enables the enantiospecific recognition and determination of enantiomeric excess of amino acid molecules.

Plasmonic nanosensors with strong chiroptical activities can provide a novel approach for analyzing molecular chirality. In particular, plasmonic CD spectral readouts can greatly enhance the detection sensitivity for trace amounts of biomolecules that cannot be detected using ordinary electronic CD techniques [1,2]. In this presentation, we introduce a new scheme for plasmon-based chiroptical sensing in the solution phase to detect and characterize molecular chirality at nanoscale interfaces. Unlike previous studies [2,3] that focused on plasmonic chirality induced by a single molecularly chiral source, our approach involves a molecules-to-nanoparticles chirality transfer system with two molecularly chiral inputs. In this chiral sensing scheme (Figure 1), gold nanorods arranged in a chiral manner serve as plasmonic nanotransducers to convert enantioselective recognition between two molecular inputs into asymmetrically amplified plasmonic CD readouts. The utilization of plasmonic CD-based chiral probes enables enantiospecific recognition and quantitative determination of the enantiomeric excess of amino acid molecules [4]. This chiroptical method exhibits advantages such as easy processing and cost-effectiveness, which hold great promise for high-throughput chiral analyses in fields such as biology, stereochemistry, and pharmaceutics.

Abstract: Recent advances in piezoelectric MEMS enabled multifunctional optical metasurfaces (OMSs) for dynamic phase and polarization control are presented. Moreover, theoretical investigations on the MEMS-OMS configuration show that control over scattering phase singularities in the parameter space determined by the MEMS-OMS separations and meta-atom sizes with the OMS, underpins these developments.

Main:

Dynamic optical metasurfaces (OMS) stand at the forefront of advancing intelligent and adaptable optical systems and networks due to their ultra-compact design and reconfigurable responses[1]. The evolution of dynamic OMS has significantly benefited from the incorporation of active materials such as 2D materials, phase-change materials (PCMs), liquid crystals (LCs) and others[2]. However, challenges persist in achieving an optimal balance between speed and efficiency. For instance, while dynamic OMS using 2D materials offer rapid response times, they tend to have limited modulation strength. Conversely, dynamic OMS that integrate PCMs and LCs can attain high modulation strength but typically suffer from slower response times. Additionally, LC-based dynamic OMS encounter issues related to polarization dependence, presenting a critical area for further improvement.

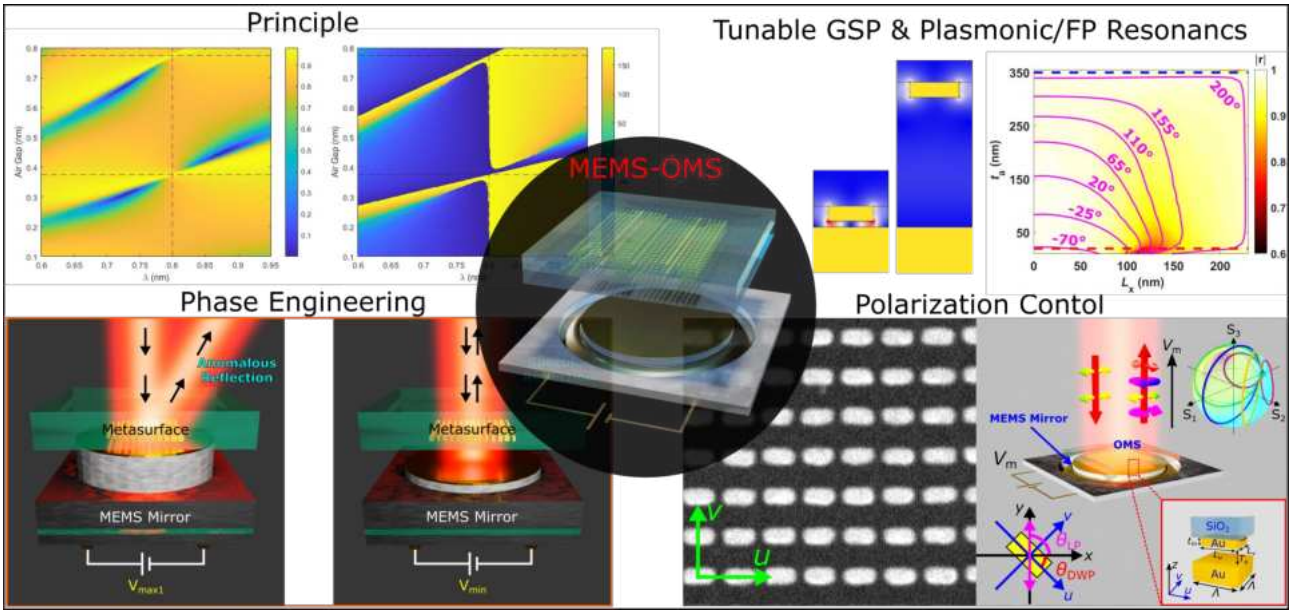

Fig. 1 MEMS-OMS platform: principles and implementations.

In a recent breakthrough, we have developed a MEMS-OMS platform that synergizes a piezoelectric MEMS mirror with a plasmonic OMS. This innovative combination has led to a ultracompact system capable of dynamically manipulating reflection phase and polarization with high efficiency, substantial modulation strength, and rapid response, as showcased in our demonstrations (Fig.1). We have successfully demonstrated a variety of

dynamic optical functionalities, such as blazed gratings[3,4], focusing lenses[3], waveplates[5] as well as both linear and chiral polarizer[6,7].

Our investigation into the mechanism behind this dynamic response has unveiled that it stems from the controllable and tunable scattering phase singularities within a specific parameter space. This parameter space is defined by the MEMS-OMS separation and the dimensions of the meta-atoms. We have explored both tunable gap-surface-plasmon (GSP) resonances and hybrid plasmonic/Fabry-Pérot resonances to design the phase singularities within this parameter space.

To summarize, we will discuss the future outlooks for this platform, highlighting its potential to revolutionize the field of dynamic meta-optics with its innovative approach to achieving rapid, efficient, and strong modulation capabilities.

Chiroptics of hybrid nanostructures: Strong coupling effect and interference effect

Wei Zhang[1*]

[1] Institute of Applied Physics and Computational Mathematics, Beijing 100088, China
[*]corresponding author: zhang_wei@iapcm.ac.cn

Abstract: We study chiroptical properties of hybrid nanostructures, paying attention to the strong coupling effect and interference effect. Strong plasmon-exciton coupling leads to double Rabi splitting in the circular dichroism spectroscopy. Mode hybridization leads to chirality transfer between bright modes and dark modes and chirality selective Rabi splitting/Fano effect.

Chiroptics plays an important role in understanding light-matter interaction and has various applications [1-6]. In this talk, I will present our recent studies on the chiroptical properties of hybrid nanostructures made of (chiral) molecules and metallic/dielectric nanoparticles, paying attention to the strong coupling dynamics and interference effect.

We explore the chiroptical response of the hybrid systems with the chirality from exciton (of molecules) or from the plasmon (of nanoparticles). The strong coupling between and plasmon and exciton leads to avoided crossing and Rabi splitting in the circular dichroism (CD) spectroscopy. We propose and justify a new criterion of strong plasmon−exciton interaction: the mode splitting in the CD spectra (at zero detuning) is larger than half of that in the extinction spectra.

We develop a plexcitonic Born−Kuhn model to take into account both effects from chirality and strong coupling dynamics of the chiral hybrid nanostructures made of nanorods and molecules. As a consequence of strong interaction between plasmons and excitons, double Rabi splittings and an anti-crossing phenomenon appear in the CD spectroscopy. The character of dual plexciton (symmetric and anti-symmetric plexciton, the hybridized states resulting from the strong coupling between plasmons and excitons) and associated chiroptical properties have been demonstrated. The interplay between mirror symmetry breaking and plasmon−plasmon/plasmon−exciton interaction leads to an optimal configuration with the maximal chiroptical response. Moreover, chirality (of incident light) selective excitation of plexcitonic modes has been achieved by structural design.

We investigate the modulation of chiroptics of metasurface with unit cell of corner-stacked nanorods and stacked nanorings, paying attention to the bright-dark-mode coupling effects and interference effect. With the help of phase modulation and mode hybridization, we can realize chirality transfer from bright modes to dark modes, which results in chirality-selective transparency due to chirality-selective excitation of binding/antibonding dark modes. Moreover, one can switch between different coupling regimes with a distinct physical effect (Fano effect vs Rabi splitting) by changing only the chirality of the incident field without varying the structure of the metasurface. Based on the mechanisms of chirality transfer and mode hybridization, our designed metasurface has achieved chirality-selective transparent window with tunable central frequency and bandwidth, which provides insight and guidance for the optoelectronic device design.

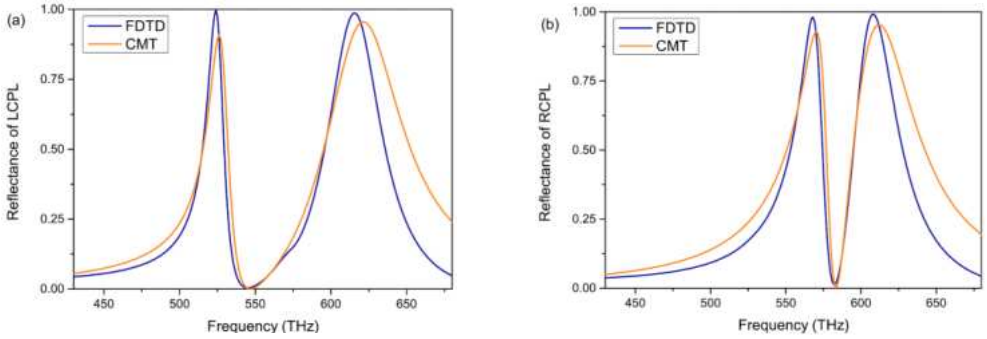

Figure 1. Chirality selective Rabi splitting (a, for left circularly polarized incident light) and Fano effect (b, for right circularly polarized incident light).

Abstract: On-chip plasmon detection is highly demanding in the plasmonic-integrated circuits. We demonstrated an on-chip plasmonic detector by placing an externally biased silicon strip at the end of the top-down fabricated gold plasmonic waveguides. The polarization and wavelength-dependent photocurrent confirm plasmonic detection under optimized near-field coupling geometry.

Owing to the advantage of small size and fast speed, plasmonic devices are promising to integrate with microelectronic chips for high-performance hybrid optoelectronic circuits. Despite the on-chip plasmon detector demonstration on chemically synthesized metallic nanowires [1] and metallic film [2], the on-chip plasmon detector remains to be explored for the top-down fabricated metallic plasmonic waveguides. Here, we demonstrated an on-chip plasmon detector solution for this purpose. The gold strip and silicon strip are top-down fabricated on the silicon-on-insulator substrate. The direct energy transfer from plasmons to electrons is achieved by optimized near-field coupling between the plasmon waveguide and silicon nanostrip. The detection is accomplished by converting the plasmons into a photocurrent signal. We confirmed the detection of plasmons through polarization and wavelength dependence of the photocurrent. Periodic oscillations in the wavelength-dependent photocurrent are attributed to the characteristic Fabry-Perot resonance in the plasmonic waveguide. According to the simulation results, up to 70% of the plasmonic energy could be absorbed in the silicon nanostrips by optimizing the thickness, width, and gap between the gold strip end and the silicon strip. Our design provides a promising on-chip plasmonic detector solution for plasmonic photocircuits.

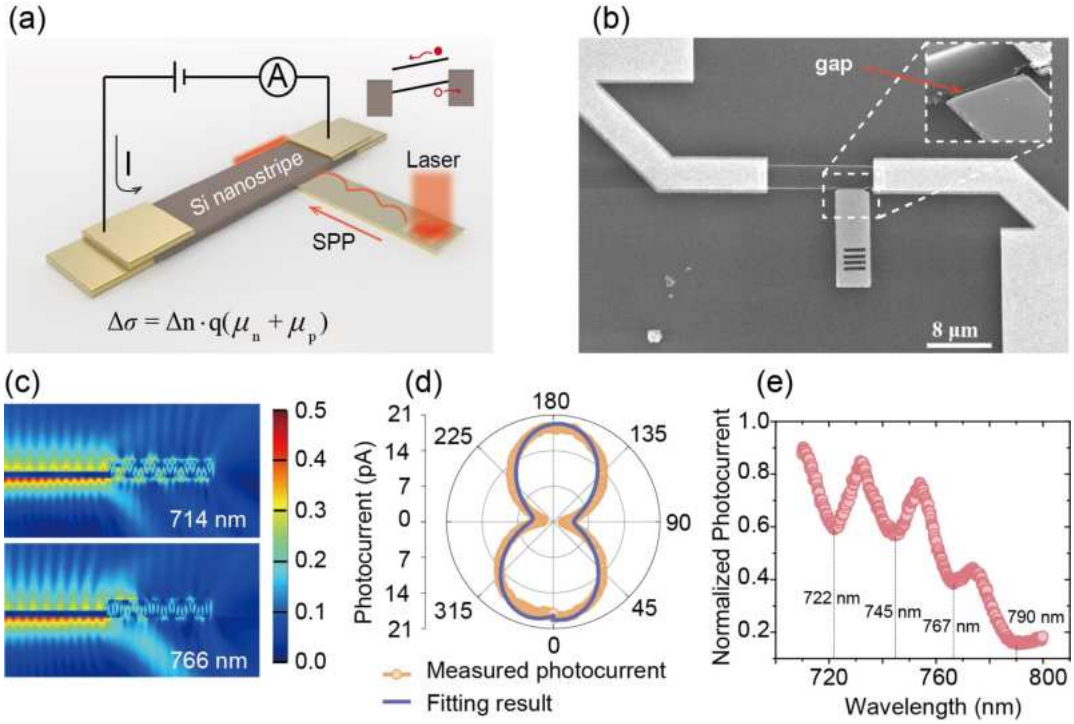

Figure 1. (a) Schematic diagram of the on-chip plasmon detector. The carriers are photo-generated through plasmon coupling into a Si strip and detected as photocurrents under external bias. (b) The SEM image of the prepared sample. It is composed of a Si strip and an Au strip. The inset showed the gap size in the coupling structure. (c) The electric field distribution in the coupling structure was calculated using the FDTD simulation for 714 nm (matching condition) and 766 nm wavelength laser(non-matching condition) excitation. (d) Measured polarization-dependent photocurrent. The angle θ was the included angle between incident laser polarization and the Au strip direction. (e) Measured wavelength-dependent photocurrent. A Fabry-Perot resonance is observed with a 23 nm oscillation period.

Dynamic plasmonics with structured alkali metals

Jie Liang[1], Yan Jin[1], Jia Zhu[1] and Lin Zhou[1*]

[1]College of Engineering and Applied Sciences, Nanjing University, China
[*]corresponding author: linzhou@nju.edu.cn

Abstract: Dynamic plasmonics has long been regarded as one of the most crucial branches for nanophotonics and integrated optics, which is urgent for active subwavelength optical devices. This report will present the recent advancements on alkali metals based dynamic plasmonics, from the fundamental optical properties to the potential applications.

Alkali metals, with their simple electronic structure, low free carrier density, and weak interband optical transition, are promising plasmonic materials expected to exhibit lower optical damping rates than conventional noble metals. Additionally, their potential as negative electrode materials in high-capacity, high-energy-density batteries offers a natural platform for dynamic plasmonics control.

I will first briefly present the basis of the electric-field driven microstructure transformation of lithium metals by employing a lithium metal battery platform. Then two kinds of application devices are explored. On the one hand, we try to utilize the real-time plasmonic signals to identify the morphology of lithium metals on the electrodes, which can serve as an in-operando monitoring technique for the lithium metal battery. On the other hand, we have developed the electric-field driven dynamic display through the reconfigurable plasmonic color of lithium particles.

A notable study involves in situ monitoring of lithium metal batteries. There's a pressing need for in situ, nondestructive techniques to monitor and control lithium metal morphology, crucial for rejuvenating lithium metal batteries. Leveraging lithium plasmonics, we devised an in situ monitoring platform (Figure 1) to study lithium deposition across various conditions and electrolytes. This technology, correlating evolving lithium morphologies with in situ optical spectra, offers an efficient means to investigate lithium morphology during electrochemical processes, accelerating electrolyte design and alkali metal-based energy storage system development.

Another most representative example, the electric-driven dynamic plasmonics for self-powered display, is shown in Figure 2. It is well known that, display and power supply have been two essential and independent cornerstones of modern electronics. A low power or even self-powered display devices are highly desired but rather challenging thus far. Our recent work reported a lithium plasmon based low-powered dynamic color display with inherited dual functionalities, the plasmonic display and energy recycling unit (see Figure 2a), through electric-driven transformation of nanostructured lithium metals. In such an intriguing operation configuration, each display pixel can work as a micro-battery cell and most excitingly, each micro-pixel (micro-battery) can be powered by its adjacent counterpart, making the manipulation of dual functionalities (information and energy) more flexible (Figure 2b).

We acknowledge the micro-fabrication center of National Laboratory of Solid State Microstructures (NLSSM) for technique supports, and these research works are supported by the National Key Research and Development Program of China (Nos. 2022YFA1404300, 2021YFA1400700); the National Natural Science Foundation of China (Nos. 12022403, 62375123) and the Excellent Research Program of Nanjing University (ZYJH005).

Nanometer-Scale Spatial and Spectral Mapping of Exciton Polaritons in Structured Plasmonic Cavities

David J. Masiello[1]

[1]University of Washington, Seattle, WA, USA
*corresponding author: masiello@uw.edu

Abstract: Exciton polaritons (EPs) are ubiquitous light-matter excitations under intense investigation as test beds of fundamental physics and as components for all-optical computing. Owing to their unique attributes and facile experimental tunability, EPs potentially enable strong nonlinearities, condensation, and superfluidity at room temperature. However, the diffraction limit of light and broad momentum content of fast electron probes preclude the characterization of EPs in nanoscale structured cavities exhibiting energy-momentum dispersion. Through an innovative combination of electron beam and optical probes, I will show theoretically that these limitations can be overcome to measure EPs in periodic nanophotonic cavities at their natural energy, momentum, and length scales via lattice electron energy gain spectroscopy. With the combined high momentum resolution of light and nanoscale spatial resolution of free-space focused electron beams, lattice electron energy gain spectroscopy can expose deeply subwavelength EP features using currently available monochromated, aberration-corrected scanning transmission electron microscopes (STEMs). Time permitting, I will also discuss the addition of polarization structure to the STEM electron probe and demonstrate theoretically how this degree of freedom can be harnessed to characterize the 3D polarization-resolved response field and local chirality of an optically excited target with nanoscale spatial resolution.

Alongside the recent proliferation of quantum materials comes the companion need to develop new measurement techniques to characterize these materials on their natural energy, length, momentum, and polarization scales. While optical methods offer unparalleled momentum and energy resolution, diffraction limits the achievable spatial resolution to hundreds of nanometers in the visible spectrum. Modern monochromated and aberration-corrected scanning transmission electron microscopes (STEMs), on the other hand, offer nanometer spatial resolution and $5-10$ meV energy resolution with a broadband spectrum spanning from vibrational to core excitations. This talk will discuss new STEM/TEM observables designed to map nanophotonic structures as well as 2D materials with simultaneously high energy, momentum, space, and polarization resolution.

Abstract: Integrating plasmonic nanostructure with 2D semiconductor materials has great potential in developing compact, high-performance photonic devices and nanoscale optoelectronic devices. In this presentation, we will introduce our recent work of employing individual plasmonic noble metal nanocrystals to integrated with 2D WS_2 and modulate the photoluminescence properties of the latter.

Two-dimensional transition-metal dichalcogenides exhibit rich excitonic properties. It is of great interest to achieve the modulation of the 2D semiconductor emission properties with spatial, spectral, polarization, and direction control. Plasmonic nanostructures can confine light to the nanoscale or even atomic scale and at the same time work as optical antennas to control light. Integrating plasmonic nanostructure with 2D semiconductor materials therefore has great potential in developing compact, high-performance photonic devices and nanoscale optoelectronic devices. In this presentation, we will introduce our recent work of employing individual plasmonic noble metal nanocrystals to integrated with 2D WS_2 and modulate the photoluminescence properties of the latter. We will first demonstrate the use of Au nanodisks and nanorods in generating and room-temperature detecting localized excitons of monolayer WS_2 with defined spatial confinement and an energy shift up to 200 meV[1]. We will then present the emission polarization and direction control of WS_2 monolayer excitons by individual plasmonic nanocrystals[1–3]. Besides the photoluminescence modulation of monolayer excitons, the plasmonic nanocrystals can form high-quality Fabry–Pérot resonators with integrating with WS_2 flakes and a Au mirror[4], providing a platform for controlling the WS_2 indirect band gap emissions.

Plasmonic-assisted 2D hybrid broadband photodetectors

I. Goykhman

[1]Institute of Applied Physics, The Faculty of Science and The Center for Nanoscience and Nanotechnology, The Hebrew University of Jerusalem, Jerusalem 91904, Israel.

[*]corresponding author: ilya.goykhman@mail.huji.ac.il

Abstract: The rich portfolio of 2D materials and favorable heterogeneous integration with silicon technology set up new horizons for integrated photonics and optoelectronics. In this talk, I will discuss the advanced plasmonic-assisted 2D hybrid broadband photodetectors for free-space and guided mode configurations. I will present key aspects of material properties, device physics, nanofabrication, and system performances.

Tip-enhanced cavity-spectroscopy for quantum light-matter interactions at the nanoscale

Kyoung-Duck Park[1]

[1]Department of Physics, University of Science and Technology (POSTECH), Pohang 37673, Republic of Korea
*corresponding author: parklab@postech.ac.kr

Abstract: In this talk, we provide a novel concept of tip-enhanced cavity-spectroscopy (TECS) overcoming the limitations of previous approaches to induce, probe, and dynamically control ultrastrong light-matter interactions. We will then talk about exciton funneling and exciton-to-trion conversion properties in 2D semiconductors at the nanoscale.

Structure, functions, dynamics, and interactions are the basic properties to systematically understand physical systems existing in nature. In particular, there have been many scientific adventures to understand light-matter interactions, yet in the classical regime at the microscale due to the diffraction-limited optical resolution. Recently, plasmonic nano-cavity enables to induce light-matter interactions and tip-enhanced nano-spectroscopy enables to probe them at the nanoscale. However, these two approaches have developed independently with their own weaknesses so far. In this presentation, we provide a novel concept of tip-enhanced cavity-spectroscopy (TECS) overcoming the limitations of previous approaches to induce, probe, and dynamically control ultrastrong light-matter interactions in the quantum tunneling regime. Furthermore, we provide several new directions of nano-spectroscopy and -imaging. First, we exploit extremely high tip-pressure (~GPa scale) to directly modify the lattice structure and electronic properties of materials. Second, we dynamically control the near-field polarization by adopting adaptive optics technique to near-field optics. Third, we develop conductive TECS to modify electrical properties of materials by directly flowing an electric current through the cavity junction.

We will then talk about the exciton funneling behaviors of 2D semiconductors at the nanoscale. Understanding and controlling the nanoscale transport of excitonic quasiparticles in atomically thin semiconductors are crucial to produce highly efficient nano-excitonic devices. Here, we present a nanogap device to selectively confine excitons or trions of 2D transition metal dichalcogenides at the nanoscale, facilitated by the drift-dominant exciton funneling into the strain-induced local spot. We investigate the spatiospectral characteristics of the funneled excitons in a WSe_2 monolayer (ML) and converted trions in a MoS_2 ML using hyperspectral tip-enhanced photoluminescence imaging with <15-nm spatial resolution. In addition, we dynamically control the exciton funneling and trion conversion rate by the gigapascal-scale tip pressure engineering. Through a drift-diffusion model, we confirm an exciton funneling efficiency of ~25% with a significantly low strain threshold (~0.1%), which sufficiently exceeds the efficiency of ~3% in previous studies. This work provides a previously unexplored strategy to facilitate efficient exciton transport and trion conversion of 2D semiconductor devices [1].

We will then talk about high purity exciton-to-trion conversion in ambient conditions. The generation of high-purity localized trions, dynamic exciton-trion interconversion, and their spatial modulation in 2D semiconductors are building blocks for the realization of trion-based optoelectronic devices. Here, we present a method for the all-optical control of the exciton-to-trion conversion process and its spatial distributions in a

MoS_2 ML. We induce a nanoscale strain gradient in a 2D crystal transferred on a lateral metal–insulator–metal (MIM) waveguide and exploit propagating surface plasmon polaritons (SPPs) to localize hot electrons. These significantly increase the electrons and efficiently funnel excitons in the lateral MIM waveguide, facilitating complete exciton-to-trion conversion even at ambient conditions. Additionally, we modulate the SPP mode using adaptive wavefront shaping, enabling all-optical control of the exciton-to-trion conversion rate and trion distribution in a reversible manner. Our work provides a platform for harnessing excitonic quasiparticles efficiently in the form of trions at ambient conditions, enabling high-efficiency photoconversion [2].

White-nanolight-source through plasmon nanofocusing for nanoimaging, nanosensing, and nano-optical switching

Takayuki Umakoshi and Prabhat Verma*

Department of Applied Physics, Osaka University, Yakadaoka 2-1, SuitaOsaka, Japan
*corresponding author: verma@ap.eng.osaka-u.ac.jp

Abstract: Plasmon nanofocusing is an alternate technique that confines the light field at the apex of a metalized nanotip, enabling background-free detection. This non-resonant method confines all wavelengths simultaneously, producing a white nanolight at the apex for multi-color optical investigations and applications such as nanoimaging, nanosensing, and nano-optical switching.

Spectroscopic methods that benefit from plasmonic enhancement, such as surface-enhanced Raman spectroscopy (SERS) and tip-enhanced Raman spectroscopy (TERS), have been extensively applied for nanospectroscopy, nanoimaging, and the detection of minuscule quantities of molecules for nanosensing [1–5]. The crux of these techniques lies in the selective amplification of the Raman signal from a sample's nanometric volume, enabling investigations at extremely high spatial resolutions and low concentrations. This necessitates precise tuning of the plasmon resonance wavelength, which is accomplished by directing a diffraction-limited focused laser beam upon a plasmonic nanoantenna, be it the apex of a metallic nanotip in TERS or metallic nanoparticles in SERS, thereby generating an enhanced and confined nanolight-source in the close vicinity of the antenna through the resonant oscillation of surface plasmons. Since the resonance condition is achieved only for a very narrow wavelength range that matches the plasmon resonance for a chosen antenna, the nanolight-source also has a narrow wavelength range. In addition, alongside the desired nanolight-source obtained in this process, one also encounters undesirable background scattering, a consequence of the sample being illuminated by the diffraction-limited laser beam at a micrometer scale. One would like to avoid this unwanted background scattering for nanoimaging with higher contrast, and in some cases, one would also like to have fast wavelength switching or even multiple wavelengths at the nanolight-source without changing or replacing the antenna for experiments involving nanosensing or nano-optical switching.

As a viable alternative, plasmon nanofocusing, which is not reliant on plasmon resonance, offers a method to produce a nanolight-source at the apex of the tip [6–9]. This phenomenon involves the excitation of plasmons at the broader end far from the apex of a metallic taper or a conical metallic tip, which then propagate towards the apex of the structure, slowing down by adiabatically compressing their energies, ultimately culminating near the apex where the energy is transmuted into light, creating a strong, localized light field at the nanometrically tapered apex. Here, plasmons are excited by transferring energy from propagating photons to plasmons using a grating that serves as the plasmon coupler. Owing to the grating and the tip apex being separated by a substantial distance, typically around 5 to 8 micrometers, the illuminating beam does not directly impinge upon the sample, thus precluding the unwanted background scattering. Moreover, as the generation of the nanolight-source arises through plasmon propagation rather than localized resonance, the technique works across a broad wavelength spectrum from ultraviolet to near-infrared. Nonetheless, the efficiency of the grating coupler is generally limited to a narrow wavelength range, which inherently constrains the spectral range of the nanolight-source at the apex.

This limitation can be overcome by designing a coupler that can couple a wide spectral range, or in other words, the white light. We have discovered that a suitably designed single slit, which mimics the superimposition of multiple gratings, can function as an effective plasmon coupler for white light, hence generating a white-nanolight-source. We have recently proposed the generation of a white-nanolight-source via broadband plasmon nanofocusing, which has been successfully employed for high-resolution spectroscopy and optical imaging.

Furthermore, sensing and controlling the physical and electronic properties of materials via optics is highly desired for both foundational scientific exploration and the advancement of optoelectronic technologies. The transition towards nanoscale devices demands that the optical interaction volume be similarly scaled down. Although optical antennas can localize light, they fall short due to the requirement of illuminating them with a diffraction-limited focal spot, resulting in unintentional illumination of the sample over a larger volume, as well as due to the significantly narrow spectral range of the enhanced light field. Since plasmon nanofocusing physically separates the illumination and the nanolight generation sites and, at the same time, also offers the generation of nanolight across a broad spectrum of wavelengths or the creation of a white nanolight-source, it is suitable for nanoscale multi-sensing and optical switching applications. The implications of broadband plasmon nanofocusing are profound, not only in optical imaging, sensing, and optical switching but across various scientific domains, serving as a versatile nanoscale broadband light source. This talk will elucidate the generation of background-free, wavelength-independent nanolight and its various interesting potential applications.

Nanocavity-dependent photon output from WSe_2 single quantum emitter with broken valley symmetry

Xulai Xu[1*]

[1]School of Physics, Peking University, China
[*]email: xlxu@pku.edu.cn

Abstract: We show experimental evidence of valley symmetry breaking for quantum emitters in WSe_2 monolayer by interacting with chiral plasmonic nanocavities. And a cavity-dependent circularly polarized single-photon output is also demonstrated.

We investigated the coupling of single localized defect excitons in a two-dimensional layer with chiral plasmonic nanocavity, as shown in Fig. 1. By designing a chiral plasmon mode with high quality factor and coupling it with a WSe_2 monolayer, we demonstrated cavity-dependent photon output from single quantum emitters. The dynamics of this coupled system shows that the chiral photon output mainly comes from the spontaneous emission of the quantum emitter which is strongly modified by the chiral plasmonic nanocavity, which proves that the valley-dependent optical selection rules are absent in such quantum emitters [1]. The coupling interactions of plasmonic nanocavity with two-dimensional excitons at the level of single quanta by using the single quantum emitter in monolayer, instead of small number of two-dimensional excitons [2], will provide platform for future research of quantum plasmonic photonics and integrated photonics.

Subnanometer Resolved Single-Molecule Optical Spectroscopy

Z. C. Dong*

University of Science and Technology of China, Hefei, China
*corresponding author: zcdong@ustc.edu.cn

Abstract: Recent progresses on two STM-based optical phenomena will be presented. One is single-molecule Raman spectromicroscopy down to single-bond resolution, allowing to track bond breaking and forming of surface reactions; the other is single-molecule electro-phosphorescence with the discovery of a new optomagnetic channel to activate the emission from triplet-to-singlet transition.

Aspirations for reaching atomic resolution with light have been a major force in shaping nano-optics, whereby a central challenge is to achieve highly localized optical fields. The plasmonic picocavity defined by the coinage-metal tip and substrate in a scanning tunneling microscope (STM) can provide highly confined and dramatically enhanced electromagnetic fields, which can modify both the excitation and emission of a single molecule inside the picocavity and improve the spatial resolution down to the subnanometer scale [1]. In this talk, I shall demonstrate two recent STM-based phenomena related to single-molecule optical spectroscopy.

The first is single-molecule Raman scattering [2]. The spatial resolution of tip enhanced Raman spectroscopy (TERS) has been further driven down to the angstrom scale at the single-bond limit [3,4]. Such a capability not only allows to track bond breaking and forming of surface reactions [5,6] as well as the local heating effect of a non-equilibrium single molecule [7], but also enables to clarify the chemical enhancement mechanism in TERS through well-controlled local contact environments [8].

The second phenomenon is single-molecule electroluminescence. Through managements over molecular quenching and energy level alignment, clear single-molecule electroluminescence and even single-photon emission can be realized [9]. By precisely controlling intermolecular distances, we can not only demonstrate coherent dipole–dipole coupling in homodimers [10], but also reveal intriguing transitions from incoherent hopping-like Forster energy transfer to coherent wavelike electronic energy transfer in donor–acceptor heterodimers [11]. Furthermore, in addition to the emission via the electric channel, the optomagnetic field is also found to be significantly enhanced in a confined plasmonic picocavity, leading to a new observation of optomagnetism induced molecular phosphorescence via the magnetic channel that goes beyond the conventional spin-orbit coupling mechanism. The microscopic mechanism for the single-molecule electroluminescence including upconversion electroluminescence will also be addressed in this talk [12,13]. Our results provide new routes to optical imaging, spectroscopy and engineering of light–matter interactions and intermolecular coupling at the sub-nanometer scale.

Strong Coupling between Surface Plasmons and Excitons

Hong Wei*

Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China
*corresponding author: weihong@iphy.ac.cn

Abstract: The strong coupling between surface plasmons and excitons leads to the formation of plasmon-exciton polariton states in nanoscale systems at room temperature. In this presentation, I will talk about our research on the strong coupling of single plasmonic nanogap structures and nanowires with monolayer transition metal dichalcogenides.

When the interaction between an optical cavity and quantum emitters is strong enough to reach the strong coupling regime, exciton polaritons are produced. The exciton polaritons inherit the properties of both light and matter, and show great potentials for applications in physical and chemical sciences and related technologies. Metal nanostructures can confine electromagnetic field into tiny spaces of deep subwavelength scale due to the excitation of surface plasmons and result in a very small mode volume, which leads to a large plasmon–exciton coupling strength. Therefore, plasmonic nanocavities are favorable for realizing strong coupling at room temperature. In recent years, the strong coupling of plasmonic nanostructures and excitons has attracted intense interest [1].

In this presentation, I will talk about our research on the strong coupling of single plasmonic nanogap structures [2, 3] and nanowires [4, 5] with monolayer transition metal dichalcogenides. We achieved the strong coupling of monolayer WSe_2 and lithographically defined single gold nanobowties, and the intermediate coupling of two exciton states in monolayer MoS_2 and the nanogap structure of silver nanowire on gold film. In the coupling system of single silver nanowires and monolayer WSe_2, we found that the photoluminescence and scattering light share the same spectral profiles resulting from strong coupling, which unifies the photoluminescence and scattering spectra in the plasmon–exciton strong coupling systems and sheds new light on understanding the rich spectral phenomena in the strong coupling regime.

Chiral Response of plasmonic metasurface

Jinwei Shi[1]

[1] Department of Physics, Beijing Normal University, Beijing, 100875
[*]corresponding author: shijinwei@bnu.edu.cn

Abstract: By breaking the interlayer symmetry, we demonstrated a bilayer metasurface that can achieve circular dichroism close to 1. A triple-layer metasurface is then designed to obtain multiple chiral bands with near unity circular dichroism. Finally, we experimentally achieved an chiral exceptional point in the optical communication band.

The chiral metasurface has broad prospects in various fields such as chiral drugs and polarized optics. Conventional bilayer chiral metasurfaces are constrained by interlayer alignment, and the resulting circular dichroism is limited. Moiré metasurfaces are not restricted by interlayer alignment, reducing the requirements for fabrication technology. However, the chirality of existing Moiré metasurfaces is still not good enough. On the other hand, non-Hermitian chiral metasurfaces based on PT symmetry have also attracted interest, but the fabrication of metamsurface within the visible to near-infrared wavelength range is hindered by multi-step processing requirement.

In this report, I will present three recent works of our group on chiral metasurfaces. Firstly, we analyzed the chirality of Moiré metasurfaces composed of anisotropic materials. Based on the analysis, by breaking the symmetry of the bilayer metasurface, we constructed a chiral device that can achieve circular dichroism close to 1 in a single direction and conducted experimental verification. Furthermore, to obtain multiple chiral bands with circular dichroism close to 1, we designed a triple-layer metasurface. In the forward direction, we used two sets of nearly independent bilayer structures to achieve two nearly ideal chiral bands, while in the backward direction, we used the overall chirality of the three layers to achieve a third nearly ideal chiral band. Finally, using the coupling of local modes and propagating modes, we experimentally achieved an exceptional point (EP) in the optical communication band in a structure made by a single material through one-step fabrication, obtaining a high chiral conversion contrast.

Statistical quantitative SERS beyond the single-molecule level and its physical foundations

Abstract: We proposed a new physical principle for ultra-sensitive quantitative SERS detection. Based on Poisson statistical distribution, the relationship between probability and average molecular number is established. Quantitative SERS of 1 fM beyond the single-molecule level is realized.

Since the discovery of single-molecule SERS nearly 30 years ago, ultrasensitive quantitative sensing is always the ultimate goal of SERS spectroscopy[1]. However, due to the intrinsic quantum fluctuation and molecule diffusion, quantitative SERS down to single-molecule level following the traditional intensity gauging is unachievable. Our work opens up a new field of statistical quantitative SERS[2,3]. By introducing a statistical physical quantity "SERS probability" (Figure 1), we accomplished quantitative SERS even beyond single-molecule level. Moreover, we reported ultra-broad quantitative concentration range from 10^{-4} to 10^{-15} M. We also established a sound physical foundation for the field of statistical quantitative SERS. For the first time, we revealed SERS probability P based on Poisson distribution which indicates the microscopic essence of SERS probability. We corroborated this discovery by correlating the measured SERS probability P and the alpha determined from bi-analytes analysis.

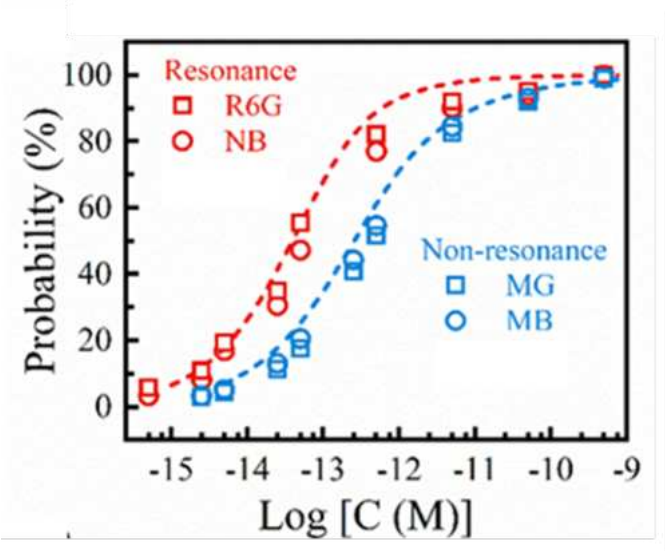

Figure 1. SERS probability as a function of concentration.

Recent Developments in Optical Nanoantennas for Enhanced Light Matter Interaction

Dynamics of Thermal Asymmetry: Interfacial Thermal Conductance in Plasmonic Janus Nanostructures

Javier González-Colsa[1], Fernando Bresme[2*], and Pablo Albella[1#]

[1]Group of Optics, Department of Applied Physics, University of Cantabria, 39005, Santander, Spain.

Abstract: Plasmonic Janus nanoparticles have shown as promising agents in biomedicine due to their controllable photothermal response. Here, we study how interfacial thermal conductance affects their thermal relaxation. The main result is a directional heat dissipation under nanosecond pulsed light, something that supports their potential in photothermal therapies and temperature-controlled devices.

Plasmonic structures and in particular Plasmonic Janus Nanoparticles have attracted great attention due to their capability to generate and control heat at the nanoscale by means of the excitation of Localized Surface Plasmons Resonances (LSPRs) [1-5]. Therefore, these nanoparticles can induce substantial temperature increases, making them valuable in hyperthermia cancer treatments. Recent studies [6] have shown that Plasmonic JNPs with contrasting thermal conductivities can asymmetrically generate heat, particularly under continuous wave excitation, holding promise for this area. However, pulsed illumination is often used in photothermal therapies as different tissues can be targeted by simply modifying the pulse features. Under these conditions, Interfacial Thermal Conductance (ITC) plays a pivotal role in accurately describing the thermoplasmonic response of JNPs.

Our work [7] investigates the impact of ITC on the transient heating and cooling of Plasmonic JNPs under nanosecond-pulsed illumination, using as an example a core-semishell structure made of a polymeric nanosphere coated with a gold spherical cap. To do so, we build a Comsol Multiphysics model able to calculate the thermoplasmonic response of arbitrary JNP geometries, implementing the ITC together with temperature dependent physical properties.

As it can be seen in Figure 1a, the gold nanocap heats first upon pulsed illumination, transferring afterwards heat internally to the polymer core and later externally to the solvent. Interestingly, during the cooling process there is a time where the temperature inside PMMA becomes higher than that of the gold side. Consequently, the conductive thermal flux is inverted towards gold, acting this as a heat sink. This suggests that the structure is inherently more efficient than homogeneous particles since part of the thermal energy is blocked backwards and redirected forwards. Furthermore, as can be observed in Figure 1b, our analysis reveals significant temperature contrasts induced by these interfaces (ITCs), with distinct temperature profiles at interfacial regions. The maximum temperature is observed inside the gold semishell. Temperature gaps at the gold/polymer and gold/water interfaces are associated with their respective ITCs, with larger jumps attributed to higher heat fluxes.

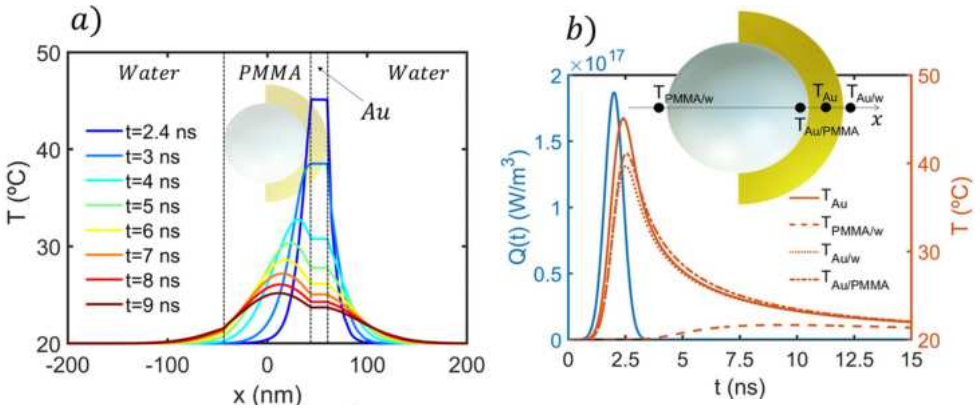

Figure 1. (a) Transient temperature profiles taken along the x-axis. The initial profile is taken at the maximum temperature increase (t = 2.4 ns), so that the cooling process is shown. The vertical lines and the inset display the the interfaces. (b) Input heat power density pulse (left plot) and temporal evolution of the temperature (right plot) taken at points T_{Au}, $T_{Au/PMMA}$, $T_{Au/w}$, and $T_{PMMA/w}$ as seen in the upper inset. Image taken from [7].

Interestingly, the PMMA/water interface exhibits a much slower temperature rising. This is associated to the low thermal conductivity of PMMA and to the ITC of PMMA/water interface. Therefore, this Plasmonic JNP shows a significant temperature contrast across opposite nanoparticle regions at nanosecond timescales. This aspect can become critical in biomedicine since photothermal therapies can benefit from the asymmetric heating. Target cells can be affected by sudden temperature rises preventing the healthy tissue from being overheated and ultimately damaged.

Abstract: High-index dielectric nanostructures work as optical antennas to control the light emission from quantum emitters, including the intensity enhancement and the directional control by Mie resonances. In this work, we demonstrate the enhancement and modification of the light emission from monolayer molybdenum disulfide by a crystalline silicon nanosphere.

Controlling the light emission from quantum emitters by nanoantennas is of great importance for the photonic application. Recently, nanostructures of high-index dielectrics such as silicon (Si) have been suggested as the highly efficient nanoantennas for the light emission control by Mie resonances. The high-index nanoantennas are capable of not only localizing the incident light in the volume much smaller than the light wavelength but also enhancing the radiative rate of the emitter that is so-called Purcell effect. Moreover, because they exhibit both the electric- and magnetic-type Mie resonances, they modify the directional properties of the emitter, including the generation of the magnetic dipole (MD) and magnetic quadrupole (MQ) radiation patterns and the unidirectionality through the interference among the multiple Mie resonances. In this work, we demonstrate the light emission control from monolayer transition-metal dichalcogenides (TMDCs) by a crystalline Si nanosphere (Si NS). As a quantum emitter, monolayer molybdenum disulfide (MoS_2) has been employed since the dipole moments of the exciton emission are oriented in-plane and benefit the efficient coupling with Mie resonances. There have been several reports on the modification of the exciton emission of TMDCs by a Si nanowire [1] and an amorphous Si NS [2]. On the other hand, the system composed of a crystalline Si NS have advantage of the higher-order Mie resonances with high-Q factors and compact size much smaller than the wavelength.

Figure 1a shows the calculated scattering efficiency (Q_{sca}) of a crystalline Si NS as a function of the diameter. The wavelength is 675 nm, corresponding to the photoluminescence (PL) wavelength of MoS_2. The contributions of magnetic dipole (MD), electric dipole (ED), and magnetic quadrupole (MQ) Mie resonances are also shown. Figure 1b shows the calculated radiative rate enhancement factor for the dipole placed 3 nm from the Si NS surface with its orientation parallel to the surface. While the

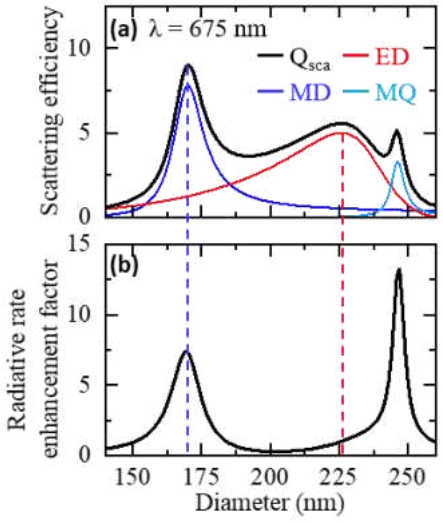

Figure 1. (a) Calculated scattering efficiency (Q_{sca}) and (b) radiative rate enhancement factor at 675 nm for the dipole placed 3 nm from the Si NS surface as a function of the diameter. The wavelength (λ) is 675 nm, corresponding to the PL wavelength of MoS_2. The contributions of ED (red curve), MD (blue curve) and MQ (light-blue curve) Mie resonances are also shown in (a).

radiative rate is not enhanced at ED resonance, it is strongly enhanced at MD and MQ resonances, leading to the intensity enhancement and the spectral modification of the PL.

Figure 2a shows transmission electron microscope (TEM) image of Si NSs developed in our group.[3] They have high sphericity and crystallinity, thus exhibiting the high-Q Mie resonances. Figure 2b shows the schematic of the preparation procedure of Si NSs placed on MoS_2 (Si/MoS_2). MoS_2 is prepared by the chemical vapor deposition (CVD) method and transferred onto a silica substrate. Colloidal solution of Si NSs is deposited on a MoS_2 and the sample is subjected to Ar^+ etching to remove MoS_2 except for the regions underneath the Si NSs. Figure 2c shows the scattering spectrum of the single Si/MoS_2 (diameter of Si NS: 248 nm). The Si NS exhibits MQ resonance around 675 nm. The peak around 575 nm shows the electric quadrupole (EQ) resonance. Figure 2d shows normalized PL spectra of Si/MoS_2 (red curve) and MoS_2 (black curve). The excitation wavelength is 532 nm. The spectral shape of Si/MoS_2 shows narrow linewidth; the full width at half maximum (FWHM) of the PL changes from 106 meV (MoS_2) to 55 meV (Si/MoS_2). From the calculation in Figure 1b, we can conclude that the PL modification is due to the radiative rate enhancement by the coupling with MQ resonance (FWHM: 30 meV).

In the presentation, we discuss the PL enhancement factors and theoretically and experimentally demonstrate the directional control of the exciton emission by a Si NS.

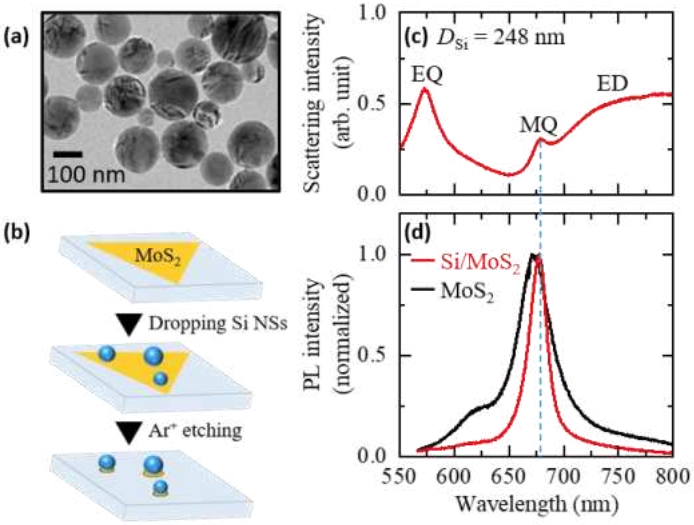

Figure 2. (a) Schematic of the preparation procedure of Si/MoS_2. (b) Scattering spectrum of Si/MoS_2. The diameter of a Si NS (D_{Si}) is 248 nm. (c) Normalized PL spectra of Si/MoS_2 (red curve) and MoS_2 (black curve). The excitation wavelength is 532 nm.

Abstract: We experimentally demonstrate temperature raising over 300 K of crystalline spherical silicon nanoparticles (Si NPs) when the low-power laser light is coupled to the multipole Mie resonances. The experimental results are supported by numerical simulations. These hot Si NPs may have potential applications in biosensing and photothermal therapy.

Keywords: Mie resonances, spherical silicon nanoparticles, temperature raising.

Introduction

High-refractive-index dielectrics supporting magnetic and electric multipole Mie-type resonances in the visible and infrared spectrum have attracted attention in different fields of optics and photonics [1]. Crystalline silicon nanoparticles, unlike their metallic counterpart suffering from high dissipative losses, owing to the low dissipation can strongly confine the electric and magnetic fields in a subwavelength scale. This light-mater interaction can be utilized in light-to-heat conversion through the absorption by Si NPs. For instance, colloidal spherical Si NPs thermally tuning the near- and far-filed of Mie resonances [2], and Si NPs fabricated by femtosecond laser ablation [3] have been proposed for applications in nonlinear optics, Raman scattering, and light-to-heat conversion. Here, we experimentally demonstrate temperature increase in well-defined spherical Si NPs supported by a glass substrate through relatively low-power laser. Due to the high-Q Mie resonances the particles and the ambient temperature can be dynamically controlled through the size of the particles and the laser wavelength.

Theory and Numerical Calculations

When a particle is illuminated by an electromagnetic (EM) wave, the EM energy can be absorbed by the particle. This absorption is quite pronounced at the resonances which leads to the elevation of the particle temperature and its surrounding matrix. In the simplest case, for spherical particles with the thermal conductivity much higher than their homogenous surrounding medium, the temperature increase can be easily calculated using Mie theory [3,4]. When the surrounding medium of the particle is inhomogeneous, for instance, the particle supported by a substrate, one can numerically solve the thermal diffusion equation [3,4]. For this purpose, we perform numerical simulations using finite element method with the implement of COMSOL Multiphysics by coupling electromagnetic wave and heat transfer modules.

Experimental Method

Colloidal spherical Si NPs were prepared by thermal disproportionation of silicon monoxide followed by hydrofluoric acid etching to liberate NPs in solution [1]. The temperature of the single NPs of different diameters on a silica glass were measured by micro Raman spectroscopy under different excitation wavelengths of 488, 532 and 633 nm. The shift of Raman frequency of crystalline Si peak from 520 cm^{-1} was converted to the temperature according to literature [5].

Results and discussion

Figure 1 shows the TEM image and scattering spectra of Si NPs. The TEM images demonstrate the sphericity and crystallinity of Si NPs. As seen in the scattering spectra for NPs with different sizes, the magnetic dipole

(MD) and electric dipole (ED) modes are quite pronounced in the visible spectrum for a smaller NP, whereas the magnetic quadrupole (MQ) and electric quadrupole (EQ) are highly excited in the larger NP.

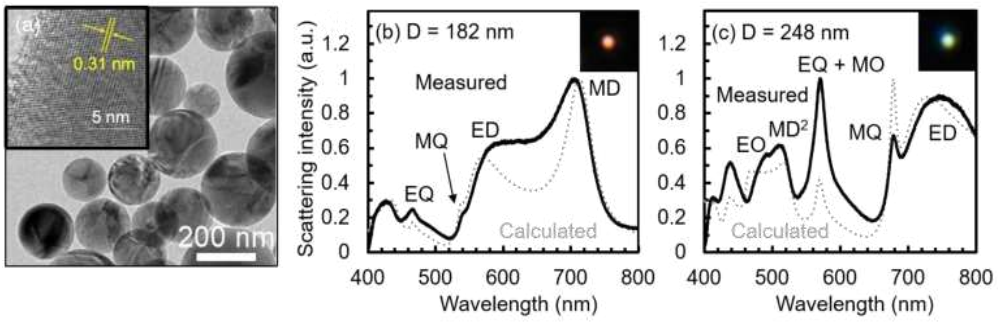

Figure 1: (a) TEM images of a Si NPs. The inset shows high-resolution of Si NP. (b) and (c) Measured (solid curve) and calculated (dashed curve) scattering spectra of a single Si NP of diameter D. The inset, located in the upper right corner, shows the dark-field image of each NP.

Figure 2 shows the experimental temperature increase of Si NPs of different sizes under a laser illumination obtained from Raman measurements together with COMSOL simulation results when the particle is supported by a glass substrate. As it is shown, the multipoles Mie resonances are excited in different particles of different sizes. However, the particles supporting MQ can be strongly coupled to the incoming EM wave and heated up over 300 K with relatively low intensity laser. In the presentation, we will discuss the experimental and the numerical calculation in more detail.

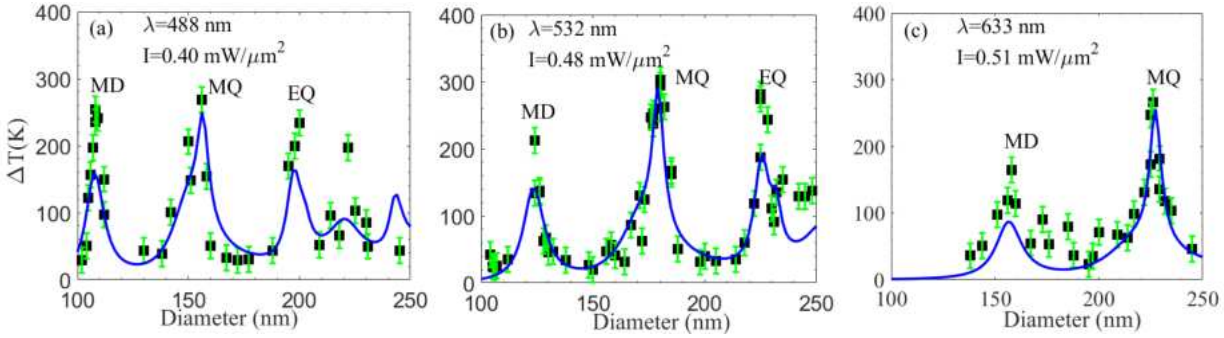

Figure 2: Measured (black dots) and calculated simulations (blue curve) temperature increase of Si NPs. The laser intensity and its corresponding wavelength, and the dominant multipoles are indicated in the inset.

Abstract: We study the role of the local curvature of plasmonic antennas on the local electromagnetic field enhancement and disentangle it from other effects contributing to the field enhancement. Our findings are supported by electromagnetic simulations and electron energy loss spectroscopy. We provide a phenomenological model for the field enhancement.

The lightning-rod effect is a well-known phenomenon in electrostatics characterized by the formation of a strong electric field near the sharp features of a charged conductor. Field enhancement is one of the key targets in plasmonics and one of the main characteristic features of localized surface plasmon resonances (LSPR) supported by metallic nanostructures known as plasmonic antennas (PAs). Intuitively, it is expected that PAs will produce a particularly strong electromagnetic field around their features with high curvature and this consideration translates to meticulous design of plasmonic structures with applications e.g. in enhanced photoluminescence [1] or strong light-matter coupling [2]. However, this so-called plasmonic lightning-rod effect (PLRE) is not rigorously understood despite studies addressing its particular aspects [3,4]. Importantly, the field enhancement in plasmonics stems from additional contributions besides local curvature, including the evanescent nature of LSPR or the magnitude of the induced charge for a specific excitation. In our communication, we isolate the contribution of the local curvature of a plasmonic antenna to the magnitude of the electric field of its dipole LSPR.

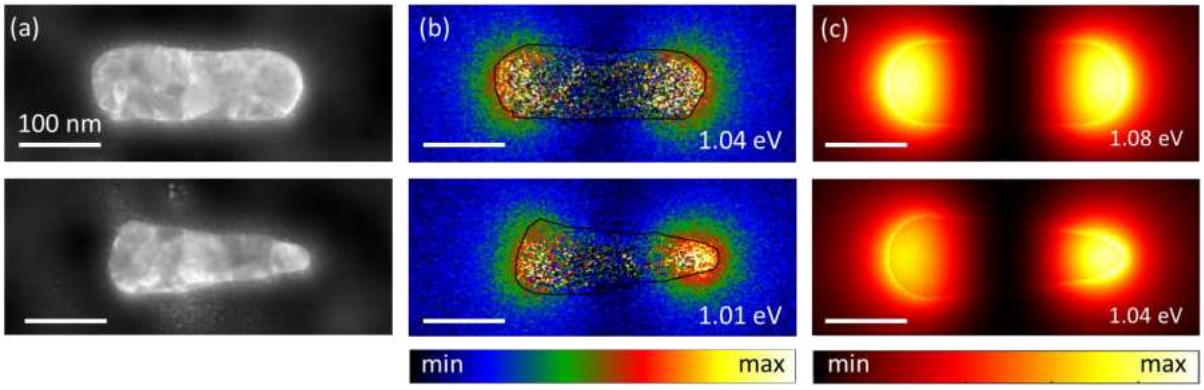

Figure 1: Two PAs with a fixed radius r_{fix} (50 nm) at the left side and a variable radius r_{var} (50 nm and 20 nm) at the right side imaged by transmission electron microscope (a) together with EELS of their dipole localized surface plasmon resonance: (b) measured, (c) calculated. The plasmonic lightning-rod effect is manifested as the intense loss signal at the sharp side of the PAs at the bottom panel ($r_{\mathrm{var}} = 20$ nm).

We design a set of rod-like PAs of identical length with two cylindrical terminations, one with a fixed radius r_{fix} and one with a variable radius r_{var}. Gold PAs are fabricated by focused ion beam lithography [Fig. 1(a)] and characterized by electron energy loss spectroscopy (EELS) and electromagnetic simulations [Fig. 1(b,c)]. A

comparison of responses at both terminations allows for assessing the role of the local curvature in the field enhancement. At the fixed-radius end, we observe the identical loss intensity [Fig. 2(b)] and field enhancement for all the PAs independent of their variable radius. This ensures that the variations in the response at the variable-radius end can be attributed purely to the local curvature. A good quantitative agreement between the experiment and simulations in both spatial [Fig. 1(b,c)] and spectral [Fig. 2(a)] domains verifies the validity of the simulations and allows to employ them for retrieval of the electric field, whose magnitude at the axis of the PA 20 nm away from the variable-radius end is shown as a function of the PA local radius r_{var} in Fig. 1(c). Finally, we present an intuitive phenomenological model for the induced electric field based on an effective induced point charge.

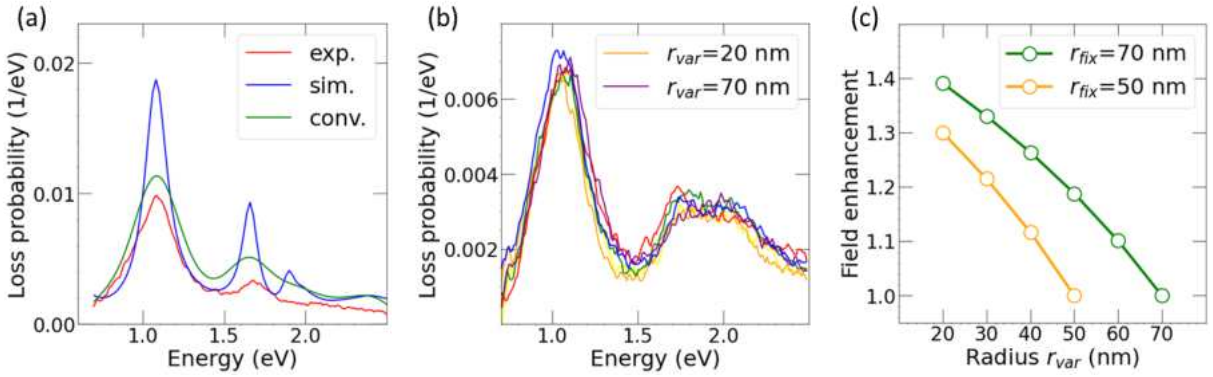

Figure 2: (a) The loss probability spectrum obtained from the experiment (red line), calculated (blue line), and calculated followed by the convolution with the instrumental broadening profile (green line). (b) The loss probability measured at the fixed-radius side of PAs demonstrates that the effects beyond the local curvature do not alter the induced field for our set of PAs. (c) The magnitude of the electric field calculated at the distance of 20 nm from a variable-radius side of the PA divided by the same quantity for $r_{\mathrm{var}} = r_{\mathrm{fix}}$ is displayed as a function of the local radius. Stronger fields obtained from sharper features of PAs represent the quantified manifestation of PLRE.

Controlled radiation modes of second harmonic generation from plasmonic nanoantennas

Yoshito Y. Tanaka[1]

[1] Research Institute for Electronic Science, Hokkaido University, Japan
*corresponding author: ytanaka@es.hokudai.ac.jp

Abstract: We have theoretically and experimentally investigated the control of the radiation mode of second harmonic (SH) generation from plasmonic nanonantennas by near-field coupling of surface SH polarization induced by the fundamental field into the plasmonic eigenmodes at the SH wavelength.

Controlling the process of second-harmonic (SH) generation in plasmonic nanostructures is important for practical applications in imaging, label-free sensing, and the selective identification of biomaterials, but remains challenging in nanophotonics. Although second-order nonlinear-optical effects are forbidden in metals within the electric-dipole approximation, a SH polarization that radiates the electromagnetic field with doubled frequency of the incident light is generated at the surface of the metal nanostructures and can be strongly enhanced by plasmonic near-field concentration, resulting in SH signals that are observable even at the nanoscale. Generally, SH radiation patterns from metal nanostructures are based on quadrupole and are strongly influenced by uncontrollable defects in the realistic metal nanostructures, such as surface roughness. Therefore, direct shaping of the SH radiation patterns is difficult. To address this issue, we control SH radiation mode through near-field coupling of surface SH polarization into plasmonic eigenmodes of nanoantennas.

To reveal plasmonic modes that can be coupled by the SH polarization, we have focused on a cross-shaped single-element plasmonic nanoantenna (Fig. 1). Owing to the symmetry of the structure, the excited plasmon modes can be expanded into many orthogonal basis modes, making it easy to determine the plasmon modes that affect the SH process. Based on theoretical and experimental studies, we found that the nanonatenna resonating with bright and dark modes at the fundamental and SH wavelengths, respectively, generates radially polarized ring-shaped SH radiations with axial symmetry by exciting the bright dipole mode with linearly polarized light [1]. Mode expansion analysis of the generated SH radiation revealed that the radial polarization arises from a dark breathing mode in which coherent dipoles are radially distributed along the arms of the cross-shaped antenna. Our results reveal that surface SH polarization generated by the electric near-field of the bright mode at the fundamental wavelength is efficiently coupled to the dark modes rather than the bright mode because its spatial distribution has the same symmetry as the dark modes. By engineering bright and dark modes at the fundamental and SH wavelengths, respectively, novel plasmonic nanodevices that simultaneously perform polarization control and efficient wavelength conversion are expected.

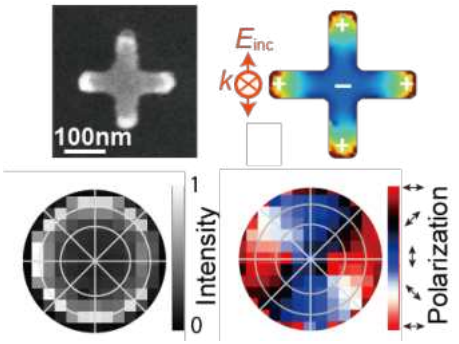

Fig. 1 SEM image of a cross-shaped nanoantenna and its measured intensity and polarization patterns of SH radiation from dark breathing mode induced by SH polarization.

However, the dark modes can not be efficiently coupled to the radiation fields. Furthermore, established approaches in linear optical processes for controlling the radiation field of bright modes are not available. To

couple the surface SH polarization into the bright modes, we studied SH radiations from symmetry-breaking V- and Y-shaped plasmonic nanoantennas [2]. Owing to spatial overlap of two orthogonal plasmonic bright (dipole) modes at the fundamental and SH wavelengths of the nanoantennas, surface SH polarizations induced by the fundamental field is efficiently near-field coupled to the SH plasmon mode, resulting in dipolar SH radiation from the antennas. Moreover, the phase of this radiation can be tuned simply by altering the part of the Y-antenna shape, which changes the SH plasmon resonance while keeping the fundamental resonance. Based on the same design approach as Yagi-Uda nanoantenna, unidirectional SH radiation perpendicularly to an incident light direction has been theoretically and experimentally demonstrated using a pair of the V-and Y-shaped antennas (Fig. 2). Our approach is a promising platform for engineering not only directional nonlinear nanoantennas but also nonlinear metamaterials.

Beam Engineering for Enhanced Light-Matter Interactions in Optical Nanostructures

Uttam Manna*, and Mahua Biswas

Department of Physics, Illinois State University
*corresponding author: umanna@ilstu.edu

Abstract: The state of polarization of scalar beams (e.g., linearly, circularly polarized beams) does not depend on the spatial location of the beam. Alternately, the cylindrical vector beams (CVBs) possess spatially variant polarization states with axial symmetry in both amplitude and phase.[1] Such beams can have their electric fields aligned in azimuthal (radial) orientations, while the magnetic fields are aligned in radial (azimuthal) directions with respect to the optical axis, known as *azimuthally (radially) polarized* beam.[1-3] For focused azimuthally polarized beam (APB) with a high numerical aperture (NA), the longitudinal (*z*)-component of the magnetic field can exceed the transverse component of the magnetic field in the focal region; whereas the electric field component is purely transverse.[3] In this talk, I will review our recent works on enhanced light-matter interactions in various optical nanostructures under illumination with cylindrical vector beams that demonstrate selective excitation of multipolar resonances and excitation of optical anapoles in high-index dielectric nanoparticles,[6] selective induction of optical magnetism in dielectric core−metal nanoparticle nanostructures,[7] etc.

Abstract: Atomically thin semiconductors such as WS_2 can sustain spin-valley polarization and emit circularly polarized light. Using few-layer WS_2, we investigate the electrodynamic nature of valley-polarized emission using back focal plane imaging. We also demonstrate a Drexhage experiment to enhance and control valley-polarized emission.

Two-dimensional semiconductors hold great promise for nanoscale photonics and optoelectronics. Based on robust excitons at room temperature, they exhibit strong light absorption and emission, and they are easy to integrate into nanophotonic structures. One of their most promising properties is spin-valley polarization. In atomically thin semiconductors such as monolayer MoS_2 or WS_2, the spin and momentum direction of carriers can be locked. As a result, using circularly polarized light, we can populate carriers with a momentum direction that depends on the handedness of the optical excitation.[1] This degree of freedom, known as valley polarization, could be exploited to add a new dimension to information processing and optoelectronics. To fully take advantage of valley polarization for nanophotonics, it is necessary to better understand the conditions for it to occur, its electrodynamic nature, and the possibilities for enhancing it through optical means.

In this presentation, we characterize the microscopic electrodynamic character of valley polarization and valley coherence in few-layer WS_2 at room temperature. We employ back focal plane (BFP) imaging to record polarization-resolved angular radiation patterns. By analyzing the spin of the evanescent part of the angular spectrum, we identify circular and linear electric dipole characteristics in WS_2 excitons under circularly and linearly polarized excitations, respectively. Such evanescent optical spin is transferable to the far field using a glass substrate and has peculiar characteristics. Our investigation compares theory and experimental results for a dipolar source of photoluminescence in few-layer WS_2 semiconductors on a glass substrate. Utilizing polarization-resolved BFP imaging, we attribute valley-polarized emission to circularly polarized electric dipoles and valley-coherent emission to linearly polarized dipoles. Interestingly, it is possible to observe emission with linear polarization under certain angles for valley-polarized emission, and radiation with circular polarization for valley-coherent emission.

The ideal valley-polarized material should exhibit high emission quantum efficiency together with high polarization. However, currently available transition metal dichalcogenides suffer from either low efficiency or low polarization. In the second part of this presentation, we follow a nanophotonic route to enhance circularly polarized emission capable of enhancing both the emission intensity and the degree of polarization. We introduce a Drexhage experiment for valley polarization, where we control the distance between a WS_2 bilayer and a mirror using dielectric spacers. Our experiment achieves nearly complete control over valley-polarized

emission at room temperature, with a degree of circular polarization varying from 0.1 to 0.75 at different distances. We characterize the lifetime of the polarized emitted photons and the angular radiation patterns. We interpret the results using a rate equation model and highlight the impact of distance and power-dependent polarization on valley dynamics, providing a new path to control valley polarization. Unlike complex arrays of nanostructures,[2] our Drexhage experiment is a simple yet effective method to exert robust control over valley polarization by exploiting exciton dynamics. Our findings elucidate the spin-valley dynamics influenced by exciton-exciton annihilation.

Our results offer valuable insights into the dipolar nature of exciton emitters with valley polarization and their intrinsic evanescent fields. By understanding, controlling, and enhancing the circular polarization of light emitted by WS_2, our results open up new possibilities for spin-based nanophotonic and optoelectronic devices. Our findings have implications for applications such as polarization-controlled light on-chip and the development of valley-based technologies and integrated photonic devices.

Multiplexed single-molecule plasmon sensing by spectral decomposition

V. Lamberti, S. Nooteboom, T. Schellekens, and P. Zijlstra[1]

[1]Eindhoven University of Technology, Department of Applied Physics and Science Education, The Netherlands

Abstract: Narrowband light-matter interactions mediated by plasmonic nanoantennae strongly modify a nearby emitter's emission spectrum. Such reshaping shrouds the original emission spectrum of the dye and hampers multicolor applications. Here, I will describe our recent efforts to elucidate single-molecule spectral reshaping and use it for continuous and multicolor single-molecule plasmon sensing.

Light-matter interactions between a plasmonic nanoantenna and a molecule have proven their value in applications like biosensing and spectroscopy. Herein coupling between the molecule and plasmonic modes in the antenna result in strongly enhanced excitation rates, modification of decay rates by the local density of states, and modulation of the radiation pattern of the emitter. In recent years this has enabled highly directional nanoantennas, fast probing of single-molecule SERS, and single-molecule biosensing mediated by plasmon-enhanced fluorescence.

These applications employ nanoantennas that are functionalized with e.g. protein or DNA using thiol-mediated surface chemistry. I will describe the use of these DNA-coated nanoparticles [1] for multiplexed single-molecule biosensing [2]. We use a sandwich assay whereby the presence of analyte is revealed by reversible binding of a fluorescently labeled detection probe. We perform spectroscopy of each single-molecule binding event, and study the spectral reshaping induced by plasmon-fluorophore coupling. Spectral decomposition enables us to extract the underlying dye spectrum from the strongly reshaped overall emission spectrum. Despite the strong spectral reshaping by the antenna we achieve 3-color multiplexed single-molecule sensing. This will pave the way toward single-molecule and multiplexed digital diagnostics

Mie resonances in silicon nanospheres probed by pump-probe cathodoluminescence spectroscopy

Abstract: We study optical Mie resonances in individual Si nanospheres (NPs) using cathodoluminescence (CL) spectroscopy, complemented with theoretical CL calculations. We couple light into the SEM-CL system to locally heat NPs and observe spectral shifts of Mie modes. Delaying the synchronized laser and electron pulses enables *in-situ* pump-probe CL for nanothermometry.

The fabrication of nanostructures with ever-decreasing sizes has increased the demand of suitable characterization methods allowing to determine their shape and size at the nanoscale and enable the investigation of their optical properties beyond the diffraction limit. Due to the high spectral and spatial resolution, cathodoluminescence spectroscopy (CL), has become a powerful characterization tool to study plasmonic and dielectric nanostructures. Of particular interest is the control over the nanoscale distribution of light fields in the optical spectral range which can be readily investigated using CL nanoscopy.

In this work, we systematically study the electric near-fields induced by free electrons coupling to optical Mie modes in individual Si nanospheres[1] (NPs) using both hyperspectral CL mapping[2] and angle-resolved CL. Furthermore, we present the first exploration of using a pulsed laser in our scanning electron microscope (SEM) to perform ultra-fast pump-probe CL spectroscopy of such single Si NPs.

First, we collect hyperspectral CL maps to identify the spectral and spatial signature of the different (magnetic and electric) Mie modes within an individual Si NP (d ~ 240 nm) suspended on a 15 nm-thin SiN membrane, as shown in figure 1. We find that the intensity of the NP's eigenmodes (electric (EQ) and magnetic (MQ) quadrupole Mie mode) changes depending on the electron beam position within the NP.

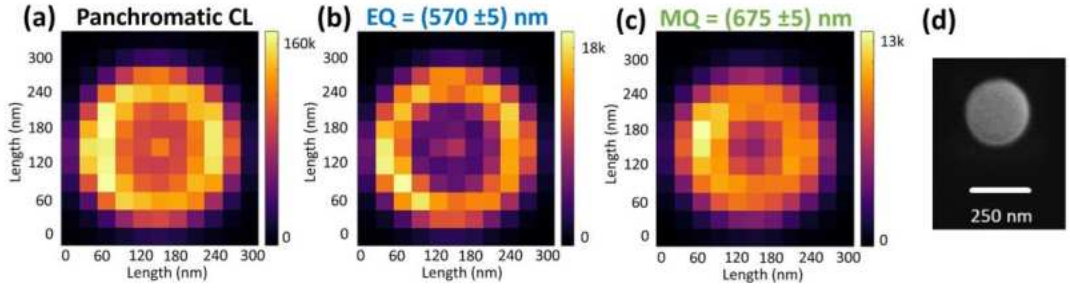

Figure 1 30 keV-CL maps integrated (a) over the entire spectral range from 350 nm to 850 nm, (b) over the electric quadrupole (EQ) and (c) magnetic quadrupole (MQ) Mie mode of the 240 nm-sized Si nanosphere suspended on a 15 nm-thin SiN membrane. (d) Corresponding SEM image.

To gain a more fundamental insight into these excited near-fields, we perform theoretical calculations of the coupling strength[3] between the incoming electron and individual Mie modes which has shown to be strongly dependent on the electron's velocity, electron beam position within the NP and the selected Mie mode. The

exemplary decomposition of the electric (ED) and the magnetic dipole (MD) Mie mode of a 180 nm-sized Si NP using a 25 keV-electron beam excitation is displayed in figure 2. We note that a swift electron moving along the z-axis only allows for coupling to the z-component of an electric near-field. To complement the near-field imaging, we also perform angle-resolved CL maps, allowing us to explore the radiation into the far-field both experimentally and theoretically.

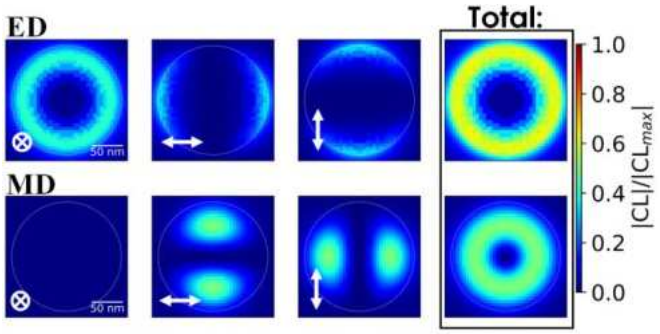

Figure 2 Calculated coupling strength between 25 keV-electron and electric (ED) and magnetic dipole (MD) mode in a 180 nm-sized Si nanosphere (top view).

Second, we couple a pulsed laser into the SEM to locally heat a single Si NP. Due to the thermo-optical effect in Si, a spectral shift of Mie modes can be observed (cf. figure 3) and ultimately, used for nanothermometry. Using an ultra-fast electrostatic beam blanker, we generate ns-electron pulses to probe those spectral shifts in Mie modes upon laser heating. We then systematically delay the synchronized laser and electron pulses to study the time evolution of temperature changes using these Mie modes.

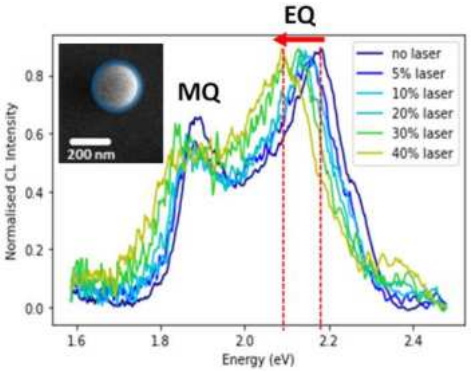

Figure 3 cw-laser (λ = 440 nm) heated Si NP (d ~240 nm) showing 100 meV-spectral shift of EQ Mie mode.

Introducing a pulsed laser in the SEM-CL chamber ultimately opens up a new world of *in-situ* studies of electron-light-matter interactions with applications in photovoltaics, photocatalysis and more.

Optical Metafluid Made from Silicon Nano-spheres

Minoru Fujii[1], **and Hiroshi Sugimoto**[1]

[1]Department of Electrical and Electronic Engineering, Graduate School of Engineering, Kobe University, Japan

Abstract: A silicon nanoparticle exhibits optical magnetism, and can satisfy the electromagnetic duality symmetry condition at the 1st Kerker condition. We demonstrate that the colloidal suspension also has the optical magnetism and acts as a metafluid that preserves the handedness of circularly polarized light.

A colloidal suspension of photonic nanostructures exhibiting optical magnetism is dubbed an optical metafluid. A promising constituent of a metafluid is a nanoparticle of high-refractive index dielectrics having the magnetic-type Mie resonances in the optical frequency. A nanosphere of crystalline silicon 100 to 300 nm in diameters is an almost ideal constituent of an optical metafluid because of the high refractive index and the low extinction coefficient in the visible to near infrared spectral range. Recently, a process to produce high-quality silicon nanospheres in large quantities has been developed [1]. This makes experimental researches on optical metafulids possible. In this work, we will show our recent work on silicon nanosphere-based optical metafluids.

Figure 1a shows water solutions of different diameter silicon nanospheres. Because of the small size distributions, distinctive size-dependent scattering color can be seen. Figure 1b and c shows the TEM images. The silicon nanospheres are almost perfectly spherical and have high crystallinity. In these solutions, the magnetic dipole (MD) resonance is as large as that of the electric dipole (ED) resonance [2]. This almost unity magnetic-to-electric response ratio is very difficult to achieve in plasmonic nanoparticle-based metafluids, and is an advantage of dielectric nanoparticles having the magnetic-type Mie resonances.

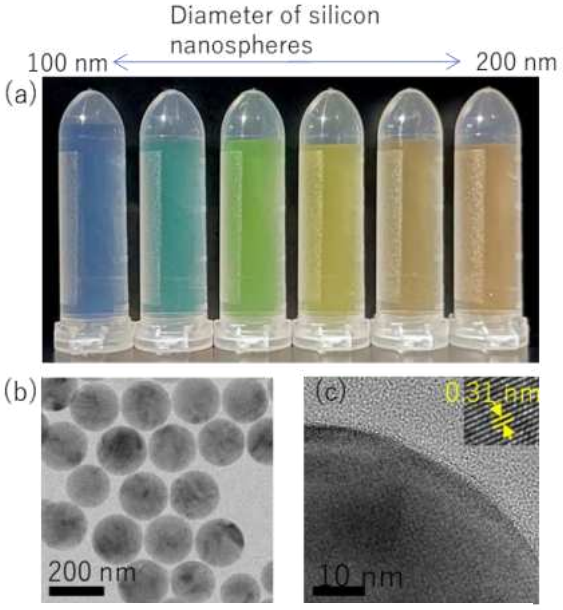

Figure 1. (a) Photos of water solutions of size-purified silicon nanospheres. (b, c) TEM images of silicon nanospheres.

Because of the strong optical magnetism, an individual silicon nanosphere can satisfy the electromagnetic duality symmetry condition at a specific wavelength, and thus can preserve the handedness of circular polarization of incident light in the scattering event to all directions. This suggests that a metafluid of silicon nanospheres also preserves the helicity of incident light. In order to experimentally demonstrate the helicity preservation in silicon nanosphere-based metafluids, we perform polarization- and angle-resolved scattering measurements.

Under illumination by circularly polarized plane wave, the expected value of the electromagnetic helicity density of a silicon nanosphere for the whole solid angle is given by,

$$\langle \Lambda \rangle = \frac{2|a_1||b_1|\cos(\varphi_{MD}-\varphi_{ED})}{|a_1|^2+|b_1|^2}, \qquad (1)$$

where a_1 and b_1 are the Mie coefficients corresponding to the ED and MD modes, respectively, and $\varphi_{MD} -$

φ_{ED} is the phase difference. This equation is equivalent to that of the degree of circular polarization of scattered light to a right angle ($\theta = \pi/2$) under RHC polarized light illumination,

$$\eta\left(\frac{\pi}{2}\right) = \frac{I_{RHC}(\pi/2) - I_{LHC}(\pi/2)}{I_{RHC}(\pi/2) + I_{LHC}(\pi/2)}, \qquad (2)$$

where $I_{RHC}(\pi/2)$ and $I_{LHC}(\pi/2)$ are the intensities of RHC and LHC-polarized componetns of scattered light, respectively [3]. Therefore, by simple scattering measurements to $\theta = \pi/2$ direction (Figure 2a), averaged helicity density for the whole solid angle is obtained. Figure 2b shows the spectra of $I_{RHC}(\pi/2)$ and $I_{LHC}(\pi/2)$, and Figure 2c shows that of the degree of circular polarization $\eta(\pi/2)$ obtained from Figure 2b. The calculated helicity density spectrum is also shown in Figure 2c. The measured spectrum agrees well with the calculated one. The measured helicity density is around 0.70 at the maximum (685 nm), i.e., at the 1st Kerker condition, where the ED and MD Mie resonances have the same amplitude and are in-phase. The slight degradation of the helicity density value compared to the calculated one is mainly due to the imperfection of the broadband λ/4 plates and other optical components. The observed large helicity density value in combination with calculations indicates that the local chiral fields around the silicon nanospheres are strongly enhanced. This enhances the chiral light-matter interaction, and may be used to improve the sensitivity of enantiomer-selective chiral molecular sensing [4].

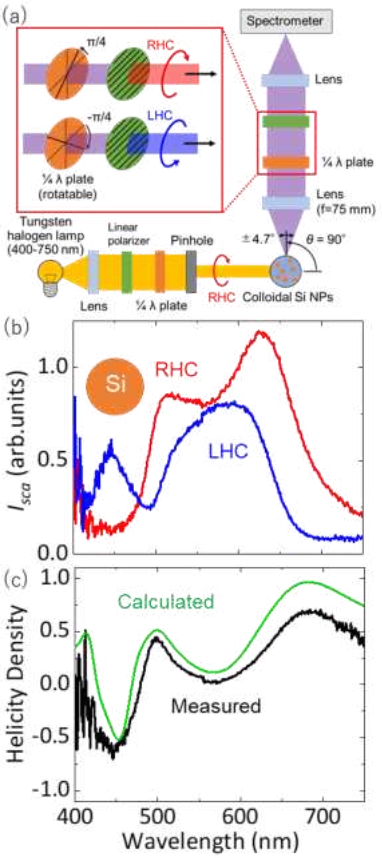

Figure 2. (a) Setup for polarization-resolved scattering measurement. (b) RHC- and LHC-polarized components of scattering spectra of a metafluid under RHC polarized light illumination. (c) Measured degree of circular polarization spectrum ($\eta(\pi/2)$) and calculated expected value of helicity density $\langle\Lambda\rangle$ spectrum.

Solving Maxwell Equations from a Single Polarimetry Measurement

Jorge Olmos-Trigo[1*]

[1]Departamento de Física, Universidad de La Laguna, Apdo. 456. E-38200, San Cristóbal de La Laguna, Santa Cruz de Tenerife, Spain.
[*]corresponding author: jolmostrigo@gmail.com

Abstract: Maxwell's equations are solved when the amplitude and phase of the electromagnetic field are determined at all points in space [1]. The Stokes parameters can only capture the amplitude and polarization state of the electromagnetic field in the radiation (far) zone [2]. Therefore, the measurement of the Stokes parameters is, in general, insufficient to solve Maxwell's equations. In this Letter, we demonstrate that measuring the Stokes parameters at a single scattering angle is sufficient to solve Maxwell's equations for a set of objects widely used in Nanophotonics. Our method for solving Maxwell's equations endows the Stokes parameters, commonly used to capture only the polarization of light, an even more fundamental role in the electromagnetic scattering theory.

The determination of the amplitude and phase of the electromagnetic field at all points in space solves Maxwell's equations. Currently, electromagnetic software packages can provide the numerical solution to Maxwell's equations. However, solving Maxwell's equations in the optical laboratory is exceptionally challenging due to the need to measure the scattered field produced by the object at all points of the radiation zone. On top of that, the internal field induced in the excited object is experimentally inaccessible.

In stark contrast, the Stokes parameters can be readily measured using a photodiode and waveplates. The Stokes parameters can capture the amplitude and polarization state of the electromagnetic field in the radiation (far) zone. As we mentioned earlier, the determination of the electromagnetic phase is necessary to solve Maxwell's equations. Therefore, the measurement of the Stokes parameters is, in general, insufficient to solve Maxwell's equations (even if restricted to the far-field).

In this tak, we demonstrate that a measurement of the Stokes parameters at a single scattering angle is sufficient to solve Maxwell's equations for a widely used set of objects [3]. This set of objects shares the following features: they are lossless, axially symmetric, and their optical response is well- described by a single multipolar order. The key to our procedure lies in linking the measurement of the Stokes parameters in the radiation (far) zone with the electric and magnetic scattering coefficients of the multipolar expansion of the scattered electromagnetic field. As we show, the determination of these scattering coefficients solves Maxwell's equations at all points of the radiation zone, ranging from far-to-near field. Additionally, in the case of spherical objects, we solve Maxwell equations at all points in space (also inside the object).

Let us highlight the main features of our procedure for solving Maxwell's equations in the radiation zone:

- Simplicity in the measurement: Our method only relies on a measurement of the Stokes parameters at a single scattering angle in the far-field.

- Generality of the material and shape of the object: Our method works for axially symmetrical objects such as disks, pillars, spheres, and spheroids. Note that these objects can be composed of a single material or not (coated objects). The only requirement is that the absorption cross-section of these objects must be zero.

- Wide range of illumination conditions: Our method can accommodate plane waves, Gaussian beams, or even vortex wavefields. The only requirement is that the angular momentum m of the light-scattering system must be well-defined.

To the best of our knowledge, this study represents the first proposal of a method capable of solving Maxwell's equations from a single polarimetry measurement. This feature endows the Stokes parameters an even more fundamental role in the electromagnetic scattering theory. Consequently, our findings, supported by analytical theory and exact numerical simulations, can find applications in all branches of Nanophotonics and Optics.

Abstract: The quantum tunneling (QT) effects in metal plasmonic gaps were revisited in a nanoparticle-dimer-on-mirror (NDoM) structure exhibiting concurrent electric and magnetic plasmon resonances. The distinct response of the magnetic resonance to the gap conductivity enable a reliable and robust strategy to deterministically probe QT events in thin metal gaps.

The electron tunneling in between two closely separated plasmonic nanoparticles constituents one of the most fundamental quantum effects in plasmonic optics. The probing of this quantum event in the particle gaps conventionally relies on inspecting the shifting trend of the bonding dipole plasmon (BDP) resonances when shrinking the gap distances, i.e., the resonance initially red shift with narrowing gaps at larger gap distance and then blue shift when the quantum tunneling effect sets on at smaller gap distances. This criterion is problematic in experimental implementation as it is difficult to precisely tune the gap distances while keeping the other geometry parameters (particle sizes, morphologies, etc.) constant. On the other hand, there is no way to deterministically confirm the occurrence of QT events in a specific plasmonic gap without reference to control experiments.

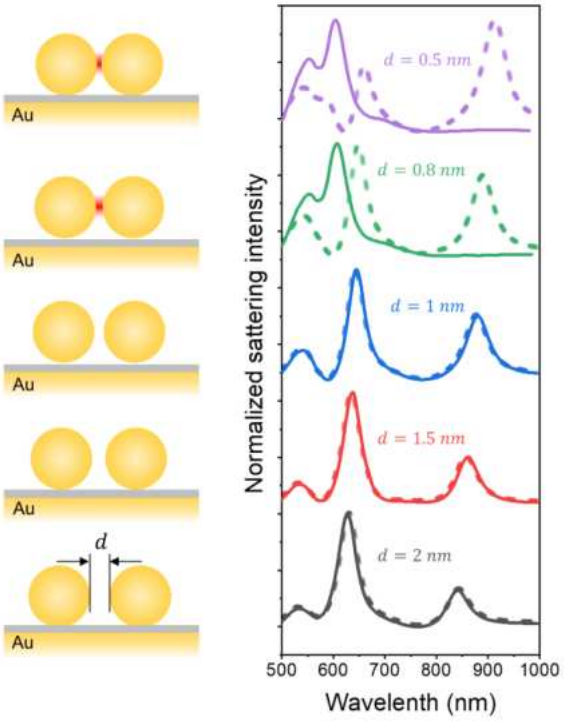

Figure 1 Schematic of nanosphere-dimer-on mirror (NDoM) structures with varying dimer gaps (left panel) and their scattering responses (right panel) simulated with the classical electromagnetic model (CEM, dashed lines) and the quantum-corrected model (QCM, solid lines).

In this work, established a new paradigm of inspecting quantum tunneling events in single plasmonic gaps with magnetic resonances, which does not rely on any control experiment. The testing nanoconstruct consists of a gold nanoparticle dimer on mirror (NDoM) structure, which exhibits concurrent electric (see Fig.1, the BDP at 625 nm for d = 2 nm) and magnetic dipole (The MD at 850 nm for d = 2 nm) resonances. We separate the dimer from the gold film with a dielectric spacer of a constant thickness of 3 nm, to avoid electron tunneling at the nanoparticle-mirror junctions. The quantum-corrected model (QCM), in contrast to the classical electromagnetic model (CEM) without counting in the quantum effects, was employed to calculate and predict the plasmonic responses of the NDoM with decreasing dimer gap distances. We saw the BDP resonances red shift first and then blue shift, indicating the occurrence of quantum tunneling at small gap distances (d = 0.8 and 0.5 nm). The magnetic resonances first slowly red shift with narrowing gaps at larger separation distances, but fully vanished when entering the quantum tunneling regime. These characters are in line with our experimental observations and suggest we can determine the occurrence of quantum tunneling events in single plasmonic gaps by inspecting only the magnetic resonances.

Abstract: We investigate high-harmonic generation in semiconductors from a quantum optical perspective and demonstrate the generation of non-classical light states. We analyze the dependence of their features on the solid characteristics and the driving field strength. Our study provides insights for generating non-classical light sources using bulk matter.

Since the first observations of the high-harmonic generation process (HHG) in gases, in the last quarter of the 20th century, strong-field physics has undergone tremendous and steady progress. Nowadays, HHG stands as one of the primary mechanisms behind extreme ultraviolet (XUV) radiation sources and attosecond pulse generation. It has found diverse applications in nonlinear XUV optics, attosecond science, molecular tomography, and high-resolution spectroscopy [1]. HHG in solid-state systems has also demonstrated significant potential for quantum technology applications. For instance, it was revealed that driving HHG in strongly correlated materials can serve as a tool for detecting topological order and for scrutinizing phase transitions [2].

Concerning the actual applications of semiconductors in the context of quantum information science, one of its main prospects is to use them as nonclassical compact light sources [3]. In this direction, the emergent connection between quantum optics and strong-laser field physics [4] has shown that, by means of HHG processes in atomic systems, one can generate nonclassical states of light with intensities strong enough to drive nonlinear processes in matter, as well as massive frequency-entangled states. Notably, these findings extend beyond HHG processes [5] in atomic systems. Specifically, for the case of solids, recent studies have demonstrated that the effect of electronic acceleration within the valence band could potentially yield analogous outcomes. While Wannier-based studies in solid-state systems have provided essential insights about the generation of nonclassical states of light after HHG in this kind of media, they are either limited to specific electron dynamics within the solid, or involve simplifications on the interaction with the material, restricting the analysis to a limited number of Wannier sites and neglecting dephasing effects. These limitations can be addressed by employing a Bloch-based description of the solid system, where the semiconductor Bloch equations (SBEs) offer a straightforward framework for describing dephasing times and the incorporation of many-body effects.

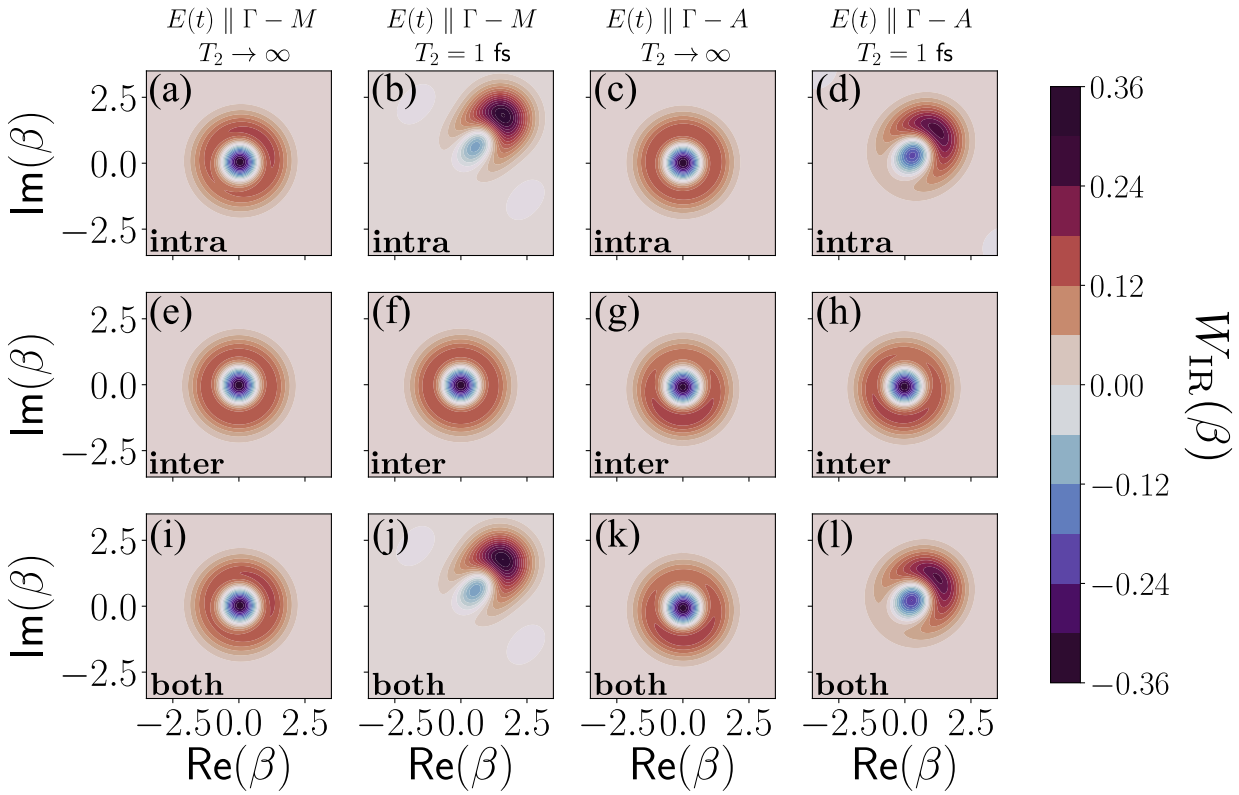

Figure 1. Wigner function representations of the generated entangled coherent state superposition under various conditions. Each column corresponds to distinct values of the dephasing time, T_2, along with different orientations of the applied linearly polarized laser field, specifically aligned with the Γ-M and Γ-A directions. The first two rows focus individually on the intraband and interband contributions, while the last row displays their combined effect. The laser parameters used in this case correspond to λ_L = 3.25 μm, field strength of 0.5 V/Å, and a duration of $\approx$ 96 fs (equivalent to nine optical cycles).

We present investigations of HHG in semiconductor materials under a quantum optical perspective. Our study focuses on the interaction of a strong infrared laser field, linearly polarized along different crystal orientations of a ZnO material, which has been extensively examined both experimental and theoretically. Similar to atomic systems, our findings show that conditioning measurements on the high-harmonic generation process, enable the creation of entangled coherent state superpositions. Thus, these results suggest that the experiments already conducted in atomic gases could potentially be conducted in typical semiconductor samples, utilized in much of the current technology.

Lie Group Theory and Topology of Structured Light

S. Saito

Center for Exploratory Research Laboratory, Research & Development Group, Hitachi, Ltd. Tokyo 185-8601, Japan.
*corresponding author: shinichi.saito.qt@hitachi.com

Abstract: We have developed a Lie Group theory for the SU(*N*) symmetry of structured light, and experimentally demonstrated their controls over a full Poincaré sphere. We show trajectories of Stokes parameters exhibit non-trivial topological features like a torus, a Möbius strip, and a bosonic Dirac cone.

Structured light attracted significant attentions in the last three decades and it is still an active area for quantum optics and potential applications in communications, computing, and sensing [1-10]. It is typically characterised as an optical vortex with the unique mode profile, described by a Laguerre-Gauss mode [1-10]. Here, we show that the structure of coherent photons is mathematically characterised by a Lie group theory, which predicts various topological features in the expectation values of SU(*N*) generators of rotations [11].

The ray of coherent photons with the SU(*N*) symmetry [11] is described by

$$|\alpha_1, \cdots, \alpha_N\rangle = \prod_{\sigma=1}^{N} \mathrm{e}^{-\frac{|\alpha_\sigma|^2}{2}} \mathrm{e}^{\hat{a}_\sigma^\dagger \alpha_\sigma} |0\rangle \quad , \tag{1}$$

where we have defined creation and annihilation operators to satisfy the Bose commutation relationship, $[\hat{a}_\sigma, \hat{a}_{\sigma'}^\dagger] = \delta_{\sigma,\sigma'}$, and σ (σ') stands for the internal structure. The state is characterised by *N* values of complex numbers, $(\alpha_1, \ldots, \alpha_N) \in \mathbb{C}^N$. The generators of rotations (X_i, i=1, …, N^2-1) satisfy the commutation relationship as $[X_i, X_j] = i\sum_k f_{ijk} X_k$, where $f_{ijk} \in \mathbb{R}$ is a real number, named as the structure constant [11]. It is important to recognise that the coherent state of (1) is a many-body state, such that the macroscopic number of photons are occupying a few states of *N*, while allowing the superposition states among them. The corresponding many-body field-operator for spin and orbital angular momentum becomes

$$\hat{X}_i = \hbar \sum_{\sigma,\sigma'} \hat{a}_\sigma^\dagger (X_i)_{\sigma\sigma'} \hat{a}_{\sigma'} \ . \tag{2}$$

It is straightforward to calculate the expectation values of generators of rotations, since the coherent state of (1) is the eigenstate of annihilation operators, such that the operators are simply converted to complex numbers. In general, we have N^2-1 generators of rotations, such that the expectation values are describe by SO(N^2-1).

The simplest example of SU(2) states of coherent photons is found in polarisation states, for which we have N=2 orthogonal states controlled by N^2-1=3 generators of rotations. Then, we can recognise that the Stokes parameters, $\mathbf{S}=(S_1,S_2,S_3)$, are quantum-mechanical expectation values of Spin operator, $\langle\hat{\mathbf{S}}\rangle$. Moreover, the radius of the Poincaré sphere (S_0) corresponds to the average number of photons per second (n_0), passing through the cross section of the beam, $S_0=\hbar n_0$. In order to confirm this picture, we have developed the arbitrary SU(2) operator, name as a Poincaré rotator [11], and demonstrated to realise the photonic C_{60} and the coastline of the earth on the Poincaré sphere (Fig. 1).

The surface of the Poincaré sphere is mathematically described as the two-dimensional sphere, S^2. We can also realise a polarisation torus, $T=S^1 x S^1$, simply preparing a polarisation dependent interferometer [11]. It is

also possible to realise a polarisation Mobius strip and a bosonic Dirac cone (Fig. 2). By extending the analysis of photonic angular momentum to include orbital angular momentum, we can realise various SU(*N*) states, which exhibit classical entanglement and associated Bell projections of coherent photons [11].

Selective Photoexcitation of Finite Momentum Excitons in 2D Materials by Using Structured Lights

Abstract: In this work, we will review our recent experiment-theory-joint studies and the developed theory of the light-exciton interactions between excitons in 2D materials and structured lights, including scalar twisted lights carrying orbital angular momenta and vector vortex beams.

A twisted light (TL) is a spatially structured light where the wavefront of the amplitude is engineered to be in a twisted form to acquire the orbital angular momentum (OAM), being a new degree of freedom of light in addition to that of spin angular momentum (SAM), i.e. polarization. To date, spatially structured light sources, including scalar TL and vector vortex beams, have given rise to broad interest and rapidly ongoing progress in the exploration of the fascinating optical physics and OAM-based photonic technology, [1] ranging from optical control of microscopic systems, high-resolution imaging techniques to high dimensional quantum information technology. Following the rapid advancement in the optical technology of TL, it is timely crucial and desired to explore the intriguing optical interaction of structured light with emergent optoelectronic nano-materials, e. g. transition metal dichalcogenide monolayers (TMD-ML). However, the research on the intriguing interplay between twisted lights and the emergent 2D TMD-MLs (MoS_2, WSe_2, etc) still remains rarely explored.

Only a few years ago, the first photoluminescence (PL) spectrum of a 2D MoS_2 monolayer under the photo-excitation of twisted light with controlled OAM was measured by Ref.[2]. With the increment of OAM of the incident TL, the measured PLs from a hBN-encapsulated MoS2-ML under the excitation of the TL are shown blue-shifted, as consequence of OAM transfer from a light to excitons and selective photo-excitation of finite momentum exciton states well explained by our theoretical analysis and numerical simulation. Theoretically, we have established the theory of the light-matter interaction between a 2D exciton and structured light by using the time-dependent perturbation theory within the electric dipole approximation. We calculate the dispersive fine structures and microscopic wave functions of exciton complexes, including bright exciton and various dark excitons, in 2D materials by numerically solving the Bethe Salpeter equation (BSE) established on the base of first principles.[3] In classical electrodynamical theory, the vector potential of twisted light in the Coulomb gauge is explicitly derived from the Helmholtz equation in the paraxial approximation.

By using the developed theory, it is established that the photo-excitation of finite momentum exciton states by a TL forms a localized exciton wave packet, whose spatially structured pattern is encoded by the OAM carried by the incident TL and suggested to read-out by using the angle-resolved optical spectroscopy.[4] Further, the developed theory of twisted-light-exciton interaction is applied to the investigation of focal TL beam and its interaction with exciton complexes, including bright and various dark exciton. Notably, the SAM and OAM in

a focal TL beam are actually coupled to each other and the resulting polarization is no longer purely transverse. The existence of the longitudinal field in a focal TL manifests the effect of optical spin orbit interaction, which makes it possible to optically access one of the dark exciton doublet of TMD-MLs, i.e. gray exciton, that is a long-lived exciton state and advantageous for the preservation of the transferred OAM from a TL. Regarding the recent study of vector vortex beam (VVB) that is formed by the superposition of two TLs with opposite angular momenta, we show that the spin-orbit non-separability of VVB enables the OAM-imprinting of gray excitons in 2D materials.

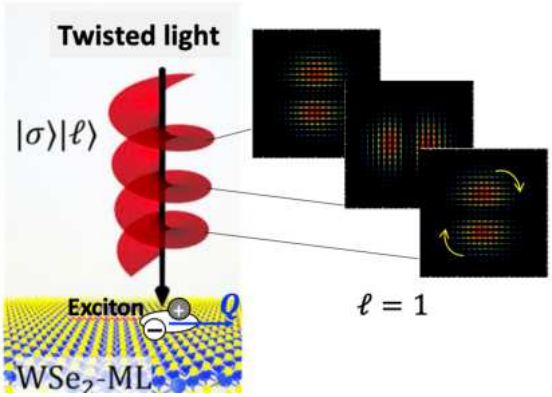

Fig.1 Schematics of a twisted light that carries an orbital angular momentum, $\hbar\ell$, normally incident to a 2D WSe_2 monolayer and photo-generates an exciton with the center-of-mass momentum, $\boldsymbol{Q}$. The square insets show the spatially structured patterns of the vector potential of the incident TL in the different cross-section planes.

Propagation-Independent Polarization Features Near Phase Singularities of Electromagnetic Fields

Andrei Afanasev*

The George Washington University, Washington, DC 20052, USA

**corresponding author: afanas@gwu.edu*

Abstract: We considered polarization properties of optical vortex beams beyond the paraxial approximation, which requires inclusion of the longitudinal component of the electric field. It is shown that even though the vortex beams expand under propagation due to diffraction, the polarization features near phase singularities remain constant. Polarization behaviors near the phase singularity is illustrated with Young's double-slit interference example. We also demonstrate propagation independence of spatial separation of magnetic end electric polarization singularities.

OCIS codes: (270.0270) Quantum Optics; (260.6042) Singular Optics; (050.4865) Optical Vortices

We have studied [1] the polarization of vector beams carrying optical angular momentum. We show the existence of polarization features within optical vortex beams that maintain constant transverse spatial dimensions independently of the beam divergence due to diffraction. The exact size of these vortex polarization structures is dictated by the presence of the longitudinal electric field in the beam, and such structures are expected for vortex beams of all topological charges. An analytical paraxial model predicts their presence in weakly focused beams and a numerical angular spectrum approach further extended this prediction to tightly focused beams, thereby proving applicability to all vortex beams. These polarization features are not affected by finite NAs and so should be experimentally measurable. It should be noted that the predicted nondiffractive polarization features have relatively small transverse dimensions of the order $\Delta\rho \approx l\lambda/\pi$, centered on a low-intensity region of the optical vortex wavefront. Therefore, future measurements will require subwavelength resolution at low l and increased sensitivity of the probe for larger values of l. The demonstrated effect allows one to pinpoint the position of a phase singularity with subwavelength accuracy independently of the size of a beam spot. This property may have useful applications in metrology, optical communications, optical networking, laser sensing, and radar operations.

These results were extended [2] to a general case of field zeros in the wavefronts of electromagnetic fields: while the transverse field might turn to zero due to interference effects, the longitudinal field becomes essential, leading to novel polarization features. Remarkably, these polarization features remain unchanged under propagation, providing a new tool for application. The effect is illustrated in Fig.1 using an example of Young's double-slit interference.

Next, we show that Michael Berry's observations [3] of magnetic vs electric singularity separation are in fact also propagation-independent. Separation of magnetic and electric singularities is considered for phased arrays of atoms [4].

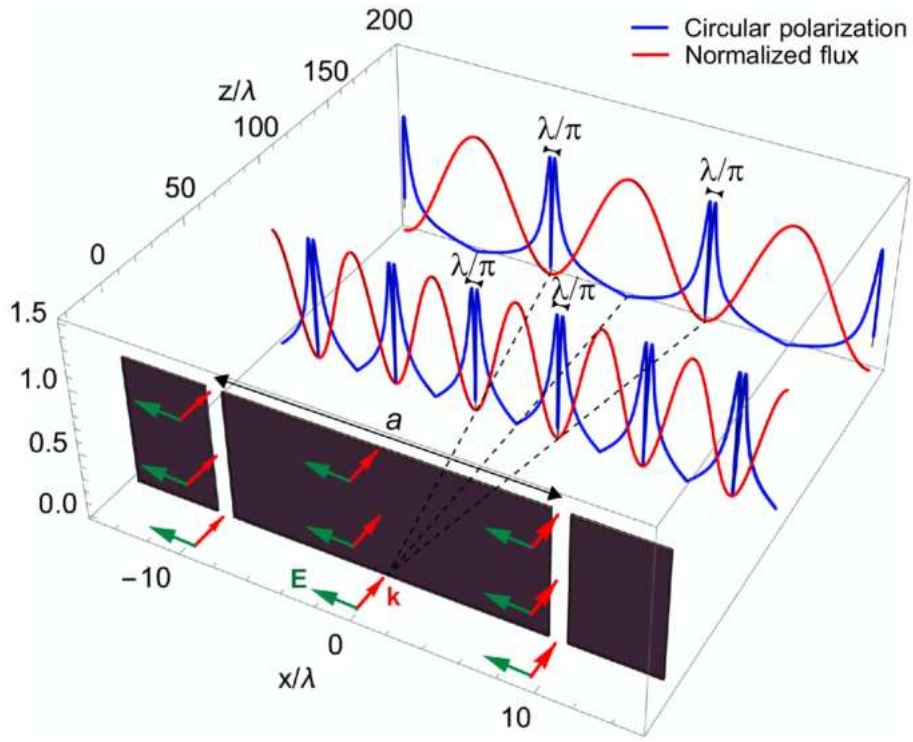

Figure 1. Non-diffractive behavior of polarization Young's double-slit interference. Shown are intensity (red curves) and circular polarization |**s**|. The incident light is linearly polarized perpendicular to the slits. Pairs of C-lines are developed due to interplay between small but nonzero z components of the electric field normal to the screen and (otherwise dominant) in-plane x-components that turn to zero due to destructive interference between two slits. For each C-line pair, photon polarization vectors point along the y-axis, reaching unit length, and are opposite in sign: s_y=±1.

Abstract: We show how optical skyrmions and their associated skyrmion field provide the natural framework to analyse the topology and geometry of fully structured light.

Structured light beams display a spatial variation in their amplitude, phase and polarization. They can exhibit topological features such as phase and polarization singularities, which in turn can trace out links and knots. Structured light beams which contain the whole Poincaré sphere of possible polarizations in every cross section are aptly called Poincaré beams. If this complete covering of the Poincaré sphere supports a mapping of the polarisation structure reminiscent of the arrangement of the magnetization in magnetic skyrmions at the surface of magnetic media, the light beam forms an optical skyrmion.

The polarization pattern of optical skyrmions can readily be formed by superimposing two vortex beams of different topological charge with orthogonal polarization. Adopting a notation from quantum mechanics and denoting the two orthogonal polarisations as $|0\rangle$ and $|1\rangle$, the local polarization of a skyrmion beam can be constructed as

$$|\psi(\boldsymbol{r})\rangle = \frac{|0\rangle + v(\boldsymbol{r})|1\rangle}{\sqrt{1+|v(\boldsymbol{r})|^2}}, \qquad (1)$$

where $v(\boldsymbol{r}) = \beta u_1(\boldsymbol{r})/\alpha u_0(\boldsymbol{r})$ contains the amplitude of the superposition $\alpha u_0(\boldsymbol{r})\,|0\rangle + \beta u_1(\boldsymbol{r})|1\rangle$, and u_1 and u_2 are spatial modes with different topological charges. The local direction on the Poincaré sphere is then simply given by $\boldsymbol{S} = \langle \psi(\boldsymbol{r}) \,|\, \boldsymbol{\sigma} |\, \psi(\boldsymbol{r}) \rangle$, where $\boldsymbol{\sigma}$ is a vector of Pauli matrices. Skyrmions are characterized by an integer winding number, or skyrmion number, which encapsulates how often the Poincaré sphere is covered, and is given by

$$n(z) = \frac{1}{4\pi}\int \boldsymbol{S} \cdot \left(\frac{\partial \boldsymbol{S}}{\partial x} \times \frac{\partial \boldsymbol{S}}{\partial y}\right) dx\, dy. \qquad (2)$$

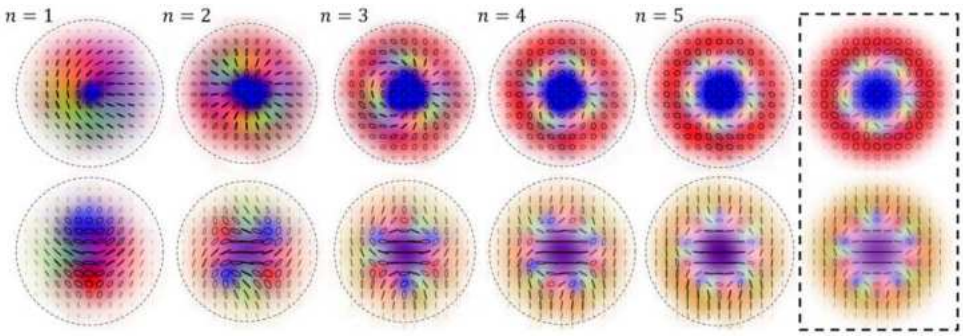

Figure 1: Experimentally measured polarization textures for beams with skyrmion numbers n = 1 to 5. The top row shows N´eel-type skyrmions defined in the circular basis (|0⟩ = |l⟩ , |1⟩ = |r⟩), and the bottom row Neel-type bimerons in the linear basis (|0⟩ = |h⟩ and |1⟩ = |v⟩). The inset at the right shows the theoretical polarization textures for n = 5.[3]

The polarization structure of skyrmion and more generally any fully structured light beam is given by the transverse, that is divergence-less, skyrmion field, $\boldsymbol{\Sigma}$, defined as

$$\Sigma_i = \frac{1}{2}\varepsilon_{ijk}\boldsymbol{S}\cdot\left(\frac{\partial \boldsymbol{S}}{\partial x_j}\times\frac{\partial \boldsymbol{S}}{\partial x_k}\right), \qquad (3)$$

which makes it possible to write the skyrmion number as

$$n(z) = \frac{1}{4\pi}\int \Sigma_z \, \mathrm{d}x \, \mathrm{d}y \, .$$

The streamlines of the skyrmion field have a significance beyond their connection with skyrmion beams, they form the skeleton of all smoothly varying, fully structured light beams. Interestingly the family of streams lines is invariant under a basis transformation of the underlying polarisation structure.[2]

The transverse nature of $\boldsymbol{\Sigma}$ allows us to write it as the rotation of a skyrmion potential $\boldsymbol{\Sigma} = \boldsymbol{\nabla}\times\boldsymbol{V}$. This potential, although not unique, provides a simple expression for the skyrmion number in paraxial optical skyrmion fields based solely on topological considerations. This has the advantage that the surface integral in Eqs. (2) and (3) can be replaced by a line integral utilizing Stokes's theorem. We have shown that this technique allows an experimental determination of skyrmion numbers with exceptional precision.[3]

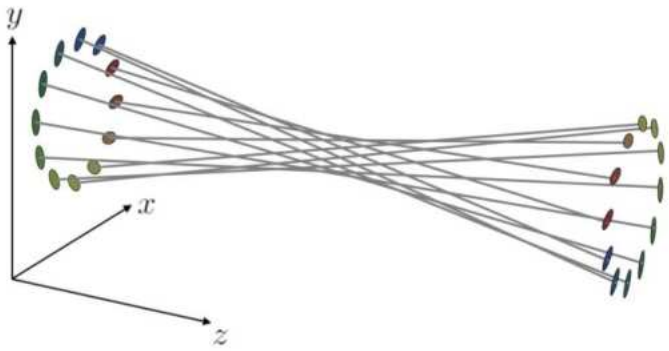

Figure 2: Field lines of the skyrmion field map out lines of constant polarization and show the rotation of the skyrmion pattern on propagation.

While optical skyrmions fall into a specific category of structured light beams, studying their fundamental properties uncovers powerful tools for examining the topological properties of paraxial light beams.

Abstract: Structured attosecond light pulses with designed light properties can be currently generated in the extreme ultraviolet thanks to high harmonic generation. We demonstrate how the topological properties of the structured harmonic beams can be properly controlled, and how they can be used to reveal ultrafast electronic dynamics within matter.

The development of structured ultrafast laser sources is a key ingredient to advance our knowledge about the fundamental dynamics of electronic and spin processes in matter. It is widely recognized the relevance of ultrafast sources structured in their spin angular momentum (SAM)—associated to the polarization of light—and orbital angular momentum (OAM)—associated with the transverse phase profile, or vorticity of a light beam—to study chiral systems and magnetic materials in their fundamental temporal and spatial scales. In the last decade, the possibility to generate high frequency structured ultrafast laser pulses–in the extreme-ultraviolet (EUV) or even soft x-rays—has triggered substantial developments in nonlinear optics. Among other x-ray sources such as free electron lasers or plasma-based soft x-ray lasers, high-harmonic generation (HHG) stands as a robust mechanism to generate highly spatially and temporally coherent radiation from the EUV to the soft x-ray regimes [1], with exquisite temporal accuracy in the attosecond regime [2]. During the last decade several works have explored the possibility of up-convert light's angular momentum from the infrared into the high frequency regime thanks to HHG [3].

In this contribution we will review our recent advances in the generation of structured coherent EUV/soft x-ray pulses through HHG, and their applications to reveal ultrafast electronic dynamics within matter. Since the first works of HHG driven by vortex beams [4], the use of driving field configurations with custom OAM is opening novel control opportunities over the properties of the high-order harmonics. The generation of attosecond vortices with controlled polarization [5], high harmonic pulses with time-dependent OAM or self-torque [6], or low-divergence harmonic combs with controlled frequency line spacing extending into the soft x-rays [7], represent some of the most exciting advances. More recently, the generation of attosecond vortex pulse trains (Fig. 1) has been realized [8] thanks to the generation of high-order harmonic vortex beams with the same topological charge. In addition, the application of structured light to HHG driven in solids, is opening interesting avenues for the study of ultrafast electronic dynamics. For instance, the anisotropic nonlinear response of thin materials such as graphene [9] allowed us to propose topological harmonic spectroscopy to reveal ultrafast nonlinear dynamics through light's topology [10]. Finally, ultrafast vector beams offer the opportunity to obtain magnetic pulses that are spatially isolated from the electric field [11]. Such unique magnetic pulses can be used to drive nonlinear magnetization dynamics [12] or to assist HHG in order to achieve Fourier limited attosecond pulses [13].

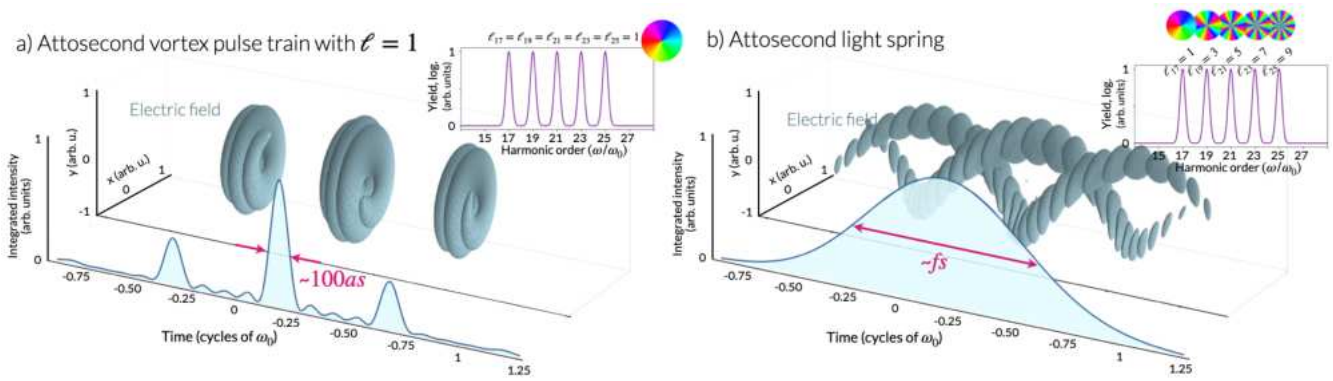

Figure 1. a) Attosecond vortex pulse train obtained after synthesizing several harmonic orders with the same topological charge [8]. If the topological charge scales with the harmonic order, an attosecond light spring is obtained [4].

Abstract: We study the nondipole excitation of trapped ions by structured light. Particular attention is paid to finding the optimal light polarization and external magnetic field orientation to obtain simultaneously the maximum Rabi frequency and the minimum light shift. The theoretical predictions are compared with experimental data.

The production and use of structured (or twisted) light beams has been intensively discussed over the past decades in many areas of modern physics [1]. In contrast to “usual” plane-wave radiation, these beams possess phase singularities, complex polarization patterns and highly inhomogeneous intensity profiles. The latter feature is of particular interest to metrology because it can allow the excitation of narrow-line clock transitions with simultaneous suppression of the undesirable light (or a.c. Stark) shift. This is achieved as follows. An atom or ion, placed in the dark (low-intensity) center of a structured light beam, is exposed to an electric field of low strength but high gradient, which favors the excitation of non-dipole transitions and at the same time weakly perturbs atomic levels. Such “excitation in the darkness” has been successfully demonstrated on the example of an electric quadrupole transition in a single trapped $^{40}Ca^{+}$ ion in the experiment performed by the group of F. Schmidt-Kaler [2].

In the present study we evaluate the effectiveness of the “excitation in the darkness” scheme for the case of higher-multipole transitions which are of interest for use in optical atomic clocks. In particular, we have developed a theory to describe the excitation of electronic transitions in atoms by structured Bessel and Laguerre-Gaussian modes for arbitrary orientation of the atomic quantization axis [3]. Based on our theoretical results, the group of E. Peik and N. Huntemann conducted an experimental study of the excitation of the $^{2}S_{1/2} \rightarrow {}^{2}F_{7/2}$ electric octupole transition in a single trapped $^{171}Yb^{+}$ ion [4]. In the dark center of the Laguerre-Gaussian beam, excitation was observed with a fivefold reduction of the light shift compared to excitation by plane-wave radiation at the same Rabi frequency. The dependence of the transition probability on the direction of the applied magnetic field was also measured. We compared the experimental data with theoretical predictions and found good qualitative agreement.

The experiment with $^{171}Yb^{+}$ represents an important step towards precision spectroscopy with structured light. In this experiment, however, suppression of the light shift was limited by imperfect ion positioning relative to the low-intensity center of the laser beam. Such uncertainty in the localization of the target arises not only due to the thermal motion of an ion in a trap, but also due to the lack of laser beam pointing stability. The group of T. Mehlstäubler proposed to partially solve the latter problem using the integrated schemes in which the light

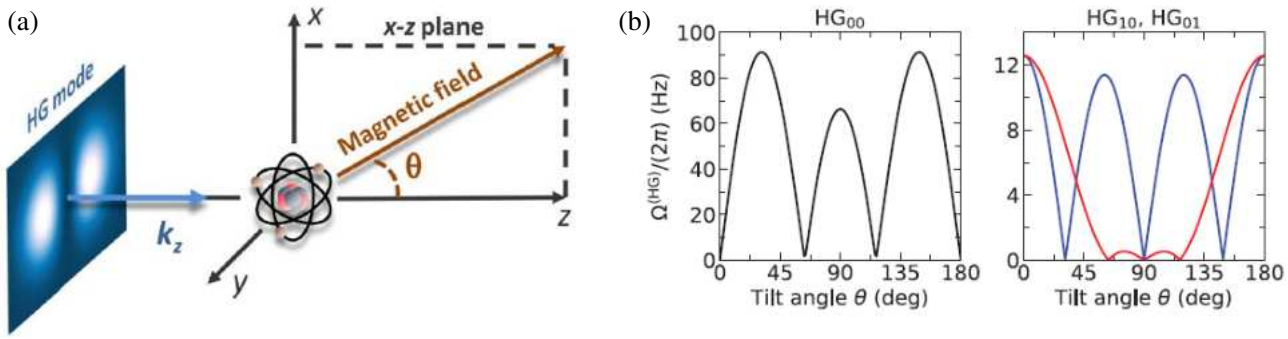

Figure 1: (a) Geometry of the excitation of a single trapped atom by Hermite–Gaussian (HG) modes. (b) Rabi frequencies as a function of the magnetic field tilt angle for HG_{00} (black line) and HG_{10} (blue line) modes linearly polarized in the x-direction and for HG_{01} (red line) mode linearly polarized in the y-direction. The atom is placed in the beam center.

delivery optics is fabricated directly into the ion trap. The geometry of such structures allows fairly straightforward excitation of Hermite-Gaussian modes, which, unlike Laguerre-Gaussian modes, do not have rotational symmetry. To assess the feasibility of this approach, we have conducted a theoretical study of the interaction between a single trapped $^{171}Yb^{+}$ ion and structured Hermite-Gaussian beams [5]. For example, we found that the Rabi frequency of the $|F=0, M=0\rangle + \gamma \rightarrow |F=3, M=0\rangle$ transition can be enhanced by choosing the polarization of the HG_{10} mode along the *x* axis and the direction of the external magnetic field along the *z* axis.

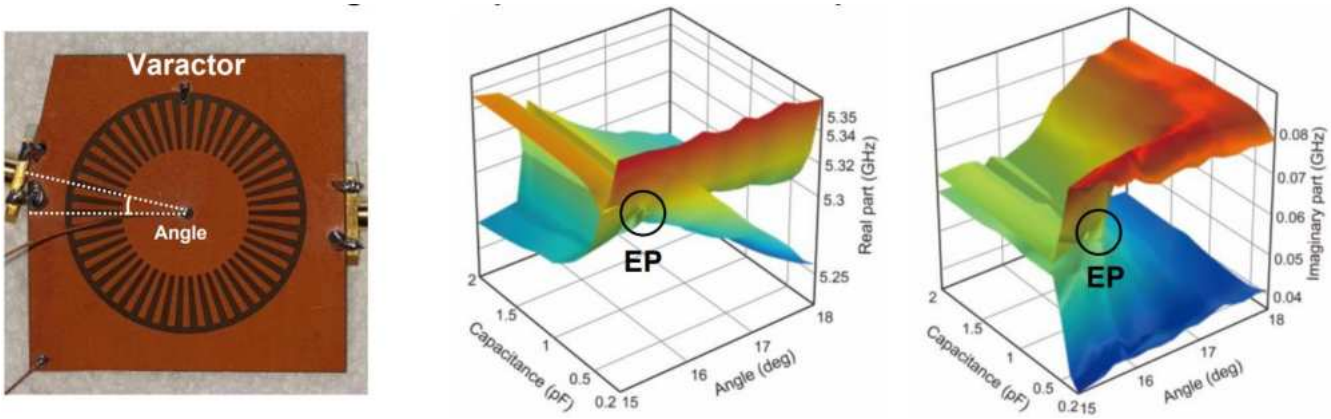
Non-Hermitian Photonics: Topological, Disordered and Quantum systems

Electrical tuning of exceptional points in microwave plasmonic structures

H. Y. Jeong[1*]



[1]Korea University, Republic of Korea
[*]corresponding author: hoonyeub@gmail.com

Abstract: We propose and experimentally demonstrate electrically addressable EP in a plasmonic structure. We employ a localized spoof plasmon structure that supports circulating plasmonic modes in compact single-resonator geometry. Plasmonic modes are perturbed by an angled metal line, and the interaction between the plasmonic modes is electrically controlled using a varactor.

Exceptional points (EPs) are intriguing phenomena arising within non-Hermitian systems, where eigenvalues and eigenvectors converge simultaneously. These singularities are pivotal in energy exchange dynamics with their environment and have emerged as pivotal elements across diverse domains, spanning novel laser, nonlinear optics, and high-precision measurements. EPs and non-Hermitian photonic systems have attracted considerable attention and may provide new platforms for photonic device design.

Optical microdisks and microtoroidal cavities have notably served as versatile platforms for probing EPs, particularly by manipulating the circulating optical modes influenced by particles strategically positioned along their circumference [1, 2]. This control affords manipulation of the real and imaginary components of the complex eigenfrequency, enabling the observation of EP-related phenomena such as mode crossing or anti-crossing. Despite these strides, much of the research surrounding EPs has been confined to static configurations, posing inherent challenges in precisely targeting and manipulating these points.

In recognition of the potential of dynamically tunable systems, recent endeavors have ventured into the realm of electrically controlled EPs, particularly within the terahertz range such as ionic electrolyte gating of graphene and the manipulation of reflection properties using phase-change materials have been explored [3]. However, the quest for compact, integrated device platforms capable of dynamically tuning EPs remains an active pursuit.

In this context, we propose a novel paradigm centered around a single-resonator structure inspired by insights gleaned from optical microcavity structures. Leveraging a spoof plasmon configuration, we introduce an angled metal line to perturb circulating plasmonic modes, thereby realizing EPs within a compact resonator geometry.

Our innovative approach integrates a voltage-controlled capacitor (varactor), offering precise electrical control over EPs' characteristics. Through a comprehensive exploration comprising numerical simulations and experimental validations, we delve into the intricate coupling dynamics of plasmonic resonances, demonstrating the feasibility of dynamically and continuously tuning EPs.

Spontaneous disentanglement and thermalisation

Eyal Buks[1]

[1]Technion, Israel
[*]corresponding author: eyal@ee.technion.ac.il

Abstract: The problem of quantum measurement can be partially resolved by incorporating a process of spontaneous disentanglement into quantum dynamics. We propose a modified master equation, which contains a nonlinear term giving rise to both spontaneous disentanglement and thermalisation. We find that the added nonlinear term enables limit cycle steady states, which are prohibited in standard quantum mechanics.

The problem of quantum measurement is considered as one of the most important open questions in physics. This problem arguably originates from a self-inconsistency in quantum theory. This long-standing problem has motivated some proposals for nonlinear extensions to quantum theory. Moreover, processes giving rise to spontaneous collapse have been explored. For some cases, however, nonlinear quantum dynamics may give rise to conflicts with well-established physical principles, such as causality and separability. In addition, some predictions of standard quantum mechanics (QM), which have been experimentally confirmed to very high accuracy, are inconsistent with some of the proposed extensions.

A modified Schrödinger equation having a nonlinear term that gives rise to suppression of entanglement (i.e. disentanglement) has been recently proposed [1]. This nonlinear extension partially resolves the self-inconsistency associated with the measurement problem by making the collapse postulate of QM redundant. The proposed modified Schrödinger equation can be constructed for any physical system whose Hilbert space has finite dimensionality, and it does not violate norm conservation of the time evolution. The nonlinear term added to the Schrödinger equation has no effect on product (i.e. disentangled) states. The spontaneous disentanglement generated by the modified Schrödinger equation gives rise to a process similar to state vector collapse.

The nonlinear extension that was proposed in Ref. [1] is applicable only for bipartite systems, and only for pure states. To allow incorporating spontaneous disentanglement for more general cases, we propose a modified master equation for the time evolution of the density operator ρ. The modified master equation contains a nonlinear term that gives rise to spontaneous disentanglement. For a multipartite system, disentanglement between any pair of subsystems can be introduced by the added nonlinear term. Moreover, thermalisation can be incorporated by an additional nonlinear term added to the master equation.

In contrast to the above-discussed modified master equation, which is nonlinear in ρ, in standard QM the time evolution of ρ is governed by the Gorini-Kossakowski-Sudarshan-Lindblad (GKSL) master equation, which is linear in ρ. This linear dependency excludes any nonlinear dynamics in the time evolution of ρ, and, in particular, it excludes a limit cycle steady state for any quantum system having a Hilbert space of finite dimensionality and time independent Hamiltonian. On the other hand, the modified master equation yields rich nonlinear dynamics. In particular, both a Hopf bifurcation and a limit cycle steady state may occur.

Generation of orbital angular momentum by optical non-Hermitian skin effect in mirror-time symmetric media

Issei Takeda[1*], Taiki Yoda[1], Yuto Moritake[1], Kenta Takata[2,3], and Masaya Notomi[1,2,3]

Abstract: In this study, we investigate propagation states of two-dimensional optical non-Hermitian skin effect in closed mirror-time (MT)-symmetric media and have found that skin modes rotating around the edges of the system can be realized and orbital angular momentum is generated, especially in rectangular cavities with MT-symmetric medium.

The phenomenon called the Non-Hermitian Skin Effect (NHSE), in which all bulk eigenstates are localized at the edge of a non-Hermitian system, is a unique phenomenon that occurs only in non-Hermitian systems and has been actively studied recently as a new method of localized state formation [1,2]. Although conventional NHSE systems are based on periodic lattices, we have recently shown that optical NHSE can be realized in anisotropic uniform media [3].

In this study, we numerically investigate the propagation state using optical NHSE in two-dimensional MT-symmetric anisotropic uniform media. The basic model of MT-symmetric NHSE media in the present study is shown in Fig. 1(a). The mirror plane of the inversion is shown in Fig. 1(a), and the time reversal is complex conjugation of the dielectric constant. In infinitely long MT-symmetric media with reflective boundaries (perfect electric conductor (PEC)) on the left and right (Fig. 1(b)), a skin mode without amplification or attenuation propagates in one direction. The location of the skin mode depends on the sign of k_y.

First, we examine the nature of this one-way propagating mode by adding a defect at the edge. We numerically simulate the structure shown in Fig. 1(c) assuming MT-symmetric anisotropic permittivity $\varepsilon_{\parallel} = \varepsilon_{\perp}^{*} \sim 1.67 + 0.97i$ and place a defect at the left edge. When we excite a left-side skin mode propagating in the +y direction at the excitation port, light travels in the +y direction at the left edge without reflection but a right-side edge mode propagating in the -y direction is also generated. As a total, a rotating-like mode is formed. We regard that this is due to the inter-edge coupling resulting from the scattering by a defect.

Inspired from this unique phenomenon, we then investigate a closed structure which has PEC boundaries on the top, bottom, left, and right sides. We found that in the symmetric square structure, clockwise rotating modes localized at the left-right boundary and counterclockwise rotating modes localized at the top-bottom boundaries appear at the same time (Fig. 1(d)). In this case, the counterclockwise rotation and the clockwise rotation are balanced, resulting zero orbital angular momentum (OAM). However, when the structure become rectangular, one can select either of clockwise or counterclockwise rotation. In Fig. 1(e), the clockwise rotating modes localized on the left and right sides selectively emerge and generate substantially large OAM (Fig. 1(f)). Here we define the degree of asymmetry by $r = L_y/L_x$ and examine the dependence of OAM on the asymmetry r in Fig. 1(f). First, OAM grows with r. Then it saturates around $r = 5$ and reaches its maximum value.

In summary, we have found an interesting way to generate OAM by employing NHSE in a closed MT-symmetric anisotropic media. We will discuss other methods to generate OAM by breaking the symmetry in NHSE

systems. Since OAM of light is important due to its applicability for high-capacity and high-efficiency optical communications, and this study is expected to be applied as one of the new methods for generating optical OAM.

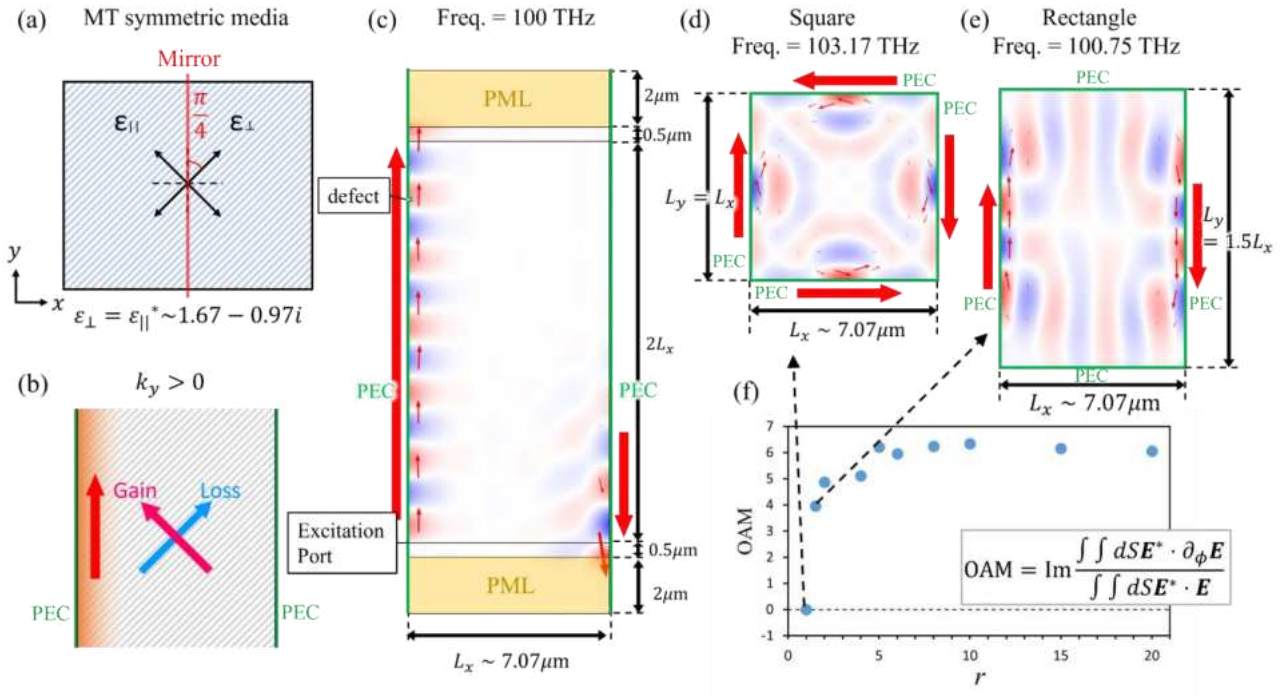

Fig. 1 (a) Anisotropic dielectric medium with MT symmetry. (b) Skin mode with $k_y > 0$ and real eigenfrequency. (c) Scattering of skin modes in structures with defects. (d) Eigenmodes in MT-symmetric square system bounded by PEC. (e) Eigenmodes in MT-symmetric rectangular system bounded by PEC. (f) Dependence of OAM on rectangle length, where r is the ratio of the length of the rectangle to the length of the sides of the original square.

Abstract: In the framework of non-Hermitian photonics, we investigate the wavepacket diffraction dynamics in non-Hermitian one-dimensional quasiperiodic and two-dimensional quasicrystal waveguide lattices. In particular, the effect of spatial symmetries and localization on the spectral sensitivity is examined in terms of pseudospectra.

Recently it was understood that the non-Hermitian analogue of the Anderson original problem can be experimentally realized [1]. Since then, in the context of non-Hermitian photonics [2], there has been a renewed interest in non-Hermitian Anderson localization problems [3–8].

In this work, we provide a systematic study of wavepacket diffraction on two different non-Hermitian potentials: a one –dimensional quasiperiodic Aubry-André-Harper [9,10] lattice and a two-dimensional generalization of Penrose lattices [11–13]. We investigate the possible ways that one can realize these types of quasicrystal optical waveguide arrays, by appropriate spatial combinations of gain-loss materials. We consider parity-time (PT)-symmetric potentials, as well as, purely dissipative ones. The spectral sensitivity is studied in terms of pseudospectra. On the other hand, the dynamics is based on the global quantity of optical power and its logarithmic derivative. In fact, the wave diffraction in a disordered non-Hermitian lattice is highly non-trivial [4, 6–8]. Even though all the eigenstates are localized, the wave exhibits “non-Hermitian jumps” between distant sites, and thus we obtain short-range transport. In our case, of a non-Hermitian quasicrystal, the situation is far more complex, since not all the eigenmodes are localized. Thus, we investigate the conditions under which such jumps occur or not. Our results, are highly relevant to disordered photonics and complex media, where wave transport through highly scattering media is the ultimate goal.

Extremely Narrow, Sharp-Peaked Resonances at the Edge of the Continuum

Abstract: We report a critical narrowing and sharpening of resonances of a potential well when their eigenfrequencies approach the edge of the continuum. The situation was realized for the electromagnetic wave propagating across the dielectric thin films with a periodically modulated interfaces.

It is well known that the wavefunctions in a potential well can form bound states for their energies below the background of the potential well, and the continuum states for their energies above the background. Although the basic wave behavior in the potential wells has been established since the beginning of quantum mechanics, new findings are constantly being reported. One such example is the phenomenon of Bound States in the Continuum,. Here we report another effect never considered before –extreme sharpening of the peaks of the resonances when their energies approach the background energy of the potential well, just before crossing the boundary of the continuum.

The physical situation is depicted in Fig.1. The situation can be realized in thin, nano-modulated dielectric films, where the periodic modulation of the interface serves as a drive of the potential well. The situation mathematically can be described by an externally driven Schrödinger equation:

$$\frac{\partial^2 A_1(z)}{\partial z^2} + \big(E - V(z)\big)A_1(z) - i\gamma(z)e^{ik_{0,z}z}A_0(z) = 0 \qquad (1)$$

The γ(z) is the normalized coupling profile, see Fig.1, V(z) is the profile of the potential (corresponding to the refraction index profile in optics), and E is the position of the driving ion the energy (frequency) domain (corresponds to frequency of excitation in optics).

When the energy of the driving force is below the edge of the continuum, the usual discrete resonances are excited. These are Fano resonances with their typical (asymptotically Lorenz-like) form [2]. However when the potential is deformed so, that one of the resonances approaches the edge of a continuum, a critical sharpening of the resonance is observed. The usual Lorentzian-like shapes, which asymptotically at around their peaks follow the parabolic law 1-dw^2, deforms into sharp-peaked ones with the asymptotical shapes of 1-|dw|. Also the scalings of the width of the resonance with the coupling parameter at the continuum boundary is different from the usual scalings of Fano resonances.

We demonstrated such sharpening of the resonances also experimentally, in thin, nano-modulated dielectric films,

We will discuss the possible realisation of the effect in passive systems (the thin film on the dielectric substrate) as well as in active (the film on amplifying material).

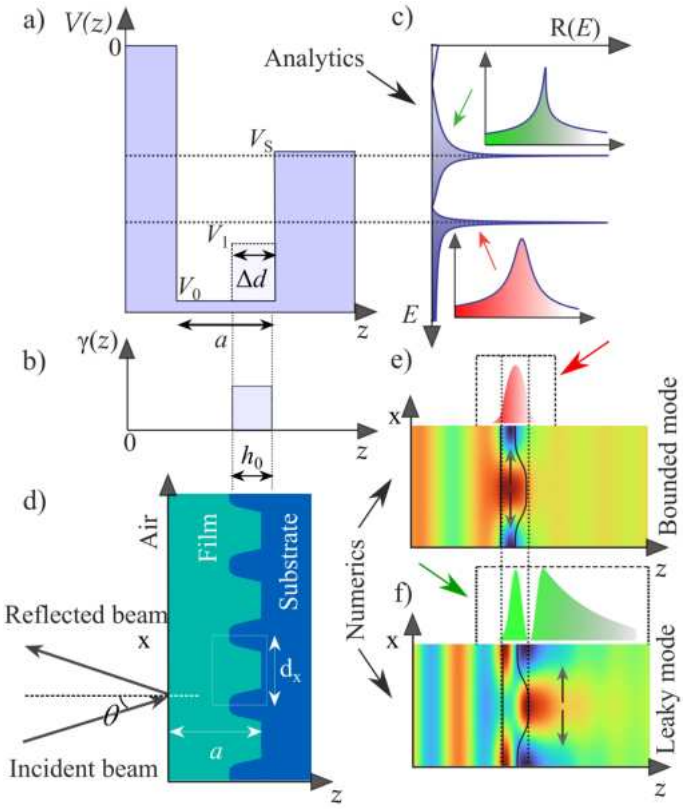

Fig.1. (a) A driven potential well (a,b) is equivalent to the thin film of high refraction index with periodically modulated interface (d). Mathematically driving is equivalent to imaginary part of the potential (b). The interface modulation couples the nearly-normal FP mode into the bounded waveguided modes (e) or leaky surface modes (f), resulting in the usual Lorenz-shaped resonance, or sharp-peaked resonances, respectively (c).

Topological enhancement of non-normality in non-Hermitian systems

Masatoshi Sato[1]

[1]Yukawa Institute for Theoretical Physics, Kyoto University
msato@yukawa.kyoto-u.ac.jp

Abstract: The non-Hermitian skin effects are representative phenomena intrinsic to non-Hermitian systems. Whereas a non-trivial topology under the PBC characterizes the non-Hermitian skin effects, their proper measure under the OBC has not been clarified yet. In this talk, I argue that topological enhancement of non-normality under the OBC accurately quantifies the non-Hermitian skin effects. The topological enhancement of non-normality governs the perturbation sensitivity of the non-Hermitian systems and the anomalous time-evolution dynamics. I also discuss related subjects intrinsic to non-Hermitian systems.

Bunching states and memory loss in noisy non-unitary dynamics of bosons

K. Mochizuki[1,2], **R. Hamazaki**[2,3]

[1] Department of Applied Physics, University of Tokyo, Japan.

[*]corresponding author: ken-mochizuki@ap.t.u-tokyo.ac.jp

Abstract: We explore noisy non-unitary dynamics of bosons exposed to random measurements and postselections. We find that noisy dynamics typically exhibit bunching states with no memory of initial states, where all bosons occupy one time-dependent mode. We also show a universal power law of relaxation times to the fluctuating bunching state.

Spectral analysis has played a key role for understanding noiseless linear dynamics described by time-independent generators. Indeed, various intriguing phenomena have been uncovered through the eigenvalues and eigenmodes of the generator. Examples include Parity-Time symmetry breaking related to the complexity of bosons [1] and steady state phase transitions accompanied by gap closing [2]. Meanwhile, temporally noisy dynamics has also gathered huge attention as versatile platforms for exploring intriguing phenomena and universal features of non-equilibrium dynamics. Examples include information scrambling in unitary dynamics [3] and measurement-induced transitions in non-unitary dynamics of monitored systems [4]. However, the direct spectral analysis for noisy dynamics has not been fully developed, which is contrasted to noiseless dynamics with time-independent generators.

In this work, we propose an analysis based on a noisy spectral gap, which is a generalization of the spectral gap in noiseless systems. We apply the analysis to noisy non-unitary dynamics of bosons where the system is coupled to the environment. As a result, we reveal that bosons typically exhibit the fluctuating bunching state in the long run; all bosons asymptotically occupy one time-dependent mode [5]. The fluctuating bunching state has several unique features. First, the bunching state is distinct from stationary states in noiseless dynamics since the former is largely fluctuating in time while the latter is independent of time. Second, the occupation of one mode leads to the memory loss where there is no information about the initial state, which is contrasted to unitary dynamics. Third, the probability distribution of bosons corresponds to that of distinguishable particles that classical computers can easily sample, which is contrasted to unitary dynamics where the boson sampling problem can exhibit quantum supremacy [6]. We also find a universal power law of relaxation times, which bosons take to reach the bunching state, with respect to the strength of noise [5].

Resonance energy transfer near PT-symmetric and non-Hermitian multilayer systems

F. Marozka[1], A. Arlouski[2], A. Karabchevsky[1], and A. Novitsky[2*]

[1]School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel
[2]Belarusian State University, Minsk, Belarus

Abstract: Non-Hermiticity provides a fascinating route for the control over nanophotonic phenomena. Here we study the resonant energy transfer (RET) between acceptor and donor molecules for optically thick PT-symmetric layers. We relate spectral and RET features, show stochastic-like behavior of exceptional point positions, and give insights into machine-learning optimization of RET.

Non-Hermitian photonics is an important part of modern physics that allows realizing fundamental ideas in practice [1,2]. PT-symmetric systems exhibit prominent topological and scattering phenomena in pure form. The PT symmetry can be obtained in different designs, the simplest of which is a multilayer one, which supports a plethora of famous properties known for non-Hermitian systems. Many properties are related to the exceptional points bordering PT-symmetric and broken-PT-symmetric phases. Exceptional points facilitate enhancing of physical effects; they can be used for realization of lasing and improvement of the sensor's sensitivity [3].

Here we study the resonance energy transfer (RET) as a non-radiative energy transfer between quantum dipole emitter and receiver. The rate of RET is expressed by means of the emission and absorption spectra of the respectively donor and acceptor chromophores and spectral function presented below

$$T(\omega) = \frac{2\pi\omega^4}{\hbar^2 c^2 \varepsilon_0^2} \left| \overline{d}_d G(\omega, \overline{r}_d, \overline{r}_a) \overline{d}_a \right|^2 \quad . \tag{1}$$

The spectral function depends on non-Hermitian environment through Green's function and, hence, is of our interest. Here $\overline{d}_d$ and $\overline{d}_a$ are the electric dipole moments at the points $\overline{r}_d$ and $\overline{r}_a$, respectively.

We consider a couple of dipoles in vicinity of the gain layer boundary as shown in Fig. 1(a). The gain (dielectric permittivity $\varepsilon_g = \varepsilon' - i\varepsilon''$) and loss (permittivity $\varepsilon_l = \varepsilon' + i\varepsilon''$) slabs form a bilayer PT-symmetric system, which exceptional points can be found using the scattering matrix technique. In Fig. 1(b), the exceptional points for various layer thicknesses *L* and non-Hermiticity parameters ε'' are demonstrated [4]. The exceptional points in Fig. 1(b) look random due to dense oscillations of the spectral reflection and transmission functions for optically thick layers. The total intensity as a sum of reflection and transmission is illustrated in Fig. 2(a). Positions of the exceptional points well correspond to the maximum of the total intensity, because this exceptional point is a predecessor of the lasing-like phenomenon.

In Fig. 2(b), the spectral function *T* normalized by the spectral function in vacuum T_0 is depicted. At small values of the slab thickness *L* the PT symmetry feebly alters. The peak value at greater *L* is related to the spectral peak in Fig. 2(a). Besides the high peak of the spectral function, we observe also the suppression of *T*. The spectral function has an asymptote at extremely large slab thicknesses, which might be useful for the stable achieving of the resonance energy transfer enhancement.

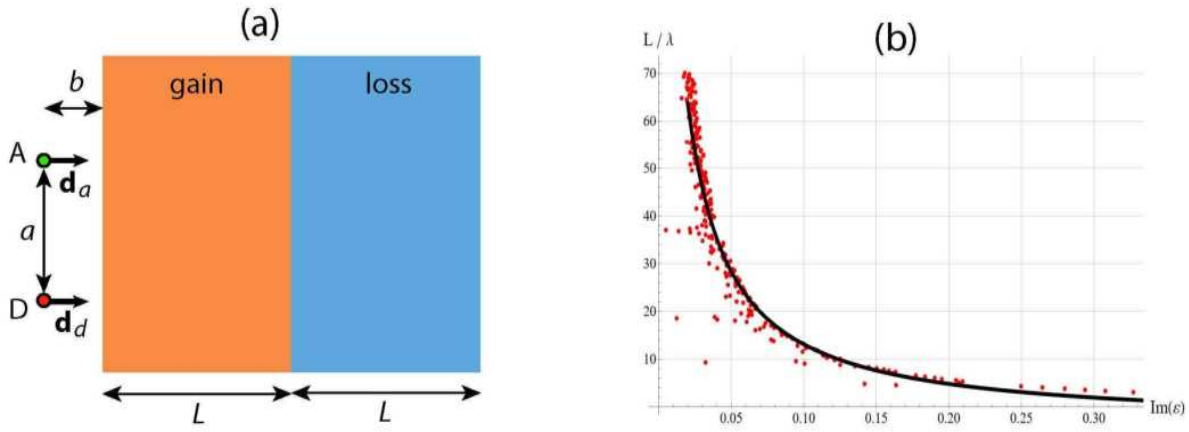

Fig. 1. (a) Sketch of the system in question. (b) Exceptional points depending on layer's thickness L and imaginary part of dielectric permittivity.

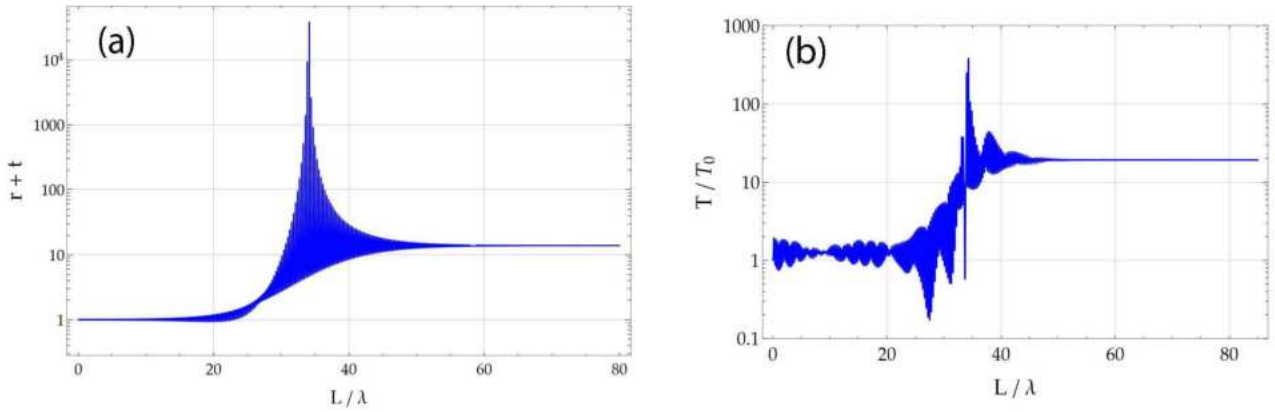

Fig. 2. (a) Total intensity and (b) normalized spectral function of the resonance energy transfer rate. Parameters: $\lambda = 500$ nm, a=10 nm, b=50 nm, and $\varepsilon'' = 0.05$. Dipoles are oriented as in Fig. 1(a).

To sum up, we have revealed that the resonant energy transfer rate might be enhanced owing to strong enlargement of the spectral function near exceptional points. Deeper analysis into this problem can be carried out using the machine learning algorithms.

Abstract: We study the non-Hermitian skin effect of photonic crystals by establishing the non-Bloch band theory, which allows us to calculate the continuum band of the localized eigenmode. We reveal the qualitative and quantitative properties of the skin modes in photonic crystals.

Optics is an ideal platform for studying non-Hermitian physics due to the ease of incorporating optical gain and loss. Recent years have witnessed remarkable developments to emulate a variety of non-Hermitian phenomena. One of the most important progresses in non-Hermitian optics is to observe a parity-time symmetry breaking and associated exceptional points [1]. On another front, the non-Hermitian skin effect, a phenomenon localizing numerous eigenmodes at boundaries, has played a vital role in non-Hermitian physics. While the non-Hermitian skin effect gives rise to rich, intriguing phenomena, it has not been a research subject in optics. So far, the non-Hermitian skin effect has been mainly investigated by using tight-binding models.

To study the non-Hermitian skin effect in optics, we establish the non-Bloch band theory in continuous models and apply the theory to several photonic crystals. The non-Bloch band theory allows us to calculate the continuum band under the non-Hermitian skin effect, reproducing the eigenvalue of the finite-size system with open boundary conditions. The key idea is that one can determine the generalized Brillouin zone for the complex-valued Bloch wave number. We remark that the inverse of the imaginary part of the complex-valued Bloch wave number means the localization length of the skin mode.

We first consider the eigenmode of the photonic crystal composed of the layered dielectric media [2]. Let us suppose that the dielectric tensors of the layers are given by

$$\hat{\varepsilon}_j = \begin{pmatrix} \varepsilon_{xx,j} & \varepsilon_{xy,j} & 0 \\ \varepsilon_{yx,j} & \varepsilon_{yy,j} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{pmatrix}, (j = 1,2). \tag{1}$$

The magnetic field of the transverse-electric mode then obeys the Strum-Liouville type equation written as

$$\left\{ -\frac{d}{dx}\eta_{yy}(x)\frac{d}{dx} - \frac{i}{2}\left[-2k_y\eta_{xy}(x)\frac{d}{dx} + \frac{d}{dx}\left[-2k_y\eta_{yx}(x) \right] \right] + k_y^2\eta_{xx}(x) \right\} H(x) = \left(\frac{\omega}{c}\right)^2 H(x), \tag{2}$$

where c is the speed of light in vacuum, and $\hat{\eta}(x)$ is the inverse of $\hat{\varepsilon}(x)$. Based on the original non-Bloch band theory [3], we analytically derive the localization length of the skin mode as follows:

$$\lambda = \left| \frac{2a}{k_y \mathrm{Im}\left(\sum_{j=1}^{2} \frac{\varepsilon_{xy,j} + \varepsilon_{yx,j}}{\varepsilon_{xx,j}} a_j \right)} \right|, \tag{3}$$

where $a(= a_1 + a_2)$ is the lattice constant. Thus, Eq. (3) indicates that the anisotropy of the permittivity and the

optical gain and loss give rise to the non-Hermitian skin effect in the photonic crystal. Furthermore, based on Eq. (3), one can define the Zak phase from the generalized Brillouin zone to discuss the topology of the photonic crystal. Indeed, we demonstrate the bulk-edge correspondence of the nonzero Zak phase and the existence of the topological edge mode.

We next consider the eigenmode of the photonic crystal composed of the layered chiral metamaterials [4]. Let $\hat{\xi}_j$ and $\hat{\zeta}_j$ denote the chirality tensors of the layers. We remark that the form of the chirality tensors determines the polarization of the eigenmode of the photonic crystal. For example, when the chirality tensors are given by

$$\hat{\xi}_j = \begin{pmatrix} 0 & \xi_{xy,j} \\ \xi_{yx,j} & 0 \end{pmatrix}, \hat{\zeta}_j = \begin{pmatrix} 0 & \zeta_{xy,j} \\ \zeta_{yx,j} & 0 \end{pmatrix}, (j = 1,2), \tag{4}$$

the photonic crystal has the linearly polarized eigenmode. The non-Bloch band theory based on the transfer-matrix method allows us to derive the analytical form of the localization length of the skin mode as follows:

$$\lambda = \left| \frac{2ca}{\mathrm{Im}\left(\sum_{j=1}^{2} \omega\left(\xi_{xy,j} + \zeta_{yx,j}\right) a_j\right)} \right|. \tag{5}$$

Meanwhile, when the chirality tensors are given by

$$\hat{\xi}_j = \begin{pmatrix} \xi_j & 0 \\ 0 & \xi_j \end{pmatrix}, \hat{\zeta}_j = \begin{pmatrix} \zeta_j & 0 \\ 0 & \zeta_j \end{pmatrix}, (j = 1,2), \tag{6}$$

the photonic crystal has the circularly polarized eigenmode. Notably, under the non-Hermitian skin effect, the left- and right-circularly polarized eigenmodes are localized at the opposite boundaries with the localization lengths represented by

$$\lambda = \left| \frac{2ca}{\mathrm{Re}\left(\sum_{j=1}^{2} \omega\left(\xi_j - \zeta_j\right) a_j\right)} \right|. \tag{7}$$

Equations (5) and (7) indicate that the chirality parameters contribute to the non-Hermitian skin effect in the photonic crystal. In the former, the non-Hermitian skin effect vanishes when the system becomes reciprocal, i.e., $\hat{\xi}^{\mathrm{T}} = -\hat{\zeta}$. Meanwhile, in the latter, the non-Hermitian skin effect persists even if $\hat{\xi}^{\mathrm{T}} = -\hat{\zeta}$. Furthermore, while all the eigenmodes have the typical localization length in the photonic crystal composed of the dielectric media, the localization lengths of the eigenmodes depend on the corresponding eigenvalue in the present case.

Classifying topology in photonic crystal slabs despite their radiative environment

S. Wong[1*], T. A. Loring[2], and A. Cerjan[1]

[1]Center for Integrated Nanotechnologies, Sandia National Laboratories, Albuquerque, New Mexico 87185, USA

Abstract: The spectral localizer is used to probe the topology in a full-wave simulated photonic systems. Using a topological photonic crystal slab, we show the genuine topological protection where the radiative loss is taken into account.

Over the past few years, there has been significant work on photonic topological insulators (PTIs) because of their potential to improve photonic devices through their topological protected edge states [1]. The study of PTIs has first focused on two-dimensional (2D) photonic crystals using topological band theory, and soon after was realized in photonic crystal slabs where a 2D, and Hermitian, approximations are assumed for the characterization of the topology. However, the out-of-plane radiative loss, an important aspect of photonic crystal slabs, has been neglected in previous theoretical treatments and cannot be accounted for using a band theoretic approach. In particular, above the light-line, photonic crystal slabs do not possess a true band structure of bound states – instead, while a resonance band structure can be defined, resonances are not true eigenstates of a Hermitian Hamiltonian. Moreover, it is not known whether topological invariants can be meaningfully calculated, especially given that the surrounding environment is gapless [2]. Here, we present a general framework for studying topology in realistic three-dimensional (3D) photonic systems that directly accounts for out-of-plane losses. The framework relies on the spectral localizer, a real-space approach that uses the position matrices and the Hamiltonian matrix of the system to draw a local picture of the topology of the system, along with finite element method (FEM) to discretize the system describe by the full-wave Maxwell equations. Finally, we illustrate this general framework using a non-trivial topological photonic crystal slab, specifically a Chern slab.

The spectral localizer takes an operator-based approach to classify the topology of a system. This approach directly uses the positions matrices and Hamiltonian matrix of the system to assess any obstructions to continuously deforming the system to an atomic limit. To some extent, this local approach can be seen as a real-space analogue to topological quantum chemistry. For a d-dimensional Hermitian system, the localizer can be defined as [3]

$$L_{\lambda=(x_1,\dots,x_d,E)}(X_1,\dots,X_d,H) = \sum_{j=1}^{d} \kappa\left(X_j - x_j I\right) \otimes \Gamma_j + (H - EI) \otimes \Gamma_{d+1}, \quad (1)$$

where $X_1,\dots,X_d$ are the positions matrices and H is the Hamiltonian matrix of the system, I is the identity matrix, and $\lambda = (x_1,\dots,x_d,E)$ is to be seen as an input for the local probing of the topology in space $(x_1,\dots,x_d)$ and energy (E). κ is a hyperparameter that makes the units consistent between the position and Hamiltonian matrices. The eigenvalues of the spectral localizer $\sigma(L_\lambda)$ can heuristically be understood as a real-space, local analogue of the bulk bands. Similarly, the topology of the system can only change through a gap closing of the localizer spectrum, namely when $\min(|\sigma(L_\lambda)|) = 0$. The topological robustness can then be represented by its localizer gap $\mu_\lambda^{\mathrm{C}} := \min\left(\sigma(L_\lambda)\right)$. The spectral localizer is applied to the study of topology in photonic systems as follows. A photonic system is typically described by the full-wave Helmholtz equation which we discretize using FEM via COMSOL Multiphysics [4]. The position matrices are then diagonal matrices with entries corresponding to the positions of the FEM degree of freedom. The effective Hamiltonian matrix H_{eff} is the FEM matrix from the Helmholtz equation after FEM discretization where the eigen-solution of $H_{\mathrm{eff}}(\omega)\Psi = 0$ gives the physical states at frequency ω. As only the zero eigenvalue of H_{eff} is physically meaningful, the topology in photonic system via FEM is probed using the following version of the spectral localizer $L_{\lambda=(x_1,\dots,x_d,0)}\left(X_1,\dots,X_d,H_{\mathrm{eff}}(\omega)\right)$. This approach directly incorporates radiative boundary conditions by using the non-Hermitian line-gap extension of the localizer [5].

As an example of a photonic system which is not fully describe by topological band theory, we consider here a free-standing Chern slab in air as shown in Fig. 1(a)-(b). The slab of thickness $t_{\text{slab}} = 0..5a$ is made of gyro-electric material that breaks time-reversal symmetry with $\epsilon_{jj} = 1, \epsilon_{xy} = 0.4i$ and dielectric rods with $\epsilon_{jj} = 14$ of radius $r = 0.37a$ patterned as a triangular lattice with lattice constant $a = 1\mu m$. Although the system is genuinely 3D, the z-dimension is projected into a single z value and the effective 2D version is used for the spectral localizer in Eq. (1). This projection allows us to restrict the study of the topology via the point-of-view of a path from one topological insulator to another into the xy-plane while keeping all the 3D information, such as the radiative loss, in the effective Hamiltonian H_{eff} derived from the full 3D system. Physically, this dimensional reduction is necessary for a Chern number to have meaning; complex 3D systems do not generally possess an integer topological invariant. The non-Hermitian spectral localizer used for classifying 2D systems is then written as [5]

$$L_{\lambda=(x,y,0)}(X, Y, H_{\text{eff}}(\omega)) = \begin{pmatrix} H_{\text{eff}}(\omega) & \kappa(X - xI) - i\kappa(Y - yI) \\ \kappa(X - xI) + i\kappa(Y - yI) & -H_{\text{eff}}(\omega)^{\dagger} \end{pmatrix}. \quad (2)$$

Given a position in y, the topology is probed from outside the topological photonic crystal in the slab to the middle in Fig. 1(c). The figure demonstrates a crossing in the spectrum of L_λ which is representative of a change of topology (red arrow) in accordance with topological band theory. However, the topological protection given by the localizer gap now takes into account the radiative loss of the topological edge slab state and is not just a single value corresponding to the bulk band gap in the bandstructure.

To conclude, using the operator-based approach of the spectral localizer, we study the topology in photonic system derived directly from the full-wave Maxwell equations. Besides, the spectral localizer allows us to give the genuine topological protection of the topological edge slab state when taking into account possible radiative loss of the slab state. Moving forward, this framework is suitable to accurately probe the topological information of a photonic system for future practical application but is also general for tackling problem in other platforms such as in acoustic materials.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

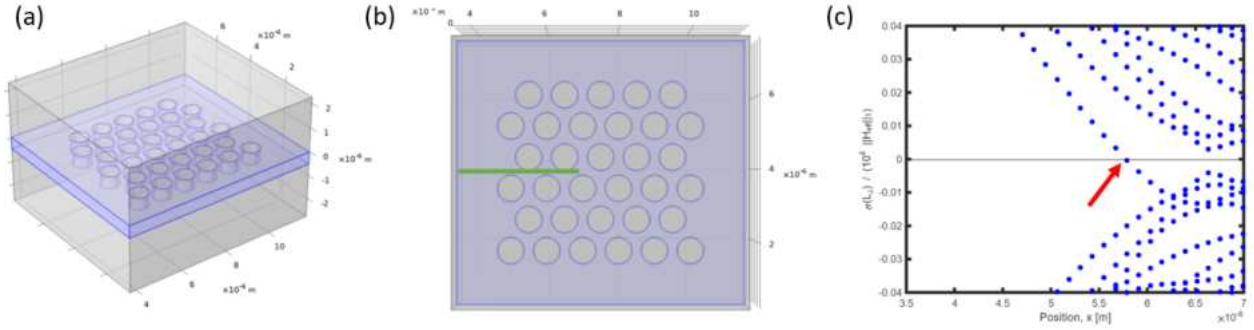

Figure 1: (a) Design of the free-standing Chern slab with the slab highlighted in blue. (b) xy-view of the Chern slab. (c) Spectrum of the localizer $\sigma(L_\lambda)$ normalized by $10^4\|H_{\text{eff}}\|_1$ with $\kappa = 0.5$ $\|X\|_1/(10^4\|H_{\text{eff}}\|_1)$ along the green line in (b). The red arrow indicates the change in topology at the given position.

Non-hermitian coupled modes controlled by the slot chirality in a parity-time symmetric waveguide pair.

A. De Corte[1], B. Maes[1], H. Benisty[2] and M. Besbes[2]

[1]Micro- and Nanophotonic Materials Group, Research Institute for Materials Science and Engineering, University of Mons, Belgium

[2]Laboratoire Charles Fabry, Institut d'Optique Graduate School, CNRS, Université Paris Saclay, France

Henri.benisty@institutoptique.fr

Abstract: Chiral materials inserted in the gap of PT-symmetric coupled dielectric waveguides induce a coupling of their non-Hermitian modes. The interplay of chirality-induced polarization-related anticrossing and exceptional points unveils a rich physics, featuring enhancement mechanisms such as slot geometries and providing unusual dispersion around exceptional points.

Coupling of two polarizations is at the core of chirality. Another coupling, the coupling of two waveguides, has been widely revisited in the presence of parity-time symmetric setting, i.e. a gain waveguide and a lossy waveguide, leading to the occurrence of an exceptional point (EP) where eigenvalues and eigenmodes coalesce. The aim of this exploration is to investigate the interplay of polarization coupling and mode coupling in terms of dispersion and fate of exceptional point, but in the waveguide geometry[1], unlike studies of layered systems such as [2]. To this aim we chose to study the case of two waveguides of identical elongated shape with a thin spacer between them, filled of chiral or achiral material (see black contours on Fig.1, the single guide cross section is 100x400 nm and the real part of its refractive index has a real part Re(n)= 2, the gap has index n=1.479 (achiral basis), the rest around is vacuum n=1). Among the scopes of keeping the chiral material thin is the issue of performing sensing of very small, comparable to those of the most sensitive biomolecular label-free techniques.

We thus study the dispersion and eigenmodes of coupled waveguides with a "chiral gap" as compared to an achiral gap, and attempt to get interactions that involve on a similar footing the PT symmetry features and the chiral features. Specifically, the chosen geometry, basically establishing non-interacting TE and TM polarization in the achiral case, is such that the achiral EP due to gain+loss in one polarization is also met by one of the branches of the other dispersion, so that the study can be seen as the quest of the nontrivial features arising from the anticrossing induced by chirality combined with a standard EP. Prior studies of 4-mode coupling [3] unveiled "symmetry recovery" effects, for instance, that we find as well here.

We model waveguide structures with using the SimPhotonics software implementing the finite element method. SimPhotonics is a Matlab toolbox developed at the Laboratoire Charles Fabry, it was modified to include the core coupling of chirality, the direct local coupling of E-field to H-field with a linear coefficient.

Besides the results of exact modal calculations, we have also exploited various basis to provide a quasi-analytical form to the dispersion. Specifically, we use either the individual mode basis (TE,TM in each waveguide) or the supermode basis (coupled waveguide) to interpret the various phenomena and check the underlying physical mechanisms.

Beside the specific interplay of the two effects (the EP behavior and the chirality), we explore the amount of "effective chirality" as observed from the coupling of modes and compare it to the bulk coupling. With a specific

gap of 32 nm, we find the E-field patterns of Fig.1 (*x* is horizontal, *y* is vertical, *z* is along the waveguide), whereby a large field enhancement exists for the E_x component in the slot in the achiral case (top). We hypothesize that this slot effect is of foremost importance to get to the same degree of "effective chirality" as a bulk medium with the same chiral constant (κ=0.012 here, a value to make coupling appear neatly enough) as the one present only in the 32 nm gap.

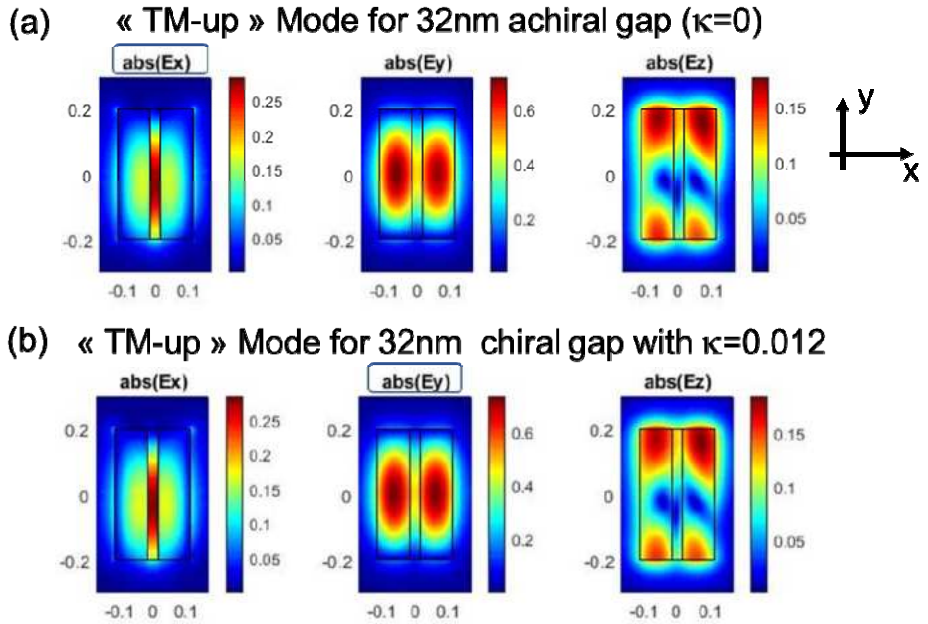

Figure 1 : Modes and coupled PT-symmetric waveguide geometry (black lines), operated at λ=350 nm, with a 32 nm gap. The right-side guide has gain and the left-side guide has loss. The gap is either achiral for the mode pictured in (a) or chiral for the mode pictured in (b). The mode is the « TM up » mode [1].

To conclude, we have unveiled a novel potential of PT-symmetric waveguides to get sensitive responses to chiral materials in small volume, thanks to the interplay of the various coupling operating in this situation.

Dual symmetry classification of non-Hermitian systems and point-gap topology

Zhiyu Jiang[1], Geonhwi Hwang[1], and Hideaki Obuse[1,2*]

[1]Department of Applied Physics, Hokkaido University, Sapporo 060-8628, Japan

Abstract: Since there is no distinct difference in mathematical definitions for Hamiltonians and time-evolution operators in non-Hermitian systems, we show that the systems can be always classified by two ways. We demonstrate this for point-gap topology of quantum walks. We also explain the bulk-edge correspondence for point-gap topology in junction systems.

It is widely known that non-Hermitian Hamiltonians exhibit richer topological properties compared to their Hermitian counterparts. This distinction arises due to the presence of two types of energy gaps—line gaps and point gaps—as well as an increased number of symmetries[1]. Additionally, the symmetry of time-evolution operators plays a crucial role in Floquet topological phases. However, the symmetry relation for time-evolution operators is described differently from that of Hamiltonians. These concepts extend to non-Hermitian systems, where the time-evolution operator becomes non-unitary. Until now, non-Hermitian systems have been classified based on the symmetry descriptions for non-Hermitian Hamiltonians[1] or the symmetry descriptions for non-unitary time-evolution operators[2].

In this talk, we show that since there is no distinct mathematical difference between the definitions of non-Hermitian Hamiltonians and non-unitary time-evolution operators, non-Hermitian systems can always be classified in two ways: the non-unitary time-evolution operator can be categorized using the symmetry relations for non-Hermitian Hamiltonians, and vice versa. We refer to this dual classification as dual symmetry classifications[3]. Furthermore, we delve into the bulk-edge correspondence for point-gap topology in junction systems[4].

To illustrate the dual symmetry classifications with a specific example, we introduce a non-unitary quantum walk classified in class AII† using the symmetry relations for non-Hermitian Hamiltonians. Notably, this non-unitary quantum walk exhibits point gaps with a Z2 topological phase and satisfies the bulk-edge correspondence for Z_2 point-gap topology, demonstrating Z_2 skin effects.

We also discuss the bulk-edge correspondence for point-gap topology in junction systems. In Hermitian systems, it is well known that the bulk-edge correspondence can predict the number of edge states appearing at an interface where two subsystems with their own topological numbers are attached. This prediction is based on considering the difference in the topological numbers. Now, we extend the concept of the bulk-edge correspondence to non-Hermitian junction systems, specifically focusing on point-gap topology[4] and clarify that the difference in the topological numbers in point gap for subsystems.

Topological control of OAM in photonic lattices

Zhigang Chen
The MOE Key Laboratory of Weak-Light Nonlinear Photonics, TEDA Applied Physics Institute and School of Physics, Nankai University, Tianjin, China
zgchen@nankai.edu.cn

Graphene has attracted immense attention due to its fundamental interest and highly exploited applications. Apart from carbon-based monolayer graphene materials, various synthetic honeycomb lattices (HCLs) have been employed as artificial graphene for electrons, atoms and photons. In particular, photonic graphene - an HCL of evanescently coupled waveguide arrays, has been proposed and demonstrated as an ideal platform for investigation of unconventional edge states and pseudospin angular momentum, among other intriguing phenomena. In this talk, I will present a few examples of our recent demonstrations on topological control and manipulation of OAM modes in photonic graphene-like structures, including topological singularity mapping that leads to stair-wise generation of OAM beams and topological protection of OAM transport.

Sub-symmetry protected topological states

Abstract: A hallmark of symmetry-protected topological phases are topological boundary states, which are immune to perturbations that respect the protecting symmetry. It is commonly believed that any perturbation that destroys such topological phase simultaneously destroys the boundary states. However, we find that the boundary states are protected by a weaker sub-symmetry condition when the symmetry equation holds only in part of the Hilbert space. By precisely controlling symmetry-breaking in photonic lattices, we experimentally demonstrate such sub-symmetry protection of topological states.

Symmetry protected topological (SPT) phases of matter are ubiquitous in nature and exist on versatile platforms including condensed matter physics, ultracold atomic gases, and photonics [1,2]. Topological insulators (TIs) induced by spin-orbit coupling protected by time-reversal symmetry (TRS) are a paradigm for SPT phases [1-3]. In topological crystalline insulators, a crystalline point group symmetry protects topological metallic boundary states [1,4]. Imagine an SPT phase with a topological invariant characterizing the bulk states and the associated symmetry protected boundary states. Any perturbation that respects the protecting symmetries will not destroy these boundary states or change the topological invariant without closing the gap between bands [1,2]. However, as pictured in Fig. 1, the situation can be more complex: there are perturbations that preserve the topological invariant but oppose the existence of boundary states [5,6], and vice versa, there are perturbations that leave the boundary states unhurt while destroying the topological invariant [7]. We explore these questions by using the concept of sub-symmetry (SubSy), where the symmetry equation does not hold in the whole Hilbert space, but only in its subspace. For a one-dimensional (1D) Su-Schrieffer–Heeger (SSH) and breathing Kagome lattice (BKL) models, the SubSys arise from their chiral symmetries.

We demonstrate, theoretically and experimentally, that the boundary states in the SSH and BKL models are protected by their pertinent SubSy. Any SubSy-preserving perturbation will leave its corresponding boundary state eigenvalue at zero, even though the bulk topological invariant is lost. We utilize zigzag and twisted lattices, and “bridge” waveguides to experimentally introduce SubSy-breaking and -preserving perturbations in a controlled manner, and thereby demonstrate SubSy protected topological states. In the case of non-negligible long-range hopping (i.e., non-negligible coupling between distant lattice sites) in BKLs, we find that SubSy and an additional long-range hopping symmetry are sufficient to protect the corner states. Our experiments are performed in photonic structures, which have been established as a fertile platform for exploring novel topological phenomena [8-10]. The main message from our findings is summarized in Fig. 1, and more details can be found in Ref. [11].

Based on the concept of sub-symmetry, we propose a method that transforms an in-gap topological boundary state into a bound-state in continuum (BIC) [12]. More specifically, we design coupling between a

system possessing an in-gap topological modes and a system possessing a continuum of states that results in topological BICs. We define the criteria for the coupling that yields the desired results. Finally, we will present our recent results related to the non-Hermitian Skin effect induced by the synthetic gauge fields [13].

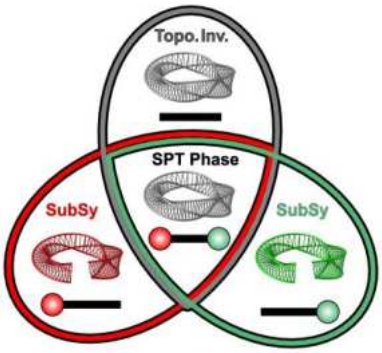

Fig. 1. Classification of perturbations with respect to symmetries in SPT phases. A set of perturbations, that preserves the topological invariant (or invariants) and respects a particular symmetry (or symmetries), is encircled with a grey line. Every boundary state is protected with its pertinent sub-symmetry (SubSy). In the illustration, two sets of SubSy-preserving perturbations (encircled with red and green lines) are sketched, but their number depends on the actual system. At the overlap region, one has an SPT phase with a topological invariant characterizing the bulk, and all associated boundary states. See Ref. [11] for details.

Non-Hermitian Many-body Landau-Zener Systems: Quantum Dynamics & Correlations

Avadh Saxena[1], Rajesh K. Malla[2], Julia Cen[1] and Wilton J. M. Kort-Kamp[1]

[1] Los Alamos National Lab. [2] Brookhaven National Lab.

We provide a general framework to solve a diverse class of linearly driven non-Hermitian quantum systems. In the context of Hermitian systems such models are commonly known as multistate Landau-Zener models. The anti-Hermitian couplings between the diabatic levels introduce non-Hermiticity. We find a conservation law which is unique to this class of models that describes the simultaneous growth of the unnormalized wave functions. For practical applications these models are pertinent to Bose-Einstein condensates, and can describe the dynamics of multispecies bosonic systems. The conservation law is related to a pair-production mechanism that is relevant to the dissociation of diatomic molecules into atoms. We address both solvable and semiclassically solvable non-Hermitian Landau-Zener models. These results are also useful in studying emergent phenomena in time-dependent non-Hermitian quantum systems. Finally, we make some general remarks about out-of-time ordered correlations in non-Hermitian systems.

Abstract: We demonstrate high-quality-factor dielectric metasurfaces working in the deep-ultraviolet (DUV) range. The metasurfaces were designed by incorporating several device schemes to enable the strong light confinement for high Q resonances. The applications of the reported metasurfaces will be discussed.

DUV light plays a critical role in many key technologies ranging from nanolithography, clinical imaging, to biomolecular spectroscopy(1). It has been shown that metasurfaces can improve those applications by their capability to enhance electromagnetic fields (2). Previously, metasurfaces and plasmonic devices in the DUV range are majorly made of aluminum(3-5). It is because that aluminum has a larger plasma frequency compared with other metals and thus still shows proper plasmonic properties below 300 nm. Despite many novel advancements with plasmonic metasurfaces in the DUV, the intention to further boost the light-matter interactions using metasurfaces usually suffers from their relatively moderate resonance quality due to the resistive loss of aluminum. This issue can be circumvented by replacing aluminum with low-loss dielectric materials. Dielectric metasurfaces made of high-index materials such as Ge, TiO2, and GaN have been used for many applications in the visible and IR range including light focusing, biosensing, and nonlinear optics. However, as commonly available low-loss DUV dielectric materials show moderate refractive index, it is challenging to realize high-Q metasurfaces due to the insufficient dielectric contrast between the resonance unit cells and the substrate. Here, we demonstrate feasible approaches to realize high-Q metasurfaces by introducing various device schemes in the designs. One of the reported methods is shown in Figure 1a, which is to place the metasurface on a freestanding membrane with a refractive index of 1.8. The thickness of the membrane is 15 nm. In our work, we tested aluminum nitride and hafnium oxide as the constituent materials for our DUV high-Q metasurfaces due to their neglectable optical absorption beyond ~230 nm. We use commercial simulation software Lumerical to design and characterize the optical properties of the metasurfaces. The resulting metasurface shows a high Q factor beyond 1000 with field enhancement of more than 30-fold compared with the incident light. As shown in Figure 1c, by gradually scaling the size of the resonance unit cells, we can move the resonance of the metasurface across the DUV range. In addition, we performed tests to verify the capability of the reported metasurfaces for biomolecular sensing. The results show that the reported high-Q metasurfaces can provide a striking platform for biomolecular sensing in the DUV range. The other design schemes and the applications of the reported metasurfaces for various surface-enhanced spectroscopy techniques and DUV chiral optics will be reported.

In conclusion, we demonstrate high-Q metasurfaces made of low-loss dielectric materials for DUV applications. The reported design schemes enable many novel applications in this critical wavelength range. This work will pave a novel route toward novel nanophotonic devices for sensing, quantum optics, and nonlinear

optics in this critical wavelength range.

Electric Field Driven Trion Drift in suspended 2D Transition Metal Dichalcogenides

Woo Hun Choi[1,2], Seong Won Lee[1,2] and Su-Hyun Gong[1,2*]

[1]Department of physics, Korea University, Seoul, Korea
[2]KU Photonics center, Korea University, Seoul, Korea
[*]Su-Hyun Gong: shgong@korea.ac.kr

Abstract: Trions, quasiparticles composed of an exciton bound to an excessive charge, in transition metal dichalcogenide (TMD) are potential candidate of information carriers that can be controlled using external electric fields. In this work, we demonstrate drift of trions in a suspended TMD monolayer by using a simple electromechanical device.

Transition-metal dichalcogenide (TMD) materials emerged as an indispensable platform for studying exciton-related physics because of their rich exciton landscape[1]. Among the diverse research field, controlling the exciton transport in a TMD monolayer are considered as a crucial step for developing TMD-based excitonic devices[2]. However, an external electric field cannot be utilized since excitons are charge-neutral quasiparticles. In contrast to neutral excitons, trions (charged excitons) carry a nonzero net charge, which provides great potential for their manipulation using externally applied electric fields as in conventional electronic devices[3,4]. In this study, we achieved free-trion drift in a suspended TMD monolayer by exerting a gate-tunable electric field using a simple bottom-gate device. Our device consists of TMD monolayer suspended on a patterned SiO2/Si substrate, Si bottom gate, and top Au contact (Fig. 1a). When a voltage was applied at the bottom gate, electric fields were induced in the vicinity of the monolayer (Fig. 1b). Induced electric field plays two roles in our device. First, because the monolayer is connected to the ground through the top contact, the electric field leads to electrostatic doping in the monolayer result in increasing the density of trions. The second role of the electric field in our device is to apply an electric force to the suspended monolayer which pulls down the suspended layer and induces in-plane trion motion.

Figure 1

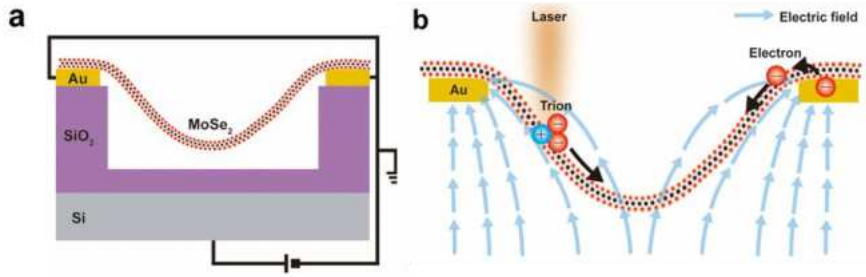

Figure 1. Gate-tunable suspended MoSe2 monolayer device. **a**. Schematic diagram of the suspended MoSe2 monolayer on a patterned SiO2/Si substrate. **b**. Schematic diagram of the suspended MoSe2 monolayer under the electric fields.

To confirm the trion drift motion, we locally excited trions and compare the PL distribution at various position in the suspended region. Figure 2a–d shows the spatial distribution of the trion PL intensity for different excitation positions at a bottom-gate voltage of 170 V at a cryogenic temperature (3 K). At the hole center, trion PL distribution followed the symmetry of the Gaussian profile. However, PL distribution at about 350 nm away from the hole center exhibited

an asymmetric behavior along the radial direction. The asymmetric intensity with a stretched tail toward the hole center suggests that the trions tend to drift toward the center at a finite positive gate voltage. Furthermore, in order to utilize trions as information carrier at practical usage, they must be able to exhibit same phenomena even at room temperature. Therefore, we also conducted a similar study in WS_2 monolayer at room temperature and successfully observed trion drift.

Figure 2

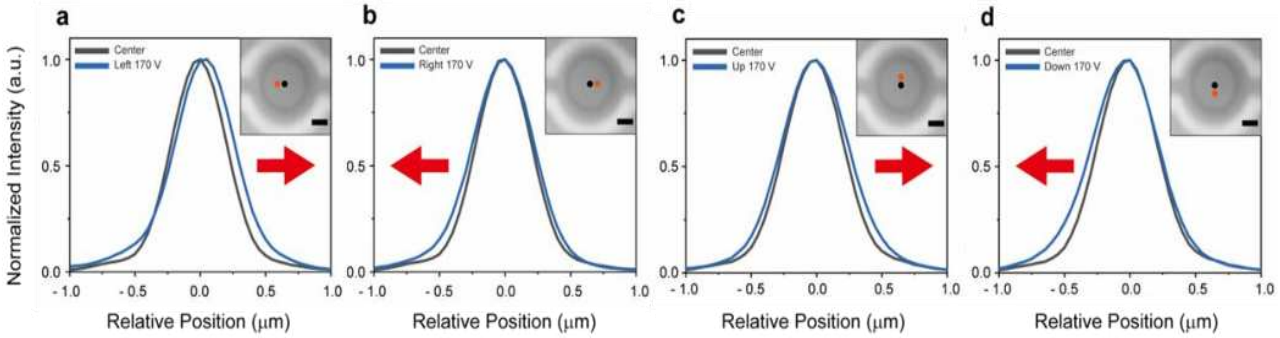

Figure 3. Drift of trions toward the center of the hole. (a–d) Cross-sectional PL intensity distribution of trions for different excitation positions at a gate voltage of 170 V.

In conclusion, we successfully demonstrated the drift motion of a trions in a suspended TMD monolayer at both cryogenic and room temperature. We emphasize that previous studies on the transport of excitons or excitonic complexes in TMD monolayers conducted on time-resolved techniques under pulse-excitation[4,5]. In this study, we observed the drift of trions under continuous-wave (CW) excitation without time-resolved spectroscopy which provides more direct result that are easy to interpret. It is recently reported that the suspended geometry of the device and electrostatic doping increase the trion lifetime hence enabling us to observe enhanced transport phenomena of trions[6]. Our findings clearly demonstrate the untapped potential of trion-based optoelectronic devices.

Tunable Transition Metal Dichalcogenide Based Metasurfaces in Liquid Crystal Medium

K. M. Anu[1], and Jayasri Dontabhaktuni[1*]

[1] Department of Physics, Mahindra University, Hyderabad, India

*corresponding author: jayasri.d@mahindrauniversity.edu.in

Abstract: In this work, we demonstrate versatility and tunability of transition metal dichalcogenide based metasurfaces in air and liquid-crystal medium. We explore the tunability in electromagnetic response, near-field, far-field radiation profiles, sensitivity, strong coupling between excitons and polaritons in WS_2 based metasurfaces as a function of liquid-crystal orientations in visible region.

Summary:

Transition metal dichalcogenides (TMDCs) is a rapid growing field in the nanophotonics due to their extraordinary excitonic, optical, mechanical, thermal and electronic properties [1-3]. The creation of innovative dielectric metasurfaces with a high refractive index has garnered significant attention and research interest due to TMDCs. Compared to commonly utilized dielectric materials with high refractive indices, bulk TMDC materials have naturally very high refractive indices in the visible and near-infrared spectral region. TMDCs, specifically MoS_2 and WS_2 have direct bandgap and strong excitonic characteristics. Bulk WS_2 exhibits self-coupled exciton-polaritons and distinct Mie modes [4, 5]. WS_2 metasurface has been useful for sensing applications [6], light harvesting [4, 6] and exciton-polariton devices [4, 6, 7]. Liquid crystals (LC's) are a flexible medium that can support programmable, multifunctional, and tunable electromagnetic response through optical, thermal, electrical, and magnetic tuning [8, 9]. WS_2 has variety of uses in electronics and optoelectronics and we investigate the tunability liquid crystal (LC) can bring in the light matter interaction in bulk WS_2 metasurface.

We designed the model using finite element method (FEM) simulations in commercially available CST software. A nanocuboid metasurface made out of bulk WS_2 is deposited onto a SiO_2 substrate of thickness t = 100 nm, illuminated by a normally incident y-polarized plane wave. The periodicity of each unit cell is p = 300 nm and every nanocuboids has sides a = 240 nm and a height h = 30 nm, respectively. Each nanocuboids consists of a rectangular hole (100 × 50 nm) at a fixed distance d = 25 nm between center of WS_2 to center of rectangular hole. The simulated design has been studied in the air medium and liquid crystal (LC) medium of thickness 200 nm. Results are obtained by simulating unit cell with periodic boundary condition (PBC) along X and Y directions in the visible frequency range.

Conclusions:

The tunability that LC gives to the bulk WS_2 metasurfaces light matter interaction has been investigated in this paper. As per the literature, for the first time, we are showing LC's can tune quasiparticle interactions. We numerically examine the effect of electrically driven anisotropic LC medium on bulk WS_2 metasurface and their orientation in Quality factor, sensitivity, strong coupling between excitons and non-radiating states, near and far-fields, and thus expanding the possibilities of applications for phase modulators, multifunctional metasurfaces, tunable exciton-polariton devices and sensing.

Photoluminescence and electroluminescence control of 2D semiconductors coupled to nanophotonic structures

A. J. Moilanen[1*], T. Taniguchi[2], K. Watanabe[2], and L. Novotny[1]

[1]ETH Zürich, Switzerland

[*]corresponding author: amoilanen@ethz.ch

Abstract: We present control of photoluminescence and electroluminescence properties of two-dimensional (2D) semiconducting materials, monolayers of transition metal dichalcogenides (TMDs), by incorporating them into plasmonic and photonic cavities as well as waveguides. As another way to control the emission properties, we exploit electrostatic doping of the TMDs by using gate electrodes.

Nanophotonic cavities, such as plasmonic lattices (periodic arrays of metal nanoparticles) have been used to modify the photoluminescence (PL) properties of emitters such as fluorescent molecules and quantum dots, leading ultimately to the generation of coherent light in the nanoscale by lasing or Bose–Einstein condensation (BEC) [1-4]. While most of the previous works have relied on optical excitation of the gain material, electrically excited and controlled active materials would be desirable for on-chip integration. Two-dimensional (2D) semiconducting materials, monolayers of transition metal dichalcogenides (TMDs), have a direct optical bandgap and excitons with high binding energies, making TMDs a promising class of materials for light-emitting optoelectronic devices. We present ways to control the PL of these materials by coupling them into nanophotonic cavities and by applying gate electrodes to our devices. In addition, we demonstrate the integration of a 2D light-emitting device into a photonic waveguide made of hexagonal boron nitride (h-BN) [5]. Our results pave the way for novel on-chip optoelectronic devices such as integrated nanoscale light sources and optical interconnects.

Abstract: Here, we demonstrate strong second-order and third-order susceptibilities of 64 pm/V and 6.2×10^{-19} m^2/V^2, respectively, in the even-layer PdPSe. It also simultaneously exhibited strong SHG anisotropy with an anisotropic ratio of ~45, which is the largest reported among all 2D materials to date, to the best of our knowledge.

Nonlinear optics has been a fundamental building block of modern optics and lies at the core of laser technology, optical spectroscopy, and quantum networks. Second-harmonic generation (SHG) and third-harmonic generation (THG) processes in 2D materials are emerging branches of nonlinear optics and have been widely exploited for various applications, such as nonlinear optical modulators[1], nonreciprocal optical devices[2], and quantum sources[3]. Several methods have been proposed to generate SHG in 2D materials by breaking the inversion symmetry.

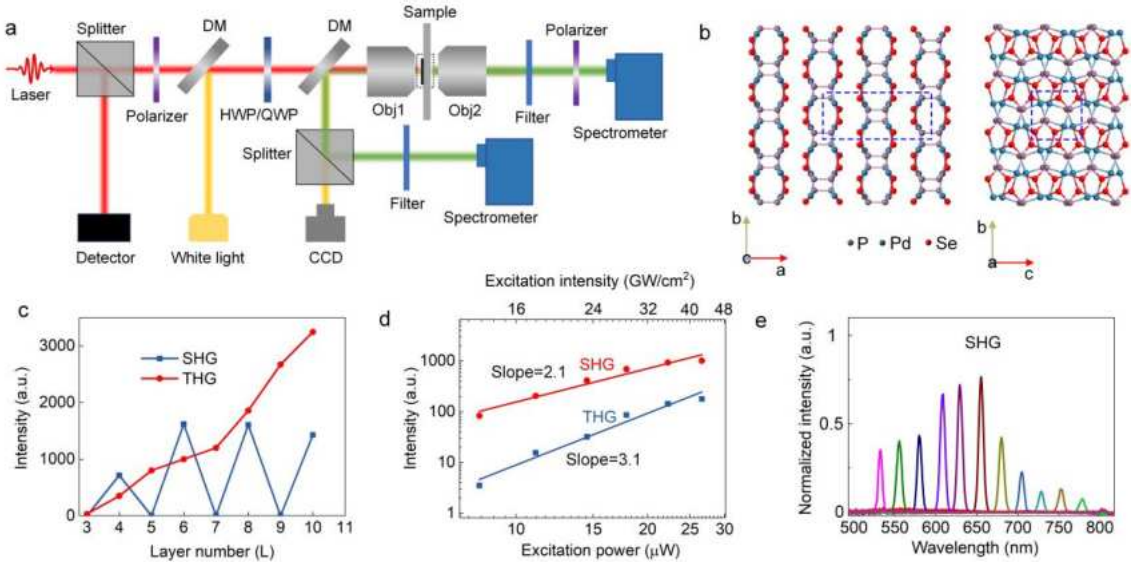

Figure 1. (a) Experimental setup. (b) The crystal structure of PdPSe. (c) SHG and THG intensities as functions of the layer number (L). (d) Excitation power (intensity) dependent SHG and THG intensities in 6 L PdPSe. (e) The SHG spectra with the excitation wavelength from 1064 to 1600 nm in 4 L PdPSe.

Anisotropic nonlinear optical responses generated from the difference of polarization P(t) in two crystal orientations have become a recent research focus, such as anisotropic nonlinear absorption, anisotropic SHG, and anisotropic THG in asymmetric 2D materials. Exploring new inversion-symmetry-broken 2D materials with the coexistence of strong nonlinear optical anisotropy and strong optical nonlinearity (including SHG and THG) is highly desirable for fundamental research as well as novel optoelectronic applications. Here, we describe our finding that even-layer PdPSe has strong inversion-symmetry-broken behaviors, which are distinct from other

common TMDCs[4], with a strong second-order susceptibility of 64 pm/V and a third-order susceptibility of 6.2×10^{-19} m^2/V^2. Importantly, in contrast to MoS_2 and GaSe without in-plane anisotropy, we showed that 2D PdPSe possesses strong nonlinear optical anisotropy with a maximum anisotropic ratio (ρ_{SHG}) of ~45, which is the largest in all atomically layered 2D materials, to the best of our knowledge. The maximum ρ_{THG} value of PdPSe crystal is ~7, which is also larger than that in all the 2D layered materials. The simultaneous realization of strong nonlinear optical anisotropy and strong nonlinear optical coefficients in 2D PdPSe opens up opportunities for the next-generation miniaturized photonic devices with polarization functions.

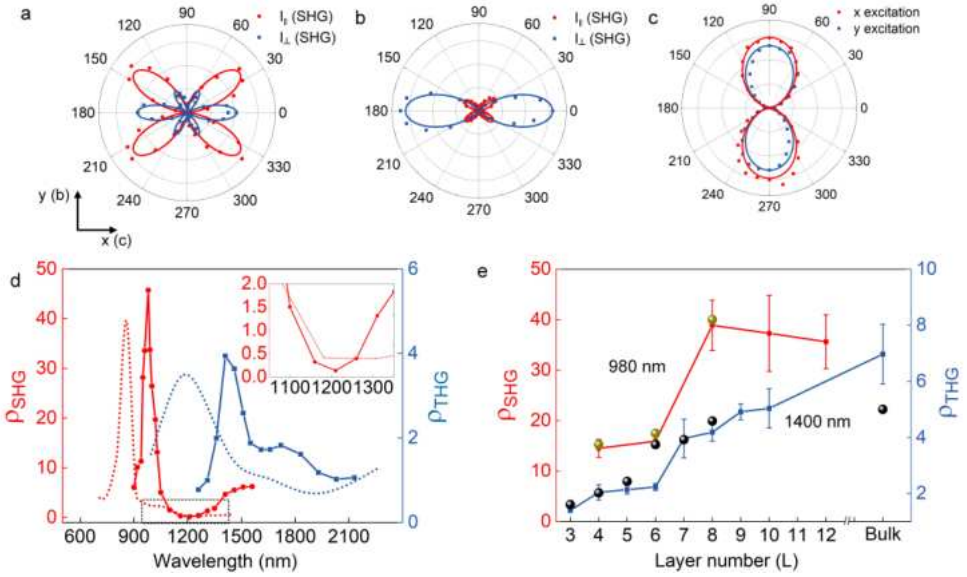

Figure 2. (a-b) Polar plots of the SHG intensity versus the polarization angle (θ) with parallel (red) and perpendicular (blue) configurations under 1550-nm and 980-nm excitations. (c) SHG polarization orientation with excitation polarization along x-(red) and y-(blue) axes of PdPSe under 1300-nm excitation. (d) ρ_{SHG} (red) and ρ_{THG} (blue) versus the excitation wavelength for 8 L PdPSe. (e) ρ_{SHG} (red) and ρ_{THG} (blue) as functions of the layer number under 980-nm and 1400-nm excitations, respectively.

Abstract: We demonstrate the state-of-the-art scanning near-field optical microscopy (SNOM) imaging of 2D materials. We identified the exciton quenching behavior at sharp WS_2 and MoS_2 lateral heterojunctions with a 68 nm NF-photoluminescence resolution. Furthermore, the bandgap evolution and interlayer coupling in the $W_xMo_{1-x}S_2$ alloy were visualized using the NF-transmission method.

With the development of advanced chemical vapor deposition (CVD) methods [1], many artificial 2D semiconductors have been synthesized, which increases the chances of forming disrupted interfaces and nonperiodic or small-sized systems (defects and grain boundaries). All such systems create local electronic band structures within a finite scale, which cannot be readily explained by solid-state band theory or probed easily by confocal microscopy and macroscopic transport.

In this study, we investigated abrupt heterojunctions and graded alloys between two transition metal dichalcogenides (TMD), which involve nonperiodic band structures and require high spatial resolution. We employed near-field photoluminescence (NF-PL) imaging to study the atomically sharp 1D interfaces between WS2 and MoS2 (Fig. 1b). With an optical resolution of 68 nm, a 105 nm-wide region for quenched PL was confirmed using NF-PL imaging [2]. Our NF-PL imaging resolved the narrowest quenching width and sharpest strain mapping because of the superior spatial resolution and stability of our home-built SNOM [3].

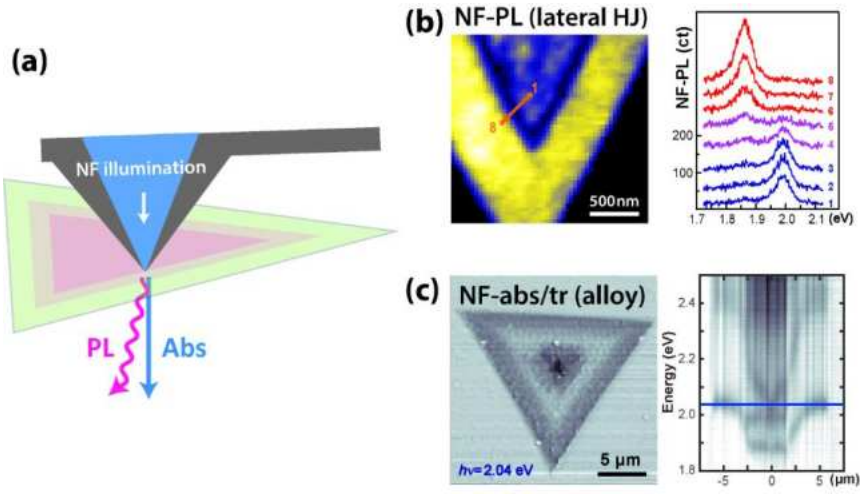

Fig. 1 (a) Schematic of the near-field absorption/transmittance (NF-abs/tr) and near-field photoluminescence (NF-PL) measurements. **(b)** NF-PL imaging and spectra of the lateral heterojunction. **(c)** NF-tr spectroscopic imaging and band structure of graded alloy.

We further developed a near-field broadband absorption (or transmittance, NF-tr) imaging method to overcome the limitations of NF-PL in low-quantum-yield materials. The NF-tr technique provides abbreviation-free and nanoscale-resolution imaging capabilities of the entire conduction band over a highly lateral inhomogeneity. We utilized NF-tr microscopy to investigate the varying bandgap and bowing factor of a single-layer WxMo1-xS2 alloy [4]. For the bilayer WxMo1-xS2 alloy, the energy contour maps present the bandgap evolution in the alloy and reveal bilayer coupling between the top and bottom layers (Fig. 1c). We can conclude that the bottom layer is alloy in nature, whereas the top layer is composed of pure WS2. High-spatial-resolution spectral capability is essential for analyzing compositional and location-dependent bandgap evolutions.

Absorption Enhancement of Exciton of WS_2 by Silicon Metasurface Based on Degenerate Critical Coupling

Dingwei Chen[1], **Junichi Takahara**[1, 2*]

[1]Graduate School of Engineering, Osaka University, Japan

Abstract: We study an absorption enhancement of two-dimensional transition-metal dichalcogenides coupled to a Silicon metasurface by degenerate critical coupling. Here, we demonstrate in numerical simulations that the absorption of A mode of exciton in WS_2 can be increased 15.5 times by degenerated Mie modes.

Atomically thin two-dimensional (2D) transition-metal dichalcogenides (TMDCs), such as WS_2, have gained prominence in recent years due to their unique optical and transport characteristics, particularly in the field of optoelectronics and photonics applications[1, 2]. Nevertheless, their ultrathin thickness results in weak optical absorption. To accomplish light absorption enhancement, an all-dielectric metasurface utilizing Mie resonance along with degenerate critical coupling (DCC)[3] has been developed, achieving synergistic enhancement effects on WS_2. With increasing light-matter interactions, the emergence of exciton-polaritons in strong coupling is poised to engender more interesting phenomena, thereby expanding the potential applications significantly.

In this study, we achieve a huge absorption increase of WS_2 with an all-dielectric metasurface, when peaks of electric and magnetic dipole (ED and MD) modes of metasurface overlaps in the wavelength near the peak related to A excitonic transitions in monolayer WS_2.

First, we design the Mie resonator metasurface substrate to increase absorption of WS_2 and study its optical spectrum. Figure 1 shows the structure of WS_2 on the Silicon (Si) metasurface. Among them, the metasurface is comprised by cylindrical resonator arrays with period *d*, radius *r*, and thickness *h*.

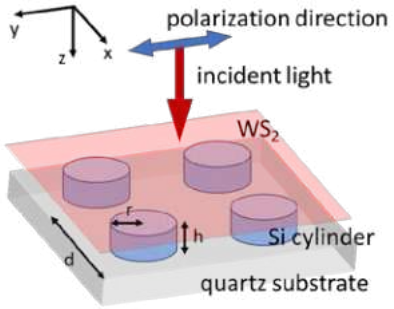

Fig. 1: Schematic view of WS_2 on Si metasurface composed of Mie resonator arrays.

Figure 2(a) shows the calculated absorption spectral map of Si Mie resonators with h = 55-115 nm. The resonant wavelengths of ED and MD modes increase as h increases, while the MD mode experience a larger red shift compared to the ED mode. We observe an overlap of two modes at h = 89 nm. When ED and MD modes overlap, DDC is realized and simulated absorption of metasurface is shown as the red dotted line in Fig. 2(b). Furthermore, in Fig. 2(b), we fabricated the designed sample shown in the inset and measured its spectrum shown in the blue dotted line. Because the height and radius of prepared sample was different from designed, overlap was not completely achieved. However, we partially realized DDC with ED and MD modes shown as the fitting curve 1 and 2.

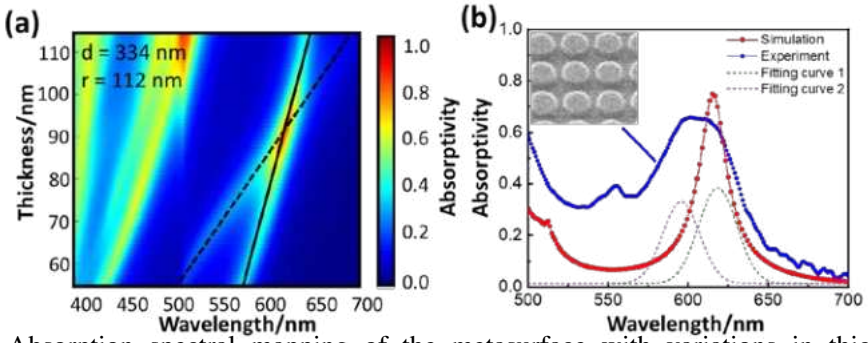

Fig. 2:(a) Absorption spectral mapping of the metasurface with variations in thickness *h*, (b) experimental and simulated[4] absorptivity for the metasurface, and modes fitting curve of experimental spectrum. Inset: Scanning Ion Microscope image of the sample.

We simulate the absorption spectrum of WS_2 on metasurface, and obtain the A exciton absorption peak of WS_2 by fitting as shown in Fig. 3(a). By subtracting background from Fig. 3(a), we obtain the absorptivity of WS_2, which is increased by about 0.52 (15.5 times) under DCC condition compared with WS_2 on Si substrate as shown in Fig. 3(b). At the same time, we observe that the peak position shows a 9 nm red shift. Note that such red shift is attributed to the coupling effect of exciton and dipole modes.

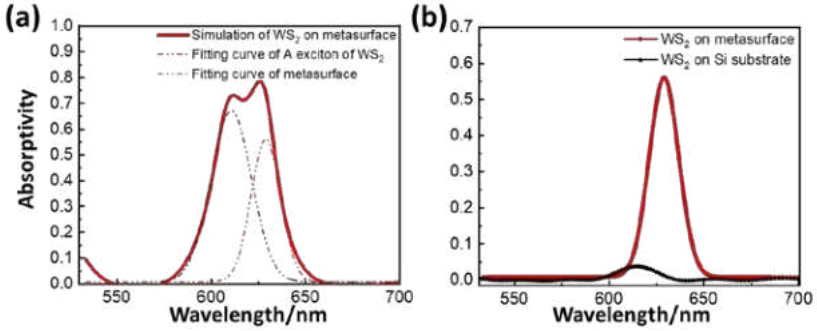

Fig. 3:(a) Simulated absorptivity of WS_2 on the metasurface and corresponding fitting curves. (b) Simulated absorptivity subtracting background for WS_2 on Si substrate and the metasurface in 2(b).

In summary, we designed an all-dielectric Si Metasurface based on DCC, and found that the absorption of WS_2 monolayer as high as 0.56 (before 0.036) was achieved. This architecture could be used in the future as a highly efficient tunable single-color photodetector. Moreover, the suggested dielectric metasurface holds promise for improving application possibilities of semiconductor 2D materials in visible wavelength range.

Hundred- to thousand-fold enhanced luminescence and the quantum nature manifested in continuous 2D materials coupled with metasurfaces

Masanobu Iwanaga*, Xu Yang, Vasilios Karanikolas, Takashi Kuroda, and Yoshiki Sakuma

National Institute for Materials Science (NIMS), Japan

Abstract: Atomic-layer 2D materials are attracting huge research interest. Transition metal dichalcogenide (TMDC) monolayers exhibit efficient luminescence. By coupling a continuous TMDC monolayer with all-dielectric metasurfaces or plasmo–photonic metasurfaces, significant luminescence enhancement was achieved. Furthermore, the quantum nature of the enhanced luminescence was visualized in confocal microscopy.

TMDC monolayers, specifically MoS_2 monolayers, were found to have direct-transition exciton luminescence at room temperature in 2010 [1,2]. They were microscale triangles at the early stage. Now, wafer-scale continuous TMDC monolayers can be grown by some groups [3,4]. Here, we address our recent experimental findings regarding coupled systems of the continuous cm-scale TMDC monolayer and metasurfaces that were shown to have prominent fluorescence-enhancing ability [5–7].

Figure 1A illustrates a TMDC monolayer located on an all-dielectric metasurface that is periodic array of Si nanocolumns on an SiO_2 layer. Actual sample [8] is shown in Figure 1B. The metasurfaces were fabricated on a silicon-on-insulator substrate of 2 cm square, being aligned vertically at the center (orange in Figure 1B). The continuous TMDC monolayer of almost 1 cm square, which was nearly WS_2 monolayer, was transferred onto the metasurface substrate, indicated by four arrows. Photoluminescence (PL) of the TMDC monolayer was greatly enhanced on the metasurface, exhibiting 300-fold PL intensity in comparison with the PL intensity off the metasurface [8].

Figure 1C shows a confocal PL image recorded in a photon-counting manner; the white rectangular part corresponds to a metasurface area. It is evident that the image is dark outside the metasurface, meaning that PL is at zero photon level. We analyzed the photon number distribution at the pixels in the image and determined that the distribution is reproduced using the Poisson distribution. This result indicates that the PL emission comes from a coherent single-mode emission [9].

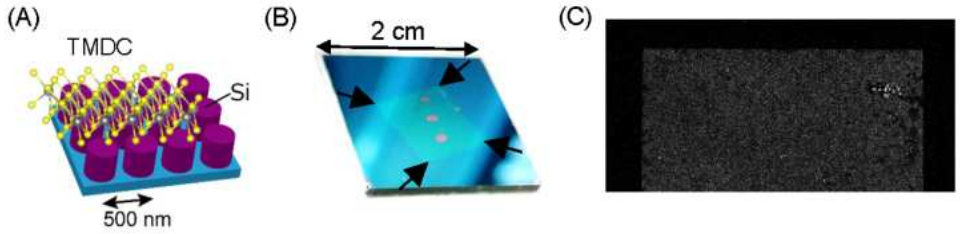

Figure 1. (A) Illustrations of TMDC monolayer transferred onto an all-dielectric metasurface of Si nanocolumn array. (B) Photograph of a sample, cited from [8]. The TMDC monolayer is almost 1 cm square, whose corners are indicated by four arrows. Three metasurfaces (orange) are aligned vertically at the center of substrate. (C) A confocal PL image of the TMDC monolayer shown in gray scale. The PL was observed only on the metasurface area of rectangular shape in the image.

Plasmo–photonic metasurfaces were also found to exhibit strong PL-intensity enhancement, exceeding 1000-fold in comparison with the PL intensity off the metasurface, where flat Au film existed. The PL was also found to have quantum nature, similarly to the case of the all-dielectric metasurface in Figure 1.

Thus, the metasurfaces are good platform to efficiently extract PL from the TMDC monolayer without losing the quantum nature. The details of the experimental results and analysis, as well as the designs and optical properties of the metasurfaces, will be shown in the presentation.

Abstract: Strong coupling between the membrane metasurface and TMDC monolayer via the quasi-BIC mode is demonstrated, presenting enhanced photoluminescence emission. The significance of membrane metasurface design for achieving highly confined quasi-BIC modes, distinct from conventional photonic guided modes, is clarified, offering new possibilities for 2D material-based nanophotonic and quantum devices.

In recent years, there has been significant interest in the strong light-matter coupling observed in monolayers of transition metal dichalcogenides (TMDCs) within the fields of optoelectronics and nanophotonics. A crucial aspect of improving the coupling between photonic structures and TMDC materials, facilitating interactions between photons and excitons, is optimizing the design of photonic structures specifically tailored for materials in the atomic-scale thickness. In the photonic structures, the dielectric metasurface supports the photonic bound state in the continuum (BIC), representing an optical mode confined within a structure without radiative losses. This unique characteristic results in exceptional light-matter interactions, making it an ideal choice for designing TMDC monolayer-based nanophotonic devices [1-3]. In the field of two-dimensional (2D) materials nanophotonics, there has been growing attention towards nanophotonic applications involving BIC modes.

To achieve BIC with a strong field enhancement and a quality factor at resonance approaching infinity in practicality, membrane structures, with their inherent two-dimensional nature, provide an ideal platform. The confinement and manipulation of light within the membrane structures introduce novel possibilities for enhancing light-matter coupling. Additionally, they enable control over optical properties when compared to conventional waveguide modes. Here, we demonstrate the strong coupling between the membrane metasurface and the TMDC monolayer via a quasi-BIC mode. Utilizing the membrane metasurface, the enhanced photoluminescence (PL) emission from the quasi-BIC mode is observed, presenting distinct differences from the emission behaviors of the conventional photonic waveguided mode.

Figure 1(a) illustrates the electric field enhancement distribution of the quasi-BIC mode in the membrane metasurface, demonstrating a significantly larger enhancement than that of the quasi-BIC mode in the substrate-based metasurface. This suggests the significance of the membrane metasurface design for achieving a highly confined quasi-BIC mode. Following the investigation of the membrane metasurface, the emission enhancement

of the WSe_2 monolayer through the strong coupling of the TMDC monolayer to the membrane metasurface via the quasi-BIC mode, deviating from the conventional photonic guided mode, is demonstrated as shown in Figure 1(b). This study underscores the importance of membrane design for nanophotonic metasurfaces supporting BIC, opening a new window for 2D material-based nanophotonic and quantum devices.

Nanoengineered Transition Metal Dichalcogenides Platform for Quantum Photonics: Generation and interference of single photons

A. Paralikis[1], C. Piccinini[1], P. Metuh[1], J. F. Neto[1], P. Wyborski[1], A. A. Madigawa[1], L. Vannucci[1], N. Gregersen[1], and B. Munkhbat[1*]

Abstract: Our recent progress in nanoengineered transition metal dichalcogenides (TMDs) enables high-quality single-photon sources (SPSs). I will present a method for fabricating highly polarized, pure single-photon emitters. Additionally, I discuss the importance of employing advanced optical excitation in improving single photon characteristics and discuss on-chip SPS developments with the TMD platform.

Transition metal dichalcogenides (TMDs) have attracted significant attention as a unique excitonic and photonic platform for nano- and quantum photonics. One remarkable feature of TMDs is their easy exfoliation via the scotch tape, thanks to their van der Waals stacking nature. This feature opens the door to assembling and stacking various TMD materials to possess new properties and integrating them into other photonic platforms. Additionally, TMD mono- and bilayers can yield single photons through strain- and defect-engineering, ranging in visible [1] and telecom [2] wavelengths.

Integrating these TMD quantum emitters with photonic nanostructures and cavities promises efficient single-photon generation [3-5]. In addition to monolayers, multilayer TMDs possess exceptional optical properties, e.g., high index **($n \geq 4$) and low loss ($k \leq 10^{-4}$)** [6]**,** despite their indirect bandgap. These exceptional optical properties combined with optimized nanostructuring offer new possibilities to exploit multilayer TMDs in developing novel photonic components [7-8] for fully integrated quantum photonic circuits.

In the first part of my talk, I will present our recent advancements in fabricating highly polarized mono- and bilayer TMD single photon emitters through strain engineering [9]. This technique allows precise control over the polarization of these quantum emitters, a crucial step in their integration into desired photonic cavities for developing efficient single-photon sources. Our fabricated quantum emitters not only feature a high degree of single photon purity but also exhibit narrow zero-phonon lines with visible phonon sidebands [10]. This provides crucial details on the exciton-phonon coupling of the system and allows us to predict exciton preparation under different excitation schemes [11]. Moreover, we have explored experimentally various optical excitation schemes [10], including quasi- and resonant excitations, to understand their impact on single photon characteristics and the stability of emission lines, especially when compared to above-band excitation.

In the last part of my talk, I will discuss our ongoing research activities in developing on-chip TMD photonic components such as nanobeam cavities, on-chip beam splitters, and waveguides, harnessing the unique properties of nanoengineered multilayer TMD materials. These novel photonic components combined with our TMD quantum emitters could be a promising platform for realizing fully integrated quantum photonic circuits in future scalable quantum information technology.

Excitons in 2D TMDCs for metaoptics and photodetector applications

Zeng Wang[1*], and Jinghua Teng[1]

[1] Institute of Materials Research and Engineering (IMRE), Agency for Science, Technology and Research (A*STAR), Singapore

[*]Corresponding author: wang_zeng@imre.a-star.edu.sg

Abstract: Our research explores excitons in two-dimensional TMDCs for metaoptics and photodetectors, highlighting advancements in exciton-enabled metaoptics, tunable exciton-trion conversion, and ambipolar photoconductivity control. This demonstrates the promise of TMDCs in optoelectronics, offering enhanced performance for next-generation imaging and sensing technologies.

Excitons in 2D transition metal dichalcogenides (TMDCs) are quasiparticles formed by the pairing of electrons and holes, exhibiting strong binding energies due to reduced dielectric screening and enhanced Coulomb interactions in the atomically thin layers[1]. This results in pronounced optical properties, making 2D TMDCs promising materials for novel optoelectronic devices.

Based on the unique excitonic features, firstly, we demonstrate atomic thin metaoptics utilizing the strong excitonic resonances in MoS_2 multilayers[2]. These devices, including a photon-sieve hologram and a supercritical 2D lens, offer enhanced efficiency and resolution beyond the diffraction limit, leveraging the atomically thin MoS_2 for advanced optical wavefront engineering and imaging applications. Secondly, we show a significant enhancement in exciton-trion conversion in atomically thin WS_2[3]. This achievement, facilitated by an optical cavity and electrical modulation, leads to a 40% modulation in reflectivity for excitons and 7% for trions at room temperature, suggesting potential for tunable and ultra-compact optical devices using two-dimensional materials. Last, we present a significant advancement in photodetection technology using n+-SnSe2/n-MoS2 heterojunctions[4]. It showcases a broad wavelength operation from deep ultraviolet to near-infrared, featuring high responsivity, self-powered operation, and unique ambipolar photoresponse with both positive and negative photoconductance under various control parameters. This work highlights the potential for multifunctional optoelectronic devices leveraging the ambipolar photoresponse capabilities of transition metal dichalcogenides heterostructures.

Abstract: Incorporating plasmonic nanostructures with semiconductor compounds offers a new route to significantly improving the performance of photodetectors. Herein, we developed six hybrid structures comprised of 2D semiconductors, perovskite QDs and GaN with different design of plasmonic nanostructures to demonstrate ultrasensitive photodetection in MIR, NIR, visible and UV regions, respectively.

These six demonstrations are, 1. Plasmonic Metasurface Integrated Black Phosphorus-Based Mid-Infrared Photodetector with High Responsivity and Speed **(Figure 1**a), 2. MoS_2 Plasmonic Grating Integrated Indium Selenide for Polarization-Sensitive Multi-Band Photodetection in Near-Infrared **(Figure 1**b),

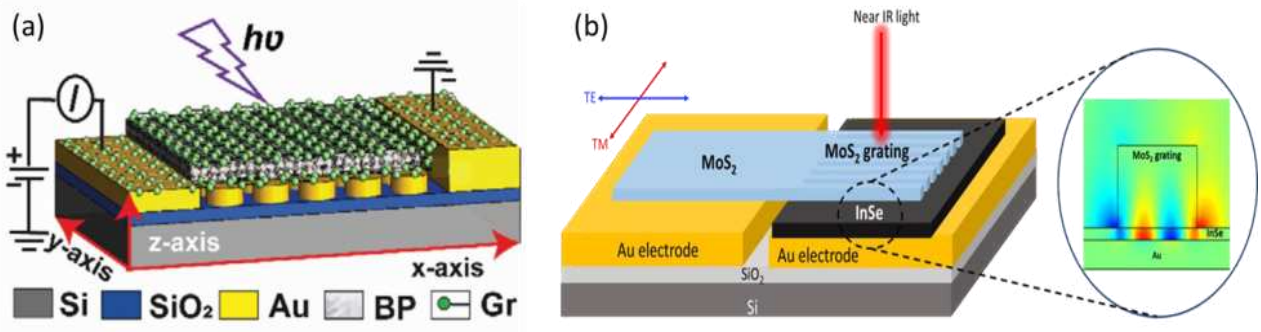

Figure 1. Schematic illustration of the (a) Plasmonic metasurface/BP MIR photodetector and (b) MoS_2 grating/InSe NIR photodetector.

3. Ultrasensitive Gateless Photodetector based on 2D Bilayer MoS_2-1D Si Nanowire-0D Ag Nanoparticle Hybrid Structure **(Figure 2**a), 4.Enhanced Photoresponsivity of Perovskite QDs/Graphene Hybrid Gate-free Photodetector by Morphologically Controlled Plasmonic Au Nanocrystals **(Figure 2**b),

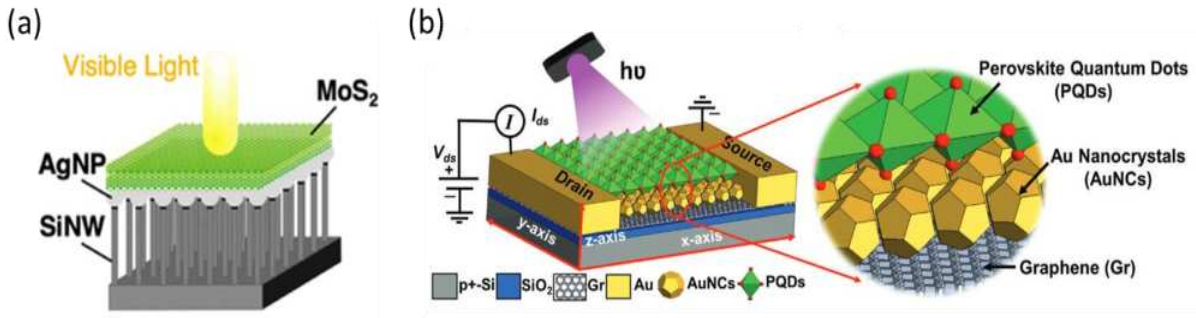

Figure 2. Schematic illustration of the (a) 2D bilayer MoS_2-1D Si nanowire-0D Ag nanoparticle hybrid visible photodetector and (b) PQDs/AuNCs/Gr hybrid electrostatic gate-free visible photodetector.

5.Ultrasensitive Photodetection of Monolayer MoS_2 using Semimetal Plasmonic Structure and Ohmic Contact (**Figure 3**a), and 6. A Multifunctional Plasmonic Sensor for Excellent UV Photodetection and NO_2 Gas Sensing by an Array of Al Nanocaps on GaN Truncated Nanocones (**Figure 3**b). These studies provide novel approaches for designing high-performance plasmonic photodetectors in different frequency regions.

Abstract: We report on exciton transfer in carbon-nanotube/tungsten-diselenide heterostructures, where the excitons within the two-dimensional semiconductor are funneled into carbon nanotubes through diffusion. When band alignment is resonant, we observe substantially more efficient excitation via tungsten diselenide compared to direct excitation of the nanotube.

Nanomaterials exhibit unique optical phenomena, in particular excitonic quantum processes occurring at room temperature. For example, excitons in one-dimensional carbon nanotubes exhibit extended diffusion lengths [1], efficient exciton-exciton annihilation [2], near-unity quantum efficiency [3], and single-photon emission at room temperature [4]. The low dimensionality, however, imposes strict requirements for conventional optical excitation, and an approach for bypassing such restrictions is desirable. Here we report on exciton transfer in carbon-nanotube/tungsten-diselenide heterostructures [5], where several advantages are offered including larger absorption areas, broadband spectral response, and polarization-independent efficiency.

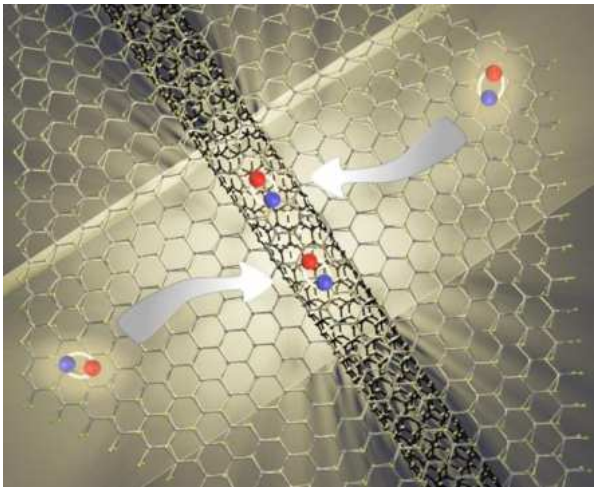

Figure 1: Schematic of the exciton transfer process in a mixed-dimensional heterostructure.

The mixed-dimensional heterostructures are fabricated by transferring a tungsten diselenide flake on top of an individual air-suspended carbon nanotube. The nanotubes are grown over trenches by chemical vapor deposition [2], and a tungsten diselenide flake is placed on top of the tubes by utilizing the anthracene-assisted transfer technique [6, 7]. The nanotube/tungsten-diselenide heterostructures are therefore entirely free-standing, which eliminates substrate-induced inhomogeneity and dielectric screening effects.

Photoluminescence excitation spectroscopy [2] and time-resolved photoluminescence measurements [1, 3] are performed to elucidate the absorption and emission characteristics. We observe a peak in the excitation spectrum corresponding to the A exciton resonance in tungsten diselenide and an emission peak corresponding to the E_{11} exciton in carbon nanotubes. Time-resolved luminescence data reveal an exciton reservoir effect where the longer-lifetime excitons within the two-dimensional semiconductor are funneled into carbon nanotubes through diffusion. Taking advantage of the chirality-dependent band gap in carbon nanotubes, band alignment in the heterostructure can be systematically varied. When band alignment is resonant, we observe substantially more efficient excitation via tungsten diselenide compared to direct excitation of the nanotube. We further demonstrate simultaneous bright emission from an array of carbon nanotubes with varied chiralities and orientations.

These observations propose that the exciton transfer process in mixed-dimensional heterostructures could be harnessed for generation of excitons in carbon nanotubes, thus providing an avenue to surpass the excitation constraints in low-dimensional materials. The high tunability of the band alignment indicates the potential for more intriguing excitons to emerge in this system, for example, indirect excitonic states at the mixed-dimensional interface under type-II band alignment. Our findings show the potential of mixed-dimensional heterostructures and band alignment engineering for energy harvesting and quantum applications through exciton manipulation.

Abundant optical properties of hexagonal boron nitride

Abstract: We will review the new aspects of hexagonal boron nitride (h-BN), especially the peculiar and outstanding optical characteristics originating from the anisotropic two-dimentional crystal structure.

Hexagonal boron nitride (h-BN) single crystal is a layered material consisting of atomically flat atomic layers with boron and nitrogen atoms bonded with sp^2 hybridized orbital. Each layer is weakly stacked by van der Waals interactions[1]. Since the early stages of graphene research, high crystalline h-BN single crystals grown by high-pressure, high-temperature (HPHT) synthesis method have been used as the best substrate dielectrics for studying two-dimensional physics[2]. It supplies "a stage" for the emergence of new two-dimensional physical phenomena[3] by the use of the clean surface of the cleaved h-BN layer, which has almost no dangling bonds or charged traps[4].

Derived from this anisotropic two-dimensional crystal structure, this material is also known for its very interesting optical properties, such as the high luminous efficiency of excitons in the far-ultraviolet region[5], three-dimensionally confined hyperbolic polaritons[6], symmetrically controlled polarization properties[7], and single-photon emission from intentionally created point defect centers[8]. Although h-BN is an indirect bandgap material, its luminous efficiency is comparable to typical direct transition materials such as ZnO[9]. The feature of a confined hyperbolic polariton is known as a "natural metamaterial". Polar switching with a twisted layer is promising for the application of atomic-thin non-volatile memory, and single-photon sources due to intentionally introduced point defects are attracting attention as future quantum devices. We review these new aspects of h-BN, especially their abundant optical properties.

Plasmonic Strong Coupling and Tamm Plasmon Polaritons Photodetectors Enabled by 2D materials Hot Electrons

Kuo-Ping Chen*
Institute of Photonics Technology, National Tsing Hua University, Taiwan
**kpchen@ee.nthu.edu.tw*

Abstract: Two-dimensional materials are being studied for their unique optical characteristics and miniaturization capabilities. We proposed that by combining Tamm plasmon polariton (TPP) resonance and a graphene layer at the point of strong field confinement, a wavelength- and angle-selective photodetector that significantly enhances photocurrent response. This graphene-TPP photodetector could have applications in LiDAR detection, sun sensors, laser beacon tracking, and navigational instruments.

***Key Word**-- Tamm plasmon polariton; graphene; photodetectors; wavelength and angle selectivity;*

1. Introduction

In this study, an idea was developed for a graphene photodetecting device employing the Tamm plasmon polariton (TPP) structure [1]. As graphene was transferred onto the DBR, a metal film was fabricated on the graphene layer. The proposed graphene-TPP photodetector was devised and fashioned using gold electrodes to collect electrical signals. The graphene layer does not affect the TPP resonance thanks to the atomic layer thickness of graphene; however, the graphene locates the localized electric field formed by the TP structure. The structure converts incident light into TPPs that are collected and transferred into photocurrents by the graphene layer. The photocurrent generation mechanism of our device is related to the PV effect. In our proposed graphene–TPP photodetector, the photoresponse of graphene can be enhanced by the localized electric field, and the device facilitates angle and wavelength selectivity by means of the TP structure. Our device can be utilized as a miniaturized Li-DAR detector for suitable applications, lowering the processing cost, and optimizing the processing yield.

In addition, the coupling between excitons in transition metal dichalcogenide (TMD) monolayers and plasmons in nanostructures will be discussed [2]. The study focuses on enhancing exciton-polariton coupling by utilizing one-dimensional plasmonic nanogrooves (NGs) to align excitons in MoS2 monolayers with plasmon polaritons. Our approach addresses the inefficiency in coupling due to the misalignment of exciton orientations in conventional systems. We demonstrate significant Rabi splitting at room temperature and attribute the enhanced photoluminescence to parallel exciton-polariton interactions, paving the way for improved photonic device performance.

2. Results and discussion

Figure 1(a) shows the schematic of the proposed graphene–TPP photodetector. The device was constructed by stacking a glass substrate, alternating dielectric layers of the DBR, transferred graphene, and deposited TPP metal film (35 nm gold) and gold electrodes on top of each other using an E-beam evaporation machine. The graphene channel is where the strong electric field confinement caused by the TP structure is located. The SEM image of the cross-section of the dielectric layers in our DBR is shown in Figure 1(b); the thickness of all the silicon dioxide (SiO_2, refractive index n = 1.475) layers is approximately 144 nm, and that of all the titanium dioxide (TiO_2, refractive index n = 2.237) layers is about 95 nm, giving rise to the central wavelength of the DBR at 850 nm, which could be considered as an NIR-region sample.

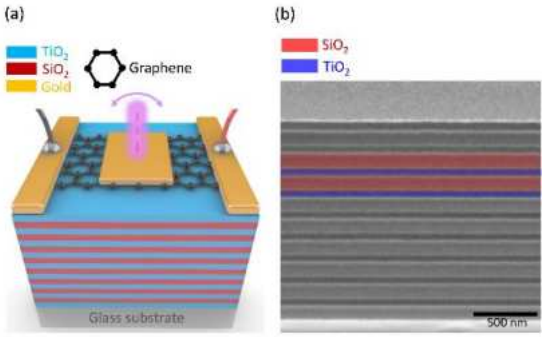

Fig. 1 (a) A schematic of the graphene Tamm plasmon polariton photodetector. (b) Scanning electron micrograph of the dielectric layers of the DBR

3. Conclusion

In summary, the contribution of this work is the simplification of the structure of the photodetector device by stacking layers to form the plasmonic structure. The results confirm that our Graphene-TPP photodetector can be universally applied to various optoelectronic materials. With the field confinement located at the metal-DBR interface, the TPP signal can be detected and converted into electrical signals.

Unlocking the technology of wafer-scale layered atomic crystal growth on dielectric substrates for electronic and photonic applications

X. Yang[1*], Y. Sakuma[2], M. Pristovsek[1], and H. Amano[1]

[1]Nagoya University, Japan

Abstract: **This study reports on wafer-scale high-quality two-dimensional atomic crystals of hBN and MoS_2 on technologically relevant dielectric substrates. Chemical vapor deposition and annealing resulted in highly ordered hBN and MoS_2 crystal layers with a quality that is comparable to or even better than the state-of-the-art.**

To bring two-dimensional (2D) atomically thin crystals such as transition metal dichalcogenides (TMDs) and hexagonal boron nitride (hBN) to practical applications, they must be produced in a highly controllable process on a large scale and with excellent homogeneity. Metalorganic chemical vapor deposition (MOCVD) has demonstrated this for conventional semiconductors (e.g., GaAs and GaN). In contrast, the scalable growth of 2D materials, including MoS_2 and hBN, using MOCVD is still in its infancy,[1,2] where the level of impurity, defect, and crystallographic misalignment in the resulting 2D crystal films is high and thus challenges practical applications.

To overcome the above issues, highly controllable routes for scalable production of high-quality 2D crystal layers of MoS_2 and hBN over larges-sized dielectric substrates were developed based on our efforts. We pioneeringly chose molybdenum oxychloride (MoO_2Cl_2) as the Mo source together with H_2S and could thus use a standard MOCVD system for MoS_2 growth. By using this carbon-free route, the scalable growth of low-defect monolayer MoS_2 free of carbon contamination was realized. Using catalytic Dragontrail glass as the substrate, we investigated the effect of MoO_2Cl_2 flux, temperature, and deposition time on the growth. The vapor pressures MoO_2Cl_2 is well compatible with the MOCVD system, enabling precise control for uniform nucleation and reasonable growth time of large-area MoS_2 monolayers. Based on the above-mentioned findings, we demonstrated the growth of carbon-free MoS_2 monolayers on glass and other technologically important substrates (e.g., SiO_2/Si). The MoS_2 monolayers were uniform over the 2” wafer with narrow intensity photoluminescence that is on par with the best data reported so far.[3,4] Based on this, working transistors with good and uniform properties over the wafer.

Another material is hBN. The challenging epitaxial growth of high-quality hBN multilayers was enabled by pulsed-mode MOCVD[5] and the quality was further enhanced by subsequent high-temperature annealing. Besides the typically used substrates like sapphire or silicon, we explored aluminum nitride (AlN), which has a very high thermal robustness. Since highly ordered hBN epitaxy on dielectric substrates requires high temperatures (1400°C and higher), AlN is a very promising substrate. Annealing over 1600°C of epitaxially-grown hBN/AlN heterostructures resulted in higher crystallinity and optical quality in hBN multilayer. Furthermore, carbon and oxygen impurities were strongly reduced by the annealing. Especially, the low residual carbon concentration allowed the observation of single-photon emission centers in hBN at room temperature. More than 82% of them emitted with their zero-phonon line at (578.5 ± 5) nm, a narrower distribution than previously reported for CVD-grown BN. These results bring high-quality homogenous hBN multilayers close to a fully

industry-compatible and scalable synthesis with the control of the separation of carbon-related single photon emission centers for next-generation quantum devices.

In summary, our work has yielded novel insights into the wafer-scale manufacturing of high-quality 2D layers, especially hBN and MoS_2, for their development for practical electronic and photonic applications.

Nano-optical imaging and spectroscopy

Dynamics and delocalized emissions of surface plasmon polaritons in one-dimensional plasmonic crystals

Izzah Machfuudzoh[1*], Sotatsu Yanagimoto[1], Naoki Yamamoto[1], Takumi Sannomiya[1]

[1]Department of Materials Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan
[*]corresponding author: machfuudzoh.i.aa@m.titech.ac.jp

Abstract: Surface plasmon polaritons (SPPs) are vital in nanophotonics, yet local optical properties of SPP-based nanostructures remain underexplored due to their sub-wavelength field localization and propagating nature. Employing cathodoluminescence techniques, we investigate their interaction with plasmonic crystals, revealing distinctive dispersion patterns, further elucidated by SPP scattering dynamics through optical spot analysis.

Surface plasmon polaritons (SPPs) are electromagnetic surface modes existing at the dielectric/metal interface, playing a key role in nanophotonic fields. However, the underexplored optical properties of plasmonic nanostructures based on SPPs, particularly in the context of spatially-resolved dispersion curves and the simultaneous revelation of nanoscale excitation and emission, have resulted in an insufficient understanding of SPP propagation and conversion to photons upon excitation. In this work, we employ combined cathodoluminescence (CL) techniques of momentum-resolved CL and emission-position-resolved CL, by means of electron-beam approach, to investigate the interaction of excited SPPs with plasmonic crystals (PlCs).

One-dimensional (1D) PlCs with a periodicity of 600 nm, patterned on an otherwise a flat 200 nm-thick silver surface, served as the sample, with a terrace width of 420 nm and height of 100 nm. Mode excitation and data acquisition were performed using CL-based scanning transmission electron microscopy (STEM-CL), operated at an accelerating voltage of 80 kV with *p*-polarization, by scanning the electron beam across the samples. Two different sample setups, namely the “flat at top” and the “flat at bottom” setups, were analyzed, with the planar surface oriented respectively closer to and farther from the light-collecting parabolic mirror as shown in Figure 1.

The distinctive optical properties of SPP were observed when the sample orientation was flipped relative to the parabolic mirror, attributed to the phase difference between the at-impact emission of transition radiation (TR) and the grating-scattered emission of SPP [1]. In the “flat at top” setup, the backward-propagating SPP dominates with a decreasing group velocity as the spatial frequency increases (Figure 1(a)). Conversely, in the “flat at bottom” setup, it is the forward-propagating SPP that travels faster as the wavenumber increases (Figure 1(b)), as depicted by the opposing slopes in the respective area-resolved dispersion curves.

Studies on the photon emission position were also performed to evaluate where in space the light is being emitted by the samples. Through the synchronization of emission imaging with electron beam scanning, different numbers of optical emission spots (i.e., either three, two, or one spot) were observed, depending on both the sample orientation and the beam excitation position, which is understood as a result of constructive or destructive interference between the outcoupled SPP and the simultaneously excited TR. Moreover, with the aid

of emission-spot-decomposed CL maps capable of extracting the emission position, it was uncovered that photons mainly emerge not where the electron beam is being irradiated but rather at more delocalized locations on the sample, indicating the occurrence of the propagating SPP mode being scattered [2]. Additionally, the shift of the emission spots with respect to the beam excitation position shows a non-linear trend, in which the spot positions tend to be held stronger at the antinode positions of the surface charge distribution on the sample.

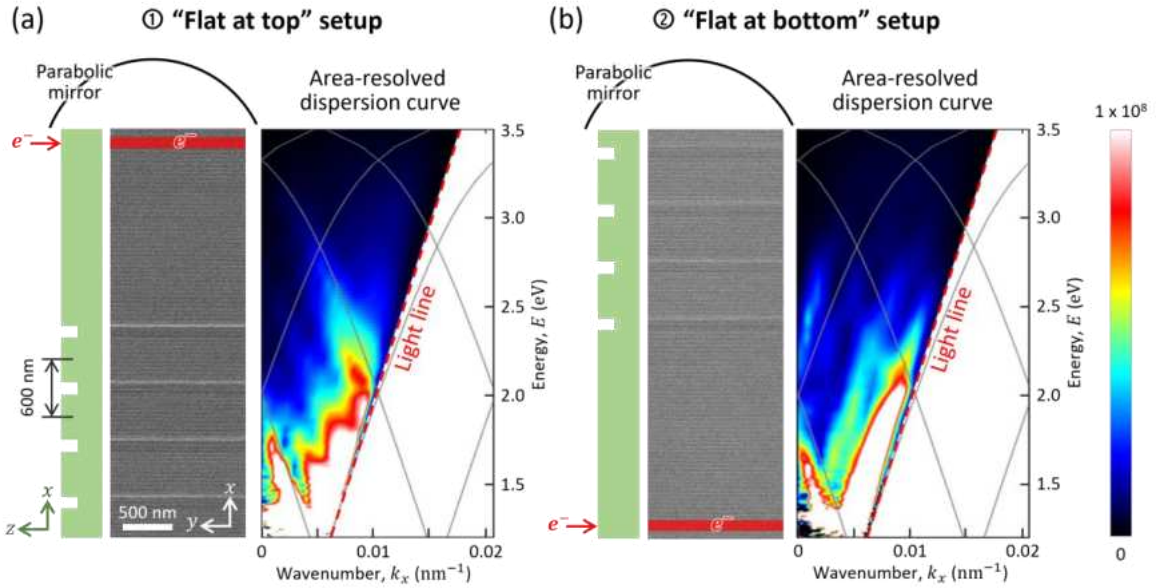

Figure 1. Illustrated *x*-*z* side view and STEM image *x*-*y* top view of a 1D silver plasmonic crystals with a 600 nm periodicity (left panel) for (a) "flat at top" setup and (b) "flat at bottom" setup, with the measured area-resolved dispersion curves integrated over an area indicated by a red arrow or rectangle shown on the sample (right panel). The solid gray curves represent the calculated SPP dispersion curves, and the dashed red line depicts the light line. The *x*-*y*-*z* coordinates, scale bar, and color bar apply to both sample setups.

In conclusion, our studies unravel how the SPPs interact with the 1D-PlCs through their propagation behavior and interference with the transition radiation, using nanoscale resolution of field mapping and optical spot analyses. These findings provide valuable insights into comprehensive details on the SPP modes, with implications for optical devices such as plasmonic sensing and antennas, and photonic integrated circuits. Optical spin sorting in a plasmonic crystal waveguide

K. Kihara[1], M. Ikeuchi[2], I. Machfuudzoh[3], T. Sannomiya[3] and H. Saito[2,3,*]

Abstract: We designed a unique plasmonic crystal waveguide composed of metallic nanodisk arrays on a metal film (MIM structure) that can convert circularly polarized light into a unidirectionally guided plasmon mode. The plasmon propagation direction can be switched depending on the orientation of circular polarization.

Spin-momentum locking is an indispensable technique for quantum information communication, where photons with opposite spins emitted from a quantum emitter must be guided to different destinations [1]. Plasmonic waveguides can compress electromagnetic fields to a small size far beyond the diffraction limit of light, drastically enhancing light-matter interactions and realizing high-speed and energy-saving active devices [2]. However, spin-momentum locking has rarely been achieved in plasmonic waveguides. To accomplish this task, we have proposed a use of plasmonic crystals (PlCs) [3], i.e., waveguiding based on band engineering. We demonstrated a valley PlC waveguide that can support topologically protected edge states [4], offering a feasible strategy for spin-momentum-locked plasmonic waveguides. The next step is to achieve optical spin sorting by attaching optical antennas to such a PlC-based waveguide, where external circularly polarized light is guided to different destinations depending on the orientation of circular polarization.

We designed a PlC with a MIM structure [5] as shown in Fig. 1(a) by using finite-difference time-domain (FDTD) simulation. In this PlC, aluminum (Al) nanodisks with a diameter of 160 nm and a height of 70 nm are arranged in a triangular lattice with a period of 380 nm. This nanodisk array is placed on 30-nm-thick SiO_2/silver (Ag) substrate. The Al nanodisks not only works as scatterers for surface plasmon polaritons (SPPs) propagating on the Ag substrate, but also supports localized surface plasmon (LSP) modes since they are isolated by the SiO_2 spacer. By utilizing the LSP modes as optical antenna effects, external light can be coupled to lattice modes or waveguide modes formed in the PlC. Figure 1(b) shows the calculated band dispersions of the designed PlC, indicating the full band gap formation from 1.5 eV to 1.9 eV. Waveguide modes are expected to appear in this energy range by introducing modified structures such as defects.

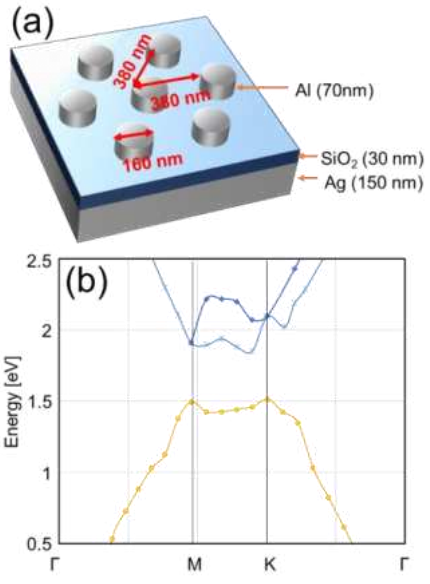

Figure 1 (a) Schematic of the designed PlC. (b) Calculated band dispersions of the PlC.

Based on the above PlC structure, we further designed a waveguide structure by introducing a flat region with a width of 780 nm, which is sandwiched by two PlCs (Fig. 2(a)). Nanodisks facing the waveguide are arranged in a zigzag manner [1] to prevent Bragg reflections in the

propagation direction (horizontal direction in Fig. 2). Figure 2(b) shows a simulation of the guided SPPs. A rotating in-plane electric dipole with the left-handed (down) spin was used to excite SPPs, which was placed at the center of one of the Al nanodisks facing the waveguide and at mid-height of the SiO_2 layer (labeled "excitation source" in Fig. 2(b)). The result shows that the excited SPPs are guided to the right side with greater intensity. Due to the symmetry of the structure, when the spin orientation of the excitation source is flipped, the propagation direction of SPPs is reversed. Figure 2(c) shows a phase map near the Al nanodisks. The black circles indicate the locations of the Al nanodisks. The result indicates that this guided SPPs generate orbital angular momentum around the Al nanodisks. This is consistent with the fact that unidirectional guided SPPs were excited by the rotating in-plane electric dipole placed at the center of the Al nanodisk. Accordingly, the designed structure can function as an optical spin sorter by modifying the structure so that the resonance energy of the in-plane dipole LSP mode of Al nanodisks facing the waveguide is matched with the waveguide mode.

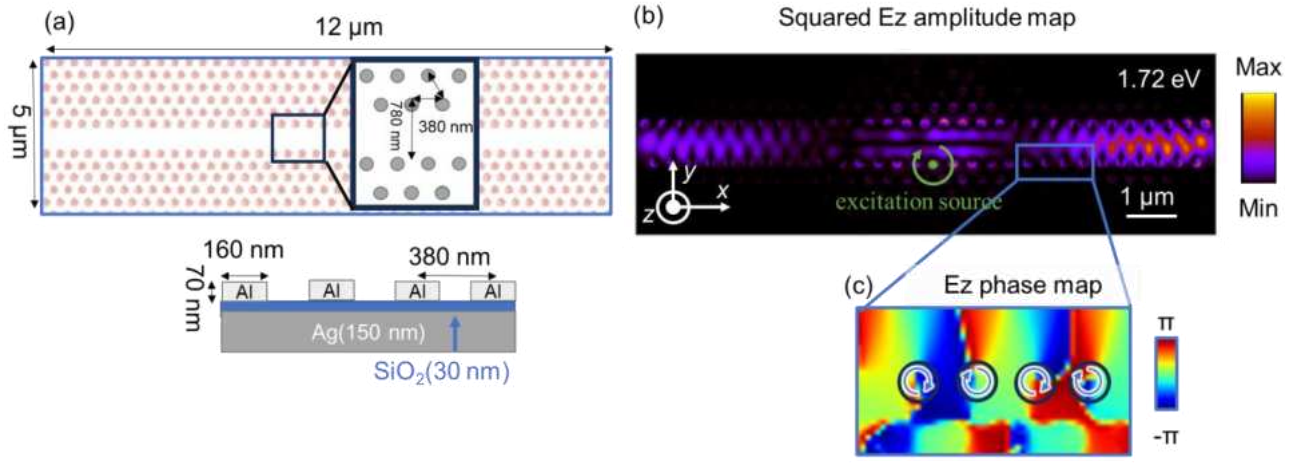

Figure 2 (a) Schematic of the designed waveguide. (b) Squared electric field amplitude in the *z* direction (*Ez*). The excitation energy was 1.72 eV. (c) Phase map of the *Ez* component in the part of calculation space indicated.

Abstract: We measured the lifetimes of nanodiamond particles with nitrogen-vacancy centers using cathodoluminescence microscopy combined with Hanbury Brown-Twiss interferometry. The experimental results showed the lifetime distribution due to the size effect of the particles. The lifetime can be further modified by coupling with surface plasmons.

Nitrogen-vacancy (NV) emission centers in nanodiamond (ND) particles exhibit highly stable optical properties even at room temperature, making them promising candidates as quantum emitters (QEs) for quantum communications and optical computing [1]. The transition probability from the excited state is one of the speed-limiting factors for the information processing using QEs. When the electromagnetic local density of states (EMLDOS) surrounding the QE is enhanced, the transition probability increases, known as the Purcell effect [2]. However, since the lifetime of the NV center may be sensitively influenced by the dielectric environment of the ND particle itself, it is essential to investigate the lifetime distribution of bare ND particles before evaluating the Purcell effect by coupling with other enhancing structures. To measure the lifetime of individual ND particle to obtain the distribution, an optical lifetime measurement technique with spatial resolution beyond the diffraction limit of light is required. Cathodoluminescence (CL) microscopy, utilizing an electron beam of a scanning transmission electron microscope (STEM), is a powerful approach for accessing nanoscale optical information, which also allows lifetime measurements by combining with Hanbury Brown–Twiss (HBT) interferometry [3]. The HBT measurement of light provides a second-order time correlation function defined by

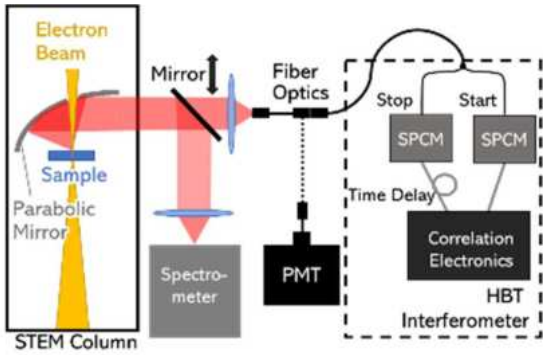

Fig 1. Schematic illustration of the CL-STEM and optical setup for the HBT measurement. A parabolic mirror collimates the emitted light to optical system.

$$g^{(2)}(\tau) = \frac{\langle I(t)I(t+\tau)\rangle}{\langle I(t)\rangle\langle I(t+\tau)\rangle}, \quad (1)$$

where $I(t)$ is the light intensity as a function of time t and τ denotes the time delay. In the case of CL, it is known that the value of $g^{(2)}(0)$ typically exceeds one [4], which is called photon bunching. The lifetime of photon emitters can be obtained by fitting the bunching curve.

In this work, we measured the lifetime of NV centers in ND particles on a SiO_2 self-standing membrane using STEM-based CL-HBT. The experimental setup is illustrated in Fig 1. The light emitted from the sample was guided out of the STEM column by a parabolic mirror and transferred either to a spectrometer for CL spectrum measurement, to a photomultiplier tube (PMT) for panchromatic CL mapping, or to the HBT measurement system. We performed the measurement at room temperature at an accelerating voltage of 80 kV and a beam current of

between 17 and 60 pA. The ND particles used in the experiment have an average diameter of 100 nm and a distribution of 70 to 125 nm . Figure 2(a) illustrates the $g^{(2)}(\tau)$ curves obtained from HBT measurements for three different ND particles. Each particle shows a $g^{(2)}(\tau)$ curve with bunching features with ~ 15 ns lifetime. We statistically evaluated the lifetime of ND particles by performing the HBT measurement of 53 ND particles, as shown by the histogram in Fig 2(b). To evaluate the particle size effect on such lifetime distributions, we performed electromagnetic field simulations with the finite element method (FEM). Figure 2(c) shows plots of the ratio of lifetimes normalized by a diameter of 100 nm, calculated from the simulations with the particle diameter varied from 70 to 130 nm. The simulation demonstrates that the Purcell factor can vary with the particle size. In the experiment, additional effects related to the shape of the particle and the location of the dipole would be included. Due to these combined effects, even bare NDs have a wide lifetime distribution [5]. We also demonstrate that this lifetime distribution shifts to smaller values by coupling with surface plasmons.

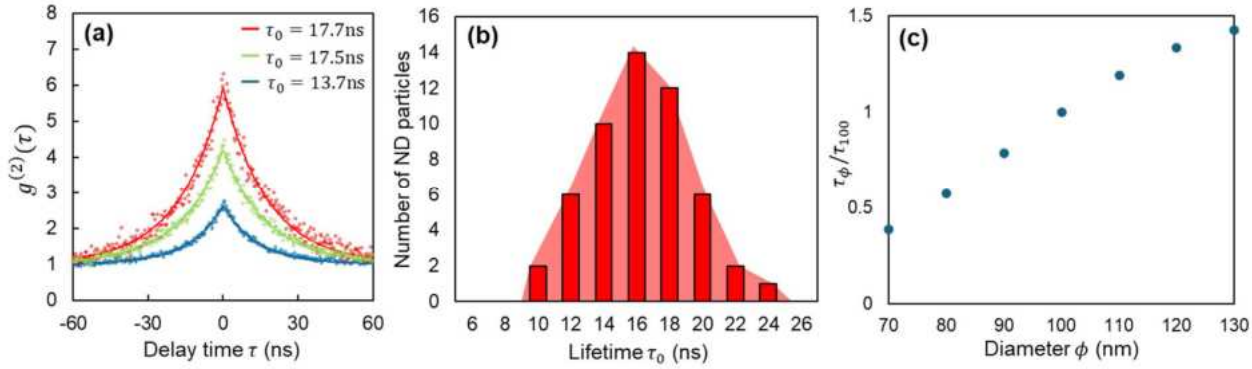

Fig.2. (a) $g^{(2)}(\tau)$ curves obtained from three different ND particles. Scattered plots are experimental data, and solid line are fitted line with exponential function. (b) Histograms of the lifetime obtained from 53 ND particles. (c) Size dependence of the lifetime with the ND particle diameter.

Abstract: Using our developed theoretical framework for photo-induced force microscopy (PiFM), we successfully visualized single molecule images of phthalocyanine molecules. The obtained PiFM images reflected the characteristics of Zinc and H_2 phthalocyanines. This not only affirms the capability of our theoretical framework but also contributes to the advancement of material science.

Photo-induced force microscopy (PiFM), a technique that detects the optical force between the probe tip and the sample in scanning probe microscopy environments like atomic force microscopy, enables the spectroscopic imaging of samples with high resolution. Typically, the performance of optical microscopy is restricted by the diffraction limit of light. However, in systems employing a probe tip, the enhanced and localized electric field at the probe tip contributes to achieving the high resolution. For example, in an experiment using dumbbell-shaped quantum dots, the surface roughness was visualized with a resolution of 0.7 nm [1]. Moreover, our group has developed a theoretical framework to evaluate the PiFM of single molecules based on the nonlocal response theory. We have successfully visualized PiFM images that depend on the molecular orbitals and the transition dipole moment of target molecules [2]. Nevertheless, despite its potential, theoretical research on PiFM under various conditions has not been sufficiently explored. Therefore, in this study, selecting the phthalocyanine as our subject, we aim to discuss the variation of PiFM image based on the differences among molecular types, and seek to contribute to the theoretical understanding of PiFM.

Figure 1 shows the simulation model, where the phthalocyanine molecule is located between the metal substrate and probe. The probe consists of two hemispheres: a smaller one (diameter approx. 0.8 nm) was attached to the bottom of a larger one (diameter 10 nm), assuming the presence of small apex. As shown in Figure 2(a) and 2(b), we employed Zinc phthalocyanine (ZnPc) and H_2-phthalocyanine (H_2Pc) as target molecules. In the energy level diagrams, S_0 represents their highest occupied molecular orbital (HOMO) and S_1 represents lowest unoccupied molecular orbital (LUMO), with LUMO+1 also indicated by S_2. The molecular orbitals and eigen energies were calculated using GAMESS, a quantum chemical calculation software [3]. To evaluate the optical force exerted on the probe under plane wave illumination, we employed the discrete dipole approximation method. In this approach, both metal structure and the molecule were discretized into cubic cell. The response electric field and induced polarization in each cell were self-consistently determined. Figure 1(b) shows the response field in the case without the molecule. The

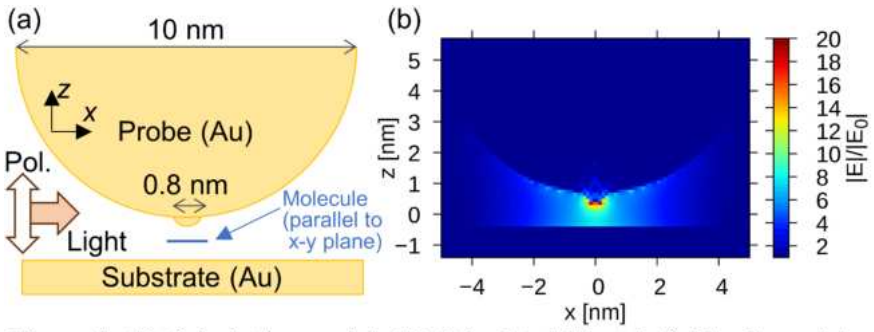

Figure 1. (b) Calculation model. (b) Calculated Electric field enhanced by the metal probe and substrate (incident light energy $\hbar\omega$ = 2.18508 eV).

molecule susceptibility was modeled as nonlocal. We assumed an incident light intensity of 10 kW/cm^2. Further detail of the method was discussed in the referenced literature [2].

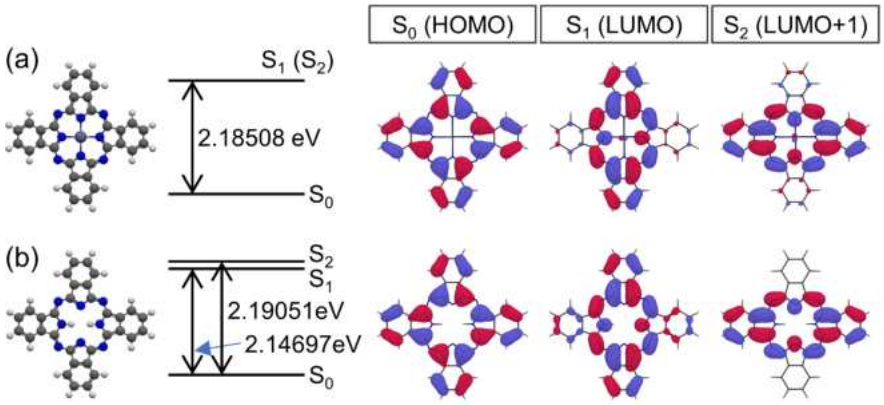

Figure 2. Molecular structure, energy level diagram, and molecular orbitals for (a) ZnPc and (b) H_2Pc. S_1 and S_2 of ZnPc is degenerate. The contour of molecular orbitals indicates the value of ± 0.05.

Figure 3 shows the calculation results of PiFM image. To simulate the scanning of probe, the molecule was displaced in x-y plane relatively. The incident light energy was varied to be resonant for each transition. In the case of H_2Pc, the PiFM image corresponding to transitions from S_0 to S_1 and from S_0 to S_2 were visualized in Figure 3(b) and 3(c), respectively. This agrees with the results we reported previously [2]. Conversely, Figure 3(a) shows that, due to degeneracy, the distribution in PiFM image reflects both transitions. A similar distribution was reported in other scanning probe microscopy technique using light, such as tip-enhanced photoluminescence [4,5].

The obtained result indicates the validity of our theoretical framework in visualizing single molecules with optical forces that are dependent on the unique characteristics of each molecule. It paves the way for future research that bridges theoretical insights with practical applications and contributes to the development of material science.

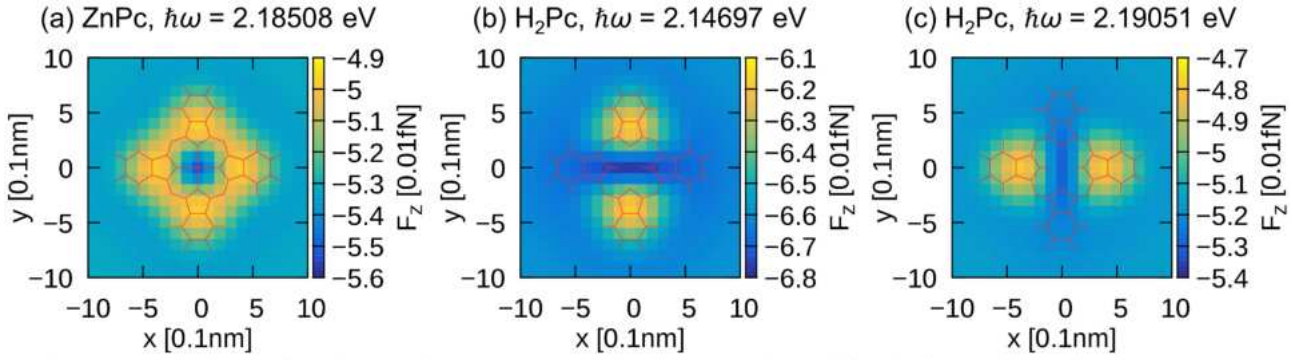

Figure 3. Calculated PiFM image for (a) ZnPc and (b)(c) H_2Pc. The red line indicates the molecular structure.

Abstract: We show how electron beams can be used to study nanooptical excitations of van der Waals materials and group III nitride heterostructures. In addition, we present methods for coherently controlling the shape of free-electron wavepackets using nanooptical excitations.

Recently, electron-beam spectroscopy techniques have become powerful probes in nanoscience, revealing detailed views of biological, chemical, and semiconductor structures with atomic-scale resolution. Moreover, this method enables the study of quantum phenomena at the nanoscale for inspecting quantum-optical excitation with spatially-resolved cathodoluminescence (CL) spectroscopy [1]. CL holds great potential for probing optoelectronic properties of nanoscale materials by collecting and analyzing the electron-beam-induced radiation inside an electron microscope. Here, we focus on the functionality of CL spectroscopy in investigating the strong interaction between excitons and photons in transition metal dichalcogenides, which gives rise to propagating exciton polaritons through the self-hybridization effect in WSe_2 thin films [2,3]. Moreover, we utilize CL spectroscopy to investigate the optical properties of undoped AlGaN/GaN heterostructures [4]. By tuning the energy and current of the incident electron beam (Fig. 1), we explore the emission from defects in GaN, as well as quantized energy levels trapped at the AlGaN/GaN interface. Indeed, the correlation between the initial electron energy and electron diffusion length in the channel formed at the interface, along with the percentage of the secondary electrons captured at the heterojunction (Fig. 1), allows for controlling the spectral luminescent peaks.

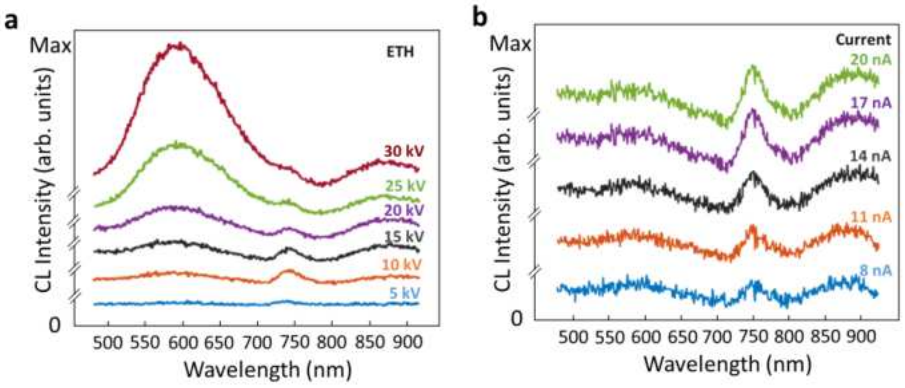

Fig. 1. Room temperature CL spectra of a heterostructure. (a) CL spectrum obtained at depicted electron beam acceleration voltages with a beam current of 12 nA. (b) Acquired CL spectrum corresponding to the 10 kV acceleration voltage at different depicted beam currents.

Recently, merging laser and electron beam spectroscopies into a single setup [5] ushered in a new era for

nanooptics within the realm of electron-beam science. This new domain revolutionized quantum-mechanical electron-light interactions to enter femtosecond and picosecond time resolutions, enabling shaping the electron wavepackets with near-field oscillations. Here, we developed a self-consistent Maxwell-Schrödinger numerical toolbox to evaluate the interaction between slow electron wavepackets and laser-induced gold nanorods [6]. Our numerical studies show that the direction and the spatial profile [7] of the dipolar near-field (Fig. 2), as well as the phase offset in a sequential-interaction system [8], can be used to control the phase and amplitude of the slow electron wavepackets. When the free electron experiences both inelastic longitudinal energy transfer as well as elastic transverse recoil (momentum exchange). These findings demonstrate that one can chart a roadmap for realizing the next generation of ultrafast electron microscopes, enriching the interaction of shaped electron wavepackets with light and matter.

Abstract: Cathodoluminescence saturation imaging is proposed as a new approach to discriminate coherent and incoherent emissions in phosphor-resonator systems. This method was applied to an integrated system of a Zn_2SiO_4 phosphor film and a plasmonic resonator array, successfully visualized plasmon-enhanced luminescence at the nanoscale.

Plasmonic resonators have realized remarkable Purcell effect for extremely small emitters as well as quantum emitters due to the small mode volume. Cathodoluminescence (CL) is a powerful imaging technique to visualize emitters with a high spatial resolution far beyond the diffraction limit. However, electron beam excitation lacks wavelength selectivity, and thus, an electron beam inevitably excites not only the emitter but also the coherent electromagnetic modes. This problem has made it difficult for CL analysis to quantify luminescence enhancement in the integrated emitter-resonator systems. Recent time-resolved or time correlation CL measurements can be reliable approaches to evaluate Purcell effect at the nanoscale [1,2]. However, especially for long-lifetime emitters such as rare-earth or transition metal dopants, time domain measurements can not be practical due to huge amount of accumulation time for real space mapping of lifetimes. There is an example in which plasmon-enhanced luminescence from an atomically thin semiconductor has been visualized by time-integrated CL [3], where the enhancement can be evaluated based on the reference CL obtained from each of the used resonator array and the luminescent material. However, general phosphor materials having an unignorable volume modifies the dielectric environment and the electromagnetic modes. Here, to directly discriminate incoherent emissions from coherent emissions in integrated phosphor-resonator systems, a simple new method utilizing CL saturation is proposed.

A phosphor-resonator structure including a 20-nm-thick Zn_2SiO_4 film was fabricated (Fig. 1a). A SiO_2 (20 nm thick) / ZnO (9.4 nm thick) bilayer film was first deposited on a commercially available Si_3N_4 film (20 nm thick) by RF magnetron sputtering. Then, by annealing this multilayer film for 1 hour at 1273 K, a Zn_2SiO_4 phosphor layer was produced at the SiO_2/ZnO interface. After covering the Zn_2SiO_4 phosphor film with a 6-nm-thick SiO_2 film, an Al nanodisk array with a triangular lattice of a 520 nm period was fabricated on top of the $SiO_2/Zn_2SiO_4/Si_3N_4$ multilayer film by electron beam lithography and thermal evaporation. The nanodisk diameter and height are 190 nm and 40 nm, respectively. From the backside of the multilayer film, a 50-nm-thick Al film was finally deposited by thermal evaporation. To study luminescence enhancement in this sample at the nanoscale, four-dimensional (4D) scanning transmission electron microscopy (STEM)-CL mapping [4] was conducted. A CL peak was observed at the wavelength of 525 nm, and its intensity depended on sweep speed of the electron probe. This 525 nm peak is due to incoherent emissions from the Zn_2SiO_4 layer

because the intensity decreases as the probe sweep becomes slower, i.e., the number of electrons per pulse increases. This CL saturation is peculiar to incoherent emissions, and thus, can be utilized to discriminate them from coherent emissions linearly depending on the sweep speed or probe current.

In the phosphor-resonator structure in which plasmonic modes have the resonance wavelength of 525 nm, three paths can be considered as the CL mechanism (Fig. 1b). Zn_2SiO_4 has a wide bandgap of ~5 eV [5], and the observed green emission suggests existence of impurity or defect levels in the bandgap of the fabricated Zn_2SiO_4 film. This radiative electron transition is path 1. The electron transition inside the Zn_2SiO_4 can partially be coupled with the plasmon modes. This resonator-mediated emission is path 2. However, lack of the wavelength selectivity in the electron beam excitation brings about the third path in CL, i.e., direct excitation of the plasmon modes (path 3). To solve the above difficulty, 4D STEM-CL mappings were performed with two different probe current 1.5 nA and 16 pA on the identical field of view. Under both the two conditions, incoherent emissions (path 1 and path 2) and coherent emissions (path 3) were contained in the data. However, at the wavelength of 525 nm, incoherent emissions from Zn_2SiO_4 (path 1 or path 2) became relatively dominant under the low current condition (16 pA) due to less CL saturation. Incoherent emission maps without the path 3 contributions were extracted by taking differences between the two current conditions. The observed luminescence enhancement distributions were similar to the field distributions of the plasmon modes, indicating the existence of near-field coupling between the luminescence centers and the plasmon modes in the used phosphor-resonator system.

Optical chiral fields and plasmon modes in gold nanostructures studied by apertured near-field spectroscopic imaging

K. Imura[1*]

Abstract: We have developed various types of near-field imaging methods to elucidate optical properties of nanomaterials. Plasmonic materials have gained much attention due to the enhancement of plasmonic and chiral fields. To gain deep insights into the localized fields, various near-field imaging methods are applied to plasmonic nanostructures.

Near-field imaging methods overcome the diffraction limit of light and achieve a nanometer spatial resolution. Scattering and apertured near-field methods developed have been utilized to examine optical properties of nanomaterials. We are developing various types of apertured near-field imaging methods to elucidate optical properties of nanomaterials from various spectroscopic points of views.[1-4] For instance, near-field nonlinear imaging is of great use for visualization of enhanced optical fields, and time-resolved imaging is for revealing spatio-temporal dynamics of elementary excitations.[2] Plasmonic materials with subwavelength dimensions have gained much attention due to the enhancement of optical and chiral fields. To reveal physical origins of the chiral fields based on the plasmon mode, near-field spectroscopic imaging is essential. In this study, various near-field imaging methods are utilized to gain deep insights into the chiral near-fields induced in the plasmonic structures.

We have performed near-field transmission and reflection imaging of single gold nanoplates.[1,2] We reveal from the near-field imaging that periodic spatial features are visualized depending on the observed wavelengths and are assignable to plasmon mode excited. The spatial features are well reproduced by eigen functions calculated for a particle confined in a two-dimensional potential well. The eigen modes are classified using the point group analysis, and by using a Lippmann-Schwinger equation, the optical selection rule can be understood.[1,3] For instance, gold nanoplate on a substrate is illuminated from a normal incidence (along z direction), plasmon mode assigned to E and A_1 modes are interpreted as the allowed (bright) and forbidden (dark) modes, respectively, as shown in Figure 1. Near-field transmission imaging indicates that the near-field local illumination enables to excite the optically dark mode.

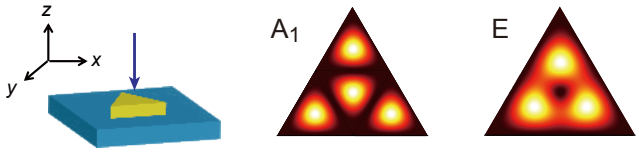

Figure 1. Schematic image of the illumination configuration and calculated eigen modes for a gold nanoplate.

Spectral bandwidth of the plasmon resonance provides the dephasing time of the plasmon. However, as two bands are spectrally overlapped, determination of the dephasing time becomes challenging. To reveal dephasing time of the plasmon mode, we performed near-field time resolved imaging of the gold nanoplate.[1] The near-field excitation image of the plate shows unique spatial features assignable to superposition of the dark and bright plasmon modes. Time-resolved autocorrelation trace taken at the apex of the plate shows indicates that the

plasmon dephasing time is an order of fs time scale. We visualized spatial distribution of the dephasing time on the plate and reveal that the dark mode exhibits longer dephasing time than the bright mode.

Three dimensional near-field imaging is also capable to reveal light confinement capability of the plasmons.[4,5] By regulating a distance between the near-field aperture-tip and sample surface, physical properties of plasmon are examined. Near-field images taken at normal operation indicates that two modes are overlapped in both spatial and spectral manners, while by regulating the distance, two-modes are spatially discriminated. Spatial extensions of the modes are examined and found that the dark mode exhibits tight light confinement compared to that of the bright mode, consistent with the result obtained in the time-resolved near-field imaging.

The dark mode discussed so far is radially polarized mode and/or out-of-plane mode. To examine the excitation probability of these two-modes, we carried out nonlinear confocal microscopy of the plate using the focused cylindrical vector beams.[6] Observed excitation image show unique spatial distributions depending on the excitation fields. Electromagnetic field simulation well reproduces the observed images and indicates that the observations are consistent with the excitation of the dark mode. From a detailed analysis of the electromagnetic simulations, we found that the out-of-plane mode is dominantly excited.

We have examined optical chiral fields in the vicinity of gold nanoplate by using three-dimensional near-field polarization imaging. Near-field transmission images taken by detecting right and left circular polarization components show very similar spatial features with the one observed by conventional transmission imaging. By subtracting the left circular polarization component from the right one in the transmission images, S_3 Stokes parameter is obtained. Optical chiral density is closely related to the S_3 parameter, and thus in this way, chiral near-field can be visualized. Spatial feature of the observed image (Figure 2) is not identical with that of the one visualized by conventional method. Electromagnetic field simulations reproduce the spatial distributions under various incident polarizations, indicating that the visualized spatial distribution is assignable to the chiral near-field. We examine spatial extension of the optical chiral field and reveal that the chiral field is more strongly localized than that of the optical field. We will discuss the plasmon mode dependency of the chiral fields and physical origins of the spatial and steric properties of the optical chiral field in the conference.

Abstract:

This contribution investigates the possibilities presented by the latest advancements in STEM techniques, specifically focusing on electron-photon time-correlations. Utilizing techniques such as CLE and EEGS, the objective is to gain deeper insights into the optical characteristics of model systems like TMD 2D semiconductors at the nanometer scale.

The optical properties of luminescent materials are intricately tied to their structural and chemical characteristics at the nanometric, or even atomic scale. Understanding this relationship has long relied on the combination of scanning transmission electron microscopy (STEM) with external optical techniques such as absorption or photoluminescence spectroscopies, probing the excitation and emission mechanisms at the micrometric scale. However, the significant gap in spatial resolution between these methods and phenomena of interest often leads to ambiguous or even impossible interpretations of the measurements.

Recent advancements in nano-optics seek to address this resolution disparity by enabling observation of luminescent material properties at nanometric scales. In that sense, STEM has undergone substantial instrumental and theoretical progress, providing valuable insights into optical properties through conventional inelastic electron scattering (electron energy loss spectroscopy, EELS) and photon emission (cathodoluminescence, CL) spectroscopies [1]. However, both techniques are hindered by spectral resolution limitations and the broadband excitation process of the electron beam. To overcome these challenges, two techniques currently in development will be highlighted in this contribution:

- **Cathodoluminescence Excitation Spectroscopy (CLE, Figure 1b)**, based on coincidence measurements between EELS and CL events. CLE offers insights into energy transfer pathways and excitation lifetimes at the nanometer scale, as previously reported [2,3].
- **Electron Energy Gain Spectroscopy (EEGS, Figure 1c)**, an extension of the photon-induced near-field electron microscopy (PINEM) technique, investigates primary electron acceleration when the beam interacts with a strong optical field generated by a laser. By changing the energy of the photons, this technique can resolve ultra-fine optical resonances in the sub-meV range, revealing novel physical properties below the energy resolution achievable with state-of-the-art monochromated electron beams. So far, it has only been applied to photonic excitations, such as plasmons or surface polaritons [4].

These techniques, with their distinct excitation and deexcitation processes (**Figure 1a**), are expected to be highly complementary, offering deeper insights into optical mechanisms at the nanometer scale. The present contribution focuses on using transition metal dichalcogenides (TMDs) as a model system of functional luminescent material to explore the insights provided by these correlated techniques.

Femtosecond time-resolved microscopy for spatio-temporal characterization of structured surface plasmon polariton wave packets

Atsushi Kubo[1*]

[1]Faculty of Pure and Applied Sciences, University of Tsukuba,1-1-1 Tennodai, Tsukuba-shi, Ibaraki 305-8571, Japan

Abstract: Recent studies of structured light (SL) have generated various optical fields with internal structures of energy flow density and angular momentum. The surface-wave correspondence of SL, structured surface plasmon polaritons (SPPs), can also be formed. We investigate the generation and visualization of structured SPPs using femtosecond time-resolved microscopy methods.

Recent progress in the study of structured light has advanced the generation and evaluation techniques for various types of light beams with complex structures of energy flow density and angular momentum (AM) states in the beam cross-section, such as optical vortices, non-diffraction beams, and skyrmion beams [1]. When pulsed light is used as a source, a so-called "light bullet" is realized in which the optical field is confined in three dimensions. Recent studies have shown that the group velocity of an optical wave packet (WP) is not simply determined by the space or material dispersion relation, but rather is a quantity that can be manipulated by applying a designed wavenumber vector to each frequency component of the wave packet [2,3]. Control of both the temporal and spatial frequencies of the optical field is the key to uncovering novel phenomena in the space-temporal regime of the WP. Surface plasmon polaritons (SPPs) are another type of structured light with strong confinement of the field perpendicular to the interface. Recent studies have realized the generation of various "structured plasmons", such as SPP vortices [4], plasmonic spin skyrmions/ melons [5,6], and non-diffractive SPP beams [7]. In these studies, time-resolved microscopy has played a critical role in observing the dynamical behavior of the SPP field in space and time. When pulsed light is used as an excitation source, three-dimensional confinement of the SPP field is realized. Such SPP WPs propagate with a three- dimensional spin angular momentum (SAM) texture associated with the localized field energy density [8,9]. Therefore, they are expected to serve as carriers of electron spin information in novel devices.

In this paper, we describe the imaging of SPP wave packets using femtosecond time-resolved two-photon fluorescence microscopy (TR-2PFM) [10].

The first is the imaging of the deformation of a femtosecond SPP WP during transmission through a metal-insulator-metal nanocavity (MIM-NC) (Fig. 1) [11]. The SPP WP is launched by irradiating a laser pulse with a center wavelength of 810 nm and a time duration of 10 fs onto the surface of deposited Au film with a linear coupler. After propagating on the Au surface, the SPP WP passes through

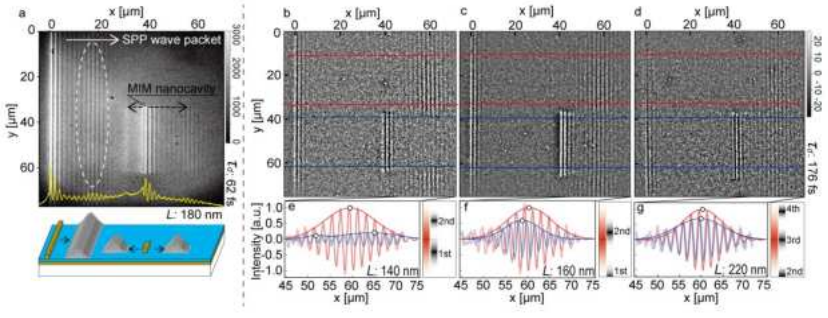

Fig.1: (a) Schematic of the TR-2PFM of a SPP WP interacting with a MIM -NC on Au surface. (b-c) Micrographs of SPP WPs after transmission through a MIM-NC with the width *L* of (b) 140 nm, (c) 160 nm and (d) 220 nm. (e-f) Profiles of (b-c). [11]

the MIM-NC with a structure width of L (50 ~ 220 nm). During this process, the SPP field is visualized by detecting two-photon fluorescence emission from a very thin fluorescent film coated on the Au surface using an optical microscope and a CCD camera. The micrographs revealed that the transmittance, shape, and peak position of the SPP WP are significantly modulated in dependence on L. The results are interpreted in terms of up-chirping in the propagation path of the SPP WP and resonant transmission in the eigenmode band of the MIM-NC. In the case of L=160 nm, a backward shift of ~2 μm in the peak position of the SPP WP transmitted through the MIM-NC was observed compared to a WP without interaction with the NC. For this MIM-NC, the second-order eigenmode overlaps with the high-energy side of the SPP spectrum. The backward shift is caused by the selective transmission of the tail part of the up-chirped WP through the MIM-NC. This result constitutes a visualization of a spatio-temporal correlation of the SPP WP.

The second is a generation and observation of a space-time SPP (ST-SPP) WP [12]. Femtosecond laser pulses are formed into optical ST-WPs using a 4f system and irradiated onto an Au surface with a linear coupler to generate non-diffractive ST-SPP WPs (Fig.2). To form striped ST-SPP, fs pulses are spectrally resolved by a grating, then all frequency components are given constant transverse momentum using a two-dimensional spatial light modulator. The spatial distribution of the SPP field was again visualized by the two-photon fluorescence from the fluorescent film applied on the sample surface. In Fig. 2, many SPP stripes with a period of about 5 μm are generated. The intensity contrast between adjacent stripes remains high after the propagation of the SPP wave, indicating that non-diffractive properties are realized.

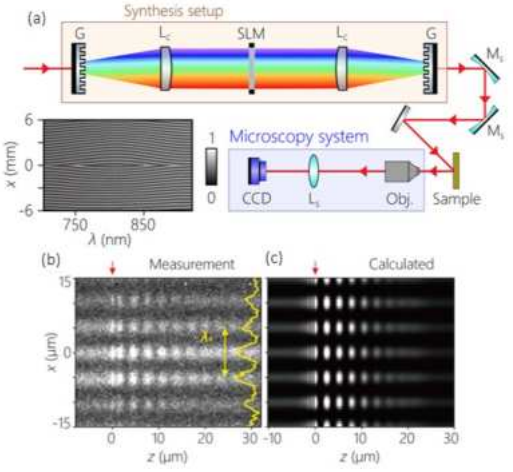

Fig.2: (a) Schematic of an experimental setup for synthesis of ST-WPs and 2PFM imaging of ST-SPP WPs. (b) Micrograph of the striped ST-SPP. (c) Simulated image of (b). [12]

Photon-STM study of exciton creation and annihilation processes in a single molecule

M. Imai-Imada[1,2*]

[1]SISL RIKEN, Japan
[2]JST PRESTO, Japan
[*]corresponding author: miyabi@riken.jp

Abstract: we report atomic-scale investigation of the electron dynamic processes that drive exciton creation and annihilation, including luminescence and photocurrent generation, in a single molecule.

The creation and annihilation of an exciton induced by electron dynamics, such as transition in a molecule or transfer between a molecule and an electrode, play crucial roles in optoelectronic energy conversion. However, the correlation between the exciton and electron dynamics in a molecule is yet to be thoroughly described, mainly because the spatial resolution of conventional techniques is not enough to resolve individual molecules. Recently, we have developed Photon-STM (Fig. 1**a**) by combining low-temperature scanning tunneling microscope with laser irradiation and photo-detection systems, and realized to investigate the exciton dynamics, such as luminescence and photocurrent generation in a single molecule [1-3].

In this study, we report Photon-STM study of photocurrent generation in a single-molecule free-base phthalocyanine (FBPc) molecule at atomic resolution. The experimental setup was carefully designed to optimize the efficiency of molecular excitation; as a result, the excitation laser energy can be tuned to the single-molecule absorption resonance with μeV precision. Moreover, the laser light field is strongly enhanced in the plasmonic nanogap between a gold tip and a silver substrate[5,6]. Figure 1**b** shows an STM image of our sample, in which an FBPc molecule is adsorbed on a 4-monolayer (ML) NaCl(100) film grown on the Ag(111) substrate. The NaCl film was used to decouple the molecule from the metal substrate[7] in order to preserve its intrinsic optical properties.

To measure the photocurrent, the STM tip was placed on a molecule while the STM feedback loop was opened, and the STM junction was then irradiated with a wavelength of 683 nm, corresponding to the molecular resonance. After adjusting the sample voltage V_s to −2.0 V, which made the dark current flowing through the molecule negligible, the tunnelling current I_t trace was measured on the molecule

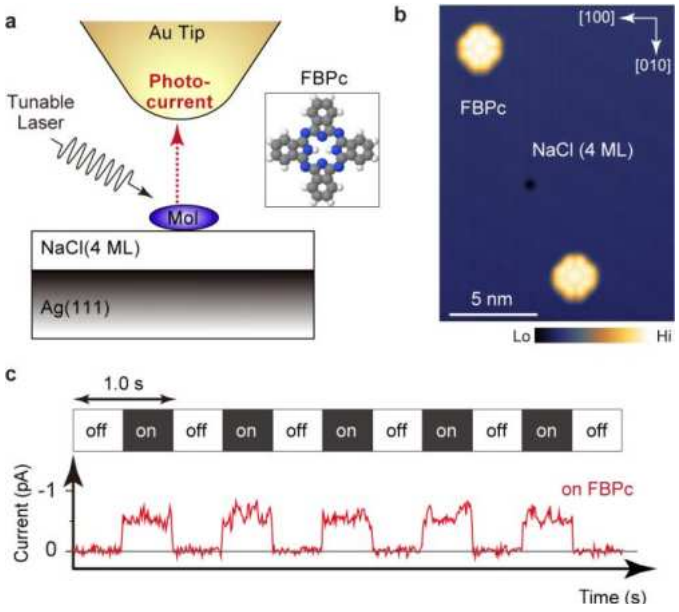

Figure 1 a, A schematic illustration of the experiment and the structure of free-base phthalocyanine (FBPc, grey, C; blue, N; white, H, D).
b, An STM image of the sample (sample bias voltage V_s = 1.0 V, tunnel current I_t = 5 pA).

while turning the laser irradiation on and off at 1 Hz using a shutter (Fig. 1**c**). The I_t flows in the laser-on state and is zero in the laser-off state. This irradiation-induced I_t switching was not detectable at the initial tip-molecule separation (where I_t = 3 pA flows at V_s = −2.5 V on the molecule with closed STM feedback loop under laser-off condition) but became so as the tip is approached the molecule by ~0.2 nm. The laser energy (hν) dependence revealed that the irradiation-induced I_t can be detected only when the laser energy is at 1816 meV corresponding to the molecular excitation energy from the ground state (S_0) to the first singlet excited state (S_1). We, therefore, conclude that the detected photocurrent is triggered by the S_0-S_1 electronic excitation.

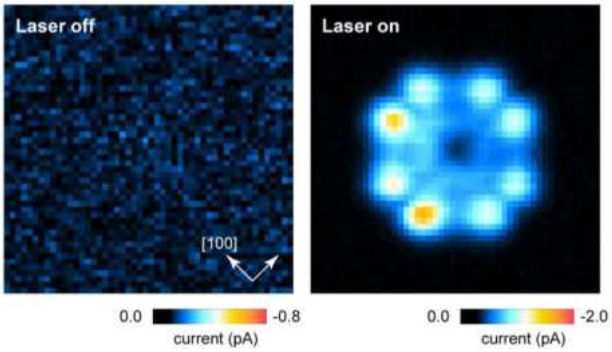

Figure 2 the current images of a molecule measured at V_s = -2.0 V under the laser-off (left) and laser-on (right) conditions.

Figure 2 shows I_t images under the laser-off and laser-on conditions. While the observed signals under the laser-off condition were within the margin of error for current measurement, signals far exceeding the noise level were obtained under illumination. The photocurrent image clearly reveals a four-fold symmetric pattern with nodes and lobes having similar characteristics to the molecular orbitals (MOs) of phthalocyanines that have been visualized by STM. Photocurrent flowing through MOs was thus successfully visualized at an atomic resolution.

Depending on the applied bias voltage, not only the direction but also the spatial distribution of the photocurrent changes markedly. Comparing the spatial distribution of photocurrent and the frontier MOs of an FBPc molecule allowed us to identify the frontier MOs which play essential roles in the photocurrent generation. Moreover, the photocurrent images, measured in the voltage region where the direction of the current is inverted, allowed us to discovered multiple counterflowing photocurrent channels even at a voltage where the averaged photocurrent is almost zero. The detailed mechanism of photocurrent generation will be discussed in the presentation.

Single-molecule photonics with scanning tunneling microscopy: nanospectroscopy and beyond

H. Imada[1]

[1]Surface and Interface Science Laboratory, RIKEN, Japan
himada@riken.jp

Abstract: The study introduces a novel single-molecule nanospectroscopy technique combining scanning tunneling microscopy and near-field optics, enabling precise investigation of molecular excited states and energy conversions at the submolecular level. This approach overcomes previous limitations in optical spectroscopy, offering new insights into organic material functions.

The electronic excitation of molecules triggers diverse energy conversion phenomena, including luminescence, photovoltaic effects, and various chemical reactions. Understanding and controlling dynamic processes of molecules in excited states are of primary importance for creating novel functions with organic materials. Optical spectroscopy has been widely used to investigate such electronic excited states, determine emission and absorption energies, elucidate dynamic phenomena occurring in materials, and so on. However, because of its limited spatial resolution, it cannot provide direct information about the local spatial distribution of molecular orbitals, which governs excitation. Conversely, atomic-resolution microscopy techniques such as electron microscopy and scanning probe microscopy can visualize local structure, but spectroscopic techniques using such microscopes are very underdeveloped. Consequently, there have been few studies on electronic excitations and succeeding processes at the atomic or molecular level and much remains to be learned about the associated energy conversions.

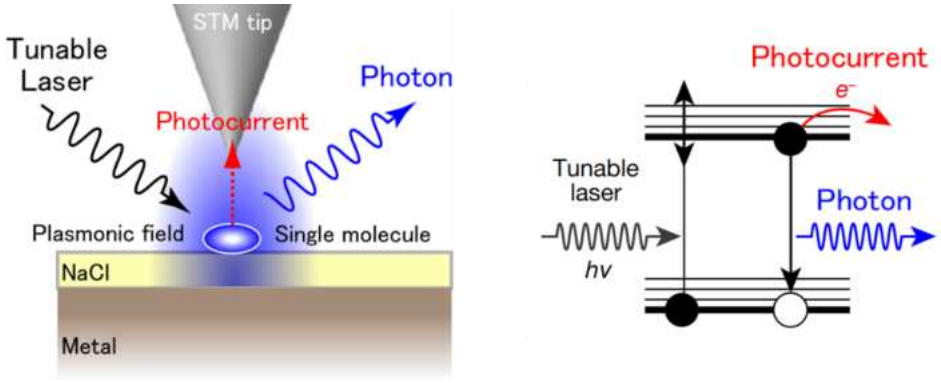

Figure: Illustration of the experimental setup of near-field optical spectroscopy in STM. Single molecule is photo excited by the laser-driven localized plasmonic field, and photon (luminescence, Raman) or electric current is measured.

Recently we have developed single-molecule nanospectroscopy techniques that combined scanning tunneling microscopy (STM) and near-field optics [1-3], which are based on plasmon-enhanced light-matter interaction at the molecular scale (Figure). STM allows us to observe molecular orbitals at the atomic scale, and various kinds of near-field spectroscopy (Raman, photoluminescence, photocurrent) now allows us to directly investigate the electronic, optical, and vibrational properties of the materials with submolecular spatial resolution.

In this talk, I will introduce recent progress of the single-molecule nanospectroscopy techniques, and discuss perspectives of the technique.

Abstract: The mid-infrared vibrational spectroscopy has been used for the detection of various molecules due to the characteristic infrared absorption features of chemical bondings. We realize high-aspect ratio plasmonic titanium nitride gratings where infrared absorption by vanillin molecules is significantly enhanced due to stronger electric fields within the deep subwavelength structures.

Vibrational spectroscopy in the mid-infrared (IR) wavelength region spanning from 2.5 to 20 μm has been extensively used for the detection and identification of molecules since molecular bondings exhibit characteristic absorption peaks in the wavelength region, allowing various sensing applications, such as production process, gas sensing for environmental monitoring, and label-free detection of proteins. In order to improve the mid-IR absorption signals of analyte molecules, surface-enhanced infrared absorption (SEIRA) spectroscopy has been developed by incorporating both plasmonic and dielectric nanostructures to confine mid-IR light at the nanoscale [1]. SEIRA employs various nanostructures supporting highly localized plasmon modes, which are made of gold and transparent conductive oxides, like Al-doped zinc oxide (AZO) [2].

Here, we report that high-aspect ratio titanium nitride (TiN) grating structures can enhance mid-IR light absorption of molecules [3]. Titanium nitride is a plasmonic material whose permittivity becomes negative from the visible to mid-IR wavelengths [4]. Up to present, a TiN-based nanostructure has not been used for SEIRA applications. The TiN nanostructures have been fabricated by the combination of deep ultraviolet (DUV) lithography, dry etching, and atomic layer deposition (ALD) techniques [5]. As shown in Figure 1(a), the fabricated TiN grating structures have the periodicity of 0.4 μm, TiN wall thickness of 0.2 μm, and height of 2.4 μm with high aspect ratio on a Si substrate. The TiN nanostructures become hyperbolic metamaterials (HMMs) for mid-IR wavelengths where permittivity tensor components parallel to trench walls are negative (plasmonic behavior) while the perpendicular component is positive (dielectric behavior) [6].

The TiN grating structures support Fabry-Pérot modes propagating within the deep subwavelength plasmonic trenches and possess strong electric field, which enhances infrared absorption by analyte molecules. We use vanillin as a model analyte that exhibits several characteristic absorption peaks for mid-infrared wavelengths of λ = 6 – 7 μm (1666 – 1427 cm−1), as shown in Figure 1(b). We observe enhancement of vibrational signal in TiN gratings, compared with unstructured Si substrate. Apart from intense electric field within gratings, the high aspect ratio geometry increases the working surface of the sensor, resulting in improved vibrational signals. Titanium nitride grating structures may serve as a highly sensitive chemical sensing platform for mid-infrared absorption spectroscopy. Additionally, such TiN grating structure can also be used for

refractometric sensing where analyte is detected as the change of local refractive index [5] and photothermal applications [7].

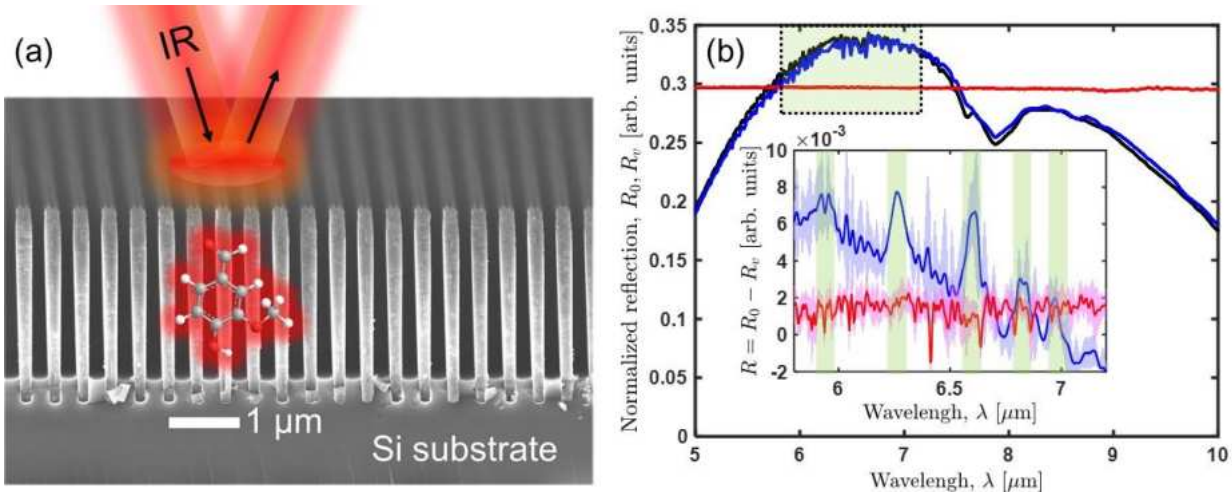

Figure 1: (a) Scanning electron microscope (SEM) image of the fabricated TiN gratings. (b) Measured free-space reflection spectra from TiN gratings (blue) and Si substrate (red) with and without vanillin sample, Rv, R_0, respectively. The inset is the reflection difference between samples with and without vanillin $R = R_0 - Rv$. Green shades show five absorption peaks of vanillin.

Abstract: Singularities of non-Hermitian systems, also known as exceptional points (EPs), have been shown to be highly sensitive to external disturbances[1,2]. By inducing a phase transition of parity-time symmetry, we have theoretically proposed and practically demonstrated a terahertz metasurface capable of supporting a plasmonic EP. This terahertz EP-based metasurface serves as a sensor for detecting residual embryonic stem cells (ESCs) among differentiated cells, offering significant value in medical diagnosis.

Summary

In this study, we introduce a planar microstructure with plasmonic EPs controlled by the breaking of parity-time (PT) symmetry. By utilizing temporal coupled mode theory (TCMT), we analyze two-mode and two-port photonic systems, identify the simple conditions for EP occurrence, and design a planar metasurface that numerically and experimentally supports EP. We successfully demonstrate the ability of a plasmonic EP-based metasurface to detect the concentration of embryonic stem cells (ESCs). Our research presents a straightforward approach to achieve second-order EP in the terahertz spectrum, showcasing that EP-based terahertz biosensors do not demand high-Q resonators, which is advantageous for conventional THz-TDS measurements. Both practical applications and theoretical investigations involving plasmonic EP hold paramount importance.

To elucidate the realization of EPs, we initially examine a dual-port photonic system comprising of a dark mode M_d, a bright mode M_b and their interactions. Assuming M_d and M_b share the same resonant frequency ω_0, with M_b having a decay rate of γ while Md possesses a vanished decay rate, and they are coupled to each other with a coupling strength of κ. By neglecting the non-radiative decay as a reasonable assumption, we describe the dynamics of the resonant modes using TCMT[3]. We discuss three scenarios based on the coupling strength κ, leading to the emergence of an EP, a passive PT-symmetric phase, or a broken PT-symmetric phase. By tuning the coupling strength κ, one can manipulate PT-symmetry to realize a second-order EP. To construct a practical planar metasurface guided by the effective Hamiltonian, we design a structure containing parallel plasmonic antennas along the x-axis and a vertical plasmonic antenna adjacent to them at a distance of g.

To experimentally validation of the EP in our designed structure, we first fabricated the metasurfaces by using regular electron beam lithography (EBL) technique on silicon substrates. The EBL provides enough accuracy to tune the structure dimension to an EP. The sample is composed of a single layer of 150-nm-thick aluminum microstructures with a lattice constant of 110 μm along the x-axis and 70 μm along the y-axis on a 1-mm-thick silicon substrate. Following that, we investigated at the possibility of using our EP-based sensor to detect residual stem cells in differentiated functional cells in vitro. We used neural cells mixed with a portion of ESCs as

analytes; these neural cells were produced from ESCs in vitro at a cell density of 400 cells/mm^2, and the proportion of ESCs was set to 0%, 1%, 10%, 20%, 30%, and 40%.

It is found that the Δω produced by the neuronal cell layer is approximately 0.05 THz, which is less than that produced by the ESCs layer with the same density (Δω~ 0.09), by varying types and quantities of chemicals contained in the cells. This result indicates that our sensor is capable of discriminating between different cell types, and that the Δω produced by mixed cells steadily increases as the number of ESCs increases. In particular, our EP-base terahertz sensor can detect the ESCs with proportion as low as 1%, which can be extremely useful in medical diagnosis. We emphasize that our method for detecting ESCs is label-free, and the detection process as a whole does not induce cell harm. It takes only about half an hour in our THz-TDS to measure terahertz pulses and extract the Δω, which is significantly faster than existing approaches for detecting remaining stem cells. Additionally, because the metasurface is chemically stable, washing with acetone and boiling water can be used to remove cells adhered to the metasurface without affecting the performance of metasurface. The reusability of EP-based biosensors proves that the device has great application potential.

In conclusion, through a combination of TCMT analysis, FDTD simulation, and THz-TDS measurements, we have developed a planar metasurface supporting a plasmonic EP in the terahertz frequency range. Our work demonstrates that the resonant frequency of the terahertz metasurface at the EP is highly sensitive to minute external perturbations, enabling the detection of ESCs at low proportions efficiently. This EP-based biosensor showcases faster detection of stem cells compared to existing methods and exhibits great potential for various applications in the field of terahertz biosensing.

Abstract: We experimentally demonstrate a plasmonic metasurface supporting exceptional points at terahertz frequencies, based on wisely tailored coupling between bright and dark modes. As an application, we use the metasurface EP sensor to trace residual embryonic stem cells in differentiated cells with a detection limit of less than 1%.

Exceptional points (EPs) [1], singularities of non-Hermitian systems, exhibit remarkable sensitivity to small external perturbations and have found applications in biosensors to enhance performance. However, these EPs have typically been realized on large and bulky platforms, such as coupled ring resonators, coupled silicon waveguides, and stacked metamaterials [2]. The advent of metasurfaces, a flat optics infrastructure, offers a revolutionary platform for compact and planarized optical devices. Plasmonic metasurfaces have been extensively utilized for optical biosensing, particularly in the terahertz frequency range. However, the sharp resonances and their shifts are challenging to measure due to the frequency resolution limitations of conventional terahertz time-domain spectrometers (THz-TDS) [3]. To address this issue, leveraging the concept of EPs in combination with terahertz metasurfaces holds promise for enhancing the sensitivity of biosensors.

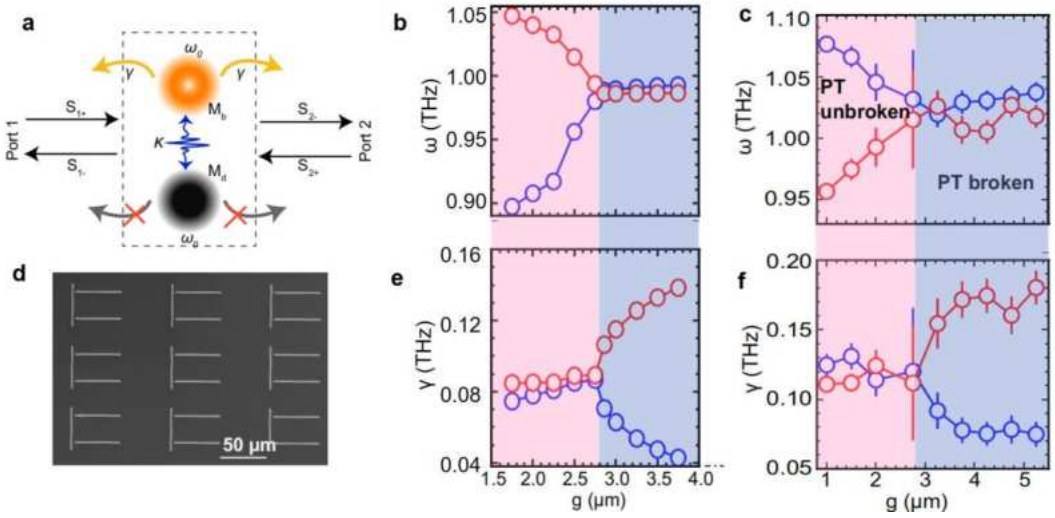

Figure 1: (a) A dual-port system consisting of adark resonant mode and a bright resonant mode. (b,e) Simulted resonant frequencies (b) and damping rates (e) changing with the parameter *g*. (c,f) Measured resonance frequencys (c) and damping rates (f).

Utilizing the temporal-coupled-mode-theory, we conducted an analysis of a two-mode and two-port photonic system illustrated in Figure 1a. Our study led us to propose a single-layered terahertz extraordinary optical transmission (EP) metasurfaces, depicted in Figure 2d. The resonant modes of the metasurfaces designed exhibit a plasmonic EP that is influenced by the breaking of parity-time (PT) symmetry [4]. Simulation results displayed in Figure 1b and 1e reveal the resonant frequencies and damping rates of our structures obtained through full-wave simulations. The EP phenomenon is observed at a specific parameter value of g = 2.75 μm, and these findings were experimentally validated using terahertz time-domain spectroscopy (THz-TDS) measurements, as depicted in Figure 1c and 1f.

Resonant-frequency splitting around the plasmonic EP sensitively characterize tiny external perturbation. We seed neural cells mixed with a portion of embryonic stem cells as analytes on the terahertz-exceptional-point metasurfaces, as shown in Figure 2a. We found that the resonance frequency split is not only sensitive to cell concentration (see Figure 2b) but also to cell proportion when mixed with neural cells (see Figure 2c). our EP-base terahertz sensor can detect the ESCs with proportion as low as 1%, which can be extremely useful in medical diagnosis.

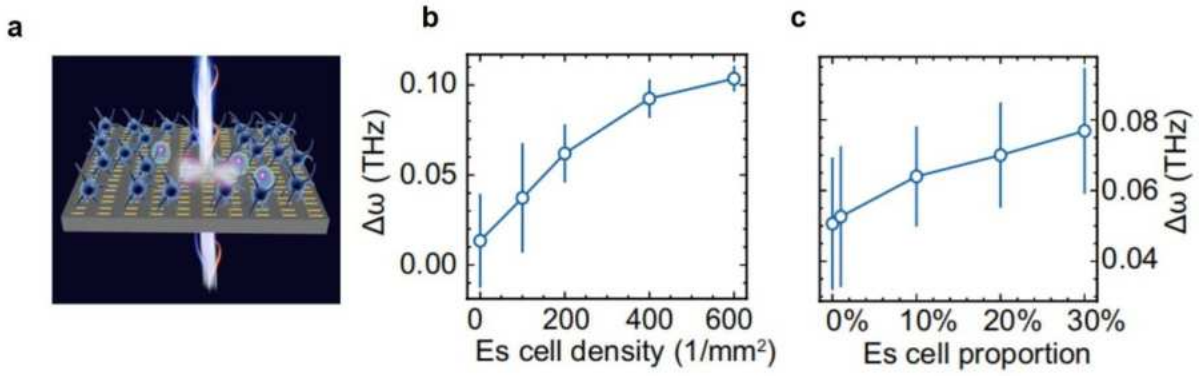

Figure 2: (a) Schematics for sensing ESC trace with the EPMS. (b) Resonant-frequency split induced by ESCs with different concentrations. (c) Resonant-frequency split at different proportions of ESCs.

Topologically dark metamaterials for optical biosensing

G. I. Tselikov[1*], G. A. Ermolaev[1], A.V. Arsenin[1], A.V. Kabashin[2] and V. S. Volkov[1]

Abstract: Our research focuses on utilizing topologically dark metamaterials to achieve exceptionally high spectral and phase sensitivity in detecting biological binding events. The proposed approach can provide a plenty of sensing modalities in wearable electronic devices like multifunctional smart contact lenses. Moreover, it was used to probe two dimensional materials.

The analysis of affinity binding interactions between a target analyte (e.g., antigen, protein, peptide, DNA, RNA segments) from a biological sample solution and its selective receptor (e.g., antibody, protein, peptide, etc.) immobilized on the surface presents one of key tasks in biomedical diagnostics [1]. Traditional label-based biosensing currently used in hospitals and laboratories uses fluorescent or radiolabels to mark analytes and thus reports biomolecular binding, but this approach is inaccurate due to the presence of a reaction that interferes with labeling, expensive in terms of required laboratory facilities, and too time-consuming. An alternative is optical transduction biosensing, which allows the recording of biomolecular interactions by monitoring the optical refractive index (RI) change associated with increasing biolayer thickness, providing immediate report of binding results and obtaining kinetic constants within minutes [2]. The most used transduction biosensing architectures are based on spectral (or angular) interrogation under surface plasmon resonance (SPR) or localized plasmon resonance (LPR) [2]. However, these schemes provide order of magnitude lower limit of detection (LOD) levels compared to label-based sensors. The solution of this problem can be found in utilizing ultrasensitive phase interrogation scheme for studying the reflection of light by properly designed plasmonic structures under the conditions of topological darkness (TD).

Recently the phenomenon of TD was proposed as a possible solution for label-free single-molecule detection [3]. It implies the exact zero linear polarized light reflection from a dedicated optical system and manifest itself as a resonant feature in reflection spectra with a point of zero light intensity. At the same time the phase of light under conditions of TD demonstrates an exact Heaviside π-jump which allows one to use it as a sensing parameter that can radically improve the sensitivity of label-free biosensors. Moreover, thanks to Jordan-Brouwer theorem the TD point is topologically protected, it means that it will be achieved regardless of any imperfection in the fabrication of topologically dark structures [4]. Recently it was demonstrated that the light phase singularities under TD can be provided by a variety of structures including the plasmonic metasurfaces and thin layers of 2D materials on the Fabry-Perot substrates [5]. However, despite the high phase sensitivity of the proposed sensing substrates its spectral sensitivity was lower than one of SPR sensors.

Here we introduce the concept of topologically dark metamaterials that assure extremely high values of both spectral and phase sensitivities due to so-called “scissor effect”. This effect can be realized by the proper design of metamaterials and implies the intersection of zero reflection surface with a spectral curve of optical constants at a small angle. The smaller the angle of incidence the higher the spectral sensitivity of TD structures (the

scissor analogy). As an example, we demonstrate the applicability of this approach for the arrays of gold nanodimers on a glass substrate fabricated by electron-beam lithography (Fig. 1).

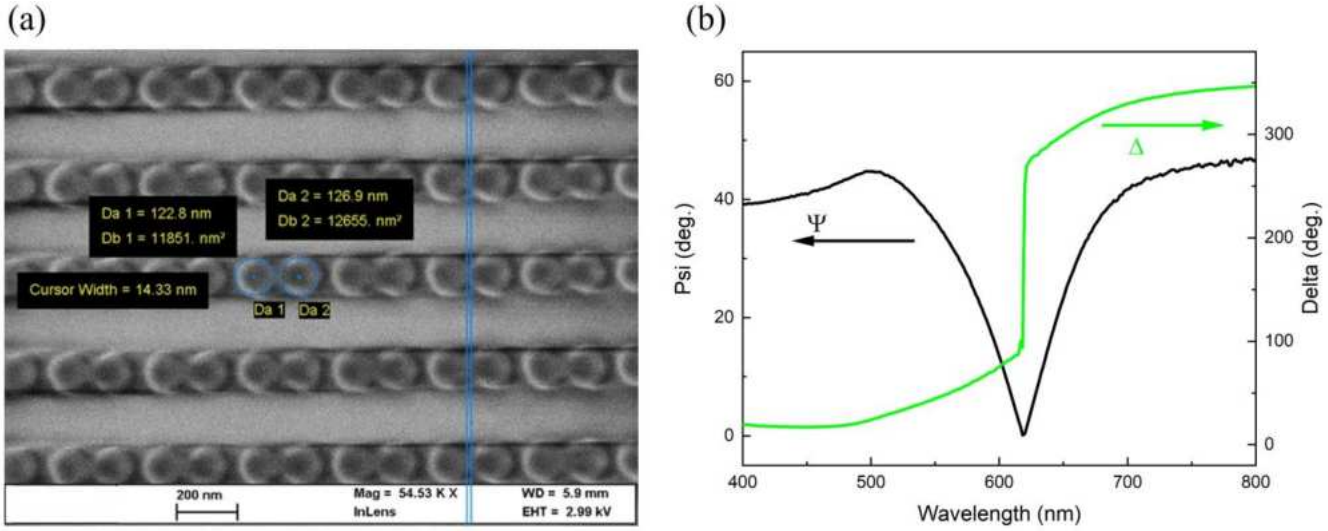

Fig.1 SEM image of topologically dark metamaterial based on 320-nm period arrays of glass-supported Au nanodimers (a) and spectral ellipsometry observation of TD phenomenon (b).

We show that for nanodimer-based TD plasmonic metamaterial the spectral sensitivity of resonances can reach values of 10^4 nm/RIU while phase sensitivity can be as high as 10^5 nm/RIU when the refractive index of local environment is changed for the model system – water-glycerol mixture. Moreover, we performed label-free biosensing tests using protocol for quantitative detection of folic acid. We show that TD metamaterials are capable of monitoring folic acid in a 3-log wide range of concentrations (5−5000 nM), while the observed LOD of 0.22 nM was orders of magnitude better than those of previously used label-free and label-based methods [4].

Finally, we have also demonstrated that high localization and concentration of electromagnetic fields that is achieved at the conditions of TD over the array of plasmonic metamaterials can be used to probe the atomically thin two-dimensional materials like graphene and molybdenum disulfide and to resonantly increase the Raman scattering of light in these layers.

Plasmon-enhanced fluorescence immunosensor using polymer-coated silver nanoparticles

Nahoko Okimi[1], Setsuko Yano[2], Yoshie Komatsu[2], Toshifumi Nanjyo[2], Mitsuhiro Uesugi[2], Ryo Kato[1], Takuo Tanaka[1], Fumihisa Kitawaki[2], and Taka-aki Yano[1*]

Abstract: We developed a one-pot method for synthesizing polymer-coated silver nanoparticles, which are suitable for plasmon-enhanced fluorescence immunosensing. The coating with the polymer layer is sufficiently thin to plasmonically enhance fluorescence, yet thick enough to effectively suppress fluorescence quenching. This enables the highly sensitive detection of blood biomarkers at picomolar(pM) concentrations.

Plasmon-enhanced fluorescence spectroscopy has attracted attention as a highly sensitive biosensing technique because the fluorescence intensity of labeled molecules can be enhanced by the electric field enhancement effect near the metal surface [1]. When fluorescent molecules are in close proximity to a metal surface, the electric field enhancement effect increases, while the quenching effect is dominant due to energy transfer on the metal surface.

In this study, we developed polymer-coated plasmonic nanoparticles by forming a functional polymer film of a few nm on the surface of silver nanoparticles to suppress the quenching effect [2]. The polymer-coated metal nanoparticles were prepared in a one-pot process using a functional polymer (PLL: Poly-L-Lysine) conjugated with disulfide-containing crosslinkers. As shown in Fig. 1(a), the disulfides played a crucial role in covalently bonding PLL polymers to the surface of the Ag nanoparticles. The covalent bond enabled the PLL layer to form a long-term stable coating on the Ag nanoparticles. The shell of the PLL layer was thick enough to effectively suppress the quenching of fluorescence and was also thin enough to efficiently produce plasmonic enhancement of fluorescence, thereby maximizing the net enhancement of fluorescence in the vicinity of the PLL-coated Ag nanoparticles.

Highly sensitive fluorescence detection of CRP (C-reactive protein), an inflammatory marker in blood, was demostrated using the polymer-coated silver nanoparticles. As shown in Figure 2(a), antibody molecules and fluorescent dye (Alexa 594) were chemically modified on the surface of polymer-coated silver nanoparticles, and CRP antigen was added to the particle solution. Figure 2(b) shows the dark-field scattering spectra of silver nanoparticles before and after antigen addition. Before the antigen-antibody reaction, the silver nanoparticles are isolated and dispersed, and have a plasmon resonance wavelength near 440 nm. When the silver nanoparticles are aggregated by the antigen-antibody reaction, a new plasmon resonance mode appears around

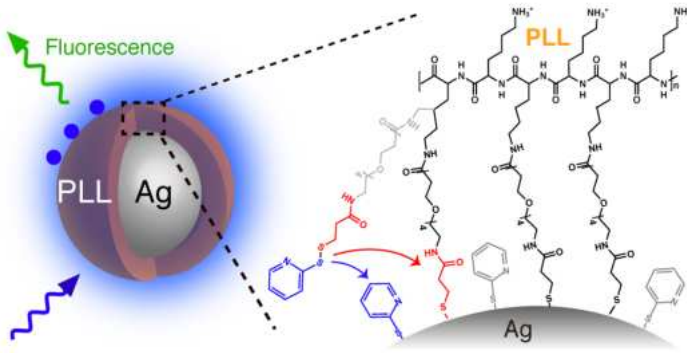

Fig. 1 Schematic of a polymer-coated silver nanoparticle for plasmon-enhanced fluorescence spectroscopy.

590 nm. This mode is derived from the gap-mode plasmon induced between nanoparticles when polymer-coated metal nanoparticles aggregate, and a high fluorescence enhancement effect can be expected between the gaps when this mode is used. Figure 2(c) shows the fluorescence spectrum measured at different concentrations of antigen (CRP). The fluorescence excitation wavelength (594 nm) coincides with the resonance wavelength of gap-mode plasmons between nanoparticles, and the fluorescence is specifically enhanced only during aggregation, resulting in a fluorescence enhancement of about two orders of magnitude. The fluorescence intensity increased in proportion to the antigen concentration, and a detection limit on the order of pM was obtained.

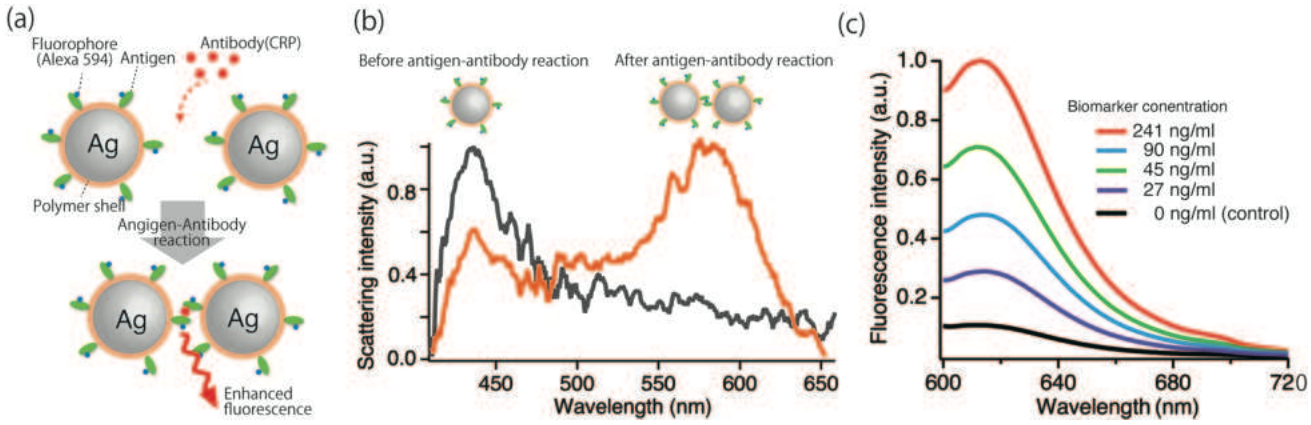

Fig. 2 (a) Principle of antigen detection using polymer-coated silver nanoparticles, (b) dark-field scattering spectra of silver nanoparticles before and after antigen-antibody reaction, (c) antigen concentration dependence of plasmon-enhanced fluorescence spectra.

Abstract: In plasmonic biosensing applications, gold nanostructures are typically attached to oxide surfaces. Here, we present an orthogonal chemical toolbox to promote adhesion of gold to glass and to selectively modify arrays of gold nanoparticles by antifouling and biofunctional moieties, based on a set of dedicated silatrane and thiol molecules bearing carboxy- and sulfo-betaine headgroups.

Surface plasmons are optical resonances originating from collective oscillations of charge density at metal/dielectric interfaces (e.g., thin metallic films or metallic nanostructures on glass substrates). They are associated with increased intensity of tightly confined electromagnetic field and become frequently employed for optical probing of chemical and biological species in numerous bioanalytical methods, including surface plasmon resonance (SPR) biosensors, surface enhanced Raman spectroscopy (SERS) or plasmon-enhanced fluorescence (PEF). The electromagnetic field intensity enhancement and quality factor of plasmonic resonances depend strongly on the employed materials and typically for gold nanostructures attached to glass an intermediate adhesion layer is required. Most commonly, thin chromium or titanium layers are used as adhesion promoting coating [1], which, however, introduce damping to the surface plasmon field. In addition, the surface of plasmonic nanostructures needs to be modified in order to preferably dock the target molecules at the metal surface and not at the oxide substrate, which is not probed by the plasmonically enhanced electromagnetic field.

In our work, we exploited a chemical toolbox containing thiol and silatrane molecules to serve as adhesion-promoting layers, antifouling coatings, and to introduce biofunctional moieties on arrays of gold nanoparticles. Silatranes are tricyclic caged structures that take advantage of silane chemistries and allow for high homogeneity and ordered assembly, to densely coat glass substrates over large surfaces [2]. The toolbox consists of mercatopropyl silatranes (MPS) for gold/glass adhesion promotion, sulfobetaine silatranes (SBSiT) for glass surface antifouling properties, carboxybetaine-thiols (CB-thiols) for functionalization with bio-recognition elements, and Sulfobetaine-thiols (SB-thiols) for antifouling properties of the sensing area. Each component of the toolbox serves a different function, and it is engineered to bind only to a specific material, making the process orthogonal (see Figure 1). Here, we carried out a comprehensive comparison between metallic (chromium) and chemical (MPS) adhesion layers and we present the benefits obtained using chemical layers. In addition, we monitored the influence of antifouling layers in biosensing sensitivity in SPR and PEF – based biosensor applications.

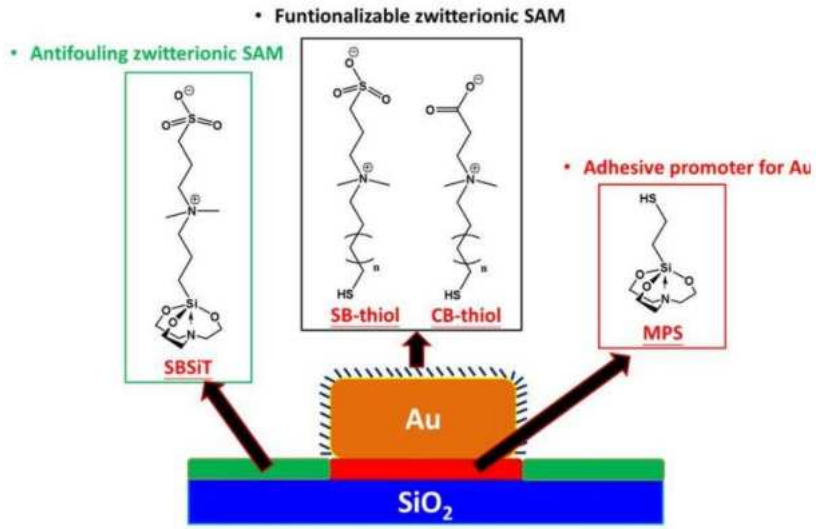

Figure 1 Components of the orthogonal chemical toolbox, in the context of gold nanostructures on a glass substrate.

This research aims to develop a plasmonic sensor capable of continuously monitoring low molecular weight analytes by exploiting reversible interactions with ligands, coupled with a plasmonically enhanced fluorescence (PEF) energy transfer readout[1]. A specific aptamer-based ligand, attached to a metallic sensor surface via a fluorophore-labeled flexible polymeric linker (FPL), regulates the distance between the fluorophore label and the surface through its affinity interaction with the target analyte. The study investigates the use of FPL based on both single-stranded and double-stranded DNA chains to switch between enhancing (>15 nm) and quenching (<10 nm) the fluorescence signal via plasmonic effects. The potential application for continuous monitoring of the antibiotic Vancomycin[2] is investigated, and the conformational changes of FPL are examined using Quartz Crystal Microbalance with Dissipation (QCM-D). Additionally, a novel toolkit for constructing a thin biointerface with antifouling zwitterionic moieties is employed[3]. This comprehensive approach aims to enhance therapeutic drug monitoring in clinical applications.

Understanding on Light-matter Interaction in Chiral Plasmonics

Jeong Hyun Han[1], Ryeong Myeong Kim[1], and Ki Tae Nam[1*]

[1]Department of Materials Science and Engineering, Seoul National University, Seoul 08826, Republic of Korea
[*]corresponding author: nkitae@snu.ac.kr

Abstract: Plasmonic materials enhance chiral sensing in a noninvasive, ultra-sensitive manner. We take note of principles of chiral light-matter interactions in chiral plasmonics driven by optical chirality and chiral perturbation. We demonstrate two strategies based on them: collective resonances in periodic chiral plasmonic nanoparticles and nanostructure optimization via machine learning.

Identifying the molecular chirality is important for many biochemical applications. Plasmonic metamaterials are of particular interest because they can enhance local chiral light-matter interaction in deep-subwavelength scale, significantly improving spectroscopic detection limits using circular dichroism. When discussing chiral molecule detection via plasmonic resonances, the focus often lies on the intensified electromagnetic fields strongly confined by plasmonic materials that enhance the molecule's intrinsic optical excitation rate and corresponding signal amplification. However, a theoretical gap has persisted due to the disparity between the wavelength of molecular electronic absorption, typically in the UV region, and the optical response of plasmonic materials in the visible and near-infrared ranges. Recent noteworthy research shifts attention to interpreting plasmonic sensing based on perturbation theory, considering the backaction of molecular energy absorption from the electromagnetic energy stored in plasmonic structures. In this case, the shift in plasmonic resonance modes can be understood as a collective effect between 1) dielectric perturbation in electric energy capacitively stored in nanostructures caused by the refractive index change and 2) chiral perturbation arising from the effect of near-field optical chirality and media's chirality parameter. Thus, this interpretation enables broad detection capabilities concerning sample type, concentration, and chirality. We introduce the physical significance of this theoretical background and present two innovative enantioselective chiral plasmonic sensing strategies derived from the chiral perturbation theory. Firstly, the fabrication and incorporation of chiral plasmonic nanoparticles into 2D photonic crystals to form spinning dipoles responsive to circularly polarized light, resulting in the strong and uniform optical chirality in three dimensions, showcases extraordinary sensing feasibility in various regimes (transmission, reflection, and sample immobilization methods). Secondly, a machine learning-based simultaneous optimization of dielectric and chiral perturbations efficiently optimizes the effect of medium backaction on electric fields, optical chirality, and spectroscopic responses, achieving tailored sensing.

Spectrometer-free colorimetric plasmonic biosensor for detection of food allergens

D. Hirabayashi[1], K. Kajikawa[1], and M. Toma[1*]

[1] Tokyo Institute of Technology, Nagatsuta-cho 4259, 226-8503 Yokohama, Japan
[*]corresponding author: toma@ee.e.titech.ac.jp

Abstract: The direct detection of a food allergen, ovomucoid from egg white, is demonstrated by a colorimetric plasmonic biosensor. Plasmonic colors of our metal nanodome arrays allow us to realize biosensing with portable equipment such as smartphones.

The development of portable plasmonic biosensors suitable for on-site detection of biomolecules is one of the important research topics for practical applications. Metal nanostructure arrays working as plasmonic metasurfaces offer a means to engineer key characteristics in plasmonic biosensors. The plasmonic coloration exhibited by metal nanodome arrays illustrated in Figure 1(a) presents an appealing property for biosensor applications. Because their color changes induced by the binding of biomolecules at the sensor surface can be detected by a normal camera including a smartphone [1-2]. This paper introduces a plasmonic biosensor capable of sensitively detecting food allergen, ovomucoid (OVM) from egg white, through the observation of color changes in metal nanodome arrays.

The metal nanodome arrays used as a sensor substrate consist of polystyrene beads (diameter: 250 nm) monolayer covered with a 50 nm-thick Ag layer and a 5 nm-thick Au layer on the top. The surface of the sensor substrate was chemically modified with a polydopamine thin film and blocked with a blocking agent after the immobilization of the anti-OVM antibody. Then, sample solutions spiked with OVM at a concentration of 0.1~3 ug/mL were flowed over the sensor surface for 20 minutes and rinsed. Measurements were made using an optical system capable of measuring reflectance spectra and acquiring reflectance images at the same spot. The color change of the sensor substrate was evaluated as the change in hue angle ΔH by converting RGB values to hue angle H in the HSV color space coordinate.

The sensor surface exhibited bluish-purple when it was in contact with an aqueous solution as shown in Figure 1 (b). When the sample solution containing 1 ug/mL OVM was introduced, the color changed by -0.39 deg in hue angle due to the binding of OVM. These results indicate that the colorimetric plasmonic biosensor can detect concentrations below the 10 ug/mL labeling threshold for food allergens.

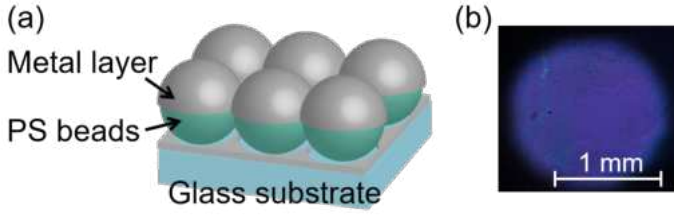

Figure 1 (a) A schematic illustration of metal nanodome arrays used as a sensor substrate. (b) A reflection image of the sensor substrate in contact with a buffer solution.

High-speed near-field optical microscopy: super-resolution plasmonic imaging for biological studies

T. Umakoshi[1,2*]

[1]Institute for Advanced Co-Creation Studies, Osaka University, Japan
[2]Department of Applied Physics, Osaka University, Japan
[*]corresponding author: umakoshi@ap.eng.osaka-u.ac.jp

Abstract: We developed high-speed near-field optical microscopy by combining near-field optical microscopy and high-speed atomic force microscopy, holding a great promise for biological studies owing to the real-time label-free imaging capability. In this talk, details of the constructed setup and its applications are discussed.

Near-field optical microscopy has been well recognized as a type of super-resolution optical microscope, which utilizes near-field light localized within a nanometric volume at a plasmonic tip. Super-resolution optical images are obtained by raster-scanning the tip or samples,. Compared to the super-resolution fluorescence microscope, which is another well-known super-resolution microscope, one of its advantages is that it is label-free because near-field optical microscopy achieves super-resolution owing to the physically small near-field light without any fluorescent molecules. Therefore, it can be combined with Raman spectroscopy and infrared absorption spectroscopy, which enables the analysis of the nanoscale label-free nature of biological samples through molecular vibrations or chemical properties. However, the imaging rate is slow because the plasmonic tip needs to be raster-scanned, typically taking several minutes or more to acquire one image. It has been possible to observe fixed samples in air, but observation of living, moving biological samples remains highly challenging. Near-field optical microscopy capable of high-speed imaging would be a powerful tool to visualize natural biological phenomena at the nanoscale in a label-free manner, greatly contributing to life science.

In this study, we developed high-speed near-field optical microscopy with an imaging rate of a few seconds per image [1]. To increase the imaging rate, we employed a high-speed atomic force microscope (HS-AFM) for rapid tip scanning [2,3]. HS-AFM enables high-speed AFM imaging, typically up to 10 frames/s. In addition, in spite of such rapid tip-scanning, it is gentle enough not to disturb biological behavior owing to sophisticated quick feedback and a soft cantilever tip. By combining it with near-field optical microscope setup, we constructed a high-speed near-field optical microscope. We successfully obtained the near-field optical image of a fluorescent polystyrene bead within 3.5 s (Fig. 1(a)). The near-field optical image of DNA was also obtained in 10 s (Fig. 1(b)). Importantly, our technique is highly biocompatible as these were demonstrated in physiological conditions (in buffer solution). We further demonstrated high-speed successive imaging, showing the dynamic behavior of a DNA fraction through frame-by-frame observation (Fig. 1(c)).

In this talk, we will describe the details of the construction of the experimental setup, including tip fabrication. Moreover, further developments recently made in high-speed near-field optical microscopy will be discussed, which further increased the imaging rate up to the sub-second order. In addition to high-speed near-field optical microscopy, we will introduce various developments made in near-field optical microscopy, which would be highly beneficial for biological studies [3].

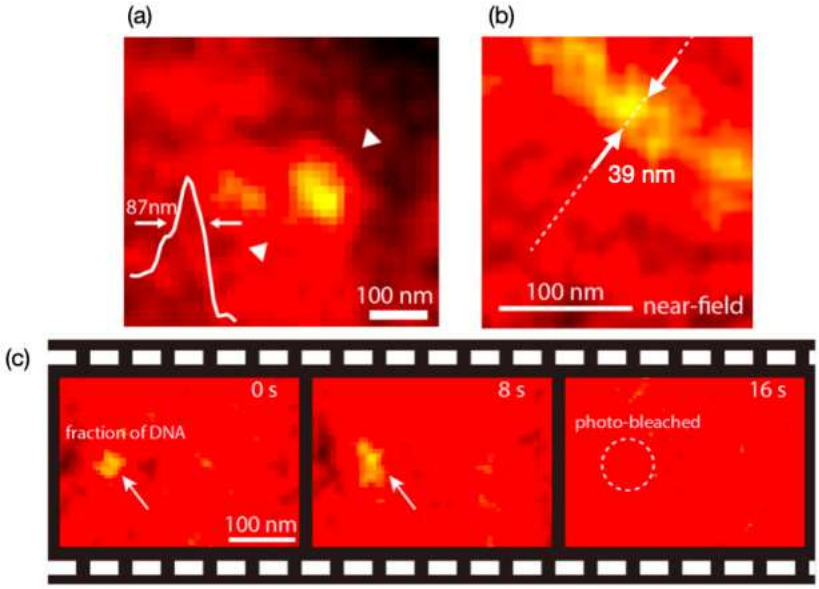

Figure 1. High-speed near-field optical images. (a) Fluorescent polystyrene bead (imaging rate: 3.5 s/frame), (b) DNA (imaging rate: 10 s/frame), (b) Successive images of a DNA fraction (imaging rate: 8 s/frame). [1]

Recent advances in metasurface fluorescence biosensors for diverse targets

Masanobu Iwanaga[1*]

[1]Research Center for Electronic and Optical Materials, National Institute for Materials Science (NIMS), Japan
[*]corresponding author: iwanaga.masanobu@nims.go.jp

Abstract: Metasurfaces have been activated as resonant-wavelength shift and fluorescence biosensors. Here, we address recent advances in metasurface fluorescence (FL) biosensors that can detect diverse targets from antigen/antibody to DNA even at one molecule per test. The metasurface FL biosensors have been realized in both all-dielectric and plasmonic types.

Among the numerous metasurface reported so far, a small number of them was found to work as extremely efficient fluorescence (FL)-enhancing platforms, which exhibited more than 1000-fold FL-intensity enhancement compared to flat non-enhancing substrates such as silicon wafers and, simultaneously, high reproducibility of the FL enhancement effect [1–3]. We found two types of the FL-enhancing metasurfaces: plasmo–photonic and all-dielectric. Figure 1A,B illustrates the plasmo–photonic and all-dielectric metasurfaces, respectively. The former comprises complementary stacked structure of Au and periodically perforated Si slab: the latter is a periodic array of Si nanocolumns. Both have the periodicity less than 400 nm and are subwavelength structures for the working wavelengths of 530 nm and longer.

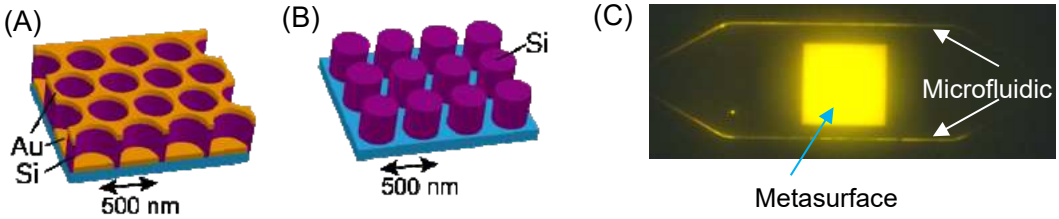

Figure 1. (A) and (B) Illustrations of plasmo–photonic and all-dielectric metasurfaces, respectively. (C) A representative FL image of the metasurface FL biosensor. Metasurface area is the central bright square of 0.72 mm × 0.72 mm, indicated by a light blue arrow. Microfluidic boundary is indicated by white arrows.

Thanks to the significant FL-enhancing ability, FL detections of biomolecules became far more feasible and simpler than before. Metasurface FL biosensors were constructed by combining the FL-enhancing metasurface substrate with a microfluidic chip. Figure 1C shows a typical FL image of captured proteins on the plasmo–photonic metasurface. The secondary FL-labeled antibody emitted the yellow FL. Evidently, the metasurface area indicated by a light blue arrow is far brighter than the area around. Microfluidic boundary is indicated by white arrows. To date, various targets such as immunoglobulin G antibody [4,5], cancer marker proteins (anti-p53 antibody [4,5], carcinoembryonic antigen, CEA [4,6], and prostate specific antigen, PSA [6]), spike proteins of the COVID-19 [7], nucleic acids of the COVID-19 [8,9], and cell-free DNA (cfDNA) [10] were detected in the metasurface FL biosensors very precisely. Especially, we achieved an ultimate limit of detection for the cfDNA to discriminate one cfDNA from zero. We realize the ultimate detection by combining short-cycle polymerase chain reaction (PCR) with the all-dielectric metasurfaces. To the best of our knowledge,

this ultimate detection has not been attained in any other techniques such as a current gold-standard technique of digital PCR.

This study was partially supported by NIMS project “Biomaterials” and a cross-ministerial Strategic Innovation Promotion (SIP) Program, Japan.

Abstract: In this study, we demonstrate the fabrication of a dual-mode miniature surface plasmon resonance (SPR) sensor using a polymeric grating prism made from a UV-curable adhesive, specifically Norland Optical Adhesive 61 (NOA 61), employing a confined sessile drop technique.

The uniform grating pattern was replicated on a polydimethylsiloxane (PDMS) circular disk with a 6-mm diameter. A hemispherical prism with a grating structure was created by directly dropping liquid NOA 61 onto the grating–PDMS circular disk. The resulting NOA61 polymeric grating prism was obtained after curing under UV irradiation. Subsequently, a 3-nm chromium layer and a 47-nm gold layer were deposited on the grating side of the fabricated prism, followed by the integration of a microfluidic cell, resulting in the complete dual-mode miniature SPR sensor chip. The SPR excitation of the dual-mode SPR sensor chip was observed through wavelength modulation at fix incident angles. As shown in Fig. 1, the results demonstrated SPR reflectivity curves spanning the vis–NIR region. The mode of each SPR reflectivity curve was elucidated by comparing the SPR dip of the experimental results with the calculated surface plasmon (SP) dispersions. Two types of SPR modes were identified: prism-coupling SPR mode (PC-SPR mode, corresponding to $+SP^{0}$ of the gold–NOA 61 interface) and grating-coupling SPR mode (GC-SPR mode, corresponding to $-SP^{+1}$ of the gold–air and gold–NOA 61 interfaces). The dual-mode SPR sensor demonstrated selective sensitivity by incorporating materials onto a gold-coated grating prism that matched the refractive index of the target analyte and exhibited overlapping absorption at the specific SPR excitation wavelength. Its enhanced response and significant wavelength amplification allow accurate performance in selective sensing situations.

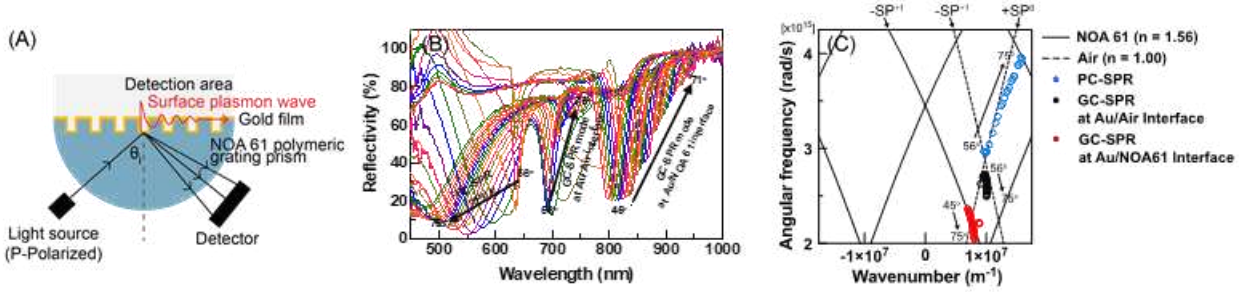

Fig. 1. (A) Schematic drawing of the dual-mode miniature SPR sensor chip. (B) SPR reflectivity curves in the air. (C) Experimental results of dual-mode SPR and calculated results of the dispersion of SPs at the gold-NOA 61 (full lines) and gold-air (dash line) interfaces.

Abstract: Optical biosensors with digital readout format for ultrasensitive biomarker analysis will be presented. It is based on counting of individual affinity-captured biomolecules by using the combination of optical plasmonic enhancement and enzymatic as well as non-enzymatic amplification without the need of compartmenting the analyzed sample.

In order to reach the ultimate single molecule sensitivity of affinity biosensors, a combination of optical and molecular interaction - based amplification means is pursued. Firstly, tailored metallic nanostructures are employed for the plasmonically-enhanced fluorescence detection that is suitable for readout on sufficiently large sensor surface areas.[1,2] These metallic nanostructures carry biorecognition elements that allow to specifically capture target analyte molecules from the analyzed liquid sample. In order to maximize the optical sensor response associated with probing the captured target analyte by the enhanced electromagnetic field of resonantly excited surface plasmons, approaches for nanoscale control of the attachment to the so called 'plasmonic hotspots' are explored through plasmon-enhanced photochemistry[3]. The response to specific affinity binding events is further enhanced by rolling circle amplification or through enzyme-free catalytic hairpin assembly method in order to associate the individual affinity capture target molecules with bright fluorescence spots.[4] Lastly, the important issue on the mitigation of false positive response events due to the unspecific sorption of bioassay constituents to the surface is addressed by antifouling polymer biointerfaces.[5] The presented methods will be put to context with liquid biopsy – based lung and melanoma cancer diagnostics through ultrasensitive detection of trace amounts of specific biomarkers circulating in blood.

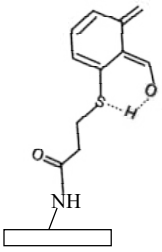
Plasmonic Immunosensor Platform Composed of a Capture Interface Formed by Photochemical Reaction

K. Tawa[1*]

[1]Kwansei Gakuin University, Japan
[*]corresponding author: ktawa@kwansei.ac.jp

Abstract: Plasmonic chips were prepared by coating periodic patterns with metal films. By exposing the surface modified with photoreactive P-*O*-MBA to the light, the intermediate was photochemically reacted with maleimide-labeled molecules on the pattern within the exposure spots. Multi-arrayed spots can induce high-throughput detection with reaction promotion and enhanced fluorescence.



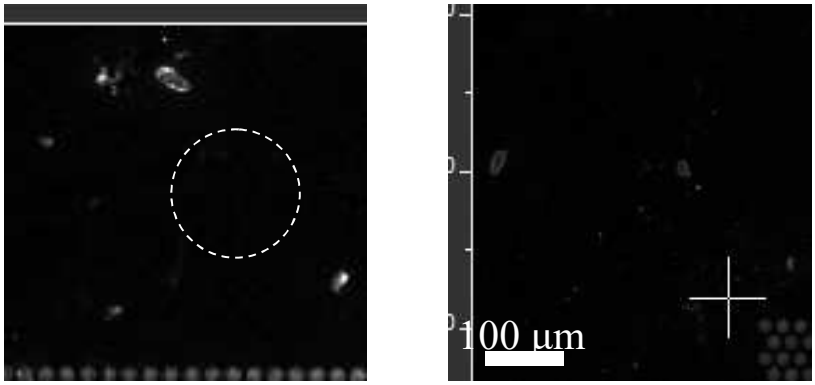


Figure 1. Intermediate of P-O-MBA formed on a plasmonic chip exposed to the light.

Plasmonic sensor platform is available to the photochemical reaction promotion and emission enhancement. Plasmonic chip surface was modified with a photoreactive molecule 3-((2-formyl-3-methylphenyl) thio)propanoic acid (*O*-MBA) (Figure 1) [1] and it has photochemically reacted with Cy5-maleimide (Cy5-M) after exposure to UV light. The plasmonic chip enhancement factor for fluorescence E_p and photochemical reaction promotion rate R_p were evaluated using fluorescence intensities inside the plasmonic pattern and outside. As the result, the mean values of E_p and R_p were 12.8 and more than two, respectively [2]. In this study, to prepare the interface capturing a protein, biotin-maleimide (Biotin-M) was added to the *O*-MBA surface of a plasmonic chip after UV or visible light irradiation. A fluorescence intensity was evaluated for the target concentration of Cy5-Streptavidin (Cy5-SA).

The replica of concentric circle called “Bull’s eye” pattern array was fabricated by UV-nanoimprint method. It was coated with silver and silica layers by rf-sputtering method, in which the silver and silica film thickness was prepared at 50 $\pm$ 5 nm and 20 nm, respectively. The pitch of a periodic structure was 480 nm and 2000 of Bull's-eye patterns with 20 μm in diameter were arrayed. *O*-MBA was modified to the aminated chip. The UV (365nm) or visible (417 nm) light was illuminated from back side of plasmonic chip using 100x objective with the upright-inverted microscope (special made, Olympus). After light exposure, *O*-MBA reacted with Biotin-M. Then, fluorescently labeled protein Cy5-SA solution was injected and fluorescence image was observed with upright-inverted fluorescence microscope under the transmitted-light. In the single plasmonic chip, multi-spots were prepared with UV exposure and Cy5-SA solution was individually injected for each spot. Fluorescence image was taken using Cy5 filter unit and 20x objective for excitation (inverted side) and Cy5 filter unit and 10x objective for emission (upright side).

Figures 2(a) and 2(b) show the fluorescence images of Cy5-SA prepared at 10 nM after the UV light exposure and without exposure, respectively. The broken lines depicted in Figure 2(a) corresponds to the UV exposure spot. The fluorescence intensity was evaluated inside the Bull’s eye patterns within the UV exposure spot and it was plotted against Cy5-SA concentration. The linear relationship was found in the calibration curve and it shows that a highly sensitive detection platform for protein detection was constructed by promoting

photochemical reactions and enhancing fluorescence on the plasmonic chip

(a) (b)

Figure 2. Fluorescence images of Cy5-SA prepared at 10 nM: (a) fluorescence image after exposure to UV light and (b) fluorescence image without exposure to UV light. The broken circle corresponds to UV exposure spot.

Abstract: We developed a Gaussian-to-top-hat metasurface beam shaper for spherical incident waves. Using dielectric pillar meta-atoms made of a-Si, a uniform intensity distribution of ±9.31%RMS and absolute diffraction efficiency of 72.1% were obtained. Fluorescent imaging was demonstrated using the fabricated metasurface.

1. Introduction

Highly uniform illumination is a crucial requirement for observation in the medical field. For this purpose, top-hat beam shapers based on refractive optical elements (ROE) or diffractive optical elements (DOE) are widely used. However, their bulky size, fabrication difficulty, and deterioration of uniformity due to zero-order light have been problems. In this study, we aim to develop a top-hat beam shaper based on dielectric metasurface for the near-infrared region using waveguide-type meta-atoms. As a result, we realized an ultra-thin optical element that converts the incident-diverging Gaussian beam from an optical fiber into a wide top-hat beam.

2. Methods

From the geometric transformation technique[1], the phase profile of a top-hat beam shaper $\varphi_{\mathrm{gt}}(r)$ is given by:

$$\varphi_{\mathrm{gt}}(r) = \frac{2\pi}{\lambda l}\int_0^r \left[\frac{w_2}{2}\left[\frac{1-\exp(-8\xi^2/w_1^2)}{1-\exp(-2D^2/w_1^2)}\right]^{1/2} - \xi\right] d\xi, \tag{1}$$

where r is the radius from the optical axis, λ is the wavelength, D is the diameter of the beam shaper, w_1 is the waist diameter of the incoming collimated Gaussian beam, w_2 is the diameter of the outgoing top-hat beam, and l is the propagation distance. As equation (1) assumes collimated input, we have to take the phase profile of a spherical lens into account to consider the diverging Gaussian beam:

$$\varphi_{\mathrm{sph}}(r) = -\frac{2\pi}{\lambda}\left(\sqrt{r^2+f^2} - f\right), \tag{2}$$

where f is the focal length. Thus, in this study, the total phase profile of $\varphi(r) = \varphi_{\mathrm{gt}}(r) + \varphi_{\mathrm{sph}}(r)$ is used to design the metasurface beam shaper.

3. Fabrication

The phase profile $\varphi(r)$ designed at the wavelength of 805 nm is expressed as a dielectric metasurface that consists of amorphous silicon (a-Si) pillar waveguide meta-atoms. Pillars are arranged in a square lattice and have square cross-sections with widths w = 110–220 nm. The phase delay and transmittance were obtained by electromagnetic field analysis.

The fabrication procedure of the metasurface is shown in Fig. 2. An a-Si layer is deposited on a 2 cm square glass substrate; a resist pattern was drawn on the substrate using an electron-beam (EB) lithography. Chromium was vacuum-deposited, and the resist was removed by lift-off. Finally, silicon was etched by deep-reactive ion etching (DRIE), and the chromium was removed to complete the process.

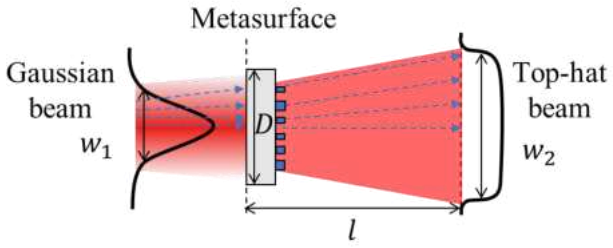

Fig. 1 Schematic of top-hat metasurface

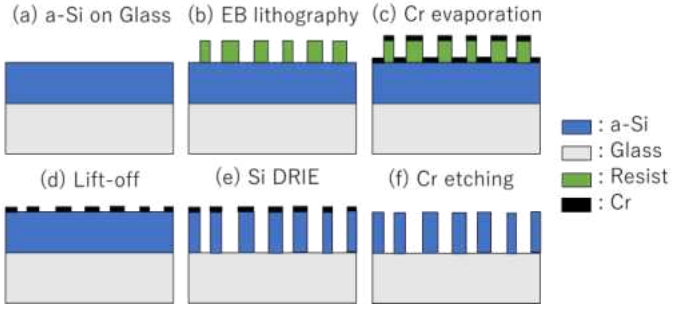

Fig. 2 Schematic diagram of metasurface fabrication procedure.

4. Results

Fig. 3 shows the observed beam intensity profile of the fabricated metasurface at a propagation distance of 100 mm. A fiber-coupled laser source with a wavelength of 808 nm and a numerical aperture of 0.37 was used. As a result, a highly uniform top-hat profile with an intensity variation of ±9.31%RMS and a high diffraction efficiency of 72.1% were obtained. Fluorescence observation was performed using the shaped top-hat beam. Fig. 4 shows the setup of the optical system, and Fig. 5 shows the observed fluorescence image. As a result, we confirmed the fluorescence was stable enough to recognize a letter.

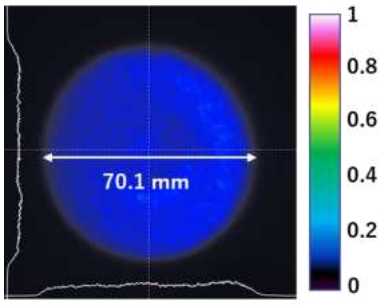

Fig. 3 Observed beam profile.

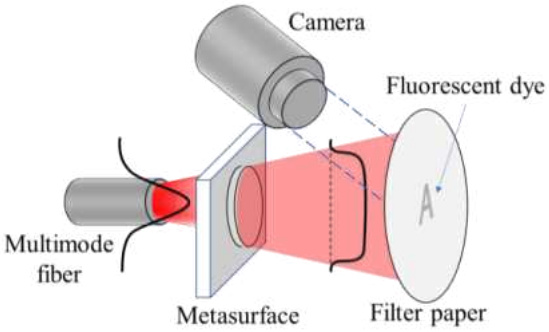

Fig. 4 Schematic image of the optical system of fluorescence observation.

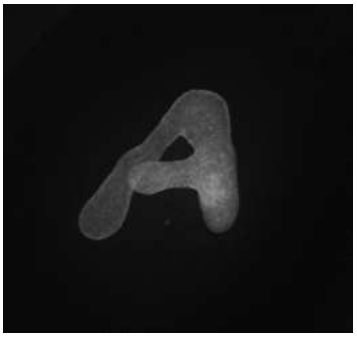

Fig. 5 Fluorescence image.

5. Conclusion

In summary, we developed a Gaussian-to-top-hat metasurface beam shaper for spherical incident waves. As a result, a highly uniform top-hat profile with an intensity variation of ±9.31%RMS and a high diffraction efficiency of 72.1% were obtained. Furthermore, observation using the shaped top-hat beam confirmed that the fluorescence was stable enough to recognize a letter.

High Transmittance 3D Metasurface Holograms Made of SiN for Multicolor Projection with Time-division-multiplexing Method

T. Onozawa[1], J. Beppu[1], M. Yamaguchi[1], and K. Iwami[1*]

[1]Tokyo University of Agriculture and Technology, Japan
[*]corresponding author: k_iwami@cc.tuat.ac.jp

Abstract: We developed large-area 3D metasurface holograms observed with the naked eyes for multicolor projection in the time-division-multiplexing method. Using dielectric SiN pillar meta-atoms, a high transmittance of 81 % was achieved. We also demonstrated an automatic optical system for the multicolor projection.

Holography is a technology that records and reconstructs light waves. Three-dimensional (3D) holography provides natural stereopsis without eye fatigue, and they are expected to be applied to displays, AR/VR devices, and high-security systems. Especially, as metasurface holograms have a wide viewing angle Θ, which is given by $2\arcsin(\lambda/2p)$, due to an array period p of meta-atoms that is smaller than a wavelength λ, it is assumed to be a key technology for these applications. In this context, it is necessary to be reproduced as a multicolor animation with naked eyes observation without using bulky objective lens[1]. In this study, we aim to large-area dielectric 3D metasurface holograms for multicolor projection. As shown in Fig. 1, we made an array of metasurface holograms for the three primary colors respectively, and we projected it by a time-division-multiplexing method.

Metasurface holograms consist of a square lattice of silicon nitride (SiN) meta-atom with a regular octagonal cross section. SiN is chosen due to its high transmittance in the visible light range[2]. We calculated the phase distribution φ of holograms by angular spectrum method. We also overlayed the prism phase given by:

$$\psi = \left(2\pi x/\lambda\right)\sin\theta\,, \tag{1}$$

where λ is the wavelength, x is the position in the direction of each pixel, and θ is the bending angle ($\theta = 20$ deg), on the calculated phase distribution to avoid overlap between the $+1^{st}$ image and the -1^{st} image. Thus, the reproduced the total phase distribution Φ given by:

$$\Phi = \varphi + \psi. \tag{2}$$

To reproduce this phase distribution, we calculated meta-atoms' phase delays and transmittance by the finite element method. They are the height of 1625 nm, and an array period of 404 nm, 340 nm, and 284 nm for λ_1, λ_2, λ_3= 638 nm, 532 nm, and 450 nm. Based on the results, as shown Table 1, we adopted the meta-atoms whose width ranges is 100-280 nm for λ_1, 90-210 nm for λ_2, and 90-180 nm for λ_3 to cover the 2π phase range with an average transmittance over 96 %. By these meta-atoms, the hologram phase distributions were finely discretized in 16384 $\times$ 16384 pixels to realize the large-area metasurface holograms. We adopt the time-division-multiplexing method for multicolor holographic projection. Each hologram is designed to reconstruct each color part of a 3D multicolor model so that they can be seen as overlayed by high-speed frame switching as Fig. 1.

The fabrication procedure of metasurface holograms is shown in Fig. 2. We used a glass substrate on which SiN was sputter-deposited. The substrate was coated with a resist, the pattern was drawn by electron beam lithography, and chromium was deposited by vacuum evaporation. The resist was removed by lift-off, the SiN was

scraped by reactive ion etching (RIE), and finally, the chromium was removed by wet etching to complete the

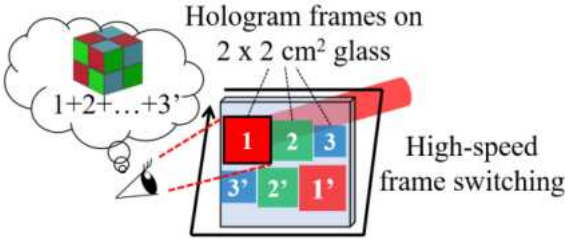

Fig. 1 Schematic of metasurface hologram for multicolor projection hologram. Their structures captured by SEM are shown in Fig. 2.

Table 1 Meta-atoms at each wavelength

Wavelength [nm]	638	532	450
Array period [nm]	404	340	284
Width range [nm]	100-280	90-210	90-180
Ave. transmittance	0.973	0.970	0.962

Fig. 3 shows the reproduced holographic images for each wavelength by the fabricated metasurface holograms. For red and green wavelengths, reconstruction was successful without overlapping with the 0^{th} and -1^{st} images due to the prism phase of 20 deg, as shown in Fig. 3. The blue reconstructed image was blurred because wide meta-atoms were not scraped by RIE in such a narrow array period of 284 nm. Hologram sizes were 6.6 mm, 5.6 nm, and 4.7 nm square for λ_1, λ_2, λ_3, respectively, so that they are large enough to be observed with the naked eyes. Their transmittance was 83 %, 81 %, and 78 % for each wavelength. We demonstrated the time-division-multiplexing method, in which the hologram array is mounted on a biaxial automatic stage and all frames are projected alternately with laser blinking repeatedly. When fast-forwarded in 42 fps (frame per second), images were multiplexed. However, it occurred deviations between each image. Simulating of the correction for them, less than 10 % deviation is required for multiplexing holographic images.

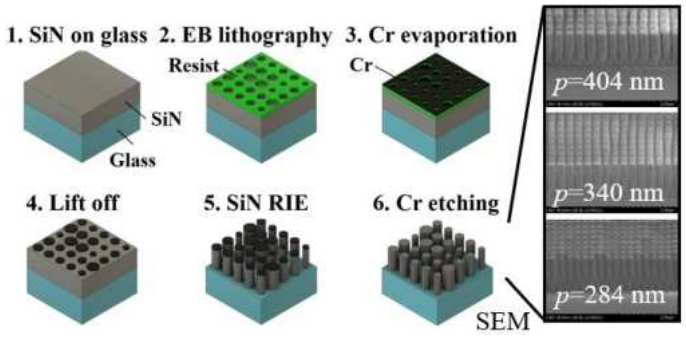

Fig. 2 Fabrication procedure and SEM

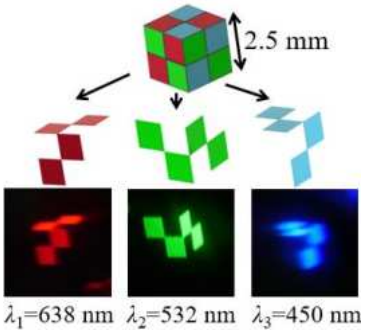

Fig. 3 Reconstructed images

We achieved 3D metasurface hologram for the three primary colors and evaluated 3D holographic multicolor projection by time-division-multiplexing method. The future plans are correction for the deviations between the images and developing holograms of simultaneous multicolor projection.

Abstract

Optical spectroscopy has become a widely used tool for various areas in science and technology. Most commercial spectrometers are bulky and exploit diffractive optics. Here we present a miniaturized design that can be utilized for hyperspectral imaging. Based on dielectric metasurfaces and Fabry-Perot resonances it facilitates optics which are directly compatible with photodetectors.

Development of Vapor Cells Based on Tri-functional Metasurface for Microfabricated Atomic Clock

R. Ito[1], P. Prutphongs[1], K. Aoki[1], S. Ikezawa[2], M. Hara[3], and K. Iwami[1*]

[1]Tokyo University of Agriculture and Technology, Japan
[2]Waseda University, Japan
[3]National Institute of Information and Communication Technology, Japan
[*]K. Iwami: k_iwami@cc.tuat.ac.jp

Abstract: We report on a microfabricated vapor cell based on tri-functional metasurfaces that combine lens, prism, and quarter-wave plate. The fabricated metasurface showed a high deflection efficiency of 65.4%, a degree of circular polarization (DoCP) of -0.78, and a focal length of 511 μm.

Atomic clocks are the most precise timing device, and the importance of time synchronization in the realization of ultra-high-speed communication between IoT devices and smartphones requires the development of microfabricated atomic clocks that can be installed in these devices. Based on the reflective vapor cells in the previous studies[1,2], this research aims to develop a highly efficient and compact reflective optical cell combining a metasurface and Si cavity with integrated deflection, quarter-wave plate (QWP), and collimating functions.

In this study, we fabricate a tri-functional metasurface consisting of a square lattice of subwavelength pillars made of hydrogenated amorphous silicon (a-Si:H) meta-atoms. The QWP function can be achieved by satisfying equation, and the library was created with meta-atoms that satisfy this equation.

$$\varphi_y(w_x, w_y) = \varphi_x(w_x, w_y) + \frac{\pi}{2}, \tag{1}$$

where φ_x, φ_y are phase delay, and w_x, w_y are pillar widths. Phase profiles φ_{prism} and φ_{lens} for the prism and collimator lens are expressed as follows;

$$\varphi_{\text{prism}} = \frac{2\pi}{\lambda} x \sin\theta, \tag{2}$$

$$\varphi_{\text{coll}} = -\frac{2\pi}{\lambda}\left(\sqrt{x^2 + y^2 + f^2} - f\right), \tag{3}$$

where λ is operating wavelength, and f is the focal length of lens, θ is the beam deflection angle, and (x, y) are the coordinate on the metasurface. The prism and collimator functions can be integrated by superposition of the phase profiles of equations. (2) and (3), and the three functions are integrated by placing meta-atoms from the meta-atom library that satisfy equation. 1.

Electromagnetic field analysis was performed for a-Si:H pillars to determine meta-atom parameters. The shape of the pillar is rectangular. As a result of the analysis, it was decided to use a 750-nm-high column that exhibits high transmittance and a phase delay of 0-2π at 795 nm, the operating wavelength.

The fabrication process of the metasurface is shown in Fig. 2. Initially, resist patterns were drawn by electron beam (EB) lithography on a glass substrate on which a-Si:H layers were deposited. Next, chromium was vacuum deposited and the resist was removed by lift-off. Finally, the process was completed by etching the silicon by deep reactive ion etching (DRIE) to remove the chromium.

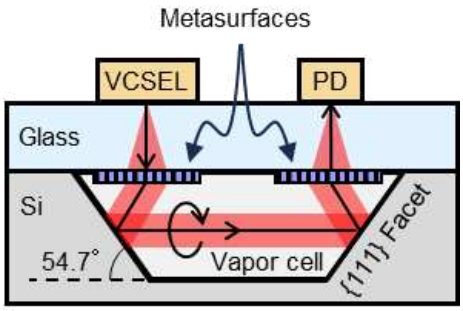

Fig. 1 Schematic of vapor cell

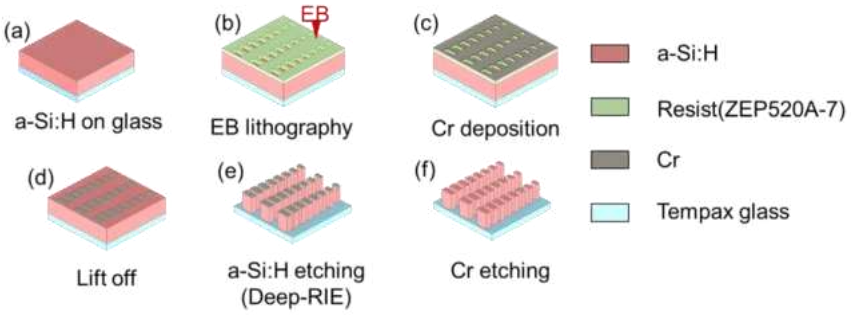

Fig. 2 Fabrication process

First, as a prototype, we fabricated metasurface with only two functions, deflection and QWP functions. The metasurface showed a high deflection efficiency of 84.1% and a DoCP of -0.90. Subsequent, the prototype metasurfaces and Si cavity were combined to simulate a vapor cell as shown in Fig. 3. The optical system shown in Figure 4 was used to measure the light yield of the vapor cell. The measurement showed a light yield of 2.2%. While there is room for improvement in light yield, as the theoretical value is 7.05%, we confirmed that the vapor cell function. Moreover, a 56.8% of light yield can be expected by depositing HR coating on the cavity surface.

Next, we fabricated tri-functional metasurface with deflection, QWP and collimating functions. The fabricated metasurface showed a high deflection efficiency of 65.4%, a DoCP of -0.78, and a focal length of 511 μm. From the above, it was confirmed that the three functions are performed simultaneously.

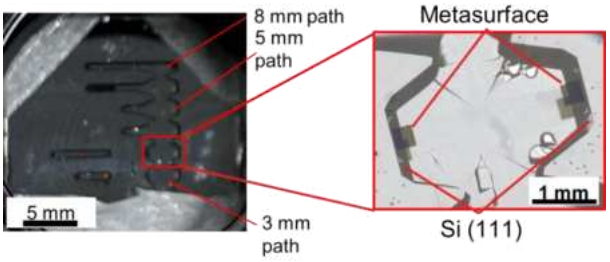

Fig. 3 Fabricated vapor cell

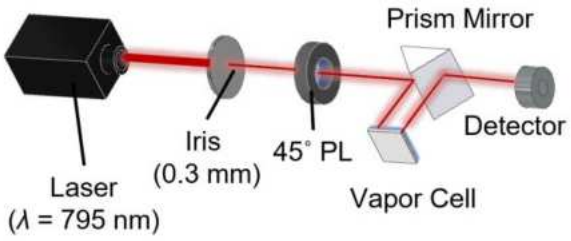

Fig. 4 Optical system used for light yield measurement

The objective of this study was to develop a reflective vapor cell with metasurfaces that integrate three functions. The two-function metasurfaces successfully measure light yield when combined with Si cavity. On the other hand, there is room for efficiency improvement in the tri-functional metasurface, so the light yield has not yet been measured. In the future, we would like to improve the efficiency of tri-functional metasurface and combine them with HR coated Si cavities for evaluation.

All-optical spectral control by perfect absorber based on quadrupole resonance and photothermal effect

Seiya Shinkai[1], **and Junichi Takahara**[1*,2]

[1]Graduation School of Engineering, Osaka University, Japan
[2]Photonics Center, Osaka University, Japan
[*]corresponding author: takahara@ap.eng.osaka-u.ac.jp

Abstract: We study all-optical spectral control of silicon metasurface by photothermal effect. We fabricated a perfect absorber based on metasurface which supports two degenerated quadrupole modes. In this study, we demonstrate 8nm red-shift and the modulation of transmission spectra induced 3% increase by 90K temperature rise.

1. Introduction and purpose

The importance of all-dielectric metasurfaces made of high refractive index materials for nanophotonics have been increasing year and year because of the development of large scale optical integrated circuit. The metasurfaces can support some kinds of Mie-resonances, such as dipole and quadrupole modes. It's known that they can achieve perfect absorption (PA) based on degenerate critical coupling (DCC) theory. The absorption equation is as follows,

$$A(\omega) = \frac{2\gamma_1\delta_1}{(\omega-\omega_1)^2+(\gamma_1+\delta_1)^2} + \frac{2\gamma_2\delta_2}{(\omega-\omega_2)^2+(\gamma_2+\delta_2)^2}, \quad (1)$$

where ω, ω_1 and ω_2 are the resonance frequencies of the incoming wave, one resonance mode, and the other mode, respectively, and γ_1, δ_1, γ_2, and δ_2 are the radiative and intrinsic losses of each mode, respectively [1]. According to Eq. (1), the absorption becomes unity at the resonance ($\omega = \omega_1 = \omega_2$) when the radiative and intrinsic losses for two modes ($\gamma_1 = \delta_1$, $\gamma_2 = \delta_2$) are matched. Hence, we can achieve PA of the dipole as well as quadrupole modes. The advantage of PA based on quadrupole modes is that they show strong confinement inside the Mie-resonator, hence the dependence on period is small.

Photothermal effect, which changes refractive index of materials, is studied as one of the methods of controlling optical properties [2]. The superior of thermal tuning is that it can realize active control without adding another structure and refractive index changes continuously. The merit keeps metasurface flat and leads to realize various modulations. Recent studies combinate nanostructure and thermo-optical (TO) effect and realized the high modulation of near-field optical properties from Mie-scattering in nanoseconds scale [3]. In this study, we design the metasurface to control transmission of signal light by controlled light, which induces TO effect at the far-field. We experimentally demonstrated the spectral shift of transmission by TO effect.

2. Result and discussion

Figure 1(a) shows the all-optical switching of periodic crystalline-silicon (c-Si) nanostructure on quartz is shown in Fig. 1(a). The mechanism is such temperature rising by photothermal effect due to absorption of light energy excites TO effect and modulates the optical responses of c-Si. We design the metasurface such that PA is achieved at light wavelength $\lambda = 450$nm by DCC of electric quadrupole (EQ) and magnetic quadrupole (MQ) and 0% transmission at $\lambda = 543$nm caused by electric dipole (ED) at the condition of radius r =89nm, height h = 100nm and period P = 265nm (see Fig. 1(b)). Since ED mode is sensitive to temperature, it is suitable to control the transmission of light. The transmission increases ~30% at maximum. The excitation intensity is only $1.1\text{mW}/\mu m^2$.

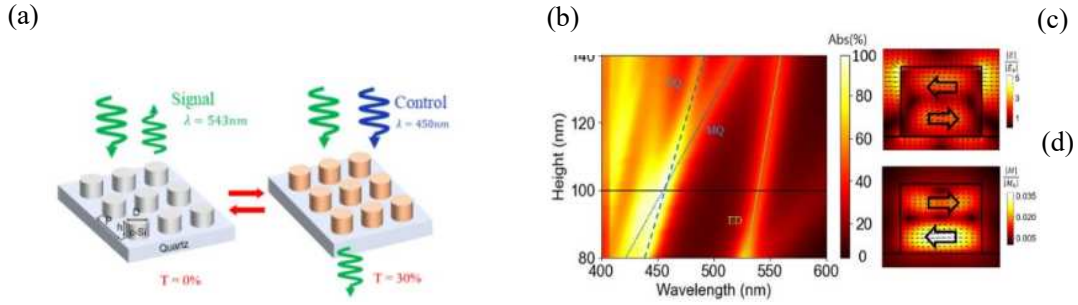

Fig. 1 (a) Concept of all-optical control based on Si metasurface, (b) absoption spectral map for different heights and the spatial distributions of (c) EQ and (d) MQ modes, which are normalized to the amplitude of the incident E_0 and M_0, respectively.

We fabricated the sample by using a silicon-on-quartz substrate (SOQ). Figure 2(a) shows the image of the sample taken by the focused ion beam (FIB) system. It is observed that the top shape of Mie resonator is not circle perfectly but ellipsoidal. Figure 2(b) shows the experiment results of transmission and absorption spectra. Regarding to the measurement, we heated the sample placed on a ceramic heater and measured temperature dependence of transmission. The result is shown in Fig. 2(c), where the red-shift of transmission spectra by TO effect is observed. Due to temperature rise, both of real and imaginary parts of refractive index increase, which leads spectral red-shift and the decrease of Transmission. We observed that higher Transmission at 300K becomes lower one at 393K. In the future, we will use CW laser to heat up samples and expand spectral range from visible to telecommunication wavelength. Our research suggests that the proposed structure can be applied for photodetectors, wave front control and all-optical switches.

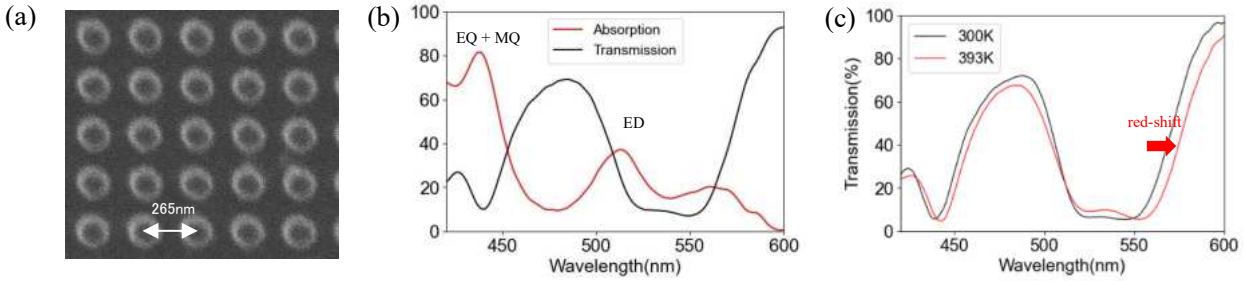

Fig. 2 (a) FIB image of the fabricated sample, (b) measured results transmission (black line) and absorption (red line) spectra and (c) transmission spectra measured at 300K (black line) and 393K (red line).

Development of wide-angle metalenses capable of simultaneously capturing near and far-view images

A. Hasegawa[1], R. Yamada[1], K. Ozawa[2], Y. Abe[2], M. Taoka[2], T Yamagishi[2], and K. Iwami[1*]

[1]Tokyo University of Agriculture and Technology, Japan
[2]Samsung R&D Institute Japan, Japan
[*]K. Iwami: k_iwami@cc.tuat.ac.jp

Abstract: We developed wide-angle metalenses capable of simultaneously capturing near and far view images. From the imaging evaluation at object distances of 5.3 mm and 15.7 mm, near and far view metalenses had angular field of views of 86.7° and 103.7°, respectively. We successfully captured simultaneous images using the fabricated metasurface.

Miniaturization of imaging lenses is strongly demanded from the viewpoint of applications in the automotive and medical industries. However, this is difficult to achieve with conventional lenses. In this study, our objective is to develop wide-angle metalenses that can simultaneously capture objects at the near and far regions with a single image sensor, as shown in Fig. 1. Our metalenses are to operate in visible light while utilizing the principle of an aperture integrated ultra-wide-angle metalens proposed in a previous study[1].

In this study, we fabricate a metalens consisting of a square lattice of tiny SiN pillars (meta-atoms). The phase distribution of the metalens fabricated in this research follows the following equation;

$$\varphi(r) = \sum_{j=1}^{9} C_j \cdot r^{2j}, \tag{1}$$

where r is the radial coordinate of the lens, C_j are coefficients to optimize the phase distribution so that the metalens has a wide field of view and high resolution. C_j for far and near metalenses are optimized using commercial ray optics software.

Electromagnetic field analysis was performed to determine the relationship between the width of the SiN pillars and the transmittance and phase delay of the transmitted light. The pillars are arranged in a square lattice and have a regular octagonal cross section. The design wavelength is 633 nm, the pillar height is 1625 nm, and the meta-atom pitch is 404 nm. Based on the analysis results, a design value of 114 nm to 312 nm was determined for the design width, which satisfies high transmittance and a phase delay of 0–2π.

The fabrication process of the metalens is shown in Fig. 2. First, (a) resist is coated glass substrate on SiN, and the structure is transferred using an electron beam lithography system. (b) Next, Cr is deposited, and (c) the resist is removed by lift off. (d) The substrate is then inverted, resist is applied, and the structural pattern on the aperture surface is exposed using a photolithography system. (e) After depositing Al, (f) the resist is removed by lift off to complete the aperture surface. (g) After the aperture surface is completed, the substrate is reversed and SiN is removed by reactive ion etching, and (h) unnecessary Cr is removed by Cr etching to complete the metalens.

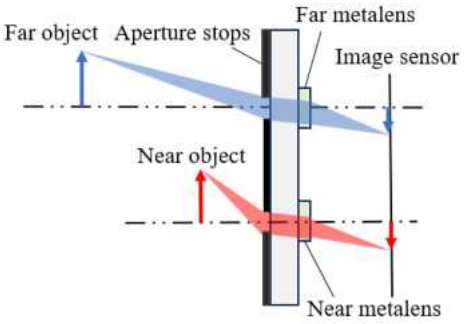

Fig. 1 Schematic of simultaneous capturing metalenses

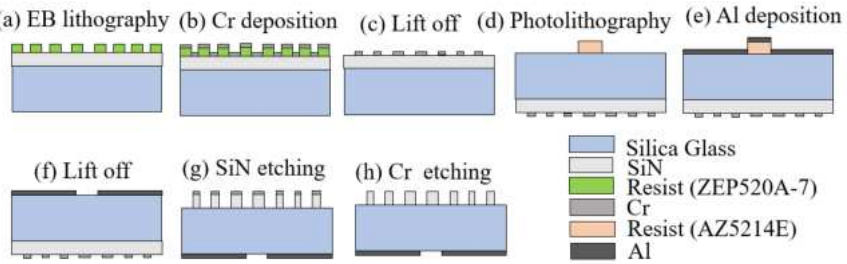

Fig. 2 Fabrication process

Fig. 3 shows photographs of a plastic ruler taken under ring illumination at a wavelength of 633 nm with (a) near and (b) far metalenses at object distances of (a) 5.3 mm and (b) 15.7 mm, respectively. A transparent plate was inserted between the object and the lens. The angular fields of view of the near and far-view metalenses read from the captured images were 86.7° and 103.7°, respectively, which decreased compared to the designed values. The reasons for the decrease in the angular field of views are the meta-atom design that limits the maximum oblique incident angle and the meta-atom fabrication error. Fig. 4 shows a photograph that consists of near and far-views captured simultaneously by a single image sensor. Two objects of a barcode placed at 16 mm and the logo mark of the Tokyo University of Agriculture and Technology at 5.3 mm are used, and the right and left halves of Fig. 4 show the near and far-views, respectively. The barcode and the logo mark were clearly imaged in the far and near view images, respectively, and simultaneous imaging was achieved.

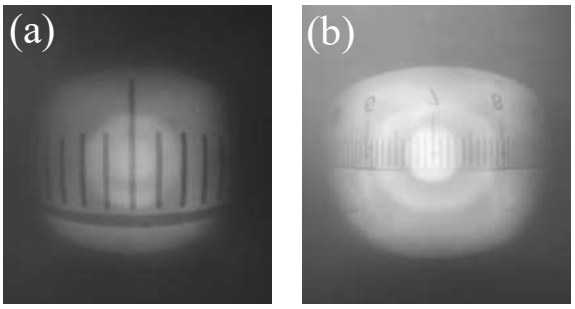

Fig. 3 Images of a plastic ruler taken with fabricated metalenses for (a) near, and (b) far views

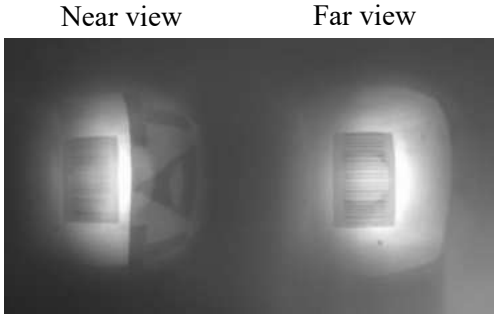

Fig. 4 Simultaneously captured near and far views

The purpose of this study was to design, develop, and demonstrate wide-angle metalenses capable of simultaneously capturing near and far views. From the imaging evaluation, near and far view metalenses had angular field of views of view of 86.7° and 103.7°. And the near and far view images were clearly formed together. In the future, we aim to bring the angles of view of metalenses closer to the designed value.

Enhancing the photo sensitivity of photo detector using nanophotonics approach

Soh Uenoyama[1*]

[1]Central Research Laboratory, Hamamatsu Photonics K.K.,

5000, Hirakuchi, Hamana-ku, Hamamatsu City, 434-8601, Japan
[*]Corresponding author: so.uenoyama@crl.hpk.co.jp

Abstract: Silicon photomultiplier has been used in various applications due to its excellent photon counting ability. We demonstrated the enhancement of the sensitivity by focusing incident photon on the photo-sensitive area of pixel using metalens array. Additionally, we report on various nanophotonic approaches for enhancing the performance of the photodetector.

Silicon photomultiplier (SiPM) has been applied in many kinds of applications such as flow-cytometry, light detection and ranging (LiDAR) due to its excellent photon counting ability. SiPM contains many single avalanche photo diode (SPAD), which operates at a Geiger mode. SPADs usually have a trench area at the boarder of each SPAD. However, it not only enables to shield crosstalk but also has known to be low-photo sensitive area. Thus, improve the performance of SiPM, such as photon detection efficiency (PDE) and timing performance requires the focusing incident photon on the photo sensitive area of SPAD while avoiding illumination to the trench areas. Our previous work demonstrated the improvement of the performance of SiPM for focusing incident photon on the photosensitive area of each SPAD using metalens array [1]. However, separated configuration between metalens and SiPM can cause the miss alignment even at a small vibration.

We thus monolithically integrated metalens with SPAD using whole CMOS process at a chip-scale for providing stable enhancement of using metalens [2]. As a result, we experimentally demonstrated the improvement of PDE >70% at a wavelength of 404 nm. Additionally, we investigated wavelength-dependent and incident angle dependent characterization for considering scintillation applications. For angle-dependent characterization, the metalens-integrated SiPM exhibits the robust performance toward the oblique incidence even at 45 degrees. In addition, for wavelength-dependent characterization, it exhibits the robust performance toward the broad wavelengths >50%, in the wavelength of 375- 450 nm. Furthermore, we are going to introduce the nanophotonis approach which effectively affects the improvement of photo sensitivity at a near infrared wavelength band.

Abstract:
Signal nonlinearity is an essential factor in all-optical switching and super-resolution imaging applications. In our research, we demonstrated strong photothermal nonlinear scattering from silicon Mie nanoresonator via utilizing several different approaches: quasi-perfect absorbing metasurface, displacement excitation by focused laser beam and optical bistability.

Silicon nanostructures efficiently support multiple modes of Mie resonances in visible wavelength region due to silicon's high refractive index and low loss optical properties, forming an important basis of the future Mie-tronics devices including optical nanoantenna, structural color pixels and metasurface[1]. While these linear scatterings in the silicon Mie resonators are widely utilized, the nonlinear property of scattering intensity is critical to extending the applications of Mie-tronics toward all-optical switching and super-resolution imaging[2,3]. In particular, our group previously discovered that the iterative photothermal and thermo-optic effect in Mie-resonant silicon nanostructure triggers the giant nonlinear relationship between scattering and excitation intensities, which is a few orders larger than that induced by Kerr nonlinearity[4], leading to significantly improved modulation depth in all-optical switching and spatial resolution in optical imaging.

In this talk, we would like to present our recent studies to further enhance the photothermal nonlinear scattering from Mie resonant silicon nanostructures. The first approach is based on critical coupling in silicon metasurface to enhance optical absorption as well as photothermal effect[5]. We designed a silicon Huygens' metasurface that exhibits quasi-perfect absorption and unidirectionality of scattering signal through matching the material loss with its radiative loss, i.e. critical coupling. By illuminating the metasurface with the single wavelength laser light at the resonance, the forward scattering signal shows sub-linear increases versus excitation intensity, while the backward scattering signal presents a super-linear trend, featuring all-optical dynamic scattering controls. Due to the high absorption of the metasurface, the required excitation intensity to induce nonlinear scattering is one-order reduced compared with that of the single silicon nanoparticle, representing low-energy consumption switching.

Another approach is the introduction of "displacement resonance", which we discovered by applying confocal laser scanning microscopy to observe silicon nanostructures[6]. The surprising finding is that when a focused light spot diameter and a silicon nanostructure are of similar sizes, not much smaller nor much larger, changing their relative positions triggers new high-order resonances that are not allowed with conventional paraxial excitation. The displacement resonance leads to a counterintuitive situation that the light-matter interactions, including scattering and absorption-induced nonlinear optical effects, are not maximal when laser focus is aligned with the particle, but become maximized when the focus spot is about 100 nanometers off-center. Combining displacement

resonance with photothermal nonlinearity, we are going to show application examples including reduction of nonlinearity threshold, sign flip of all-optical switching, and resolution enhancement, etc.

Furthermore, we recently proposed to use optical bistability to generate a steep super-linear scattering response in silicon Mie resonator[7]. It is well known that optical bistability requires the combination of nonlinear refractive index and a resonant cavity. Conventionally, because of the small nonlinear refractive index of silicon, the optical bistability of silicon optical devices was mainly limited to high-Q microcavities, for example, ring resonators or photonics crystal, whose footprints are in the order of 1-10 micrometers. As mentioned earlier, we efficiently utilized the photothermal and thermo-optic effects responses to enhance the nonlinear refractive index magnitude in nano-silicon, thus relaxing the requirement of the high-Q cavity. We experimentally and theoretically discovered optical bistable states in a single silicon nanoparticle with a Q-factor < 10 and cavity volume size of 10^{-3} μm^3, both are record low. The bistability leads to an abrupt super-linear jump of scattering intensity, reaching over ~100th order of excitation intensity. We expect it would dynamically improve both performances of all-optical switching and super-resolution microscopy.

High-sensitivity image sensors based on dispersion-engineered metalenses

Masashi Miyata*

NTT Device Technology Laboratories, NTT Corporation, 3-1, Morinosato Wakamiya, Atsugi, Kanagawa 243-0198, Japan
*corresponding author: masashi.miyata@ntt.com

Abstract: This talk will review our recent work on dispersion-engineered metalenses for color splitting on sensor pixels, which provide a path toward the development of high-sensitivity color image sensors while maintaining consistency with CMOS sensor technology.

Boosting the sensitivity of image sensors, e.g., to enable optical imaging even in low-light environments, is a never-ending issue in sensor technology [1, 2]. In particular, the development of smartphones with numerous image sensors has increased the importance of this issue. Unfortunately, in most image sensors in use today, the bulk of the incident light does not reach the sensor's photodetectors because all of the photodetectors are covered with light-absorptive color filters. Therefore, the light power detected by the image sensors is essentially capped at around 30% of the incident light power.

Recent advances in optical metasurfaces have enabled the creation of miniature color splitters, which present an opportunity to enhance sensor sensitivity [3–6]. These metasurface-based color splitters can be used as an alternative to color filters for extracting red (R), green (G), and blue (B) color information from photodetectors. Importantly, in contrast to color filters, they can guide the incident light to the photodetectors without significant optical losses, thus maximizing the detectable light power.

Our recent work has enhanced their design by making extensive use of the dispersion-engineered metasurface concept and has resulted in color-sorting metasurface-lenses (metalenses) that simultaneously act as efficient color splitters and micro-lenses [7–9]. The metalenses are consist of a single-layer pattern made of a dielectric material commonly used in the CMOS process, making them compatible with CMOS sensor technology. We demonstrated through both experiments and simulations that image sensors using such metalenses in place of filters dramatically increase the detected light power while maintaining image quality and compatibility with a variety of imaging optics. In addition, a prototype of a metalens-integrated image sensor was built and tested, which revealed its superior sensitivity [10]. Furthermore, the same concept can potentially be applied to a metalens design for splitting RGB and near-infrared (NIR) light, which would improve the sensitivity of RGB-NIR image sensors [11, 12]. This talk introduces these color-sorting metalenses and shows their potential for making filter-free, high-sensitivity color image sensors.

Abstract: When a metallic structure is formed on a semiconductor surface, the hot electrons in the metal excited by surface plasmon resonance (SPR) are extracted as an electric current. By configuring the structure that generates SPR as a continuous one-dimensional metallic diffraction grating structure, it is possible to sharply define the resonance of SPR and perform reconstructive spectroscopy.

Surface plasmon resonance (SPR) is a collective resonance of free electrons on a metal surface in contact with a dielectric. When the light incident on a metal structure satisfies the SPR matching condition, the incident light couples to the free electron resonant vibration on the metal surface. Since the resonance mode changes depending on the metal geometry, a device can operate for specific wavelengths and polarizations. Furthermore, suppose the metallic structure is formed on a semiconductor. In that case, a Schottky barrier is formed at the metal-semiconductor interface, allowing hot electrons to be injected into the semiconductor and extracted as a current, enabling electrical readout of SPR. Furthermore, since the Schottky barrier height can be tuned lower than the silicon band gap, infrared detection becomes possible on a silicon device[1].

By configuring the structure that generates SPR as a continuous one-dimensional metallic diffraction grating structure, it is possible to sharply define the resonance of SPR. Diffraction grating structures have been traditionally used as SPR coupling elements, but combining this surface plasmon coupling function with a current measurement function has revealed the potential for a new type of compact spectrometric device called a reconstruction method. When a device is irradiated with Transverse Magnetic (TM) polarized light of a single wavelength, SPR occurs at an angle satisfying the following dispersion relation (1)[2]:

$$\frac{\omega}{c}\sqrt{\varepsilon_{\mathrm{air}}}\sin\theta + \frac{2m\pi}{a} = \frac{\omega}{c}\sqrt{\frac{\varepsilon_{\mathrm{air}}\varepsilon_{\mathrm{metal}}}{\varepsilon_{\mathrm{air}} + \varepsilon_{\mathrm{metal}}}} \qquad (1)$$

By determining the frequency of the incident light and the permittivity, and solving the dispersion relation (1), the angle at which SPR occurs for a specific wavelength is essentially uniquely determined. Therefore, when TM light of different single wavelengths λ_1, λ_2, and λ_3 is irradiated and the device is angle-scanned relative to the incident light, the angular SPR photocurrent presents peaks at different SPR generation angles θ_1, θ_2, and θ_3 corresponding to λ_1, λ_2, and λ_3, respectively. If these three wavelengths are irradiated simultaneously and angle scanning measurement is performed, the photocurrent measurement value at each angle is expressed as a linear sum of the current amounts for each wavelength, for example, the current measurement value $I_{\theta 1}$ at angle θ_1 becomes

$$I_{\theta_1} = R_{\lambda_1\theta_1}P_{\lambda_1} + R_{\lambda_2\theta_1}P_{\lambda_2} + R_{\lambda_3\theta_1}P_{\lambda_3} \qquad (2)$$

and can be expressed as the sum of the product of the incident intensity and the sensitivity value at that angle. If

the number of irradiation wavelengths is extended to n and current measurement is performed at m angular positions, the current measurement value at each angular position will be a linear sum of the current amounts for each wavelength, so

$$\begin{bmatrix} I_{\theta_1} \\ \vdots \\ I_{\theta_m} \end{bmatrix} = \begin{bmatrix} R_{\lambda_1\theta_1} & \cdots & R_{\lambda_n\theta_1} \\ \vdots & \ddots & \vdots \\ R_{\lambda_1\theta_m} & \cdots & R_{\lambda_n\theta_m} \end{bmatrix} \begin{bmatrix} P_{\lambda_1} \\ \vdots \\ P_{\lambda_n} \end{bmatrix} \quad (3)$$

and it can be written in matrix form as $\boldsymbol{I} = \boldsymbol{RP}$. If the $\boldsymbol{R}$ matrix is derived in advance using a light source with known wavelengths and intensities, the spectral $\boldsymbol{P}$ can be obtained from the vector of current measurement values $\boldsymbol{I}$ at each measurement angle through the simple calculation of the inverse matrix $\boldsymbol{P} = (\boldsymbol{R}^{\mathrm{T}}\,\boldsymbol{R})^{-1}\boldsymbol{R}^{\mathrm{T}}\boldsymbol{I}$. Currently, we have confirmed spectroscopy performance using this method[3], application to gas sensing[4], integration with MEMS[5,] and extension of the measurement wavelength[6].

Spatiotemporal Metamaterials and Metasurfaces

Physics-Driven Vector-Quantized Autoencoder for Space-Time-Coding Matrix

Xiao Qing Chen[1], and Lei Zhang[1] *

[1]State Key Laboratory of Millimeter Waves, Southeast University, Nanjing 210096, China
*Corresponding author: njzhanglei@seu.edu.cn

Abstract: We have designed and trained a physics-driven vector-quantized (PD-VQ) autoencoder model that takes the target harmonic scattering pattern as an input, and this PD-VQ autoencoder model quickly outputs the optimal discrete space-time coding (STC) matrix, which can help the STC digital metasurface to perform agile multi-frequency harmonic beamforming in real-time.

The space-time coding (STC) digital metasurface was proposed by Zhang et al. in 2018[1], whose coding elements can respond dynamically in space and time so that electromagnetic waves can be accurately modulated in both the spatial and frequency domains. The STC matrix is used to characterize the dynamic coding state of each element in space and time, and its design is both critical and complex for STC digital metasurfaces. The computational complexity of traditional optimization algorithms for obtaining STC matrices is very high, which makes the efficiency of obtaining STC matrices very low (especially when the matrix dimensions become large), thus hindering the practical application of STC digital metasurfaces to a certain extent.

Therefore, we propose an encoding strategy based on a physics-driven vector-quantized (PD-VQ) autoencoder [2, 3], which consists of an encoder, a vector-quantizer layer, and a physics-driven decoder. The target scattering pattern is used as the input to the encoder and the corresponding optimized STC matrix is output. Considering that the operating states of the elements are discrete, the discrete STC matrix is obtained with the help of the vector quantization layer. Finally, the physical operation mechanism between the STC matrices and the harmonic scattering patterns is introduced so that the decoder outputs the reconstructed harmonic scattering pattern and therefore the autoencoder can be trained in an unsupervised manner. Based on the target harmonic scattering pattern, the PD-VQ autoencoder model can quickly generate the optimized discrete STC matrix with high reliability, accuracy, and generalization.

The conceptual illustration is shown in Figure 1, the target harmonic scattering pattern is fed into the autoencoder, which immediately generates the corresponding optimized discrete STC matrix. Based on the generated STC matrix, the control module periodically changes the control voltage of the elements to modulate the incident wave into the desired harmonic scattering pattern.

The proposed PD-VQ autoencoder shows high reliability and accuracy on both the training and test datasets, indicating that the autoencoder has good generalization ability. Moreover, for the target harmonic scattering patterns that are not included in the training and test sets, the autoencoder still outputs the corresponding optimized STC matrices, and the reconstructed harmonic scattering pattern matches the target very well.

In summary, we propose the encoding strategy based on the PD-VQ autoencoder to realize the inverse design of the STC matrix with high accuracy and reliability. This autoencoder is trained in an unsupervised way, which does not require a large amount of manually labeled data and greatly reduces the workload of obtaining the training set. According to the application scenario and the desired harmonic scattering pattern, we can easily construct the data set for training. Based on this encoding strategy, STC digital metasurfaces can be more easily and quickly modulated harmonics on demand, thus finding more potential applications in imaging, sensing, radar,

communication, and other intelligent information systems.

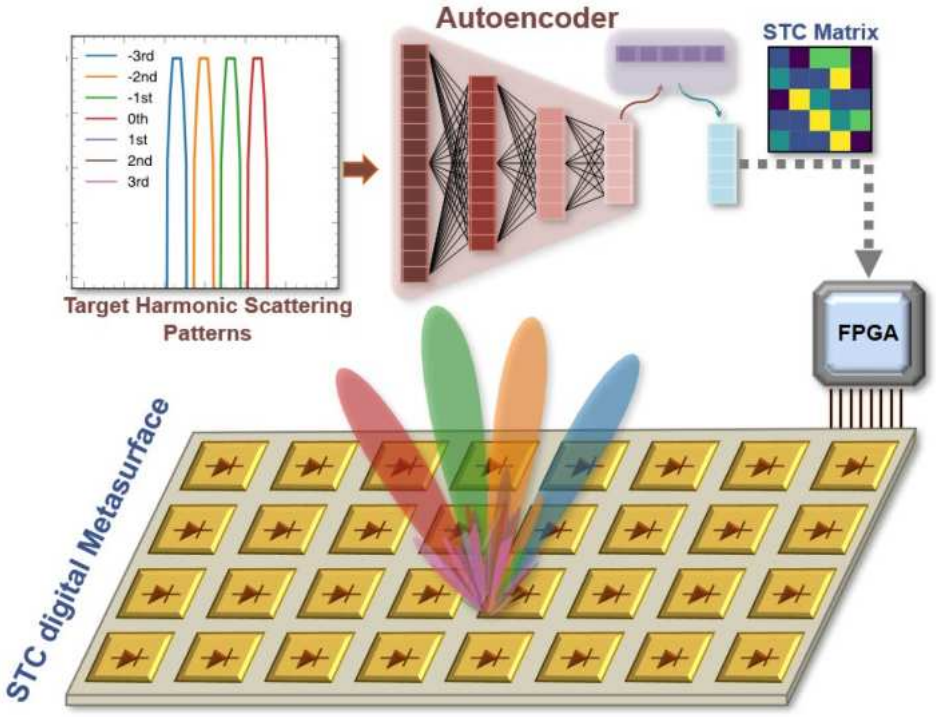

Figure 1. The autoencoder takes the target harmonic scattering patterns as input and generates the corresponding optimized discrete STC matrix with high reliability and accuracy. Thus, the STC digital metasurface can modulate the incident wave into desired harmonics scattering patterns in real time under the control of the generated STC matrix.

Enhanced optical effects based on the bound states in the continuum

Haitao Jiang*, Zhiwei Guo, and Yong Sun

MOE Key Laboratory of Advanced Micro-Structured Materials, School of Physics Science and Engineering, Tongji University, Shanghai, 200092, China

*corresponding author: jiang-haitao@tongji.edu.cn

Abstract: We reveal that the bound states in the continuum in meta-grating or metasurface structures can strongly enhance the optical effects including giant Goos-Hänchen shift, optical chirality and nonlinear optical effects. Our work provides a direct avenue towards the realization of ultra-sensitive sensors, high-efficiency chiral optical and nonlinear optical devices.

The conventional bound state can have an ultra-high quality factor, but it would be localized within a small part of the structure. However, the bound states in the continuum (BICs) can not only have ultra-high quality factors, but also have very large mode profile within the structure. As a result, the bound states in the continuum would strongly enhance the optical effects as well as the interaction between the light and matter. In this presentation, we mainly discuss how to realize the BICs in various meta-grating structures including compound single-grating structure and double-grating structures. We also discuss how to realize chiral BICs in metasurfaces by breaking the symmetry of the structures. Based on the BICs, one can greatly boost the optical effects including giant Goos-Hänchen shift [1], optical chirality [2, 3] and high-efficiency second-harmonic generation [4, 5]. The enhanced optical effects assisted by the BICs can be utilized for the design of ultra-sensitive sensors, high-efficiency chiral optical and nonlinear optical devices.

Abstract: Photoexcitation can induce a temporal boundary that alters dispersion relations of electromagnetic waves in semiconductor waveguides, leading to frequency conversion. In this study, we demonstrate frequency down-conversion of terahertz waves via coupling between transverse-magnetic and transverse-electromagnetic modes at a photoexcited temporal boundary in a waveguide made of semi-insulating GaAs.

A highly efficient device that converts frequencies of terahertz waves to desired frequencies is essential for developing high-capacity communication. To realize such a device, we can exploit time-varying systems. When a dispersion relation varies temporally during wave propagation, the frequency can be shifted. As this process involves linear wave scattering by the temporal variation, its conversion efficiency is independent of the intensity of the input electromagnetic waves. In particular, time-varying waveguides have the potential to realize highly efficient frequency conversion devices due to their strong energy confinement. So far, frequency up-conversion of terahertz waves has been reported for the transverse-electric (TE) mode terahertz waves in semiconductor GaAs waveguides[1]. In Ref. 1, an ultrashort laser pulse excited conduction electrons on the surface of the semiconductor waveguide, inducing a temporal boundary where the propagation mode switches instantaneously. The frequency up-conversion occurs due to the coupling of the incident TE mode with higher-frequency TE modes at the temporal boundary. On the other hand, photoexcitation of the semiconductor waveguide surface shrinks the electromagnetic field distribution of the propagating modes, so that frequency down-conversion usually does not occur. The waveguide structures and mode conditions for the down-conversion have not been clarified yet. In this study, we demonstrate the frequency down-conversion of terahertz waves in a GaAs waveguide by coupling an incident transverse-magnetic (TM) mode with a transverse-electromagnetic (TEM) mode at the optically excited temporal boundary.

Figure 1(a) depicts a schematic of the GaAs waveguide structure designed for the frequency down-conversion of the terahertz waves and the experimental setup. An Au film was deposited on the entire bottom surface of a GaAs substrate, which was 100 μm thick, 1 mm wide, and 10 mm long. The top surface of the waveguide was also coated with Au, leaving a 4 mm long area for photoexcitation. For TM-mode excitation, *y*-polarized terahertz wave packets were injected into the waveguide. While the terahertz wave packet was propagating through the photoexcitation region in Fig. 1(a), the top surface of the waveguide was optically excited with a time delay of $\Delta\tau$ by the pump laser pulse (center wavelength ~800 nm and pulse width ~100 fs).

The spectra of the terahertz wave packets transmitted through the waveguide are shown in Fig. 1(b).

Without the pump pulse, a peak at 0.42 THz was observed, whereas a peak at 0.36 THz was observed in a certain $\Delta\tau$ range. Thus, the pump pulse irradiation causes the frequency down-conversion. The range of $\Delta\tau$ where the frequency conversion occurs corresponds to the time range where the wave packet exists in the 4 mm long photoexcitation area at the photoexcitation timing. As the electric fields in the photoexcited surface are shielded by the conduction electrons, the semiconductor waveguide is regarded as a parallel-plate waveguide after the temporal boundary. The parallel-plate waveguide has a TEM mode with a uniform electric field distribution in the *y*-direction. The dispersion curve of the TEM mode is positioned below that of the lowest-order TM mode before the photoexcitation. The frequency down-conversion is attributed to the coupling of the incident TM and TEM modes at the temporal boundary. The power of the observed down-converted terahertz wave was more than 20% of that of the incident TM mode.

By combining the frequency up-conversion for the TE mode[1] with the frequency down-conversion for the TM mode excited by the *y*-polarized incident terahertz waves in this study, the frequency up- or down-conversion can be selected by switching the polarization of the incident terahertz waves. The frequency-conversion waveguide capable of up- and down-conversion with high efficiency can contribute to developing terahertz wave integrated circuit systems for forthcoming high-capacity communication.

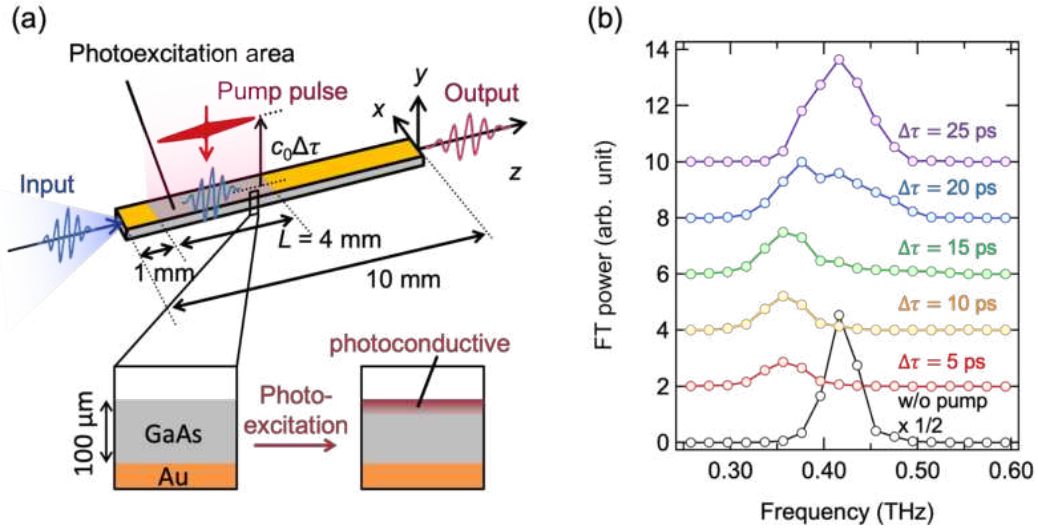

Figure 1: (a) Schematics of the GaAs waveguide and experimental setup of the frequency conversion for the TM modes. (b) Spectra of the terahertz waves transmitted through the waveguide with and without the pump pulses having several relative time delays $\Delta\tau$. The fluence of the pump pulses was 0.186 mJ/cm^2.

Waveform-Selective Metasurfaces Varying in Time and Space at the Same Frequencies in Accordance with Pulse Width

H. Wakatsuchi* and A. A. Fathnan

Department of Engineering, Nagoya Institute of Technology, Japan
*corresponding author: wakatsuchi.hiroki@nitech.ac.jp

Abstract: In this invited talk, we report recently developed circuit-based metasurfaces that show distinct behavior while operating at the same frequencies in accordance with the pulse width of incoming waves. We also demonstrate how such waveform-selective metasurfaces can be exploited for specific applications in antenna design, wireless communications, and electromagnetic compatibility.

In recent years, time-varying metasurfaces have been broadly and intensively explored to enhance control over electromagnetic waves and related phenomena [1]. These metasurfaces may adjust to their surrounding environments to establish the connection of wireless communications and enhance their quality as intelligent reflecting surfaces (IRSs) or reconfigurable intelligent surfaces (RISs) [2, 3]. However, most time-varying metasurfaces were so far developed with external power supply as active metasurfaces, which restricts the practical usage and application of these smart metasurfaces. In contrast, circuit-based metasurfaces were recently developed by introducing lumped circuit elements including diodes. These metasurfaces allow for electromagnetic response control in the time domain dependent on the pulse width of the incoming wave, without the need for extra power supply [4-10]. In this invited talk, we report such waveform-selective metasurfaces that show distinct behavior while operating at the same frequency. In particular, we present the most recent results on the design of these time-varying metasurfaces for advanced electromagnetic control, including frequency-sequence-based selectivity and ultra-fast impedance switching, which overcome long-standing physical limitations. We also demonstrate that these properties can be utilized in a range of applications such as antennas, absorbers, RISs, and cloaks. These novel time-varying metasurfaces provide a valuable contribution to addressing electromagnetic challenges with a higher degree of freedom in accordance with pulse width.

Direction-of-arrival (DOA) estimation with a programmable space-time-modulated metamaterial receiver

Shaghayegh Vosoughitabar[1], **Chung-Tse Michael Wu**[1,2*]

Abstract: A space-time-modulated metamaterial antenna is leveraged as a receiver to estimate the direction-of-arrival (DOA) of an incoming signal. This approach uses the power levels of first-order harmonics, generated due to the periodic time-modulation of the metamaterial unit-cells' phase constants, allowing for precise DOA estimation of waves impinging on the antenna.

DOA finding holds importance in wireless communication, radar tracking, and remote sensing. In this context, multiple methods and signal processing algorithms have been developed to estimate the direction of an incoming signal [1]. Furthermore, DOA estimation by employing a reflective metasurface has been recently proposed to reduce computational complexity and hardware costs [2], [3]. For example, in [2] a reflective space-time modulated metasurface is employed for DOA estimation of an incident plane wave through creating a pattern asymmetry for the scattered fields at the two first-order harmonics. In this method, a detecting antenna is required to collect the scattered waves from the metasurface for DOA finding. Here, we propose a method utilizing only one space-time modulated metamaterial antenna to estimate the DOA of a signal impinging on the antenna.

Very recently, a space-time-modulated composite right/left-handed (CRLH) antenna has been proposed in [4], exhibiting interesting properties such as non-reciprocity and harmonic beam-scanning, which can be used for simultaneous transmission and reception of signals. In this antenna, the phase constant (β) of each CRLH unit cell can be either positive or negative, depending on the bias voltages of the integrated varactors into the unit cell. By toggling β between these two states (i.e. β_0 and β_1 shown in Figure 1) in a periodic fashion, harmonics are produced within the receiving antenna upon receiving a signal at frequency f_0 arriving from angle θ. Figure 1 displays the received fundamental and first harmonic patterns for the illustrated space-time-modulated sequence, obtained by mathematically formulating the received patterns based on the array factor approach. By looking at the 1st harmonic and -1st harmonics' patterns ($f_0 \pm \Delta f$), it is noted that if the received powers at these harmonics are deducted from each other (Δ), in each θ angle within a particular range, a distinct value is achieved, as can be seen in (1) and Figure 1. Therefore, when a wave with a frequency of f_0, coming from an angle of θ within the detection range, is captured by the antenna, by calculating Δ and referring to the plotted curve in Figure 1, the DOA of the signal can be estimated. It is noted that there is a trade-off between the detection resolution and detection range. As such, it is worth mentioning that while increasing the amount of $|\beta_0 p|$ and $|\beta_1 p|$ leads to a higher slope of the Δ curve (better detection resolution), this will also result in a decrease in the detection range.

$$\Delta = Power\ of\ (f_0 - \Delta f)(dB) - Power\ of\ (f_0 + \Delta f)(dB) \quad (1)$$

Abstract. We will discuss our recent work on acoustic wave propagation in spinning fluid (air or water) that may lead to fiber applications. We reveal that spin can alter the refractive index and therefore can support waveguide modes. The propagation is asymmetric: allowing right-hand propagation and prohibiting left-hand propagation.

Propagation of acoustic waves in time-varying and/or moving media has attracted a lot of attentions and is expected to lead to many intriguing applications. In this summary, we discuss our recent work on realizing acoustic fiber via spinning motion. Most solid and liquid materials support acoustic speed that are much higher than that in air, making the confinement of the guided mode difficult. Recently, we found that by introducing rotational motion, the effective refractive index of the medium is altered and therefore, it can support guided modes. The angular velocity of the spinning determines the properties of the guided mode, and interestingly can be viewed as the strength of the acoustic analogue of Zeeman effect.

A Physical Unclonable Function Based on Time-Modulated Systems with Exceptional Points of Degeneracy

Pai-Yen Chen[1,*]

[1]Department of Electrical and Computer Engineering, University of Illinois, Chicago, IL 60607, U.S.A.
[*]corresponding author: pychen@uic.edu

Abstract: I will outline my recent findings on hardware security primitives built based upon time-variant electronic system with exceptional points at which high entropy occurs. I will show that the proposed encryption notion can provide excellent performance metrics in terms of randomness, uniqueness, and robustness against modeling attacks.

Over the past decade, non-Hermitian physical systems and their unusual singularities, known as exceptional points (EPs), have deepen understanding of engineering spectral, spatial, and temporal properties of waves, enabling new applications in signal generation, routing, and sensing across the spectrum. Particularly, the effect of eigenvalue bifurcation in the proximity of EPs has been extensively studied, as it may drastically improve the sensitivity of optical, optomechanical, acoustic, elastic, and electronic sensors[1],[2]. Furthermore, high entropy at EP degeneracy has been recently proposed to implement physical unclonable functions (PUFs) and cryptographic random number generators (CRNG)[3],[4], opening up a new pathway for development of hardware security primitives. In general, these non-Hermitian physical systems with EPs are built based on the parity-time reversal (PT)-symmetric structures with spatially-distributed, balanced gain and loss. Nevertheless, recent studies reported that contrary to PT-symmetric structures that require a delicate balance between gain and loss, EPs can occur in linear periodically time-varying systems without gain and loss. In this talk, I will present new types of PUFs and CRNGs based on simple, lightweight, and low-cost time-modulated electronic systems with EPs, along with some experimental evidence. I will show that proposed PUFs and CRNGs can exhibit excellent randomness (i.e., Shannon entropies) and uniqueness (i.e., inter-device Hamming distance), and, most importantly, robustness against machine learning-based modeling attacks. The proposed notion of PUFs based on EPs in time-modulated electronic systems may shed light on unforeseen cryptographic applications, such as RF and optical fingerprinting, anticounterfeiting labels, true random number generators, and secure wireless communications, to name a few.

Abstract: This report presents a metasurface that controls the dielectric and magnetic properties for the directivity control of near-infrared thermal radiation. We fabricate the metasurface with three-layered square Au, SiO_2, and Au patches on a supporting Si substrate. Measurements verify that the metasurface has a resonance at approximately 120 THz.

Thermal radiation is electromagnetic waves emitted from objects. The control of thermal radiation emitted from hot objects around us by artificial materials would be a welcome contribution to develop trailblazing applications such as for thermal management and energy harvesting [1,2]. A metasurface is an artificial material composed of periodically arranged subwavelength meta-atoms. Metasurfaces that control the dielectric and magnetic properties in the terahertz waveband have been applied to directivity control of terahertz waves radiated from terahertz continuous wave sources [3,4]. A metasurface that controls the dielectric and magnetic properties in the near-infrared region could be applied to directivity control of thermal radiation from hot objects. In this report, we fabricate and demonstrate a near-infrared metasurface that controls the dielectric and magnetic properties in the 100-THz band [5].

Figures 1(a) and (b) show an overall and an enlarged view, respectively, of a near-infrared metasurface. The near-infrared metasurface is composed of periodically arranged three-layered square metal, dielectric, and metal patches. The side length l and spacing s of a square patch, the thickness of the metal layer t, and the thickness of the dielectric layer d are 320 nm, 170 nm, 20 nm, and 50 nm, respectively. An adhesive layer is sandwiched between the metal and dielectric layers to improve adhesion between the metal and the dielectric. Figures 2(a)–(f) show the fabrication process of the near-infrared metasurface on a supporting Si substrate. Figures 3(a) and (b) are a photograph of the near-infrared metasurface by (a) a digital camera and (b) an image by field emission scanning electron microscopy (FE-SEM). The FE-SEM image shows the three-layered square Au, SiO_2, and Au patches periodically arranged in an area of 2.5×2.5 mm^2 of the supporting Si substrate.

Figures 4(a) and (b) show the reflectance and transmittance measurements by microscopic Fourier transform infrared spectroscopy (FT-IR) of the near-infrared metasurface and an one layer of silicon substrate, respectively. Figures 4(a) and (b) show that the near-infrared metasurface has a resonance at approximately 120 THz. Figures 4(a) and (b) show that the one layer of silicon substrate has almost constant values from approximately 40 to 210 THz and no resonance at approximately 120 THz. The resonances in the measurements of the near-infrared metasurface at approximately 120 THz could be the cause of the simultaneous control of the dielectric and

magnetic properties due to the three-layered square Au, SiO2, and Au patches on the supporting Si substrate.

Abstract: Using inverse design, a quantum algorithm emulator, made of a polyimide gradient-index and silicon, is optimized to enhance the interaction of incident light with the metamaterial showing improvements in the amplitude and FWHM of the outgoing wave in the terahertz region for the implementation of the Deutsch-Josza algorithm.

Metamaterials can be used to exploit the least used terahertz (THz) region for devices that have applications in analog computing. Gradient index (GRIN) lenses have not only been proven to operate at THz frequencies but can be integrated into photonic devices that consist of multiple subblocks for quantum algorithm emulators (QAEs). They have been used to simulate quantum search algorithms with classical light but only in the microwave region.[1] We report a new design for a QAE that operates at THz frequencies and is optimized by machine learning using an inverse design approach.

In the QAE, as shown in Figure 1, the oracle and Fourier transform (FT) subblocks are in optical contact. The oracle subblock modulates the electric field profile of the incident THz light by assigning a phase shift of 0 or π on each spatial position along y-axis via physically varying the radii of the hole array drilled in the silicon substrate which varies the effective electric permittivity along the y-axis. The FT block has various hole sizes acting as an all-dielectric GRIN lens that determines the output wave. Numerical analysis, done by finite-difference time-domain (FDTD), computed the initial optimized radii for the GRIN lens, $r_1 < r_2 < r_3 = r_4 < r_5 = r_6$, with a thickness of 127 μm and a period of 70 μm for the array. Defining the phase shift of 0 or π along the transversal axis of the QAE, two different solutions of the DJ algorithm can be realized. Either a constant or balanced function results. The constant function shows a maximum electric field intensity at y=0 and the balanced function shows a minimum intensity at y=0 with two separate peaks with an input frequency of 0.8 THz. Table 1 shows the optimized parameters for the radii and thickness of the GRIN lens after inverse design via machine learning was used. The improvement in the design shows increases in the amplitude and decreases of the FWHM as shown in Table 2 while only the third radius changes most significantly (15%). There is a two-fold increase in the thickness of the GRIN lens. Use of inverse design ML has helped construct a QAE that has an optimal distribution of the output wave intensity that creates a device that can be better equipped to handle a greater number of database inputs.[2]

Recent advances in non-Hermitian metamaterials

Realization of Geometry-Dependent Skin Effect in a Reciprocal Two-Dimensional

M. Hu[1*], and K. Ding[1]

[1]Department of Physics, State Key Laboratory of Surface Physics, and Key Laboratory of Micro and Nano Photonic Structures (Ministry of Education), Fudan University, Shanghai 200438, China
[*]corresponding author: myhu@fudan.edu.cn

Abstract: We theoretically and experimentally demonstrate the non-Hermitian skin effect in a 2D spectral and Lorentz reciprocal mechanical system in which the only non-Hermiticity is the gain and loss.

Non-Hermitian skin effect (NHSE) is characterized by the confinement of bulk modes to the boundary under open boundary conditions (OBCs), contrasting with their distribution under periodic boundary conditions (PBCs). This phenomenon is governed by the distinctive topological characteristics of complex eigenvalues specific to non-Hermitian systems. The NHSE, rooted in the non-trivial spectral winding, naturally manifests in non-reciprocal systems. Consequently, established methodologies rely on non-reciprocity to induce the NHSE. Here, we theoretically and experimentally demonstrate the NHSE in a 2D spectral and Lorentz reciprocal mechanical system in which the only non-Hermiticity is the gain and loss [Figure 1(a)]. Such NHSE exclusively occurs at boundaries where the macroscopic symmetry deviates from lattice symmetry, termed the geometry-dependent skin effect (GDSE), as shown in Figure 1(b). Experimentally, we confirm that the GDSE occurs only at the boundary where there is a mismatch between macroscopic symmetry and lattice symmetry by applying different pulse signals, as shown in Figure 1(c, d). Conversely, at the boundaries where macroscopic symmetry matches lattice symmetry, no GDSE is observed, as depicted in Figure 2.

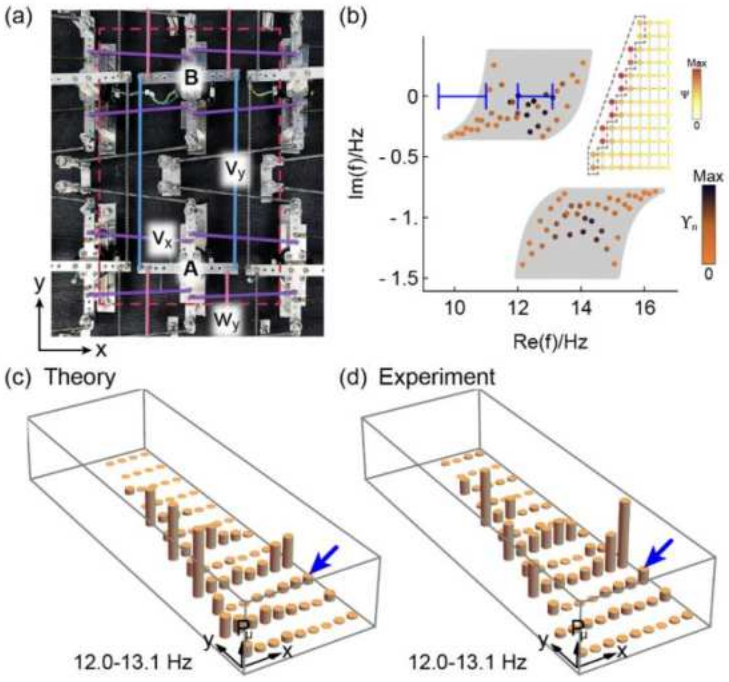

Figure 1 (a) The photo of the coupled rotational oscillators. (b) The OBC complex spectrum (colorful dots) of the trapezoidal structure with 78 sites. The gray background displays the corresponding PBC complex spectrum.

The plots of the (c) theoretical and (d) experimental spectral sum with different input chirp signals.

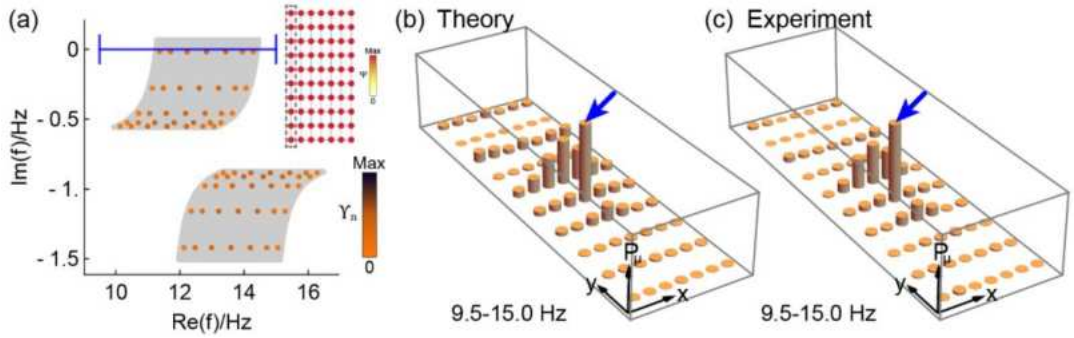

Figure. 2 (a) The OBC complex spectrum (colorful dots) of the rectangular structure with 70 sites. The plots of the (b) theoretical and (c) experimental spectral sum with different input chirp signals.

Our work not only reveals the universality of NHSEs in high-dimensional systems, but also underscores the critical influence of reciprocity and macroscopic geometry on the NHSE in two-dimensional systems and above, paving the way for novel approaches to wave structuring through non-Hermitian effects.

Abstract:
In this talk, we extend the 3D Chern insulator phase into acoustic crystals, introducing a strategy for constructing arbitrary Chern vectors. This approach facilitates surface-state torus knots or links on the surface of a single crystal with non-reciprocal coupling, offering a comprehensive understanding of bulk-boundary correspondence in topological Chern vectors.

Summary:
The topological invariant that characterizes Chern insulators (the celebrated Haldane model [1]) has recently evolved from a scalar Chern number to a topological Chern vector, extending the Chern-type bulk-boundary correspondence from one-dimensional (1D) edge states to two-dimensional (2D) surface states and forming nontrivial torus knots or links in the surface Brillouin zone [2]. However, so far, the exploration of topological Chern vector has been limited to its simplest form, $\boldsymbol{C} = (0,0,C_3)$, with only a single nonzero Chern number, resulting in the surface-state torus knots or links emerging only along an internal domain wall between two three-dimensional (3D) Chern insulators with perpendicular Chern vectors[2]. The arbitrary Chern vector $\boldsymbol{C} = (C_1, C_2, C_3)$ with multiple nonzero Chern numbers is still unexplored. On the other hand, since the first theoretical proposal[3] and experimental realization [4] of acoustic Chern insulators, it is still limited to 2D, and the acoustic 3D Chern insulators are still excluded.

As shown in Fig. 1, we extend the concept of the Chern vectors to the acoustic 3D Chern insulators that exhibit arbitrary Chern vectors, which allow the emergence of torus knots or links on the surface of a single crystal[5]. Additionally, we unveil the phenomenon of successive topological negative refraction at three adjacent faces of a single crystal, enabling acoustic chiral surface states pass through sharp edges continuously in 3D space via negative refraction without backscattering. Lastly, we illustrate that nontrivial torus knot or link surface states can manifest on the surface of a single 3D Chern insulator with arbitrary Chern vectors. This represents a stark contrast to previous findings and may find potential applications in topological acoustics.

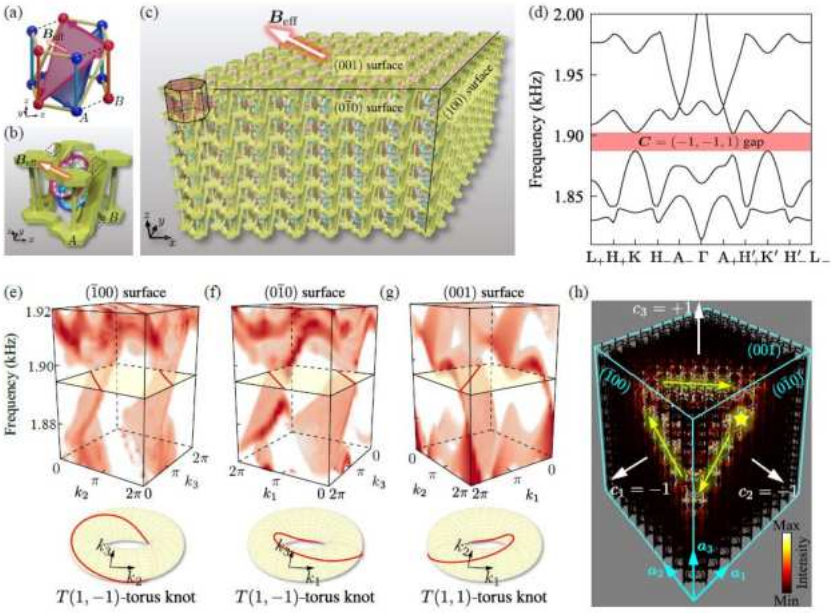

FIG. 1. Acoustic 3D Chern insulator with a Chern vector $\boldsymbol{C} = (-1, -1, 1)$. Abstract: We observe discrete-light temporal refraction by a moving gauge-potential barrier, which obeys a different Snell's law compared to traditional refraction at a static boundary. To eliminate beam splitting we find the barrier can only move at a quantized speed of integer and fractional values, which exhibit reflectionless and reflective refractions.

Main results:

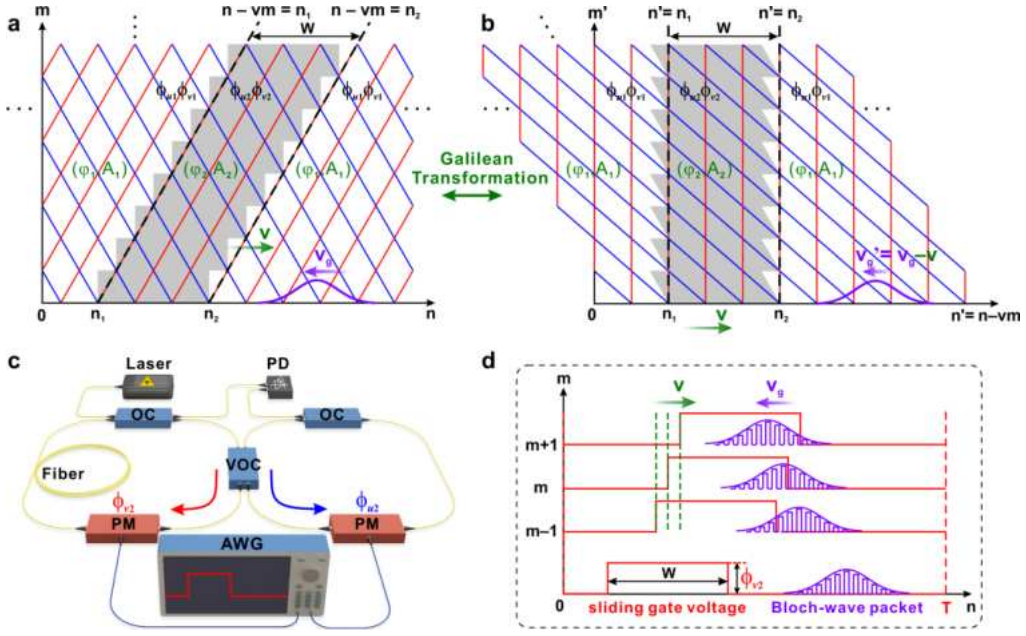

Fig. 1. a, b. Schematic of a moving gauge potential barrier in a synthetic temporal lattice described in laboratory and moving reference frames. **c.** Schematic of coupled fiber circuit to create the temporal lattice. **d.** The required sliding gate voltage to create the moving gauge potential barrier.

Figure. 1a shows a moving gauge potential barrier in a synthetic discrete-time quantum walk lattice made of leftward (blue) and rightward (red) links towards scattering nodes labeled by position n and step m. The phase modulations are (ϕ_{u2}, ϕ_{v2}) and (ϕ_{u1}, ϕ_{v1}) inside and outside the moving barrier, corresponding to a gauge potential distribution of (φ_2, A_2) and (φ_1, A_1). The two moving boundaries are $n - vm = n_{1,2}$, where v is the moving speed, n_1 and n_2 are initial positions of the two boundaries and $W = n_2 - n_1$ is barrier's width. The Bloch-wave packet (purple) is incident from the barrier's right side. Figure 1b shows the lattice and gauge potential distribution in the moving reference frame (n', m') obtained through Galilean transformation $m' = m$, $n' = n - vm$ from laboratory frame (n, m). The reason why we need to apply Galilean transformation is that in the laboratory frame, the boundaries are tilted, such that Snell's law, conservation of tangential propagation constants is not applicable.

By contrast, if we choose the moving frame (n', m') where the two boundaries become vertical that are parallel to the m' axis, the Snell's law is applicable. The Snell's law in moving frame is $\theta_{\pm}'(k_{t,\pm}) = \theta_{\pm}'(k_{r,\pm}) = \theta_{+}'(k_i)$, where

$$\begin{cases} \theta'_{\pm}(k_{t,\pm}) = \pm\cos^{-1}[\cos(\beta)\cos(k_{t,\pm} - \Delta A)] - \Delta\varphi - vk_{t,\pm} \\ \theta'_{\pm}(k_{r,\pm}) = \pm\cos^{-1}[\cos(\beta)\cos(k_{r,\pm})] - vk_{r,\pm} \\ \theta'_{+}(k_i) = \pm\cos^{-1}[\cos(\beta)\cos(k_i)] - vk_i \end{cases} \quad (1)$$

from which we can solve the refracted and reflected Bloch momenta k_r and k_t for a given incident k_i. To eliminate beam splitting during refraction, one requires $v'_g(k_{t,+}) = v'_g(k_{t,-}) = \partial\theta_{\pm}'(k)/\partial k = \pm\cos(\beta)\sin(k_{t,\pm} - \Delta A) - v$, which gives rise to the quantized condition of moving speed $v = 1/q = 1$ for integer value or 1/3, 1/5, … for fractional values.

The band structures for $v = 1$ are shown in Fig. 2a, where incident/refracted packets are denoted by blue and red circles. Figure 2b shows the field evolution for integer speed $v = 1$, $k_i = -0.5\pi$, showing the beam-splitting-free refraction. Figure 2c shows field evolution for $k_i = -0.148\pi$, which exhibit the refractionless effect, thus realizing transparent moving potential. Figures 2d-2f show the case of fractional speed $v = 1/3$, showing beam reflection compared to $v = 1$, as evidenced by Fig. 2e. Figure 2f proves the existence of transparent potential for $v = 1/3$.

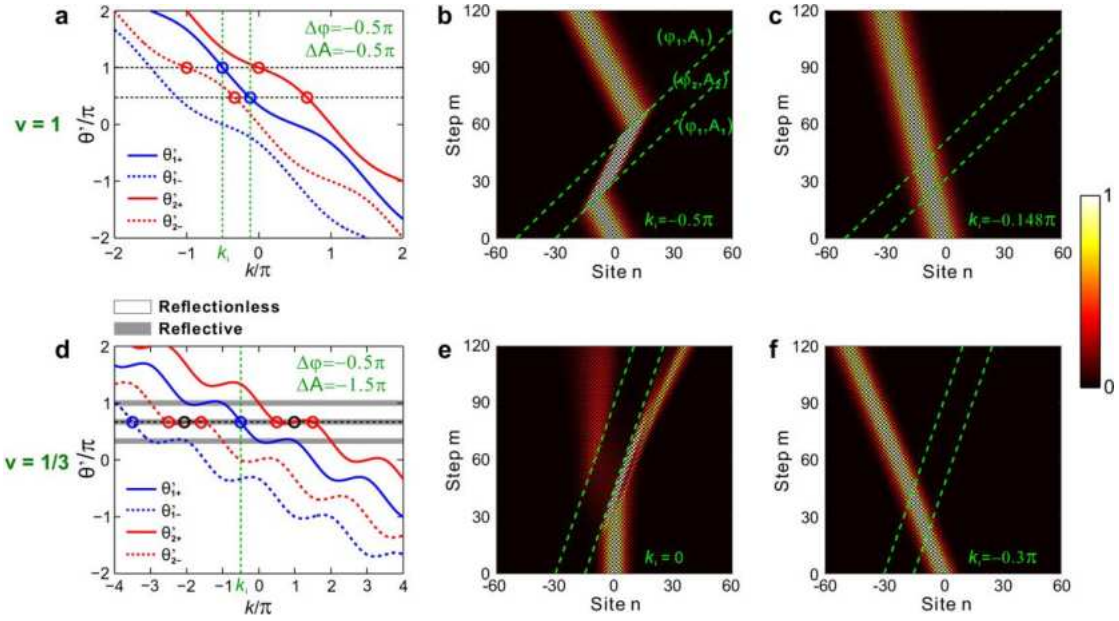

Fig. 2. a. Band structures for the $v = 1$ case. **b. c.** Field evolutions for $k_i = -0.5\pi$ and $k_i = -0.148\pi$ under $v = 1$. **d.** Band structures for the $v = 1/3$ case. **e. f.** Field evolutions for $k_i = 0$ d $k_i = -0.3\pi$ under $v = 1/3$.

Abstract: Having developed a comprehensive thermal scattering theory that describes the nonreciprocal transmission properties of temperature field effectively, this work creates a metadevice that supports both dynamic and steady-state nonreciprocal heat transfer. It uncovers the unique multiple-scattering effect at steady state, as well as the resonance enhanced nonreciprocity of thermal fields.

Nonreciprocal heat transfer is of great significance for efficient thermal energy utilization, thermal management, and performance improvement of thermal logic processing[1]. However, most existing approaches to macroscopic thermal nonreciprocity rely on nonlinear or spatiotemporal-modulation effects[2], which come with apparent drawbacks, such as limited operating temperature ranges and complex experimental setups[3]. Meanwhile, constrained by their inherent mechanisms, these methods can hardly be effective under both dynamic and static excitations[4,5].

Confronted with these challenges, here we develop a convection-based thermal metadevice where nonreciprocity can be realized under both the dynamic and steady-state temperature excitations, shown in Figure 1a. Starting from the convection-diffusion equation and the plane wave solution of the propagating thermal field[6], the scattering matrix $\boldsymbol{S}$ which relates the outgoing and ingoing signals ($(B_1, B_2, B_3)^{\mathrm{T}} = \boldsymbol{S}(A_1, A_2, A_3)^{\mathrm{T}}$) can be derived by thermally intercoupling all parts of the thermal metadevice, and the strength of nonreciprocity can be defined as $\Gamma = |S_{21}/S_{31}|$. Consequently, the dynamic thermal nonreciprocity is attributed to an asymmetric scattering matrix [7], where the nontrivial dependencies between nonreciprocity and dynamic parameters are shown in Figure 1b. However, this matrix approaches a symmetric limit at the steady state but still conveys significant steady-state nonreciprocity counterintuitively. By delving into the physical implication of the thermal scattering process, we reveal a unique nonreciprocal mechanism where the boundary-induced multiple scattering counterbalances the diminishing asymmetry[8] (Figure 1c). Then we observe a strong resonance phenomenon in this metadevice (Figure 1d and 1e). The multiple-scattering nonreciprocity Γ' can be expressed as a function of the single scattering coefficients when the number of scattering iterations n tends to infinity, where

$$\Gamma' = \left| \frac{\tilde{r} S_{31}^2 + S_{21} - \tilde{r} S_{11} S_{21}}{\tilde{r} S_{21}^2 + S_{31} - \tilde{r} S_{11} S_{31}} \right| \tag{1}$$

This theory serves as a bridge between thermal scattering analysis and traditional heat-flux analysis. Based on it, we have finally verified the nonreciprocal heat transfer effect in this metadevice experimentally (Figure 1e).

The Manipulation of Topological Modes and Anderson Localized Modes via non-Hermicity

Xulong Wang[1, 2*], Wei Wang[1, 2], Guancong Ma[1, 2]

Abstract: In this work, we utilize active resonant platforms to demonstrate the manipulation of topological modes (TMs), and Anderson localized modes (ALMs) through non-Hermicity. Localized topological modes can be reconfigured into diverse shapes via non-Hermitian interactions. Complex Anderson modes can be formed in a one-dimensional non-Hermitian disordered ring.

Non-Hermitian systems, characterized by their complex spectra, are intrinsically well-suited for simulating open systems engaged in environmental interactions. These interactions facilitate the emergence of unique effects such as energy modulation through gain and loss and nonreciprocal interaction, catalyzing a spectrum of novel phenomena. One of the most fascinating phenomena is the non-Hermitian skin effect (NHSE), where the bulk states become skin modes localized at the open boundaries. The incorporation of non-Hermiticity introduces intricate challenges in the analysis of topological modes (TMs) and Anderson localized modes (ALMs), which may yield fresh perspectives on the underlying behaviors of these systems.

In the first part, we harness the NHSE to manipulate the wavefunctions of TMs. By laying out an active mechanical lattice as a one-dimensional (1D) non-Hermitian Su-Schrieffer-Heeger (NH-SSH) model, we witness the complete delocalization of a topological zero mode (TZM) [1-3]. Advancing to two-dimensional (2D) topological lattices, our work showcases the transformation of 1D topological edge modes (TEMs) and 0D second-order topological corner modes (TCMs) into various configurations by tailoring the non-Hermiticity distribution. Despite the TMs spreading out due to the NHSE, they maintain spectral isolation within the bandgap and preserve their topological robustness. Our discoveries release TMs from their usual confinement to boundaries, opening new avenues for their application in the realm of topological phenomena.

In a chain with a topological interface, the left side is a trivial NH-SSH chain containing non-reciprocal coupling (δ), and the right side is a non-trivial Hermitian SSH chain with reciprocal coupling. With the increase of $|\delta|$, the TZM spread out more in the NH-SSH chain. The TZM re-localizes at the left end of the system for larger $|\delta|$. As for 2D non-Hermitian topological quadrupole insulator (NH-TQI):

$$H_Q(k_x, k_y) = \begin{bmatrix} 0 & R_x(k_x) & R_y(k_y) & 0 \\ M_x(k_x) & 0 & 0 & -R_y(k_y) \\ M_y(k_y) & 0 & 0 & R_x(k_x) \\ 0 & -M_y(k_y) & M_x(k_x) & 0 \end{bmatrix} \quad (1)$$

where $R_\mu(k_\mu) = v_\mu + w_\mu e^{-ik_\mu}$ and $M_\mu(k_\mu) = (v_\mu + \delta_\mu) + w_\mu e^{ik_\mu}$ with $\mu = x, y$.
v_μ and w_μ denoting the magnitude of intra/intercell hopping, respectively. δ_μ are the additional non-Hermitian terms introduced in the lattice, as shown in Fig. 1(d).

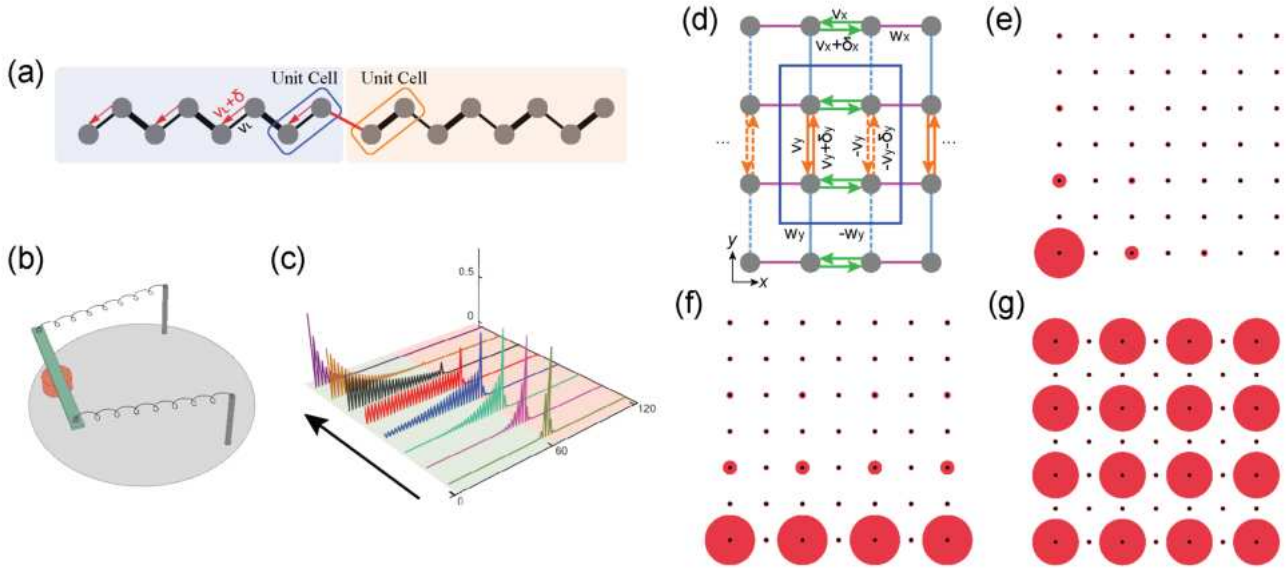

Figure. 1 (a) 1D NH-SSH chain with TZM localized at the interface. (b) The schematic of a rotational oscillator that functions as the on-site orbital within our experimental lattice. (c) The real space wavefunctions of TZMs for different δ. (d) The model of NH-TQI. The wavefunction of TCM in the NH-TQI is localized at the lower-left corner for the Hermitian case (e). The extension of the TCM along the lower edge (f), and into the 2D surface (g) under different non-Hermicity distributions.

In addition, we will also discuss the effect of non-Hermiticity on Anderson localization. The seminal contributions to this area belong to Hatano and Nelson stand out [4]. They uncovered a localization transition triggered by the introduction of a sufficiently large constant imaginary vector potential into the Schrödinger equation. Inspired by the groundbreaking work of Hatano and Nelson and recent insights into non-Hermitian systems, we explore new configurations of random potential effects in a 1D non-Hermicity ring and identify new types of localization-delocalization behaviors that relate to the complex spectrum of the system.

Acoustic orbital-related topological states and phase transitions

Feng Gao, Yu-Gui Peng*, Xue-Feng Zhu*

School of Physics and Innovation Institute, Huazhong University of Science and Technology, Wuhan 430074, China
*corresponding author: ygpeng@hust.edu.cn, xfzhu@hust.edu.cn, aalu@gc.cuny.edu

Abstract: In this talk, we concentrate on the topological states and phase transitions induced by orbital-interactions. The introduction of acoustic orbitals enables counterintuitive orbital-dependent topological edge states and versatile corner states, opening avenues for exploring orbital-related topological physics and sound-wave interaction.

Summery: Topological insulators are enabled by broken crystal symmetries and associated degrees of freedom (DoFs), such as spin or valley DoFs in a periodic lattice, significant to unveil different topological phases[1]. Beyond the degree of spin, the intrinsic orbital DoF also plays a significant role in correlated electrons and solid state materials, which induce many unique topological phases such as orbital superfluidity[2] and topological semimetals[3]. Recently, employing ODoFs on the investigation of topological matter has been frequently extended to photonics[4] and electronics[5], which has not yet been extensively explored in acoustics.

Exploiting paired degenerate *p* orbitals and the correlated orbital-interactions in the acoustic resonators, we first demonstrate counterintuitive topological edge modes and topological phase transitions in 1D orbital SSH lattices[6]. As shown in Fig. 1(a), for the leftmost and rightmost resonators, they are strongly and weakly coupled to the topological chain with different coupling tubes d_1 and d_2 ($d_2<d_1$=0.6cm), respectively. Unlike the conventional SSH model, with edge modes residing on the rightmost resonator, topological phase transitions emerge in our orbital SSH chains. Keeping the bonding angle at 90°, the p_x-like edge mode displays tunneling through the bulk chain from the right to the left termination by varying d_2 from 0.1cm to 0.4cm, and the transition appears at d_2=0.25cm in the simulations, which can be not found in the conventional counterpart obtained by setting the bonding angle as 180°. In experiments, the counterintuitive edge mode on leftmost resonator is evidenced with a p_x-like source, as shown in Fig 1(c), agreeing well with the simulations. Meanwhile, a p_y-like source cannot excite the leftmost resonator, featuring strong orbital-selectivity.

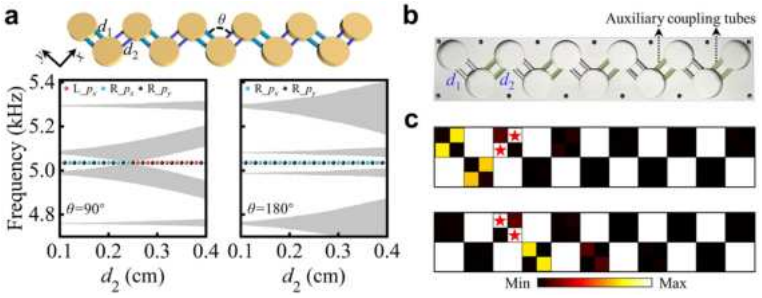

Fig. 1. Topological transitions and edge modes in dimerized orbital SSH model. (a) Top: Sketch of the orbital SSH model with dimerized coupling tubes. Bottom: Energy spectra for orbital SSH models and conventional SSH models. (b) Experimental sample. (c) Measured pressure amplitude fields.

Then, we extended exploration of orbitals of topological matter to acoustic higher-order insulators[7]. Here, we exploit degenerate orbitals in acoustic resonant cavities to demonstrate versatile, orbital-selective, higher-order topological corner states. Type-II corner states are theoretically investigated and experimentally demonstrated based on tailored orbital interactions, without the need for long-range hoppings that has so far served as a key ingredient for Type-II corner states in single-orbital systems. Moreover, we employed a judicious excitation mechanism combining both frequency and source polarization to excite and visualize these orbital corner states, and four types of orbital states can be well excited at the corners as displayed in Fig. 2.

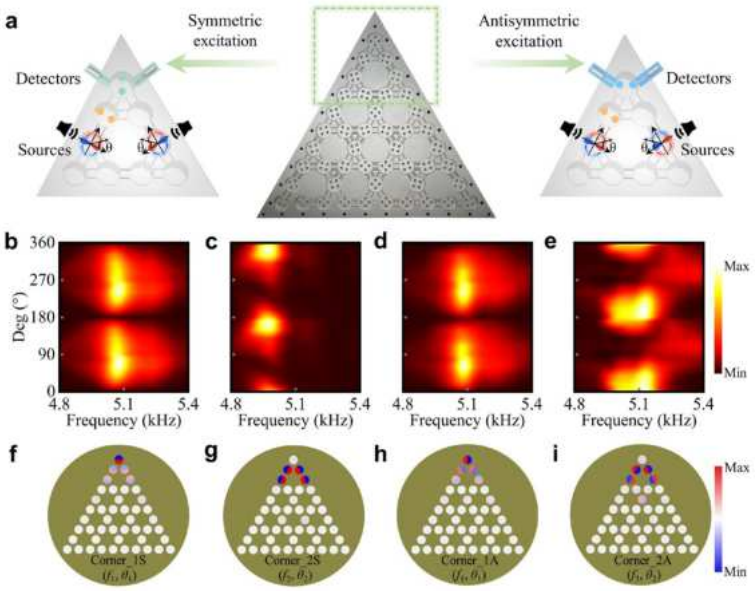

Fig. 2. Experimental characterization of orbital corner states. (a) Middle panel: The fabricated sample. Left and right panels display the schematics of symmetric and antisymmetric excitation and detection. (b-e) The measured spectra for versatile corner states. (f-i) The measured pressure field distributions under symmetric excitations and antisymmetric excitations.

Abstract: We demonstrate the occurrence of non-Hermitian skin effect (NHSE) in anisotropic metamaterials. Our experiments reveal selective excitation of skin modes based on the wave vector, where the localization of these modes is precisely controlled by an effective gauge potential stemming from the anisotropy of the non-Hermitian density tensor.

Beyond the scope of Hermitian physics, non-Hermiticity has significantly advanced our understanding of non-equilibrium phenomena, revealing novel effects such as the non-Hermitian skin effect (NHSE). While NHSE is commonly predicted in periodic lattice systems, its exploration in more general continuum and homogeneous media remains limited. Here, we demonstrate the occurrence of NHSE in anisotropic homogeneous media using subwavelength acoustic multilayer metamaterials. Our experiments reveal selective excitation of skin modes based on the wave vector, where the localization of these modes is precisely controlled by an effective gauge potential stemming from the anisotropy of the non-Hermitian density tensor. Additionally, we identify the emergence of corner skin modes, showcasing the potential of higher-order NHSE. Our research opens a new pathway for exploring NHSE in homogeneous systems, rooted in the interplay between non-Hermitian physics and anisotropy, and offers a novel method for guiding sound, light, and other types of waves.

Nanophotonics in Biomedical Applications

Ultrafast Photonic PCR with All-Solution Processed Perfect Absorber

Seho Lee[1,2], Abdulrahman Alsaadi[1,2], and Inki Kim[1,2*]

[1]Department of Biophysics, Institute of Quantum Biophysics, Sungkyunkwan University, Suwon 16419, Republic of Korea
[2]Department of Intelligent Precision Healthcare Convergence, Sungkyunkwan University, Suwon 16419, Republic of Korea

Abstract: We developed a low-cost all-solution processed metaplasmonic PCR chip using a metal-insulator-meal configuration with gold nanoparticles and MXene $Ti_3C_2T_x$. This chip featuring ultra-high absorption and low-power consumption, overcomes cost challenges associated with traditional methods. Utilizing a solution processing approach, we achieved 30 cycles of the PCR process within 8 minutes.

Research on polymerase chain reaction (PCR) technology for rapid and accurate detection of pathogens is still actively being conducted. However, PCR amplification requires more than 30 cycles of thermal cycling and high power consumption, making it generally restricted to laboratory environments. Therefore, there is a need for portable and rapid nucleic acid-based diagnostic technologies that can be used outside of the laboratory. Recently, photonic PCR technology using low-power LEDs has garnered attention [1]. However, the fabrication of metamaterial surfaces still relies heavily on equipment such as E-beam lithography and E-beam evaporators, which pose significant drawbacks in terms of cost and time [1,2].

We conducted PCR using an efficient and low-cost all-solution processed perfect absorber based on MXene. We utilized a MXene-SiO_2-Gold-nanoparticles structure to enhance absorption efficiency, achieving over 98% absorption at the targeted wavelength of 940nm for infrared LED. The high absorption efficiency of the MXene-SiO_2-Gold-nanoparticles is attributed to the plasmonic effect. In this structure, the gold-nanoparticles induce surface plasmon resonance, concentrating incident light at specific wavelengths to enhance absorption efficiency. Additionally, the MXene and SiO_2 coatings improve the efficient generation and interaction of surface plasmons, contributing to the enhancement of absorption efficiency. These plasmonic effects enable wavelength-selective absorption and overall improvement of the structure's optical performance. In the fabrication process, we circumvented the significant drawbacks in terms of cost and time by completing the fabrication using a spin-coater apparatus, without the need for equipment such as E-beam lithography or E-beam evaporators, often associated with high expenses and time consumption. Gold-nanoparticles were deposited using the drop-casting method, covering approximately 75% of the overall surface area.

We performed 30 thermal cycles from the denaturation temperature of 95°C to the annealing temperature of 65°C, achieving a heating rate of 14.7°C/s and a cooling rate of 6.3°C/s in an ultrafast photonic quantitative PCR. Overall, the low power consumption and highly efficient photo-thermal effect of our meta-absorber demonstrate the potential use of metasurfaces for ultrafast qPCR for point-of-care (POC) molecular diagnostics. This highlights MXene-based metamaterial absorbers as promising for high-speed on-site molecular diagnostics.

Abstract: We tested the suitability of Au film-porous anodic aluminum oxide (PAAO)-Al plasmonic nanomaterials as sensor substrate for optical detection of vascular endothelial growth factor A (VEGFA). These substrates are suitable for refractometric detection of elevated concentrations of VEGFA protein using simple optical microscopy setup.

The PAAO acts as a cost-effective template for the lithography-free manufacturing of nanostructured sensor substrates. This approach has the potential to overcome challenges in producing localized surface plasmon resonance (LSPR) sensor substrates, given its simplicity and applicability in standard chemistry labs. In our study, we tested the usability of Au film-PAAO-Al to detect the molecular biomarker VEGFA in water-based solutions. Vascular endothelial growth factor A plays a key role in normal and pathological angiogenesis. Increased levels of VEGFA protein in human body fluids are associated with malignant tumor development and degenerative eye diseases [1]

The two-step anodization method was used to fabricate thin PAAO layers on an aluminum surface in 0.3 M oxalic acid electrolyte at 40 V potential [2,3]. These layers feature a pore diameter of 40 nm and an interpore distance of approximately 110 nm. The obtained PAAO templates were coated with an optically thin (20-30 nm) layer of gold [4]. The gold surface of Au film-PAAO-Al substrates was functionalized with modified anti-VEGF 3'-thiolated DNA aptamer [5]. After functionalization, substrates were treated with bovine serum albumin to prevent non-specific protein absorption on sensor surfaces. The prepared substrates were used for the detection of the human $VEGF_{165}$ isoform in phosphate-buffered saline solution. Two methods of signal detection were investigated: the LSPR scattering setup and reflectance spectroscopy.

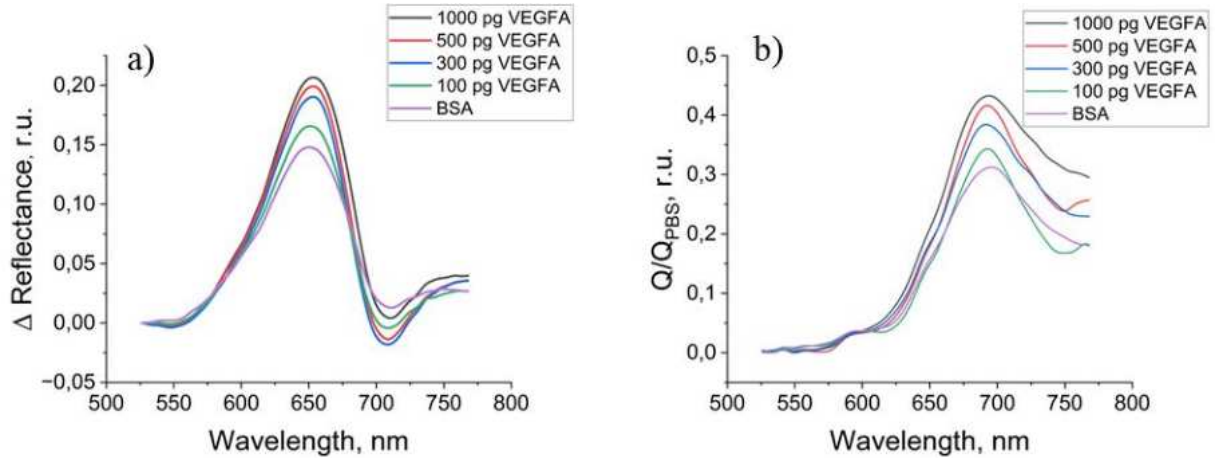

Figure 1. VEGFA protein detection sensitivity a) in reflectance mode spectroscopy (difference between VEGFA signals and reference) and b) in scattering mode spectroscopy (s-polarized illumination).

Reflection mode spectroscopy (Fig.1 a) showed good signal to background ratio and change of signal intensity was detected at presence of 100 – 1000 pg/mL VEGF protein. Scattering mode illumination with s-polarized light source (Fig.1 b) produced wider and asymmetrical spectral peaks in comparison with reflection mode spectroscopy.

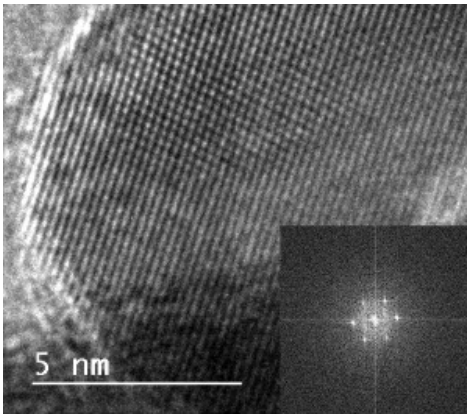
Abstract: Laser ablation allows controlling the main features of metallic nanoparticles by tuning the processing parameters. In addition, reirradiation of nanoparticles reduces its size and allows obtaining bimetallic nanoparticles without any additional reagent or contaminant that can be harmful to the healthy tissues. Applications such as antibacterial agent will be presented.

Introduction & main results



Metallic nanoparticles have attracted much attention as a subject of investigation due to their well-known properties, such as high electrical and thermal conductivity, catalytic activity, localized surface plasmon resonances, antibacterial and antifungal effects, etc. They are used in many different areas, medicine, photovoltaic solar cells, industrial applications, and scientific investigation, etc. The size as well as the shape is very important for certain applications.

There are different techniques for producing metallic nanoparticles using chemical, physical and biological routes. Each method presents its own disadvantages and restrictions, being the most used the chemical ones. But nanoparticles obtained via the chemical route could have byproducts of the reactions that could be harmful when nanoparticles are used for biomedical applications.

In the present work, laser-assisted methods such as ablation of solids in liquid phase (LASL) and laser reirradiation have been utilized to prevent the presence of contamination and impurities in obtained products. These methods are good alternatives to chemical reduction, especially when biological applications are taken into account. Different types of metallic nanoparticles, such as silver, copper or palladium, were successfully obtained as shown in figure 1.

a)

b)

Figure 1. *a) Schematic illustration of the Laser Ablation technique. b) Example of the silver nanoparticles produced by this technique. [1].*

Laser reirradiation consists on submitting the obtained solutions from the LASL to pressure to give a horizontal homogeneous and constant stream flowing from a capillary to be re-irradiated once and three times using the same laser sources with the same parameters used for the initial colloidal solution (see figure 2). As can be observed, the laser reirradiation treatment allows reducing the size (compare size of nanoparticles in figure 2b with that of figure 1b).

Also, laser reirradiation allows obtaining bimetallic nanoparticles that have synergistic effect as bactericidal agent.

Physico-chemical characterization included field-emission scanning electron microscopy (FSEM), transmission electron microscopy (TEM), selected area electron diffraction (SAED), energy dispersive spectroscopy (EDS), Ultraviolet-visible spectroscopy, High-resolution transmission electron microscopy (HRTEM)

Antibacterial activity against different bacteria such as Staphylococcus aureus, Escherichia coli, and Lactobacillus Salivarius was assessed by minimal inhibitory concentration assays. Results show that silver, copper and palladium nanoparticles are effective agents against bacteria proliferation.

Abstract: We demonstrate the formation of hybrid nanocavities by partially covering silicon photonic crystal (PhC) waveguides with suitably-sized 2D material flakes, obtaining cavity quality (Q) factors as high as 4.0×10^5.

The field of hybrid photonics has seen exciting progress with the advent of 2D van der Waals materials such as graphene, hexagonal boron nitride (hBN) and transition metal dichalcogenides (TMD) [1]. In particular, semiconducting TMDs have a direct bandgap at monolayer [2], making them optically active. For practical applications, 2D materials are often coupled to photonic structures such as cavities to manipulate light-matter coupling [3]. However, the transfer of 2D materials changes the dielectric environment of the cavities and also induce other losses which degrade the cavity quality (Q) factor. The situation becomes complicated with stacks of 2D materials with irregular shapes and thicknesses. Instead of being a detriment, the change in the dielectric environment caused by the 2D materials can be utilized to enable alternative methods for 2D material and cavity light-matter coupling.

In our work, we demonstrate a novel method to the form high Q factor nanocavities by partially covering a photonic crystal (PhC) waveguide post-fabrication with a suitably-sized 2D material flake (Fig. 1a) [4]. The presence of the flake increases the local refractive index causing a frequency mismatch of the optical fields in the regions with and without the flake which results in the formation of a nanocavity. We first performed numerical finite-difference time-domain (FDTD) and finite element method (FEM) simulations, considering specifically the air-suspended W1 line defect PhC waveguide made of silicon with a triangular array of air holes with lattice period a, with a 2D material flake covering a section of the waveguide. Fig. 1b shows a typical distribution of the E_y field amplitude of the cavity mode, indicating that the fields are largely confined to the regions with the 2D material flake. From our simulation results, the Q factor increases with decreasing flake thickness, approaching ultrahigh Q factors of the order of 10^7 at monolayer thickness (Fig. 1c). The atomically thin nature of the flake causes a less abrupt change of the refractive index in space, minimizing loss and thus resulting in ultrahigh Q factors.

WSe_2 flakes are transferred onto the PhC waveguide using the anthracene-assisted dry transfer method [5]. Figure 1d shows a fabricated hybrid nanocavity device with a trilayer tungsten diselenide (WSe_2) flake. The flake width is about $10a$. To obverse the cavity mode, we performed laser transmission measurement by exciting the laser at the grating coupler at one end of the waveguide and detecting the signal from the opposite end. The cavity peak is clearly observed in the transmission spectrum, giving a loaded cavity Q factor as high as 4.0×10^5. We have also successfully fabricated hybrid nanocavities using hBN and molybdenum ditelluride ($MoTe_2$). In particular, $MoTe_2$ is optically active in the near infrared. Since the nanocavity and the flake are spatially self-aligned, they

could couple to each other readily. We managed to observe such self-aligned optical coupling in a $MoTe_2$-hybrid nanocavity device exhibiting enhanced photoluminescence emission, as well as a reduced emission decay time due to the cavity Purcell effect.

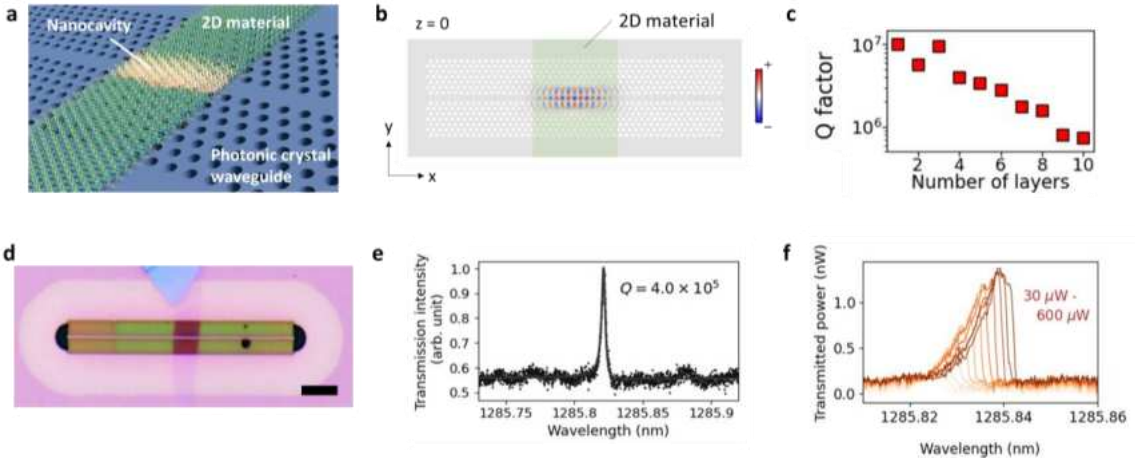

Fig. 1 (a) Schematic of the PhC hybrid nanocavity. (b) Simulated cavity mode profile for a WSe_2 flake with lateral width of 14*a*, showing that the fields are confined to the regions with the 2D material flake. (c) Theoretical Q factor against the WSe_2 flake layer number obtained from FEM simulations. The width of the flake is fixed to 14*a*. (d) Optical micrograph of a fabricated hybrid nanocavity with a trilayer WSe_2 flake. The color and contrast have been adjusted to improve clarity. (e) Transmission spectrum showing the cavity peak with a Q factor of 4.0×10^5. (f) Asymmetric cavity peak indicating optical bistability.

Our work unambiguously show hybrid nanocavity formation and self-aligned optical coupling using atomically thin materials. This versatile approach can be extended to a wide variety of materials, with further room for more complex material and photonic engineering to manipulate light-matter interaction. Therefore, our results will have a significant impact on numerous fields including layer materials nanoscience, hybrid device applications and integrated photonics.

The reduced loss of guided exciton–polariton modes in WS_2 multilayers by hBN-encapsulation

Ho Seung Lee[1], Junghyun Sung[1], Dong-Jin Shin[1], and Su-Hyun Gong[1]

[1]Department of Physics, Korea University, Republic ofKorea

Abstract: Guided exciton–polariton modes, innately form in bare TMDC layers due to self-hybridization between excitons and photons, exhibit a limited propagation distance owing to the substantial exciton absorption within the material. We overcome this limitation and increased propagation distance by utilizing hBN layers to provide flat substrates and protect surface.

Atomically thin two-dimensional (2D) transition metal dichalcogenides (TMDCs) are remarked for their outstanding potential in photonic and optoelectronic devices. 2D TMDCs experience strong light-matter interactions and valley degrees of freedom by increased excitonic effect in 2D limits and broken inversion symmetry. The unique properties of TMDCs led to studies in various fields such as exciton-polaritons demonstrated by cavity engineering [1]. Further studies have shown guided exciton–polariton modes naturally exist in bare TMDCs layers due to self-hybridization between excitons and photons [3]. However, these guided polariton modes exhibit a limited propagation distance owing to the substantial exciton absorption within the material.

Here, we demonstrated improvement of guided exciton-polariton modes in TMDCs multilayers by integrating protection layers. Tungsten Disulfide (WS_2) is selected from the TMDCs due to its outstanding excitonic properties in room-temperature regime. For protection layers, hexagonal Boron Nitride (hBN) is chosen due to its outstanding properties as protection layers and flat substrates: wide band gap, high permittivity, little dangling bonds, and continuous hexagonal lattice structure with flat plain similar to graphene. By encapsulating WS_2 layers with atomically thin layers of hBN, WS_2 layers were isolated from charge disorder at the surface of substrates and protected physical flatness [3, 4]. We observed that the hBN encapsulation reduced the inhomogeneous linewidth of exciton in the photoluminescence spectrum. The reduced linewidth of the exciton emission indicates a stronger excitonic resonance, which leads exciton-polaritons to have improved properties. To directly compare the optical properties of exciton-polaritons with and without hBN encapsulation, their spectra scattered at the sample edge were systematically investigated. We experimentally observed that the propagation distance of polariton modes substantially increased with hBN layers. Additionally, the polariton spectrum broadened due to efficient exciton relaxation to the polariton states at lower energies. The promising outcomes with hBN encapsulation suggest its potential to overcome strong excitonic losses of the guided exciton polariton in implementing nanophotonic devices.

Abstract

Distinctive structural, electrical and optical characteristics of titanium nitride films made them highly sought-after for a variety of technological applications. Investigations in their material property perspective proved it as an alternative metamaterial. Typically, these materials are produced via physical vapor deposition (PVD) and chemical vapor deposition (CVD) techniques [1]. This study focuses on the development of titanium nitride thin films by gas nitridation process of RF sputtered titanium metal films at a temperature of 600°C, utilizing ammonia gas. The fabricated films possess enhanced opto-electrical properties compared to other fabrication routes. We investigated here the titanium nitride film as new platform for further metamaterial applications with an evaluation of the dielectric function. The films that are being studied range from 50 to 150 nm in thickness. Structural analysis is carried out with the aid of Raman and GI-XRD spectroscopic methods. The reflection and transmission spectra analysis in the visible region (400–900 nm) was used to investigate the optical characteristics. The bandgap variation has been studied by processing optical transmission spectra using Tauc plot. Hall measurement in the van der Pauw arrangement was used to examine the electrical properties of the films. Study was concentrated on their electrical and optical properties to establish a correlation and also to illustrate the metamaterial characteristics of the coated titanium nitride films.

1. Introduction

The advancement in the field of hyperbolic metamaterial (HMM) requires a material, which offers low loss and negative permittivity compared to the conventional metals used for the purpose[1]. In 2017, Naik et al investigated the optical performance of layered titanium nitride and a dielectric material for HMM device application [2] and confirmed the improved performance of the same. The fabrication of each layer was done with magnetron sputtering technique.

In general, titanium nitride films were fabricated by physical vapour deposition, plasma laser deposition, and chemical vapour deposition techniques. In this work, we used gas nitridation route to incorporate nitrogen into the titanium metal films fabricated via sputtering. Purged ammonia gas will split up to nascent nitrogen and hydrogen at high temperature, the produced hydrogen creates a reduced atmosphere and prevents the traces of residual oxygen in the samples.

2. Methodology

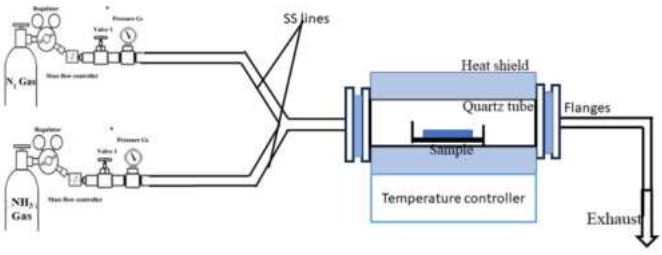

Fig 1 Ammonia gas nitridation apparatus

The Titanium metal films were fabricated via magnetron sputtering on soda lime glass substrate using metal target (99.99%) of 2 inch diameter with a sputtering power of 120W and working pressure 3×10^{-3}mbar. The films were coated with variable thickness ranging from 50 to 150nm, confirmed by Field emission scanning electron microscopic images. The sputtered metal films were immediately transferred to the nitridation chamber to avoid possible oxidation. Fig 1 shows the experimental setup for nitridation. Gas nitridation is carried out by initially purging nitrogen (99.99%) gas and then shifting to ammonia (99.99%). The nitridation is carried out at a ramp rate of 5°C/min up to temperature of 600°C for duration of 30 minutes. The samples were named according to the average thickness of the precursor metal films, as T1(50nm), T2 (100nm), and T3(150nm), respectively

Nitridated samples were subjected to structural, electrical and optical characterizations by using grazing

incident x-ray diffraction, hall measurements and UV-visible transmittance spectra, respectively. The phase formation was confirmed with x-ray diffraction (Rigaku Ultima IV) with Cu K_α radiation, at a glancing angle of 0.5°. Hall effect measurements of the films were carried out using the four-probe van der Pauw method (ECOPIA HMS3000). UV-vis-NIR reflectance spectra were recorded using a spectrophotometer (JASCO V-570)

3. Results and discussion

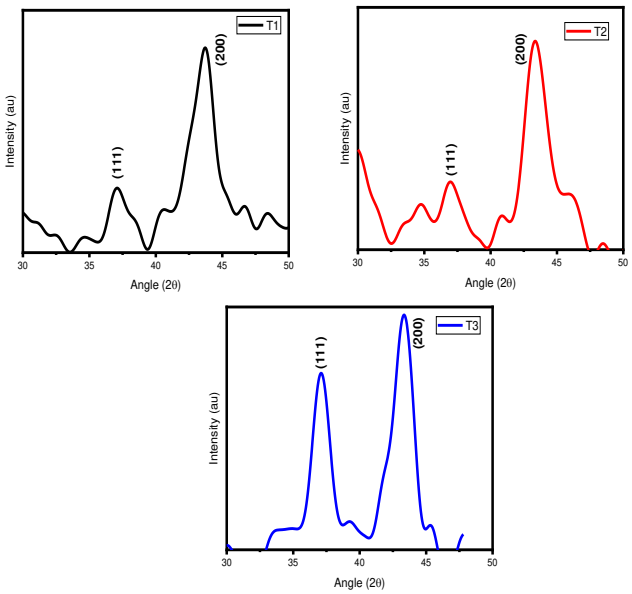

Fig 1 Grazing incident XRD patterns of the nitridated metal films, T1, T2 and T3

As shown in figure, the films prepared are having a cubic symmetry with peak orientation corresponding to (111) and (200) planes in 2θ angles at 36.5° and 42.6°, respectively (ICDD pattern, 00-038-1420). The samples were subjected to same nitridation conditions. However, being a non-stoichiometric compound, the samples after nitridation differs with respect to the film thickness. Hence, one can expect variations in the overall properties of the samples with stoichiometry. May be the increased titanium content in the film T3 contributed to an increased peak orientation in (111) direction exhibiting better crystallinity for the film [3].

Table 1 Hall measurement data of the nitridated metal films

Sample name	Carrier concentration (/cc)	Mobility (cm^2/Vs)
T1	4.19×10^{21}	0.0125
T2	8.05×10^{20}	0.493
T3	4.68×10^{20}	0.695

Table 1 shows the hall measurement data obtained for the nitridated metal films. Electrical conductivity and other properties of transition metal nitride largely depend on the stoichiometric nature of the material. Both metal rich condition and stoichiometric condition generally provide high carrier concentration in TiN films. Here, high carrier concentration exhibited by the sample T1 may be due to the stoichiometric condition. The sample T3 showed higher hall mobility among the three films, which may be due to the improved crystallinity in the film.

The measured transmittance spectra of nitridated films T1, T2, and T3 are shown in figure 2. The bandgap determinations are carried out with Tauc plot analysis. According to tauc plot the strength of optical absorption depends on the [4-5] difference between the photon energy and bandgap as

$$\alpha h\upsilon = A\,(h\upsilon - E_g)^n \ldots\ldots\ldots (1)$$

where h is Planck's constant, ν is the photon's frequency, α is the absorption coefficient, Eg is the band gap and A is the constant.

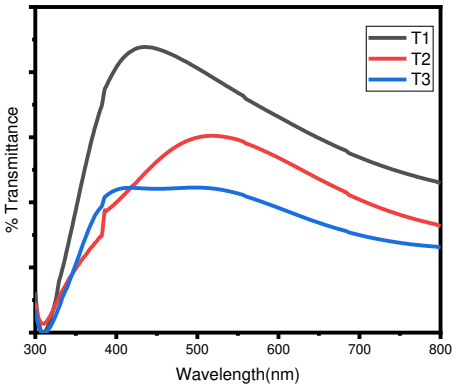

Fig 2 Transmittance spectra of nitridated metal films

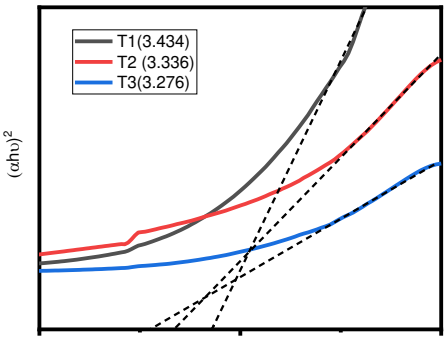

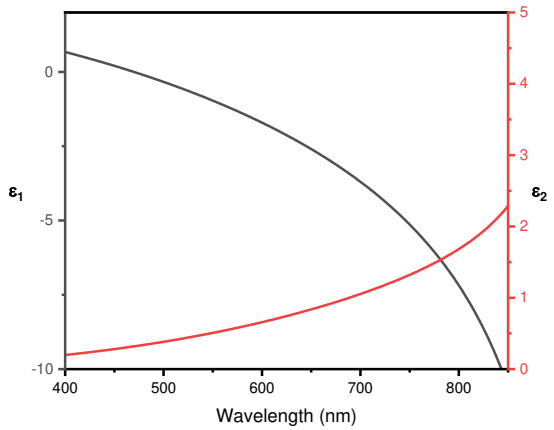

Fig 3 bandgap of metal films after nitridation

The plot $(\alpha h\upsilon)^2$ vs energy provides information about the bandgap. Bandgap values show a decreasing trend as the sample film thickness is increased. The wide band gap exhibited by the sample T1 may be due to the stoichiometric dependent nature of the film. Bandgap values showed a variation from 3.27 to 3.43eV with respect to the thickness.

Patasalas et al extracted the dielectric function from the reflectance pattern of the titanium nitride films using Drude -Lorentz approximation, by considering both free carriers and bound electrons in the sample. [6]. In a similar manner, extracted the dielectric function of the sample, and obtained the permittivity values in the visible range, are as shown in Fig. 4. The existence of negative permittivity and low loss nature is confirmed, and this indicates that the titanium nitride films prepared in this work can behave as a suitable metamaterial in visible region.

Employing wide band gap materials with negative permittivity in the desired wavelength will reduce the dielectric loss and enhance the performance of HMM devices applications [7].

4. Conclusions

Titanium nitride thin films with variable thickness were successfully fabricated from RF sputtered metal films by subjecting to ammonia gas nitridation. Structural confirmations were obtained through grazing incident x-ray diffraction. The films with stoichiometric nature exhibited higher carrier concentration with wide bandgap nature. Negative permittivity and low loss nature of the nitridated thin films were confirmed in the visible region, and this make titanium nitride a suitable hyperbolic metamaterial. Further investigations are required by combining them with dielectric material for complete understanding of metamaterial characteristics.

Abstract: Defect inspection in 2D transition metal dichalcogenides has been limited to electron microscopy which has low field-of-view and low imaging speeds. Here we propose to use expansion microscopy (ExM) to embed the defect distribution onto a swellable hydrogel and combine with localization microscopy to achieve sub-10-nm resolution with optical microscopy.

Atomic defects in 2D materials are of great interest due to their role in modifying the optical and electrical properties of their host material. The observation of such defects is of high importance when considering fabrication of 2D semiconductor devices. Currently, defect mapping in MoS_2 is carried out at both small and large scales, the former by transmission electron microscopy (TEM) and scanning tunneling microscopy (STM) and the latter by photoluminescence mapping and Raman spectroscopy. TEM and STM offer atomic resolution, but are limited by the small field of view and slow imaging speed, thus impeding large-scale defect identifications. On the other hand, optical methods are much more efficient in characterizing millimeter to centimeter scale defect distributions, but the resolution is limited by diffraction, i.e. ~300 nm with visible light.

Over the past three decades, the diffraction limit has been repeatedly broken by significant improvements in optical microscopy. For example, single-molecule localization microscopy (SMLM) has the capability to localize blinking fluorescent molecules with precision near ~20 nm, but due to their biomolecular nature, such applications have been limited to bioimaging and cannot be utilized on semiconductor samples. Recently, two works have demonstrated the capability of using thiol-containing fluorescent probes such as DNA molecules[1] or antibody fragments[2] to attach a fluorescent signal to sulfur vacancies in MoS_2. Such approaches have already pushed the resolution of defect imaging down to ~20 nm.

We extend these works further by using antibody fragments to anchor to a swellable hydrogel matrix and physically expand the hydrogel, allowing for ~4X effective resolution improvements using a conventional fluorescence microscope. This process is known as expansion microscopy[3,4] (ExM). In Figure 1, we detail the process of embedding the defect distribution onto the hydrogel and demonstrate sub-10 nm resolution imaging by also using dSTORM[5] to localize the fluorescent probes.

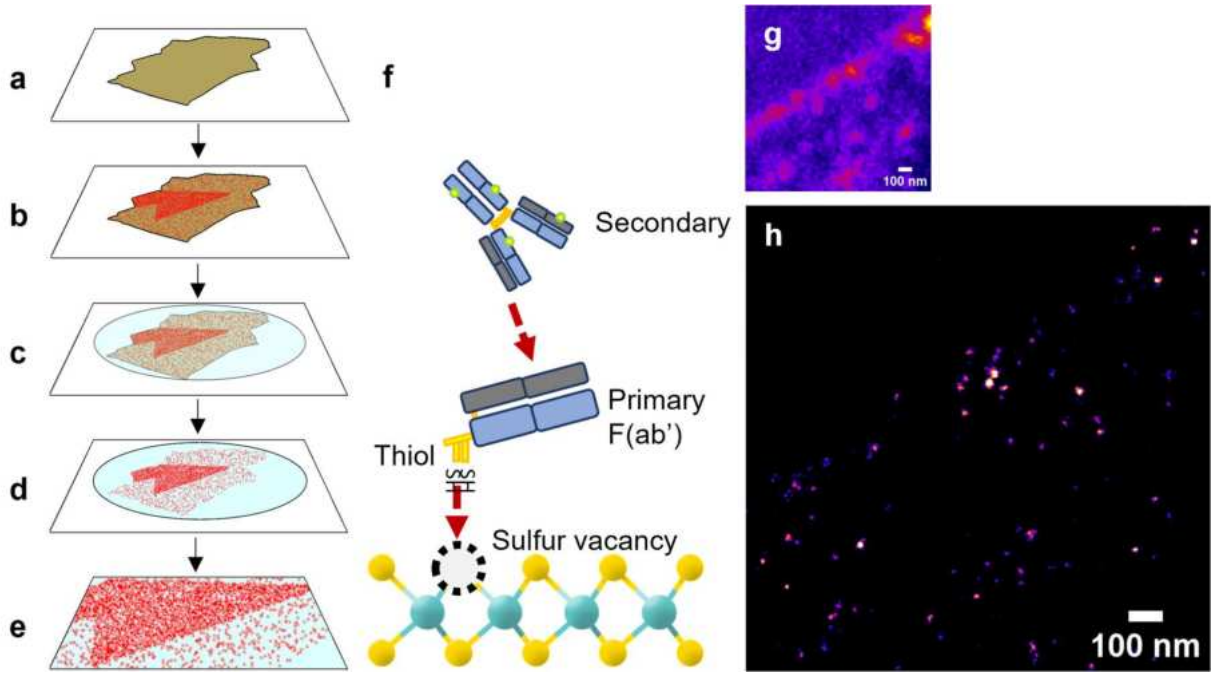

Figure 1. (a-e) Schematic of expansion microscopy on MoS_2. (b) Labelling with fluorescent probes. (c) Probes are embedded in gel. (d) Gel is digested to allow for free expansion. (e) Gel is physically expanded up to ~4X linearly. (f) Molecular view of labeling step shown in (b). (g) Fluorescence image of 4.0X expanded gel. (h) dSTORM image of the same region in (g).

While ExM alone can provide a fourfold improvement in resolution, as seen in Figure 1g, dSTORM (Figure 1h) pushes the resolution limit even further, allowing us to resolve individual defects with a distance of sub-10 nm, with a massive field of view of 50 by 50 micrometers (full image not shown). In conclusion, we successfully demonstrate using ExM to achieve super-resolution defect imaging in MoS_2. This opens exciting avenues for utilizing ExM for large-scale, high-resolution defect mapping in 2D materials.

Exciton-polaritons in van der Waals heterostructures coupled to optical bound state in the continuum

Dong-Jin Shin[1], HyunHee Cho[1], Woo Hun Choi[1], Ho Seung Lee[1], and Su-Hyun Gong[1*]

[1]Department of Physics, Korea University, Seoul, Republic of Korea

Abstract: We realized the subwavelength-thick exciton-polariton platform exclusively consists of van der Waals two-dimensional (2D) materials. By leveraging their exceptional optical properties and van der Waals nature, we achieve successful integration between bound state in the continuum (BIC) modes and excitonic resonances of atomically thin 2D semiconductors.

Bound states in the continuum (BICs) are peculiar states that, despite being embedded in the continuum spectrum of modes, remain localized without any coupling to far-field radiation. This counterintuitive phenomenon, first theorized in quantum mechanics, has found a fertile ground in photonics, offering unprecedented opportunities for enhancing light-matter interactions without the inherent loss mechanisms typical in resonant systems.

Exciton-polaritons are hybrid light-matter quasiparticles that arise from the strong coupling between excitons (bound electron-hole pairs) and photons. These quasiparticles embody the dual nature of light and matter, showing unique properties that originate from both their photonic and excitonic components. Recently, exciton-polaritons derived from strong light-matter interaction between an excitonic resonance and an optical BICs become promising candidate for polariton condensation because of their topologically protected states with theoretically infinite lifetime. Unlike previous platforms that take advantage of the local minimum at the energy-momentum dispersion[1], polariton platforms based on BICs utilizes the topologically protected meta-stable state with supposedly infinite lifetime[2,3]. This could provide achievement of extremely low threshold density of condensation of exciton-polaritons.

Here, we successfully realized exciton-polaritons in van der Waals heterostructures coupled to optical bound state in the continuum. The integration between atomically thin 2D semiconductors and optical BICs is considered challenging due to atomically thin size and their vulnerability to external environments during fabrication. By manipulating the van der Waals nature of 2D materials, we successfully realized the integration of excitonic resonances of atomically thin 2D semiconductors with optical BIC modes. Under reflectance measurement, we found our system show anti-crossing behavior with Rabi splitting of ~20 meV. Also, we found the BIC polariton show nonlinear behavior, as increasing the non-resonant pump fluence. To confirm the topological properties of the BICs polariton, we measured the degree of linear polarization of emission. We believe our system provide a robust platform for investigating exciton-polaritons in van der Waals heterostructures coupled to optical BICs.

Abstract: A coherent acoustic phonon in the alloy WSSe is revealed using double-pump-probe spectroscopy. The proposed mechanism involves a cascaded process of exciton formation, phonon recycling, thermoelastic deformation and a potential piezoelectric enhancement of the coherent oscillation. The coherent phonon response is optically controlled using a tailored pump pulse sequence.

Control of the structural properties of materials on ultrafast timescales is relevant for future high-speed logic devices. Coherent acoustic phonons (CAPs) can alter the symmetry of a material and give access to topologically protected phases [1]. Such coherent oscillations exist in several TMDs [2]. Here, we show for the first time the coherent acoustic mode in the tungsten based TMD alloy WSSe.

Approximately 100 fs long pulses at 800 nm are used for single- and double-pump-probe spectroscopy on commercially available crystals of WSSe (HQ Graphene and grown using chemical vapor transport), with lateral size of ~1 cm. The alloy's atomic species ratio is S/Se, 29.8/37.0. A controllable two-pump-pulse sequence was generated by frequency doubling to 400 nm and delaying one pump pulse with respect to the other.

Fig. 1(a) shows a schematic of the proposed activation mechanism for CAPs in WSSe. The transient dynamics are shown in Fig. 1(b), compared against its symmetric counterparts (WS_2 and WSe_2). Initially, a single pump pulse drives the material out of equilibrium. Excitons rapidly form under 400 nm (3.1 eV) excitation [3]. The decay constant, τ=369 fs, agrees with previously reported data on TMDs [4]. At high pump fluence (~5 mJ/cm^2) not all photoexcited carriers can form excitons, instead carriers thermalize to the bottom of the conduction band emitting phonons in the process. The phonon recycling effect [5] can re-excite trapped carriers into the conduction band, thus repopulating available states and increasing the transient reflection signal, as highlighted in Fig. 1(b). Additionally, the generated phonons increase the lattice temperature, subsequently causing a deformation of the material via the thermoelastic effect that initiates a CAP. The CAP is seen as a modulation of transient reflection at a frequency of 26.98 GHz.

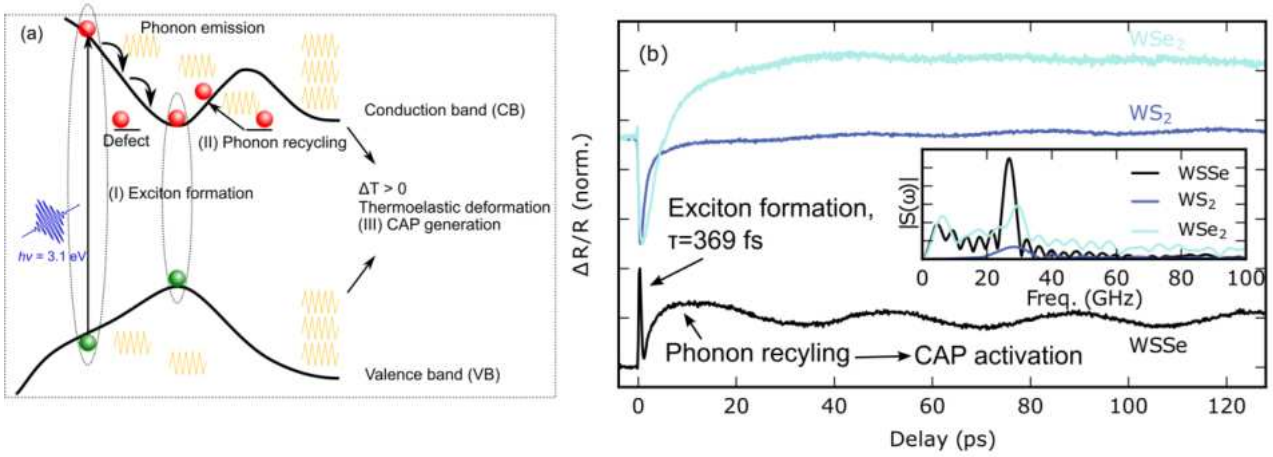

Figure 1. (a) CAP generation mechanism in WSSe. (b) Transient reflection of tungsten-based TMDs. Inset: spectrum.

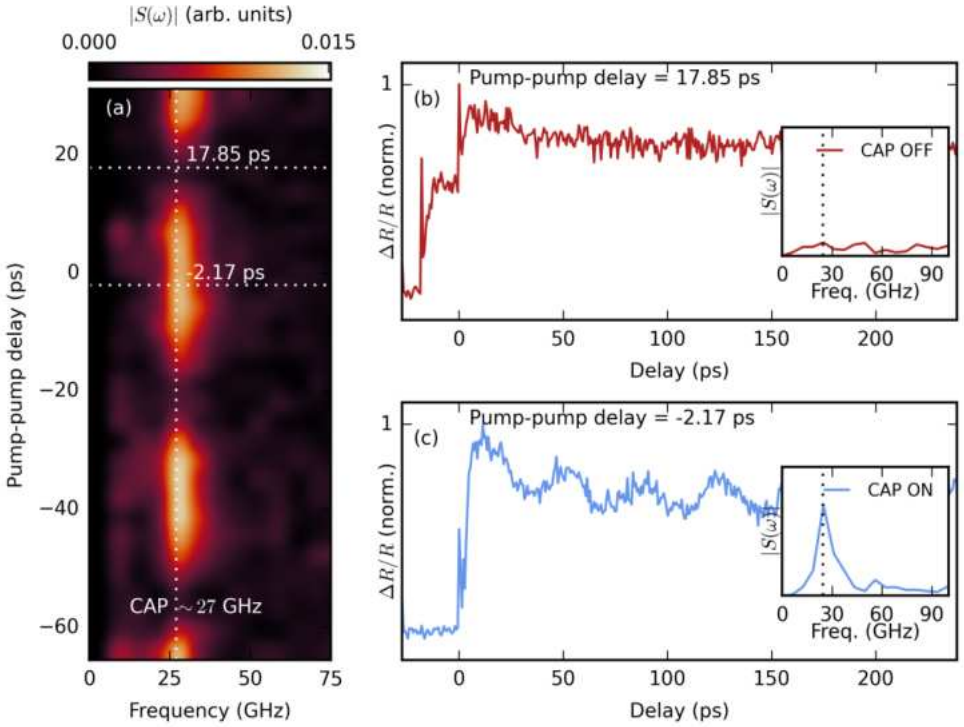

Figure 2. (a) Spectrum vs. pump-pump delay. All-optical suppression (b) and enhancement (c) of CAP oscillations.

Comparison with WS_2 and WSe_2 shows CAPs are also activated, but with much smaller amplitude. We propose that the asymmetric composition of the alloy breaks the inversion symmetry of the crystal and induces a piezoelectric field that enhances the change of the refractive index of the strained layer via the Franz-Keldysh effect [6].

A second 400 nm pump pulse of a similar fluence, but variably adjusted in time with respect to the arrival of the first, can optically control the amplitude of the coherent oscillation by careful tuning of the temporal separation between the respective pump pulses. In Fig. 2(a), we plot the two-dimensional (2D) frequency-delay dynamics over a relative pump-pump delay time of 90 ps. The magnitude of the CAP at 27 GHz shows a sinusoidal variation as a function of the delay, with an extinction of 10 dB. Corresponding minima and maxima in the 2D map represent constructive and destructive interference of the excited acoustic phonon wave-packets. In Fig. 2(b) and 2(c), we plot horizontal cuts of the time-domain (inset spectral) dynamics at 17.85 ps and -2.17 ps, which correspond to a suppression and enhancement of the coherent oscillation, respectively.

Our results highlight the potential of asymmetric alloys as a platform for high-Q acoustic resonators with a broad range of potential applications in quantum nanoacoustics and nanophononics. Using a tailored sequence of carefully timed pump pulses, we can optically control the amplitude of the coherent oscillation, with implications for the future development of ultrafast logic devices.

Metal-Insulator Transition in Vanadium Dioxide Inspected by Analytical Electron Microscopy

J. Krpenský[1,2], M. Horák[1], J. Planer[1], P. Kepič[1], J. Kabát[1], A. Konečná[1], and V. Křápek[1*]

Abstract: Vanadium dioxide is an emerging plasmonic material with metal-insulator transition, relevant for active plasmonics and switchable optical metasurfaces. We study the metal-insulator transition with analytical electron microscopy, locally correlating signatures of the transition in chemical, crystallographic, and optical properties.

Vanadium dioxide (VO_2) stands out among materials exhibiting metal-insulator phase transition (MIT) due to the proximity of its transition temperature (about 68 °C) to the room temperature, which makes it a promising candidate for applications in photonics including fast optical switching or tunable optical metasurfaces [1]. Here we probed the MIT in a scanning transmission electron microscope (STEM) with in-situ heating. A combination of imaging, diffraction, and spectroscopy with nanometer spatial resolution allowed us to locally correlate the optical properties of VO2 with applied temperature and local variations in stoichiometry.

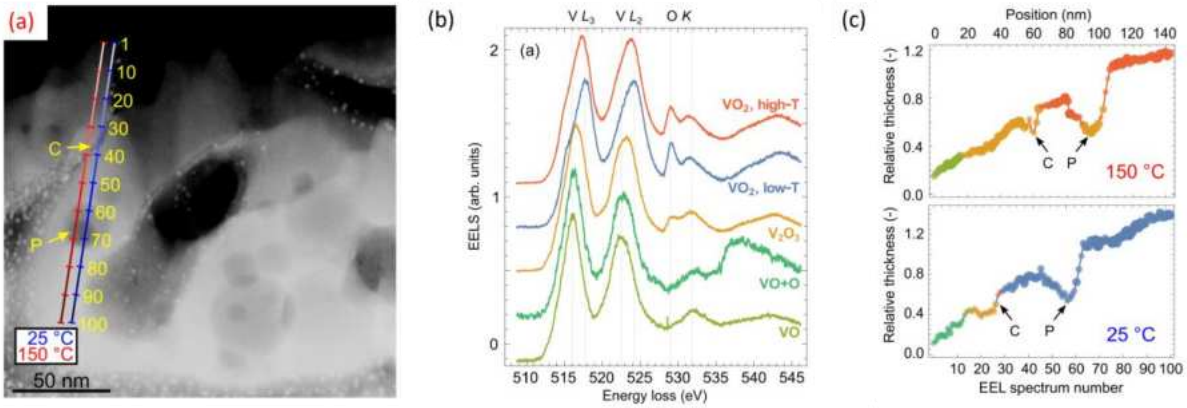

Figure 1: (a) HA ADF of the lamella with a crack (c) and a pore (P). The lines denote the positions where EEL spectra were recorded. (b) Characteristic EEL spectra determined by cluster analysis were attributed to distinct stoichiometries (VO, V_2O_3, VO_2). (c) Distribution of the stoichiometry across the sample. EEL spectrum number corresponds to the position indicated in panel a, the color of the symbols corresponds to the color of the spectra in panel b (green – VO, yellow – V_2O_3, red or blue – VO_2), and vertical position of the symbols indicates the local thickness.

We fabricated a thin layer of VO_2 by evaporation and verified the presence of MIT by ellipsometric characterization of the dielectric function. Next, we fabricated V-shaped lamellas for STEM from the thin layer by focused ion beam milling with Ga ions. The high-resolution and high-angle annular dark field (HA ADF) STEM imaging revealed pronounced structural inhomogeneity – a porous and polycrystalline character of the examined lamella (Fig. 1a). Energy-dispersive X-ray spectroscopy (EDX) revealed a rather homogeneous elemental

composition with only discernible contamination by Ga ions implanted during the milling. Core-loss electron energy loss spectra (Fig. 1b) were processed by cluster analysis and interpreted with ab-initio simulations and by comparison with recent literature [2, 3]. They revealed the presence of the oxides with reduced oxidation number (VO, V_2O_3). Interestingly, the local thickness of the lamella was found as the only parameter determining the local stoichiometry (Fig. 1c).

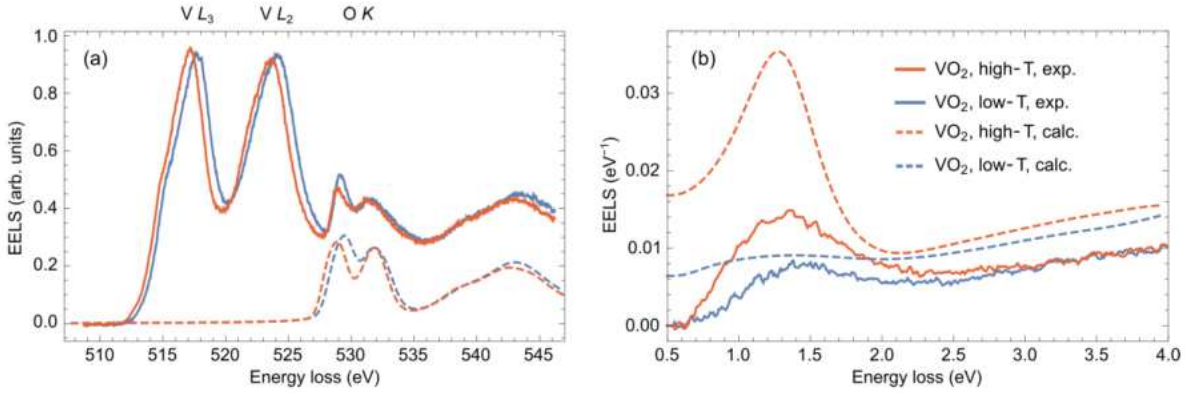

Figure 2: (a) Core-loss EEL spectra of VO_2 obtained at 25 °C (solid blue line), and 150 °C (solid red line) are compared with ab-initio-calculated O K peaks corresponding to the monoclinic phase (dashed blue line) and rutile phase (dashed red line). (b) Comparison of the experimentally acquired low-loss EELS at 25 °C (solid blue line), and 150 °C (solid red line) compared with calculations using a classical dielectric formalism (dashed blue and red lines).

Figure 2 shows the signatures of MIT in the part of the lamella attributed to VO_2. In core-loss EELS [Fig. 2(a)] we observe an increase in the relative intensity of the 1st to 2nd oxygen K peak upon heating. Ab-initio simulations explain this increase by the change of the crystal lattice from monoclinic to rutile phase, as expected for the MIT. In low-loss EELS [Fig. 2(b)] the emergence of the plasmon peak around the energy of 1.4 eV upon heating clearly manifests the change of the phase from dielectric to metallic.

During the conference, we will discuss further details, including a comparison of a porous VO_2 lamella to VO_2 nanocrystals, a manifestation of the MIT in electron diffraction, and a hysteresis curve of the transition. Additional information is also available in Ref. [4]. Abstract: We have study the local photobleaching in TDBC layers for grating and strong coupling applications. With this method, the refractive index can be both locally and spectrally modulated. In this work, fundamental properties and fabricated micro-devices have been investigated highlighting the high potential of this interesting materials for photonics applications.

Tetrachlorodiethyl Benzimidazo Carbocyanine (TDBC) layers are very interesting for photonics applications due to their huge oscillator strength, narrow absorption, local photo bleaching, and low-cost fabrication. They are mainly used in strong coupling studies [1], but also for light concentration [2], absorption enhancement [3]… However, these intrinsic properties are still not very well understood and need to be investigated to fully exploit the high potential of this material, especially regarding the bleaching properties (i.e photochemical alteration of a molecule that become unable to fluoresce).

During the recent past years, we have studied different TDBC micro-devices showing that micro-structures with resolutions down to 1 µm can be successfully fabricated using a laser writer for strong coupling applications [4] and grating fabrication [5]. Furthermore, material intrinsic properties studies have been also investigated. Using Raman spectroscopy, we have shown that a slight change in the molecule give a huge oscillator strength modification [6,7].

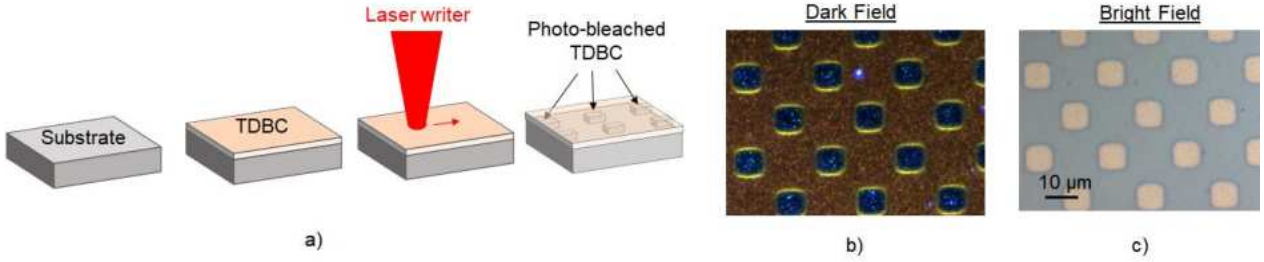

Figure 1 : a) process flow of the local photo-bleaching using a laser writer; fabricated sample observed with an optical microscope in b) dark field and c) bright field

Figure 1-a presents the process flow used to locally bleached TDBC layers. 17 nm thick TDBC layers are spin-coated [8] on SiO_2 or Ag on SiO_2 substrates [9] and then insolated with a laser writer (µPG Heidenberg). The Figure 1-b and c presents examples of a fabricated structures with insolated periodic squares on 50 nm Ag layer on a SiO_2 substrate. Images were measured with an optical microscope in both dark field (DF) and bright field (BF) modes. In the BF image, we clearly see that the refractive index is modulate at the microscale since the TDBC become transparent in the bleached region. For the DF image, the outline are detected indicating that the interface are abrupt between the bleached and active regions.

Furthermore, we also investigated the refractive index change as a function of the bleaching. The Drude-Laurentz model [6] is the most used in the literature with 5 constant material parameters: f_{osc} the oscillator strength, Eg the energy of the HUMO-LUMO (Highest Occupied Molecular Orbital and Lowest Unoccupied Molecular Orbital) transition, ΔE the absorption spectral width and ε_0 the constant part of the dielectric function. After bleaching, only the fundamental transition at around 590 nm wavelength range is modified in the refractive index. Furthermore, since many values are reported in the literature, we have studied the potential origins of these differences. Several parameters can lead to an undervaluation of the oscillator strength such as the layer thickness evaluation, the roughness, the use of polyvinyl alcohol as hang layer and the layer bleaching. Therefore, we highlight here the need of a better investigation of these layers for further applications of this promising materials.

Ultrathin bismuth and antimony films as alternative materials towards versatile and sustainable metastructures

F. Chacon-Sanchez, C. Ruiz de Galarreta, R. Serna
Instituto de Óptica (IO-CSIC), Serrano 121, 28006 Madrid, Spain
*corresponding author: fernando.chacon@csic.es

Abstract: Semimetals are versatile, unconventional materials with great potential for their application on metasurfaces. We will study the tailoring potential of their dielectric function via ultra-thin film morphology control and apply this tailoring for structural coloration, combining them with industrial materials like silicon or steel to achieve vivid, sustainable structural colors.

When designing an optical device, like plasmonic metasurfaces, interference-based cavities or perfect absorbers, the choice of material is crucial due to its refractive index (or dielectric function). Because of their near-ideal refractive index, the more extended materials used for the above-mentioned photonic applications are either transparent dielectrics or very conductive metals. Lossy materials were frequently not even taken into consideration since optical losses have been traditionally considered suboptimal. However, in the last ten years the scientific community has started to look for alternative, usually lossy materials to try to overcome some material limitations and to look forward to new developments such as active or switchable devices [1,2]. Among all these alternative materials, the semimetals bismuth (Bi) and antimony (Sb) have proven to be very attractive, showing a rich optical behavior arising from their strong interband transitions in the NIR [3]. As a result, Bi and Sb -based nanostructures can display epsilon-near-zero and interband plasmonic behavior as a lossy metal in the VIS-UV and act as a lossy dielectric with ultra-high refractive index (n~10) that can support Mie resonances. Another very interesting feature is their potential as a phase-change material (PCM), exploiting the low-temperature (270ºC) solid-liquid transition for Bi and the metastable amorphous-crystalline transition for Sb. Towards their potential day-to-day application, they can prove advantageous since they are inexpensive, abundant materials, that show low toxicity and good biocompatibility, making them ideal candidates for sustainable photonics.

The scientific relevance of Bi and Sb is undoubtedly on the rise, with an increasing number or reports in the last few years studying different fundamental phenomena [4, 5] and designing devices for their application, addressing different regions of the UV-NIR spectra [6, 7]. We have recently reported the design and fabrication of Bi-based gap-surface plasmon metasurfaces (GSP) and Fabry-Perot cavities (FPC) for non-diffractive structural color generation [8].

In this contribution, we move forward to the study of Bi and Sb within the ultrathin film regime (t~10nm) with the aim to further investigate the potential tailoring of their optical response. The films are prepared via pulsed laser deposition (PLD). We will show how with the fine tuning of the deposition parameters we are able to successfully modify the morphology and/or structure of our films in a robust and consistent way. This unprecedented control of the morphology and structure allows us to access to new optical properties with a well-defined dielectric function while using the same building blocks. An example of the achieved tailoring of the optical properties is displayed on Fig. 1 in which we have plotted the dielectric functions (ε) for different films as a function of thickness and approaching the near percolation regime, or achieving the amorphous phase for the case of Sb. The unique optical properties of Bi allow us to modulate the spectral regions of the spectra where high losses or epsilon-near-zero are displayed, therefore enabling am effective control of the dielectric function that has

not been possible for the archetypical noble metals (Au and Ag) although this approach through the modification of their morphology was atempted [9]

Once the tailoring potential of the Bi and Sb ultrathin films has been established, we have studied their application to structural color generation via FPC. Moreover, we will show the possibilities to generate vivid, robust structural colors directly using the substrate as a back-mirror, focusing on industrially ubiquitous substrates like silicon or steel. This opens the possibility of the use of structural color generation for consumer products, as well as in specific high-tech applications.

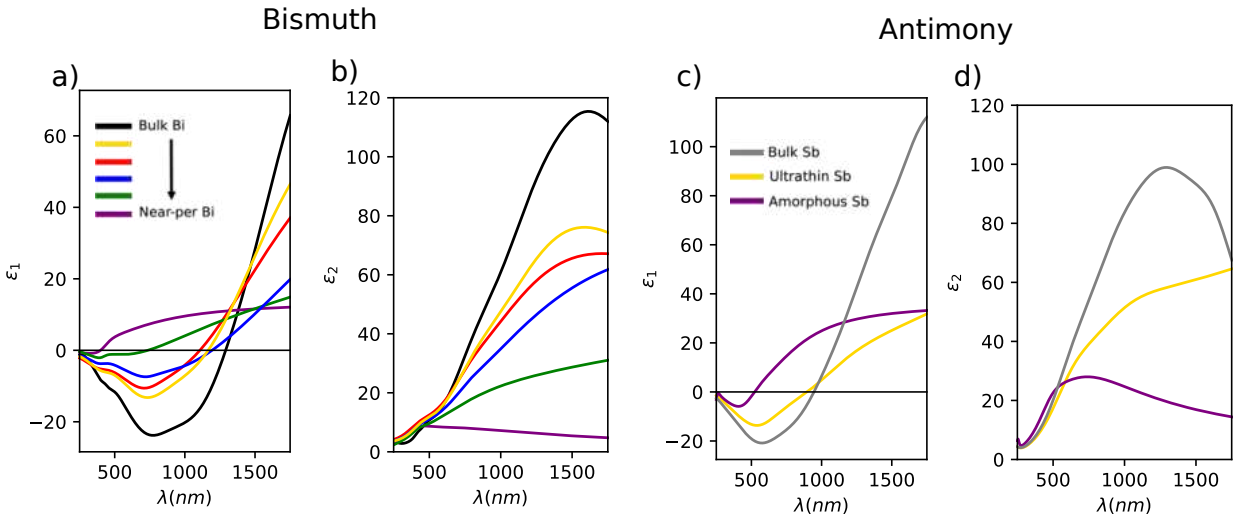

Fig.1 Real (ε_1) and imaginary (ε_2) part of the dielectric function for several deposited Bi (a,b) and Sb (c,d) films. As can be seen in the legend, Bi dielectric functions range from bulk Bi to near-percolation films (i.e. almost nanoparticles), whereas for Sb we have bulk Sb, an ultrathin crystalline film and an amorphous film.

Abstract: Time-varying surfaces are a promising emerging means for the generation of higher frequencies in future THz communication systems. In this work, we present a novel time-varying Fabry-Perot setup to enhance generated higher-order harmonics. The design is aided by a rigorous semi-analytic technique that aims to empower optimization efforts.

Recently, the THz regime has been approached due to the continuous progress of the telecommunication systems beyond the 5G limits. Therefore, efficient excitation setups are required to generate these frequencies and recently emerging time-varying media applications are increasingly considered suitable for this task [1–3]. Nevertheless, early cavity antenna solutions with a time-varying graphene generated only minimally enhanced harmonics [3]. In this work, we propose a time-varying Fabry-Perot configuration for the improvement of the produced higher-order harmonics, based on a rigorous semi-analytic methodology that enables rapid optimization processes.

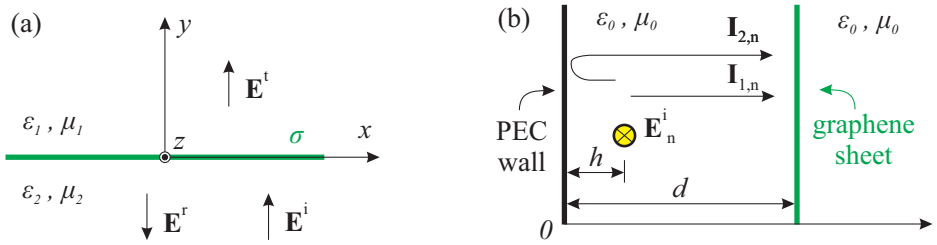

Figure 1: Setup (a) for normal incidence on a single graphene sheet on the xz-plane and (b) of the time-varying 1D Fabry-Perot resonator with an E-field source in its interior, generating the initial waves $\mathbf{I}_{i,n}$.

Let us assume a graphene sheet on the xz-plane and an incident wave $\mathbf{E}^{\mathrm{i}} = E^{\mathrm{i}} \cos(\omega t - k_2 y)\, \hat{\mathbf{z}}$, with $k_2 = \omega\sqrt{\varepsilon_2 \mu_2}$ (Fig. 1a). For the sake of simplicity, also, we assume for the graphene that $\bar{\bar{\sigma}} = \sigma\, \hat{\mathbf{z}}\hat{\mathbf{z}}$. In this context, the boundary conditions can be written, after some manipulation, as

$$E^{\mathrm{t}} - E^{\mathrm{i}} = E^{\mathrm{r}} \qquad \text{and} \qquad (\eta_1 + \eta_2)\, E^{\mathrm{t}} + (\eta_1 \eta_2)\, \sigma * E^{\mathrm{t}} = (2\eta_1) E^{\mathrm{i}}, \qquad \eta_i = \sqrt{\varepsilon_i \mu_i} \tag{1}$$

Next, we perform the convolution in the second formula of (1), considering that for non-time-varying media, $\sigma(t - t', t') = \sigma(t')$, i.e. invariant with respect to t. Additionally, for media with an instantaneous response, it holds that $\sigma(t - t', t') = \sigma'(t)\delta(t - t')$. In the general case of dispersive media, the Fourier transform of the convolution in (1) turns to [4],

$$(\eta_1 + \eta_2)\, E^{\mathrm{t}}(\omega) + (\eta_1 \eta_2) \int_{-\infty}^{\infty} \sigma(\omega - \omega', \omega')\, E^{\mathrm{t}}(\omega')\, d\omega' = (2\eta_1) E^{\mathrm{i}}(\omega). \tag{2}$$

In order to work further with (2), we need to discretize it for a specific number of n frequencies, or $\omega_n = \omega_0 + n\omega_{\mathrm{s}}$, where s is the sampling frequency. As a result, in (2) the convolution can be calculated in a discrete form for a given value n, as

$$\frac{\eta_1 + \eta_2}{2\eta_1}\, E^{\mathrm{t}}[n] + \frac{\eta_2}{2} \sum_{m=-N}^{N} \sigma[n - m] E^{\mathrm{t}}[m] = E^{\mathrm{i}}[n] \Rightarrow \left\{ \frac{\eta_1 + \eta_2}{2\eta_1}[I] + \frac{\eta_2}{2}[S] \right\} \mathbf{E}_n^{\mathrm{t}} = \mathbf{E}_n^{\mathrm{i}}, \tag{3}$$

where for all sampled frequencies ω_n, (3) receives the matrix form $[A]\mathbf{E}_n^{\mathrm{t}} = \mathbf{E}_n^{\mathrm{i}}$, with $\mathbf{E}_n^{\mathrm{t}}$ and $\mathbf{E}_n^{\mathrm{i}}$ the vectors containing the harmonics of the transmitted and incident/source waves, respectively. The $\mathbf{E}_n^{\mathrm{i}}$ vector is known and with the assumption of a monochromatic incidence at ω_0, only its E_0^{i} element is

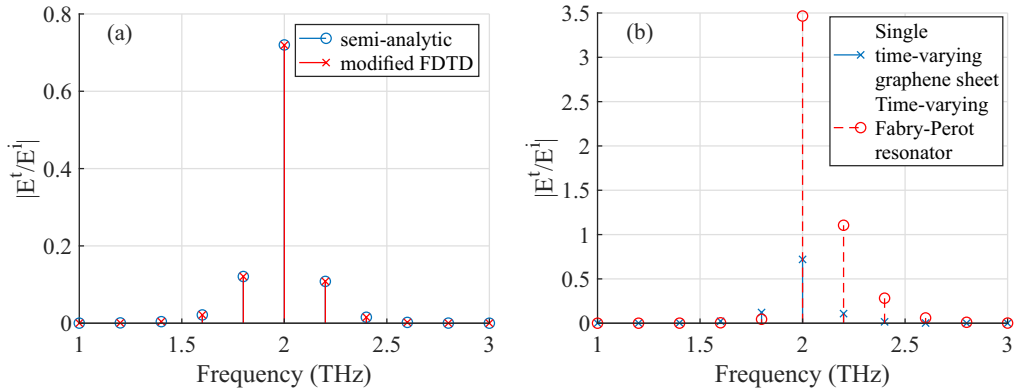

Figure 2: (a) Semi-analytic results validated with a modified FDTD algorithm for a $\delta(f - f_0)$ incidence on a single time-varying graphene sheet. (b) 1st harmonic ($f_1 = 2.2$ THz) enhancement via the optimized time-varying Fabry-Perot resonator, calculated with the proposed semi-analytic technique.

non-zero. Therefore, the computation of matrix $[S]$ and the solution of the system in (3) leads to the response of the time-varying graphene sheet. Note that the surface conductivity of graphene follows a Drude type dispersion [1]. Hence, if the surface conductivity is controlled (modulated) along a sinusoidal way via the chemical potential, $\mu_c(t) = \mu_{c,0}\,(1 + M\cos(\omega_{\rm mod}t))$, we arrive at

$$\sigma(t) = \frac{e^2\mu_c(t)}{\pi\hbar^2}\,e^{-2\Gamma t}\,u(t) \Rightarrow \sigma(\omega) = \frac{e^2\mu_{c,0}}{\pi\hbar^2}\,\frac{1}{\mathrm{j}\omega + 2\Gamma}\left[\frac{M}{2}\delta(\omega-\omega_{\rm mod})+\delta(\omega)+\frac{M}{2}\delta(\omega+\omega_{\rm mod})\right]. \quad (4)$$

for M the modulation strength and $\omega_{\rm mod}$, the modulation frequency. In that way, the $[S]$ matrix in (3) can be filled and, thus, $\mathbf{E}_n^{\rm t}$ and $\mathbf{E}_n^{\rm r}$ can be acquired. Let us, now, try to enhance the generated harmonics by the time-varying graphene via the 1D Fabry-Perot resonator of Fig. 1b. After some algebra, and if $[T] = [A]^{-1}$ and $[R] = [T] - [I]$, the total transmitted field after the multiple reflections is evluated as

$$\mathbf{E}_{n,\rm tot}^{\rm t} = [T]\left([I] + \mathrm{diag}\{e^{-\mathrm{j}2k_nd}\}\,[R]\right)^{-1}\,\mathrm{diag}\{e^{-\mathrm{j}k_nd}\}\,\mathrm{diag}\{\mathrm{j}2\sin(k_nh)\}\,\mathbf{E}_n^{\rm i}. \quad (5)$$

For the validation of the proposed semi-analytic scheme and the featured resonator, the extracted results of our method are compared with a properly modified FDTD algorithm that treats graphene as an equivalent surface current $\vec{J}_{\rm gr} = \sigma\vec{E}$ in the frequency domain. The latter is introduced in the FDTD update equations via Ampère's law, while the Drude frequency dispersion model is straightforwardly resolved through an auxiliary differential equation (ADE) scheme [5]. In our investigation, we assume a monochromatic source in the Fabry-Perot resonator of Fig. 1b with $f_0 = \omega_0/2\pi = 2$ THz. Moreover, $h = \pi c_0/2\omega_0$, $\eta_1 = \eta_2 = \eta_0 = \sqrt{\mu_0/\varepsilon_0}$, $M = 0.5$, $\mu_c = 0.5$ eV, and $\omega_{\rm s} = \omega_{\rm mod} = \omega_0/10$, whereas $2N$ harmonics of f_0 are examined in (3), with $N = 5$, or $f_n = f_0 \pm nf_{\rm mod}$. The verification results of (5) via the modified FDTD algorithm is presented in Fig. 2a, which reveals a perfect match. Subsequently, we proceed to our initial goal of enhancing one of the generated harmonics with the time-varying Fabry-Perot resonator of Fig. 1b, setting $f_1 = 2.2$ THz. After performing a very rapid sweep for the thickness d, using (5), we find that the maximum transmitted E-field for f_1 is achieved for $d = 4.4\lambda_0$. In particular, as shown in Fig. 2b, the amplitude of the first harmonic is enhanced more than ten times, when compared with the one generated by a single sheet of a time-varying graphene.

As future work, a more optimized structure to suppress other harmonics is envisioned as well as the implementation of the proposed setup on a novel THz antenna.

Abstract: Identify the quality through variations of anisotropic exciton resonances. The optical power requirement through exciton anisotropy is 10^{10} times smaller than Raman measurements while obtaining an optical signal with a standard deviation of 10 times smaller. Therefore, we believe that exciton anisotropy is much more sensitive to characterize TMDCs films.

Two-dimensional (2D) materials have emerged as promising for next-generation devices, owing to their unique properties. Fundamental research and emerging applications in various fields rely on the availability of high-quality 2D materials. Nevertheless, defects and strain significantly affect the various properties of 2D materials; hence, developing rapid and non-destructive inspection technology is essential.

Polyethylene terephthalate (PET) substrate performs low thermal conductivity.[1] Strong laser irradiation increases the local temperature of the PET substrates, resulting in surface damage on the WSe_2 films, as shown in **Figure 1**. We adjusted the intense laser irradiation (8.79 mW) time from 0 to 20s to create different defect densities. To avoid damaging the surface, we used a laser excitation intensity of 2.82 mW for Raman measurements. The wavenumber of E^1_{2g} mode upshifted from 256.18 to 257.44 cm^{-1}, indicating that defects increased, as shown in **Figure 2(a)**. Moreover, we analyze the exciton anisotropy of WSe_2 films through the wavelength-dependent spectroscopic ellipsometer (SE). We can obtain ellipsometric parameters Ψ where the absolute amplitude ratios (tan Ψ) of the reflection coefficient of TE- and TM- polarized light from the film surface. In addition, exciton anisotropy would perform different absorption and reflection coefficients of TE and TM-polarized lights.[2] Therefore, Ψ and exciton anisotropy are highly correlated. As defect densities increase, the value of Ψ spectra at the D-exciton resonance in WSe_2 film decreases from ca. 9.53° to 8.94°, which means the exciton anisotropy diminishes, as shown in **Figure 2(b)**. Due to the lower signal-to-noise ratio through Raman spectra than Ψ spectra, we obtain the E^1_{2g} mode with relatively larger error bars than the Ψ value of D-exciton anisotropy, as shown in **Figure 2(c)**.

Furthermore, we explore the effect of uniaxial tensile strains on the exciton anisotropy and phonon vibrations of a monolayer WSe_2 film on the polydimethylsiloxane (PDMS) substrate. Since the E^1_{2g} mode is an in-plane lattice vibration mode along the direction parallel to the applied strain, the downward shift in wavenumber is caused by an increase in the lattice constant with increasing tensile strain, as shown in **Figure 3(a)**. In addition, the wavenumber of the E^1_{2g} mode in the Raman spectra with a slope of approximately 2.63 cm^{-1}/% strain. Due to the low signal-to-noise ratio, we obtain the E^1_{2g} mode with relatively large error bars and an average SD of about 0.437, as shown in **Figure 3(b)**.

Furthermore, exciton anisotropy is affected by applied strain due to lattice distortion. We propose that the in-plane exciton resonance is disturbed in WSe_2 films. The tensile strain changes from 0.0% to 1.0%, and the D exciton in the Ψ spectrum significantly decreases, as shown in **Figure 3(c)**. We estimate the relationship between the Ψ value of the D exciton and the strain by a linear fit with a slope of approximately ca. 1.693°/% strain, as shown in **Figure 3(d)**. The SD of the Ψ value in the exciton anisotropy signal is about 0.030, which is much smaller than the SD of the Raman spectra. Moreover, the optical power requirement for WSe_2 through exciton anisotropy in Ψ is 10^{10} times smaller than in

Raman spectroscopy. The exciton anisotropy signal fluctuates less than the Raman scattering signal. Here, we consider that changes in exciton anisotropy are more sensitive than Raman scattering signals.

Abstract: Atomically thin transition metal dichalcogenides are a promising class of novel materials, that provide new approaches in photonics, for instance, in nonlinear optics. Coupling two-dimensional semiconductors with dielectric resonant metasurfaces provides an opportunity to achieve higher efficiencies of nonlinear optical processes.

Metamaterials appear to be one of the most promising materials for numerous applications in photonics. They can be used to control various properties of light, such as direction, polarization or phase, as well as to enhance light-matter interaction due to their resonant interaction [1]. If a high-quality resonance is excited, then the interaction occurs more effectively [2].

However, such three-dimensional structures are difficult to manufacture at the nanoscale, which is required for operation in the optical range. Therefore, planar metamaterials, or metasurfaces, are used for optical range applications, as they can be easily fabricated by means of existing technologies such as lithography and nanoprinting methods.

Our research is focused on dielectric metasurfaces. They have low ohmic losses and their resonant features are associated with Mie resonances [3], that can be decomposed into a multipole series. These modes depend on the particle size and other structural properties [4]. They are widely used to enhance optical [5] and magneto-optical effects [6]. Due to the high localization of the field nonlinear effects, such as third harmonic generation, are enhanced in the vicinity of Mie resonances [7].

As a noncentrosymmetric material, a transition metal dichalcogenide monolayer possesses a large second-order nonlinear susceptibility [8], thus second-harmonic generation is greatly enhanced due to excitonic states [9]. These resonances are significantly increased at cryogenic temperatures [10] and when coupled with metasurface due to the spectral overlap with its high-quality resonance [11, 12].

In this work, a high-quality resonant dielectric metasurface is used to enhance non-linear effects, that occur in a transition metal dichalcogenide monolayer placed on top of the array and coupled with metasurface. We observe the amplification of the second-harmonic signal in the presence of the mentioned above spectral overlap of material and structural resonances. A metasurface consisting of titanium dioxide nanodiscs on a silicon dioxide substrate provides a high-quality structural resonance in the optical range. The spectral position of this resonance can be adjusted by tuning the angle of incidence of the incoming radiation. A monolayer of molybdenum diselenide is chosen as a source of non-linear optics, since it has exciton resonances in the studied spectral range [13]. When the two resonances overlap, the signal is significantly amplified. The second-harmonic signal is amplified compared to the exciton resonance of a two-dimensional film and compared to the metasurface resonance as well.

Abstract: Structured light exhibits spatially varying phase or polarization, implying intriguing physical properties for advanced optical applications. Here, we introduce naturally-crystalized spherulites as the structured light generator. The cylindrical anisotropy of the spherulite can be engineered through molecular design, offering a flexible toolbox for structured light generation.

Structured light is characterized by its spatially varying phase or polarization, setting it apart from classical light fields. This structured phase or polarization leads to intriguing physical phenomena such as optical orbital angular momentum (OAM), optical inseparable states, vector diffraction, infinite number of modes, and et al[1-4]. Those remarkable optical properties of structured light have inspired advanced applications particularly in optical communication, quantum technology, and optical manipulation[1]. Significant progress has been made in generating structured light over the past several decades, hastening the process towards practical applications.

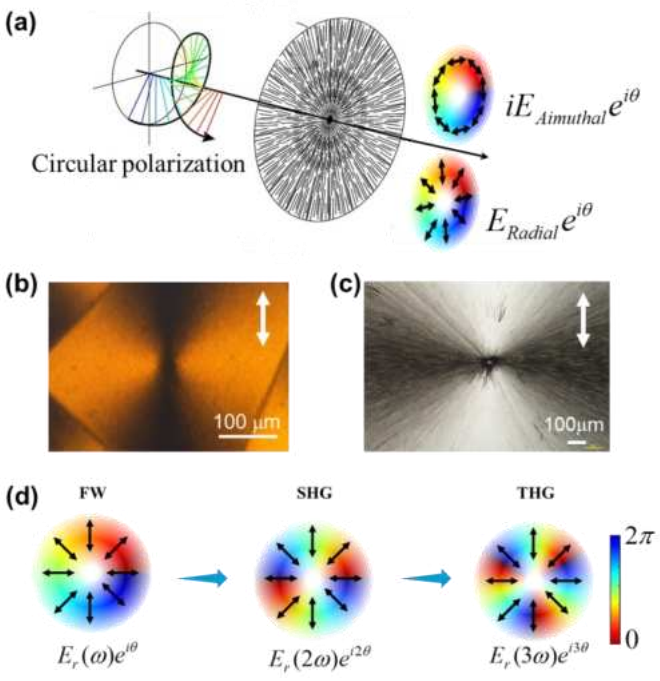

Fig. 1. Generating structured light using spherulites. (a) The schematic of generating a vector vortex beam using a circularly polarized beam as the incidence. (b) The optical image of a spherulite under transmissive mode. The incidence light is vertically polarized. (c) The optical image of a 7OCB spherulite under transmissive mode. The incidence light is vertically polarized. (d) The phase and polarization evolution from fundamental wave (FW) to SHG and THG for a radial polarization vortex beam.

Metasurfaces play a significant role in structuring the polarization and phase of light due to their flexible design capabilities, ultra-thin thickness, and ease of on-chip integration. Nevertheless, metasurfaces encounter some challenges related to fabrication costs, lithography limits, and scattering losses of meta-atoms. Here, we propose spherulite material as a new avenue for structured light generation. The spherulite material is prepared using a self-assembly method to induce cylindrical molecular orientation and optical anisotropy. It should be noted that the cylindrical symmetry of spherulite perfectly matches the symmetry of cylindrical-type structured light such as the radial polarization beam, the azimuthal polarization beam, and the OAM beam. Therefore, the spherulite material can potentially serve as the structured light generator, which is unique compared to conventional crystals with symmetry under Cartesian coordinate.

To illustrate the working principle of spherulite in generating structured light, a circularly polarized beam can be decomposed into radial polarization and azimuthal polarization components:

$$E_L = \frac{P(r)\left(\boldsymbol{e}_r + i\boldsymbol{e}_\theta\right)e^{i\theta}}{\sqrt{2}}, \quad E_R = \frac{P(r)\left(\boldsymbol{e}_r - i\boldsymbol{e}_\theta\right)e^{-i\theta}}{\sqrt{2}} \tag{1}$$

The $P(r)$ is the amplitude. $\boldsymbol{e}_r$ and $\boldsymbol{e}_\theta$ are the unit vectors along radial direction and azimuthal direction[5]. Because of the optical cylindrical anisotropy of the spherulite material, one can easily tune the electrical field of light in the radial and azimuthal directions (Fig. 1a). Specifically, extinguishing the radial polarization component results in the generation of an azimuthal polarization beam. Similarly, extinguishing the azimuthal polarization component results in the generation of a radial polarization beam. Herein, we prepared two types of spherulites for generating azimuthal (see Fig. 1b) and radial polarization beams (see Fig. 1c)[5]. Moreover, one can extend the linear optical behavior into nonlinear realm. For example, if a cylindrical anisotropy spherulite exhibits a prominent nonlinear optical coefficient in the radial direction, one can generate second-harmonic (SH) and third-harmonic (TH) vortex beams with radial polarization (Fig. 1d).

In summary, we introduce spherulite materials as a novel approach for structured light generation. The spherulite is easily fabricated through self-assembly, exhibiting uniformity at the molecular level, and is versatile through molecular engineering, thus holding great promise for structuring light in both linear and nonlinear realms.

Abstract: Various techniques, including strain engineering and surface treatments, have been tested for spatially deterministic generation of quantum light emitters in 2D layered semiconductors. Here, we develop a more cost-efficient and simpler method by placing mechanically exfoliated GaSe flakes onto a substrate carrying dispersed radiative microparticles with a distinctive bipyramidal shape.

Localized defect states in two-dimensional (2D) van der Waals (vdW) materials, including semiconducting transition metal dichalcogenides (TMDs), GaSe and insulating h-BN, have emerged as a promising physical system for scalable quantum technologies. Addressing the challenge of achieving scalability and reliable deterministic generation of quantum light emitters (QLEs) at precise locations, various strategies have been explored. The most comment state-of-the-art technique includes ***(i)*** strain engineering achieved by placing the active material (in the form of exfoliated 2D sheets) onto micro- or nano-scale structures obtained via lithographic substrate patterning, as well as ***(ii)*** different local surface treatments of the active medium. The former technique, in particular, has shown to be quite useful for the production of large-scale arrays of QLEs at predetermined sites in (few)monolayer thin vdW systems. The produced QLEs originate from optically active electronic states associated with extrinsically induced structural imperfections within the crystal lattice forming either ***(i)*** localized exciton trapping sites (e.g. excitons bind to impurity atoms or trapped in a potential dip created by structural defects or local strain) as in the case of TMDs and GaSe or ***(ii)*** deep-level atom-like defects as in the case of h-BN, both acting as recombination centers, resulting in non-classical light emission. While these methods have demonstrated considerable success, their high cost renders them less accessible, highlighting the need for a more economical approach to deterministically generate strain-induced QLEs in these materials. In this work, we demonstrate scalable and lithography free approach toward creating large areas of spatially localized non-classical emitters in 2D semiconductors flakes. The proof of concept was achieved by placing the WSe_2 and GaSe flakes, which were previously mechanically exfoliated from commercially available bulk crystals, over luminescent rare earth ion doped micro particles dispersed onto a Si substrate coated with 300 nm-thick SiO_2 layer. Once the location of the dispersed particle on the Si/SiO_2 surface was identified by an optical microscope, the precise placement of the flake was achieved using all-dry viscoelastic polydimethylsiloxane stamp method.[1] Because of the strong intra-layer bonding and weak van der Waals forces between the layers in 2D materials, the flake accommodates around the underlying microparticle inducing microscopic strain deformation at fixed spatial position. This, in turn, creates site-controlled 3D confinement potential for charge carriers with quantized energy levels, yielding optically allowed excitonic transitions which are necessary to produce quantum light. The advantage of using luminescent microparticles is that their optical activity enables the precise determination of their position, hence, revealing the location of the exciton traps instigated in the 2D sheet by the underlying microparticles. In addition, their bipyramidal shape containing

several sharp corners, which are inherent to this geometry, allows to create nanoscale sites for exciton confinement. Low temperature micro-photoluminescence (μ-PL) measurements performed on the flake at different spatial locations around and on top of the microparticle reveal significant spectral changes determined by the unique strain condition at each location. At some positions, we observed the appearance of narrow emission peaks associated with quantum confinement of excitons. The excitation power dependent measurements reveal linear and sub-linear power dependencies of different PL lines, thus enabling their assignment to the specific excitonic radiative transitions (i.e., exciton, X and biexciton, XX). The X-XX assignment was also corroborated by the polarization-resolved μ-PL measurements which show collinear elliptical polarization of the specific excitonic transitions with the same polarization degree, therefore confirming their origin from the same microscopic trap. Photon correlation measurements evidenced the quantum nature of the detected X and XX PL peaks. Moreover, employing conventional μ-PL spectroscopy eliminates the need for the use of scanning electron microscopy (SEM) or atomic force microscopy (AFM) imaging for precise (sub)micrometer scale QLEs site identification within the flake.

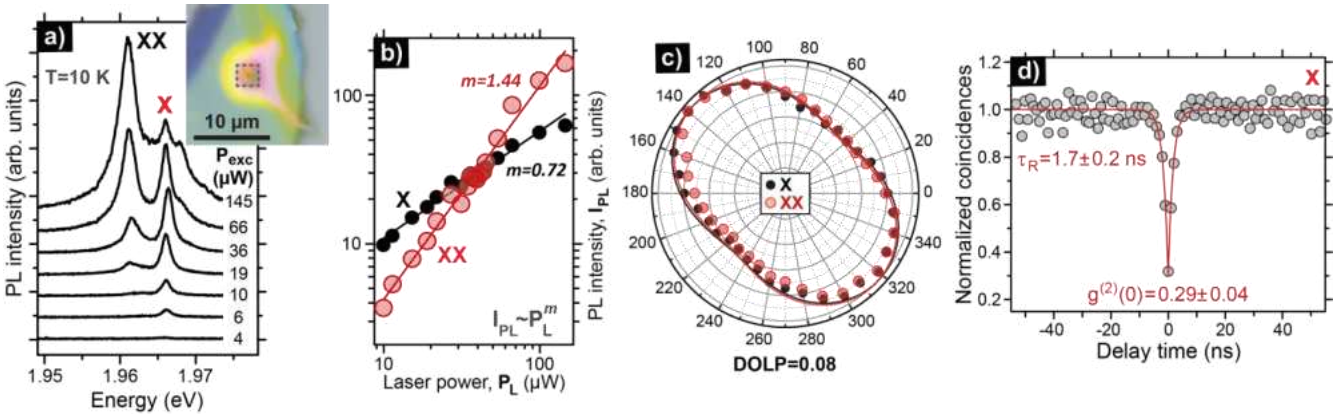

Figure 1. **(a)** Low-temperature μ-PL spectra for different laser excitation powers on exciton trap induced within the GaSe flake by strain deformation localized in the region above the luminescent $LiYF_4:Nd^{3+}$ microparticle. Inset: Optical microscopy images of GaSe flake deposited on top of the $LiYF_4:Nd^{3+}$ microparticle. **(b)** Excitation power dependent and **(c)** normalized polar plots of the integrated peak intensities of exciton (X, black circles) and biexciton (XX, red circles) in (a). **(d)** Normalized coincidence counts for the exciton emission peak X in (a).

The observed excitonic complexes originating from strain engineered localized traps in GaSe sheets suggest that this system is suitable for entangled photon pairs production via XX-X radiative cascade. This is especially relevant given that the polarization state of the emitted X-XX cascade could also be controlled by e.g. strain, as seen for WSe_2 in Ref. 2. The excellent agreement between our results and the previous reports on strain-induced emission of antibunched photons in GaSe[3] unequivocally confirms the suitability of our approach for the deterministic generation of highly localized QLE. The introduction of such cost-effective and practical platform for quantum light generation expands the accessibility of 2D QLEs, fostering advancements in both research and practical applications in nanophotonics and the related quantum technologies.

Investigating the Optical Properties of Thin Films Coated with MWCNTs

S.Islam[1*], H.Furuta[1*]

[1]Kochi University of Technology, Japan
[2]Kochi University of Technology, Japan

Abstract: The study aimed to investigate the relationship between the density and alignment of randomly aligned multi-walled carbon nanotube (MWCNT) coatings and their optical properties in the visible region. The results showed that 0.0002 gm of MWCNT exhibited low reflectance and high absorption, making it suitable for optical applications.

Carbon nanotubes (CNTs) have attracted significant attention in optoelectronics applications due to their unique light absorption properties[1]. Ghai et al. [2] reported that structurally modified flower-like CNTs (FCNTs) exhibited an impressive absorption capacity of 99.97% within the wavelength range of 300-2000 nm. Wood et al.[3] explained that CNT forest density, surface roughness, and forest height are crucial factors influencing optical reflectance and attenuation, which are important for meeting the optical requirements of CNT-based devices. However, the impact of CNT density and alignment on optical absorption in the visible region remains unexplored. In this study, we have varied the amount of CNTs on a fixed substrate surface area and investigated the effects of CNT density, alignment, and inter-tube distance to determine the optimal CNT density for achieving low reflectance in the visible region.

Thermally oxidized mid-resistive silicon substrates measuring precisely 1 cm x 1 cm were used. Prior to deposition, the mass of each individual substrate was measured using an analytical microbalance and recorded. A dispersed multi-walled carbon nanotube (MWCNT) ink obtained from Meijo Nanocarbon was used, with MWCNT loadings ranging from 0.00005 gm to 0.008 gm studied. The deposition was carried out via a simple drop-casting technique, where using a micropipette, precise volumes of the MWCNT ink were deposited drop-wise onto the center of each silicon substrate and then allowed to dry naturally at ambient conditions. The mass of MWCNTs was calculated by subtracting the substrate's mass before deposition.

Samples with varying MWCNT coating weights were analyzed using an integrating sphere spectrometer to measure the total reflectance over 400-800 nm wavelengths. For total reflectance measurements, samples were tilted 10° from the incident light direction. This configuration approach using an integrating sphere enabled the characterization of optical properties as a function of MWCNT coating weight under controlled experimental conditions.

A scanning electron microscopy (SEM) analysis was performed on three different multi-walled carbon nanotube (MWCNT) films, as shown in Figure 1. The first film, weighing 0.0002 gm and characterized by low weight, exhibited a thickness of 1.67 um. The second film, weighing 0.0014 gm and considered moderate weight, displayed an average thickness of 3.11 um. Finally, the third film, weighing 0.008 gm and characterized by heavy weight, showed an average thickness of 77.197 um. Furthermore, a top surface analysis revealed that the intertube distance between carbon nanotubes (CNTs) in the 0.0002 gm MWCNT film was greater than that in the 0.008 gm MWCNT film.

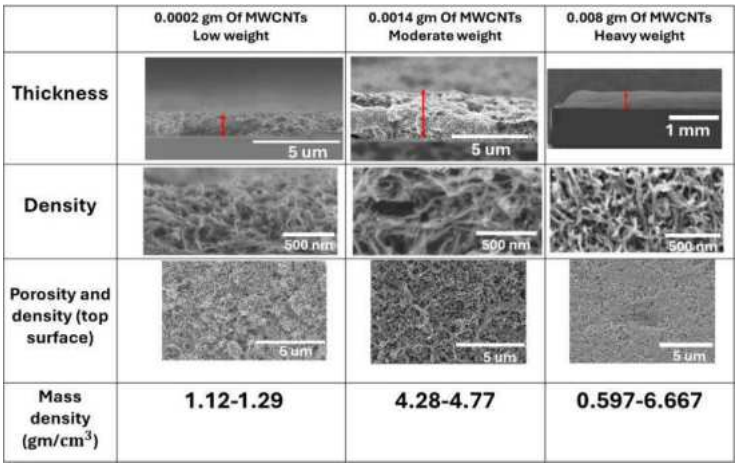

Figure 1: Morphological analysis of low, moderate, and heavy weight of MWCNTs coating.

The coated samples were classified based on the weight of multi-walled carbon nanotubes (MWCNTs) into three categories: low (0 gm to 0.0002 gm), moderate (0.001 gm to 0.005 gm), and high (0.007 gm to 0.008 gm). In Figure 2, it can be observed that the MWCNT coating with a weight of 0.008 gm (with a mass density ranging from 0.597 gm/cm3 to 6.667 gm/cm3) exhibits a total reflectance of 5.55% at 400 nm. Similarly, the MWCNT coating weighing 0.0014 gm (with a mass density ranging from 4.28 gm/cm3 to 4.77 gm/cm3) shows a total reflectance of 3.3% at 400 nm. Notably, the 0.0002 gm (mass density range 1.12 gm/cm3-1.29 gm/cm3) MWCNT coating shows an extremely low reflectance of 2.7% at 400 nm.

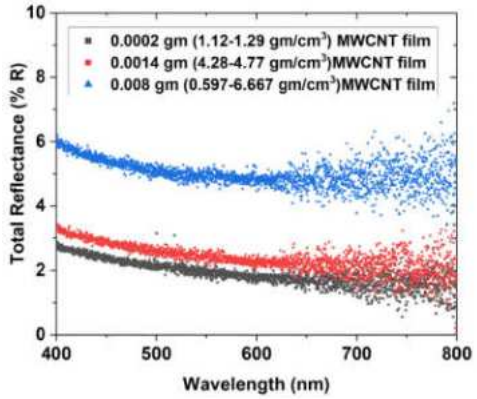

Figure 2: Reflectance analysis of low, moderate, and high densified MWCNT coated samples.

The above analysis revealed that MWCNT coatings with lower density exhibited reduced reflectance, with the 0.0002 gm (mass density range 1.12 gm/cm3-1.29 gm/cm3) MWCNT coating demonstrating the lowest reflectance of 2.7% at 400 nm. These findings emphasize that the optimized density of MWCNT-based coatings plays a significant role in governing their optical properties and enhancing light absorption for optoelectronic applications.

Abstract: Glucose is a key metabolite and primary nutrient in the metabolism; thus, its monitoring is imperative for the prevention, early diagnosis, and treatment of diabetes. Great efforts are invested in the development of highly efficient non-invasive sensors able to detect glucose from body fluids such as sweat or tears.

In this scientific context, this work aims to develop a versatile flexible hybrid plasmonic sensor for the non-invasive reliable real-time dual SERS – electrochemical (Surface Enhanced Raman Spectroscopy) glucose detection in artificial sweat. Concretely, the approach proposes an innovative fabrication process which relies on the use of a flexible and biocompatible polydimethylsiloxane polymer substrate whose surface roughness was modified during the thermal curing process by the imprinting of the 3D matrix of Whatman No 1. filter paper. A self-designed filter paper electrode mould was attached to its surface for the deposition of a 20 nm gold thin film via a physical vapor deposition technique to obtain the counter electrode (CE) and working electrode (WE). The Ag/AgCl reference electrode (RE) was fabricated using a similar mould through a screen-printing method. Thus, the dual SERS – electrochemical sensor is obtained. Further, WE was functionalized with Thiol-Polyethylene glycol-Amine in order to immobilize gold nanobipyramids for the enhancement of the sensors detection capabilities. Next, an enzymatic biosensing protocol was developed by successively grafting onto WE a well-known Raman reporter for SERS detection and the biorecognition molecule - glucose oxidase enzyme. The as-developed sensor was then exposed to several different glucose concentrations to assess its dual detection performance. Finally, to validate the flexible hybrid plasmonic sensor was exposed to artificial sweat spiked with glucose to demonstrate its potential as a lab-on-the-skin sensing devices for efficient glucose monitoring and, implicitly, diabetes management.

Abstract: Here, attractive features of spatiotemporally modulated graphene-based waveguides are utilized to integrate all functionalities of a THz transceiver front-end in one device. We have implemented the leaky wave antenna, isolator, and mixer all in one device using spatiotemporal modulated structures.

Spatiotemporal modulation, defined as the periodic modulation of a structure's constitutive parameters in both time and space, leads to unique properties such as nonreciprocal response, frequency mixing and mode conversion [1-4]. At microwave frequencies, these features are realized using varactors as the modulating part [3,4]. Here, in the realm of THz frequencies, we have used graphene as an appropriate material to implement time and space modulation utilizing its exceptional tunable surface conductivity [5-7].

In this study, we introduce an integrated device that encapsulates the entire front-end of a THz transceiver within a single unit, employing a spatiotemporally modulated graphene-based waveguide. This innovative approach leverages spatial modulation, frequency mixing capabilities, and a nonreciprocal response to simultaneously realize a leaky-wave antenna, mixer, and isolator, all within one cohesive structure.

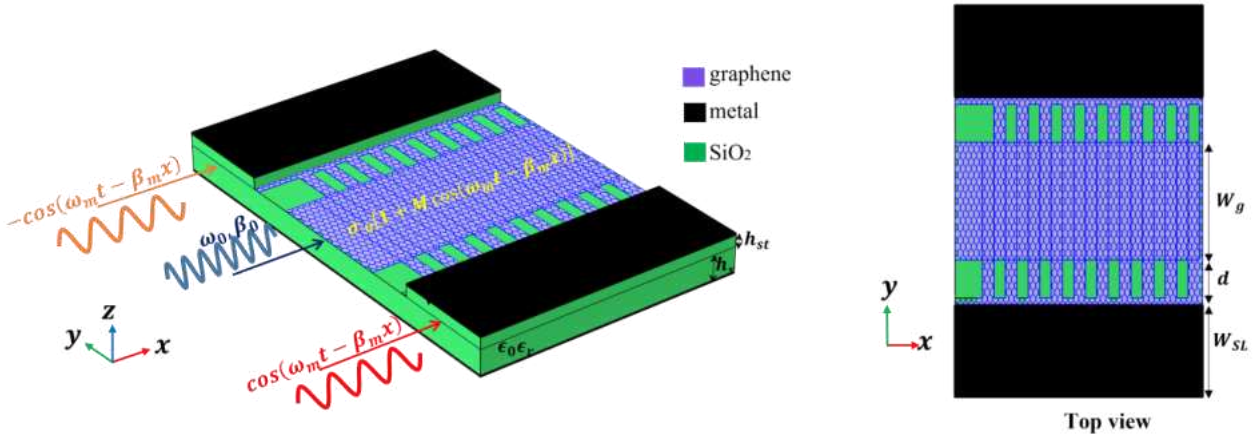

Figure 1. The structure of the proposed integrated THz transceiver front-end. $\boldsymbol{h_s = 20\ \mu m, h_{st} = 5\ \mu m, , \epsilon_r = 3.8,}$ $\boldsymbol{W_g = 200\mu m, W_{SL} = 100\mu m, d = 10\mu m}$

The proposed structure of THz transceiver is shown in Figure 1. It consists of a main plasmonic waveguide, constructed from a graphene layer on top of a back-metalized SiO_2 substrate, in the middle of the structure which is guiding the main signal with the frequency of $f_0 = 2\ THz$. This waveguide is accompanied by two quasi-TEM side waveguides, carrying the modulating waves. These waveguides are strip line waveguides with the graphene layer as the middle strip. The graphene of the main waveguide is modulated by frequency of $f_m = 200\ GHz$. The middle graphene layer is divided into two ribbon groups with periodicity of $\lambda_r = 20\ \mu m$ biased by two out of phase side modulating waveguides to increase the modulating propagation constant and make it big enough to generate leaky waves.

The proposed integrated THz transceiver is numerically investigated using full wave numerical simulation performed by COMSOL Multiphysics software. In this simulation, the effect of the modulating waveguides is modeled through the modulated surface conductivity of graphene sheet, and three different physics for three harmonic frequencies of f_0, $f_0 \pm f_m$ are introduced and studied. The results are shown in Figs. 2, 3.

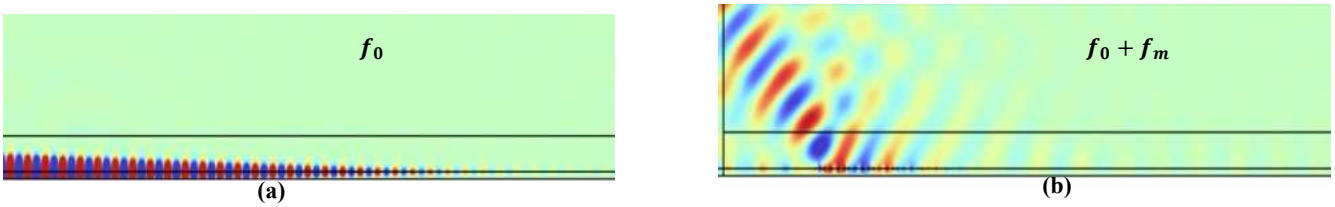

Figure 2. Numerical full wave simulation results a) The structure is excited by a plasmonic wave at the frequency of f_0 b) the wave is converted to the frequency of $f_0 + f_m$ and radiates away from the structure.

As shown in Fig. 2, when the structure is excited at the frequency of f_0 (see Fig. 2a), the modulation happens and the frequency is shifted to the $f_0 + f_m$ and interestingly it radiates away from the structure (see Fig. 2b). Therefore, the proposed spatiotemporal modulated device works simultaneously as a leaky wave antenna and as a mixer. The device also is able to do beam steering as shown in Fig. 3. Figure 3 shows the radiation pattern of the device when the modulation frequency f_{m} varies from 100 GHz to 400GHz. As clearly shown in this figure, the beam steers as the modulation frequency changes proofing the ability of the proposed structure for providing beams at different directions.

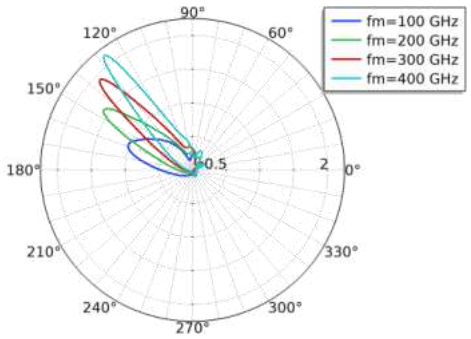

Figure 3. The radiation pattern of the proposed device for different modulation frequencies.

Abstract: Structural color filters propose an advanced alternative to conventional color filters. However, their optical response shifts with angle variations of the incident light. We address this problem by introducing a conformal tunable VO_2 layer onto bare aluminum structural color filters. This approach is adaptable and suits any existing structural filters.

Structural color filters are maintaining a trending status in the discussions of the future imaging and spectroscopic techniques. Compared to their traditional counterparts based on pigments and dyes, structural color filters offer less complicated and thus cheaper fabrication, minimal environmental impact and little to no degradation in performance over time. One of the remaining challenges that keeps structural color filters from overtaking the market is the dependence of their spectral response on the angle of incident illumination. So far, researchers have addressed this problem by fixating the geometry of color filters, either by using ultrathin metallic structures [1] or often restricting the allowed polarization states of incoming light [2] and thus limiting their overall efficiency.

In our work, we demonstrate a versatile solution for angle-dependent spectral shifts by introducing a thin conformal vanadium dioxide (VO_2) layer onto holey aluminum structural color filters illustrated in Fig 1. [3] Using the optical response of a bare holey aluminum color filters as a reference, a spectral redshift occurs as the angle of light incidence increases. As VO_2 undergoes its insulator-to-metal transition, a contrary effect can be observed; upon heating, the spectral response of VO_2 shifts towards small wavelengths. [4] The insulator-to-metal transition (IMT) in VO_2 occurs relatively close to room temperature, at ca. 67°C, and is easily reversed by cooling the material below the transition temperature. Other commonly used phase-changing materials, including GeSbTe, Sb_2S_3 or other chalcogenide glasses necessitate more extreme conditions for their phase transitions; temperatures ranging from 100-200° C or higher are required to initiate the phase transition or its reversal. [5] Such a comparison highlights VO_2 as a material with easily accessible IMT that can be well-incorporated into complex devices. The IMT of VO2 can be induced by thermal, optical or electrical excitation, is fully and easily reversible, and resists material degradation at both its phase states. [6]

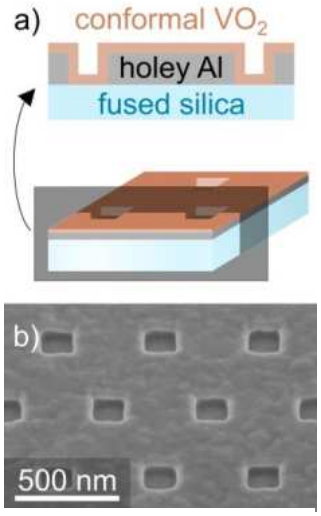

Fig. 1: VO_2-filled holey Al structural color filters. a) Sample layout. b) SEM micrograph of the structural color filter shown in a), imaged under 40° tilt.

The presented research inspects the shifts in the spectral response of such systems upon varying angles of light incidence both below and above the IMT temperature of VO_2. We show that by driving the VO_2 through its easily repeatable

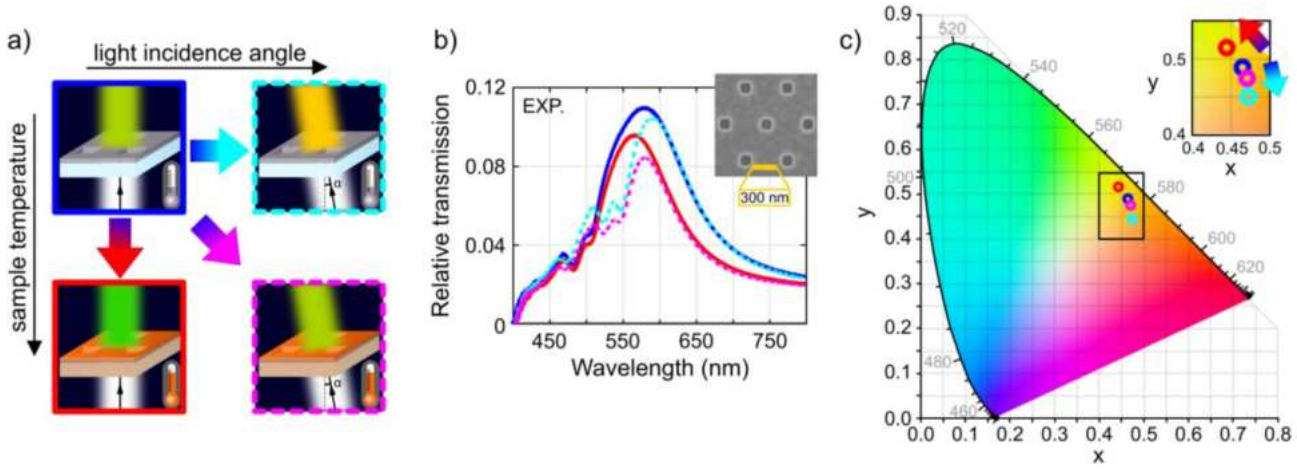

Fig. 2: VO_2-filled structural color filter can be used for compensation of spectral red-shifts caused by non-normal sample illumination. (a) A schematic of the experimental concept. (b) Relative transmission of the VO_2-filled color filter corresponding to the four settings shown in (a) – curve colors correspond to the frame colors in (a). The VO_2-filled color filter illuminated at a non-zero angle of incidence regains its original transmission peak position when heated. A SEM micrograph of the measured VO_2-filled color filter is shown in the inset. (c) A CIE diagram showing the color compensation illustrated in (b).

IMT, the original spectral position of the color filter's transmission maximum can be efficiently retrieved, i.e. that VO_2 can be used to mitigate angle-dependent shifts in structural color filters. This is enabled by the compensation of the angle-related redshift using a blueshift that accompanies the IMT in the conformal VO_2 layer deposited on the color filters, as displayed in Fig. 2.

Available through the atomic layer deposition method, a conformal VO_2 layer can be seamlessly integrated into the fabrication of virtually any structural color filter regardless of its design and preceding fabrication steps, rendering the color filter less prone to angle-dependent shifts by easily achievable thermal control.

Abstract: We figured out that induced magnetic dipole of chiral meta-atom is critical to CD like a chiral molecule. And we suggest the simple method to enhancing magnetic dipole by MIM (Metal-Insulator-Metal) motif with chiral geometry.

Bio-chemical responses in nature depend on chiral recognition. Organisms are sensitive to chirality and specialized in tailoring chirality of biomolecules to achieve specific function. Therefore, the modern drugs are generally chiral. People use light interaction with chiral molecule to recognize chirality of molecules. Especially circular dichroism (CD) is generally used for measuring the chirality of molecule in the medical world. But CD signal of molecule which density is low is very weak and have resonance in UV band, not visible range. For this reason, people need to enhance the CD signal of molecule and lengthen the resonance wavelength by coupling with artificial chiral nanostructure.

The interaction between the chirality of molecules and light conveniently tested by measuring circular dichroism (CD) and optical rotational dispersion. Especially CD is generally used for measuring the chirality of molecule in the medical world. According to the Rosenfeld's calculation, the strength of the CD signal of a chiral molecule is given by.

$$\mathrm{CD}_0 \sim \mathrm{Im}(\boldsymbol{\mu}_{12} \cdot \boldsymbol{m}_{21}) \qquad (1)$$

Where $\boldsymbol{\mu}_{12}$ and $\boldsymbol{m}_{21}$ is electric and magnetic transition dipole of molecule, respectively. And the indices 1 and 2 is the ground and excited states of the molecule. This equation means that a CD signal in molecular system occurs by the coupling between the electric and magnetic dipole of the molecule which induced by incident light.

On the other hand, the plasmonic chiral optical interaction corresponds to classical electromagnetism that follows Maxwell's equations. But the classical results can also be understood in terms of the quantum equation. Therefore, the non-zero CD signals in chiral complex originate from dynamic magnetic moments which are induced by incident light in nanostructure. Therefore, to the large chiral optical response, it is important to strengthen the dynamic magnetic dipole moment and break the orthogonality with the electric dipole moment.

We would like to introduce a novel strategy to modulate circular dichroism (CD) using isotropic, 432-symmetric chiral gold nanoparticles (helicoids) which are plasmonic nanoparticles with biomolecule-encoded chiral nanostructures. Interestingly, through a versatile metal layer deposition on helicoids, the reflected CD can be reversed, which can make both reflection and transmission exhibit unnatural CD of the same sign.

As the hat-shaped structure is on the helicoid particles, the strengths of electric and magnetic dipole of helicoid particles become boosted through capacitive plasmonic coupling which is confirmed through the redshifts of the resonance mode.

In this study, we showed that it is possible to control the CD by increasing the overall chirality of the nanostructure through metal deposition on plasmonic chiral particles.

Plasmon-enhanced photovoltaics, photocatalysis, and solar fuels

Noble Metal – Chalcopyrite Hybrid Nanostructures for Enhanced Plasmonic Photocatalysis

B.M. Reinhard[1,*]

[1]Department of Chemistry and The Photonics Center, Boston University, Boston, MA 02215, United States

[*]corresponding author: bmr@bu.edu

Abstract: Chalcopyrite ($CuFeS_2$) nanocrystals, which support quasistatic resonances in the visible, and noble metal nanoparticles are combined into one nanostructure to provide a bi-resonant hybrid material. The interplay of metal and $CuFeS_2$ resonances on the photoreactivity of the hybrid material is characterized for different nanoarchitectures and reactions.

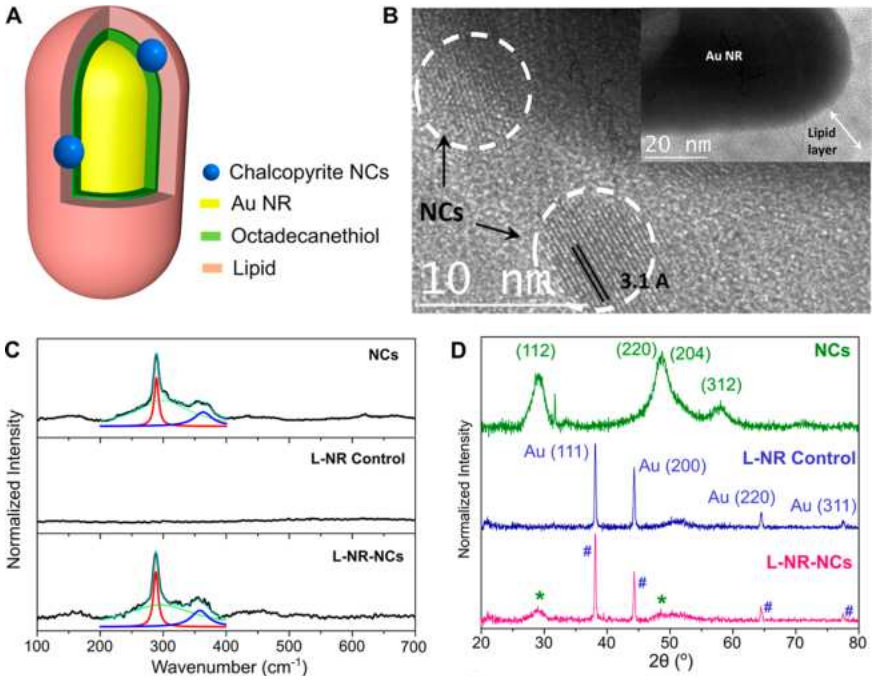

Figure 1: A) Schematic drawing and B) TEM image of hybrid $CuFeS_2$ NC – Au NR hybrid nanocatalyst. C) Raman spectra of (top to bottom): NCs, NRs, and hybrid structure. D) XRD spectra of (top to bottom): NCs, NR, and hybrid structure. Reprinted with permission from An et al, ACS Nano 16, 6813 (2022). Copyright American Chemical Society.

Chalcopyrite ($CuFeS_2$) nanocrystals (NCs) provide quasistatic resonances in the visible,[1,2] which provides unique opportunities for implementing noble-metal – semiconductor hybrid structures with plasmonic resonances supported by both building blocks. These resonances are of high interest for facilitating charge and energy transfer in the hybrid nanostructures.

We have integrated $CuFeS_2$ NCs in a lipid coating self-assembled around gold and silver nanorods (NRs) and nanoparticles (NPs).[3] Figure 1 provides characterization data for a representative hybrid structure. Importantly, in

the case of the gold NRs as central core, the hybrid structures were observed to support enhanced oxygen and hydrogen evolution reactivity when excited at 530 nm or 730 nm, respectively.[3] The wavelength-dependent reactivity suggests the existence of different light-driven charge transfer processes between NR and NCs that can generate different reactive centers under excitation with green or red light. A model for the light-dependent reactivity is presented and discussed.

The mechanism of the reactions and, in particular, the role of the chalcopyrite NC as catalytic site was independently evaluated through Raman spectroscopy. These spectroscopic studies indicate the existence of a Cu(I)/Cu(II) redox pair coupled catalysis on the chalcopyrite NC surface that synergistically cooperates with plasmonic effects.[3]

To obtain further quantitative insight into the effect that the coupling of the resonances in NCs and NPs has on light-driven reactivity of the hybrid structures, hybrid materials assembled from $CuFeS_2$ NCs and noble metal NRs and NPs with different overlap between the resonances of the two building blocks were implemented and the resulting performance characterized. The evidence for synergistic interactions between noble metal nanostructures and $CuFeS_2$ NC components in facilitating light driven reactivity collected in these studies will be presented.

In the last part of this presentation we will review strategies to further enhance the performance of plasmonic photoreactors containing both noble metal and chalcopyrite building blocks in the future.

Light-accelerated NiFe oxyhydroxides-alloy photoanode metasurfaces for efficient and stable solar water splitting

Fei Xiang[1], Ning Li[1], Arturo Burguete-Lopez[1], Zhao He[1], Maxim Elizarov[1], Andrea Fratalocchi[1*]

[1]PRIMALIGHT, King Abdullah University of Science and Technology (KAUST), Thuwal 23955-6900, Saudi Arabia

Abstract: We report a light-accelerated NiFe oxyhydroxides-alloy metamaterial as a catalytic-protective layer on Si photoanodes for efficient and durable solar water splitting. This technique enables a record applied bias photon-to-current efficiency (ABPE) efficiency of 4.24% in homojunction-free photoanodes. It extends the device's lifetime to beyond 250 hours.

Green hydrogen production through photoelectrochemical (PEC) water-splitting with solar energy attracts significant research interests in contributing to a clean energy economy and sustainable development [1–3]. Currently, the efficiency of the hydrogen evolution reaction at the photocathode side is relatively high (ABPE above 12%) [4, 5], while the bottleneck for the entire device is at the photoanode side due to the sluggish kinetics, with a bestreported ABPE of 3.91% for buried homojunction-free photoanodes [5]. Thus, current research efforts on PEC devices aim to develop new photoanodes with enhanced efficiency [6, 7].

Besides the efficiency performance, the stability of the photoanodes is another aspect that needs improvement. For the buried homojunction-free photoanodes with ABPE above 3%, the reported device lifetime is below 100 hours [5, 8]. The poor stability of the photoanodes originates from the photo-corrosion of the co-catalyst and the chemical instability of the semiconductor absorber in the strong alkaline medium (pH ∼14) [7]. While many protective layers, such as the Al_2O_3 and SiO_x, were proposed to prolong the Si photoanodes lifetime to above 200 hours, the efficiency of the photoanodes drops to below 1%, which is impractical for the large-scale implementation of the PEC devices [9, 10].

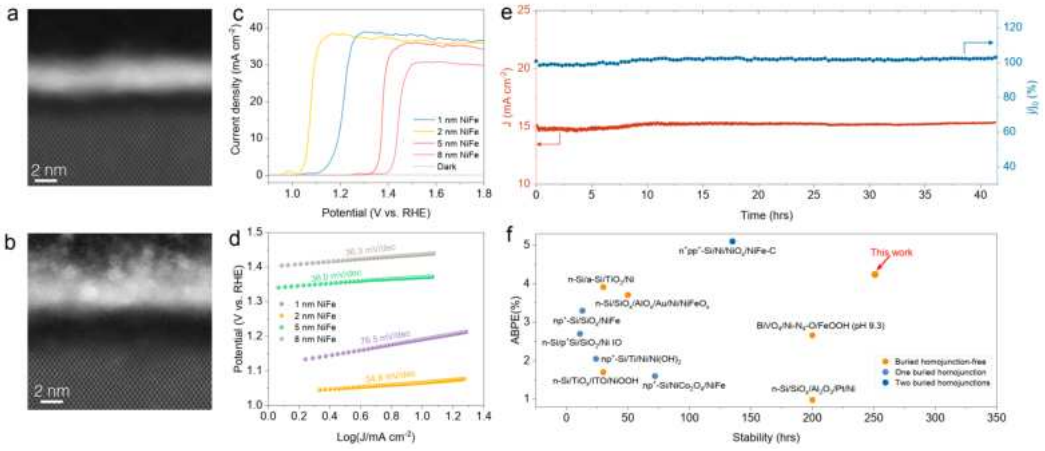

Fig. 1 (a) Cross-sectional STEM image of the as-fabricated photoanodes. (b) Cross-sectional STEM image of the photoanodes after 20 hours working under 1.09 V vs. RHE. (c) J-E curve of photoanodes with varied NiFe alloy thickness. (d) Tafel slope calculated from the J-E curves in (c). (e) Long-term stability test of the device with an optimized thickness of NiFe nanolayer at the initial current density of 15 mA cm^{-2}. (f) Applied bias photon-to-current efficiency and stability of the device compared with the state-of-the-art.

Ni-based oxyhydroxides were reported as highly efficient and stable catalysts in electrochemical water splitting [11, 12]. However, this type of material is not directly available. The traditional generation of state-of-the-art Ni-based oxyhydroxides requires a bias above 1.4 V for at least 24 hours in electrochemical

conversion or a multistep hydrothermal treatment with a high temperature above 70°C for at least 6 hours [12–14]. These approaches require vast energy powers and are impractical for fabricating PEC photoanodes.

In this work, we report a light-accelerated atomic reconfiguration in the NiFe alloy film to self-generate a NiFe oxyhydroxides-alloy metamaterial as a catalytic-protective layer for the Si photoanodes. This dynamic evolution process of NiFe oxyhydroxides involves surface amorphization and chemical state changes in Ni/Fe-containing species, reporting an ABPE efficiency of 4.24% in the optimized photoanodes with a 2 nm NiFe alloy layer. Figure 1a reports the scanning transmission electron microscope (STEM) image of the as-fabricated photoanodes, demonstrating the layered structure from the top NiFe alloy layer to the Si substrate. After continuous working under 1.09 V *vs.* reversible hydrogen electrode (RHE) for 20 hours, the surface region of the NiFe alloy expands above 137% in volume. It forms a porous NiFe oxyhydroxides layer hybridized with the NiFe alloy film (Fig. 1b). Figure 1c reports the J-E responses of the photoanodes with different NiFe alloy thicknesses. The optimized photoanodes with 2 nm NiFe alloy layer show a low onset potential of 1.06 V *vs.* RHE to reach a current density of 10 mA cm^{-2} and a high saturated current density of 38.4 mA cm^{-2}. Besides, the optimized photoanodes with 2 nm NiFe alloy layer show the fastest reaction kinetics in water oxidation, reporting the lowest Tafel slope of 36.0 mV/dec (Fig. 1d). During the continuous working process under constant bias conditions (Fig. 1e), the engineered photoanodes maintain nearly 100% retention of the initial current density over 40 hours, demonstrating the high stability of the evolved NiFe oxyhydroxides-alloy photoanodes. Figure 1f compares the ABPE efficiency and the stability performances of the engineered photoanodes against the state-of-the-art. This technique paves the way for designing and implementing highly efficient, stable, and large-scalable PEC devices beyond hydrogen production.

[*]corresponding author: ning.lyu@uni-jena.de

Abstract: Photocatalysis holds immense potential for harnessing clean energy through chemical processes, such as water splitting and CO2 reduction [1]. This typically encompasses multistep electron transfer processes that culminate in the simultaneous generation of diverse products [2,3]. However, achieving a highly efficient and selective conversion of a specific product remains a challenge. Thus, we first concentrated on a single-step reaction: the N-demethylation of Methylene blue (MB) driven by light with an effective wavelength range between 530 to 710nm [5]. Here, gold nanoparticles (Au NPs) exhibit a strong resonance and significant efficiency at this wavelength range, and provide active control when coupled with other resonances, such as in a Fabry-Pérot cavity [4].

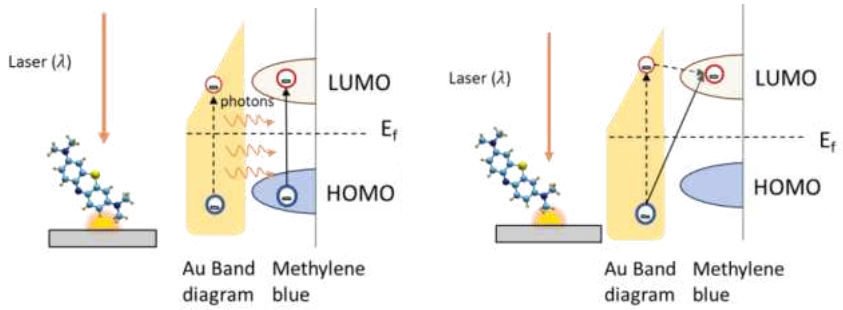

Figure 1: Localized Surface Plasmon Resonance (LSPR) band diagram for MB and gold nanoparticles showing the radiative decay (left) and non-radiative decay (right).

A thin layer of titanium dioxide (TiO2) was sputtered onto the surface of a metal mirror film. This interface displays a high reflectance, facilitating the occurrence of Fabry-Pérot (FP) resonances with a peak position determined by the TiO2 thickness. Additionally, Au nanoparticles were synthesized using an annealing process deposited onto the TiO2 layer. Coupling the Localized Surface Plasmon Resonance (LSPR, Fig. 1) with the constructive peak ('switch on') and destructive valley ('switch off') of the Fabry-Pérot resonance allows tailored designs for enhancing and suppressing photocatalysis, respectively, enabling selectivity of the reaction pathway.

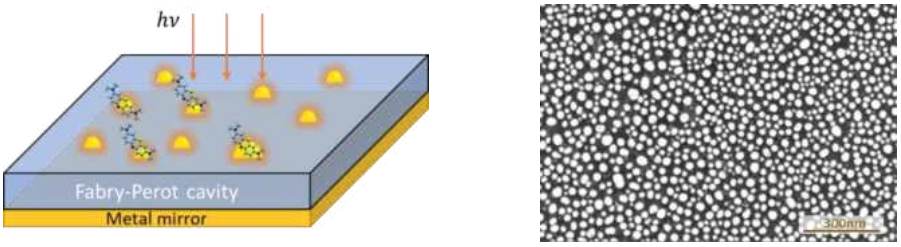

Figure 2: Configuration of plasmonic FP cavity showing random Au NPs on the TiO2 cavity with MB attached (left) and an SEM image of the gold nanoparticles with average radius r_{ave}=13nm and gap size g_{ave}=8nm (right).

Analysis of scanning electron microscope (SEM) images revealed that the interparticle gap of Au NPs is smaller than its size, indicating a non-negligible coupling between the Au nanoparticles (Fig.2). In simulations, utilizing a periodic model with averaged parameters proves inaccurate for describing this specific design. Consequently, we imported a 200×200nm^2 Atomic Force Microscopy (AFM) image into the model to describe the location and shape of nanoparticles and employed the Finite Element Method (FEM) to assess its optical performance.

The coupling of LSPR and FP resonances were characterized with a spectrophotometer, resulting in an absorption peak and dip in the absorption spectra of 'switch on/off' samples, respectively. With Ti metal mirror, the absorption doubles for the 'switch the resonance on' sample. Furthermore, to assess catalysis capability, surface-enhanced Raman spectroscopy was employed to monitor the progression of the MB N-demethylation reaction. The yield of the reaction is analyzed with the integration of the Raman peak of the reaction product. It was observed that the active design with enhanced absorption maintained a 7-fold enhancement in comparison to the low absorption 'switch off' sample over a 30s period (Fig. 3).

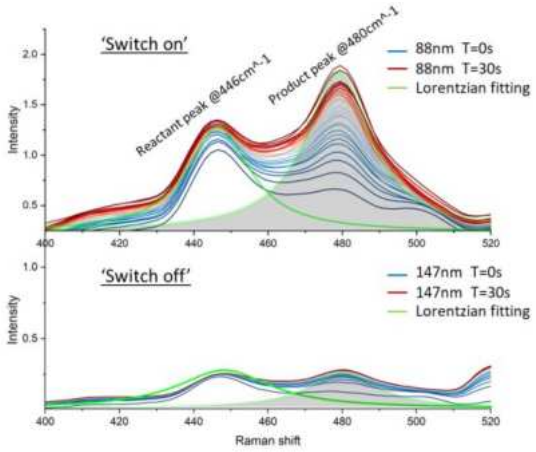

Figure 3: Temporal SERS results of 'switch on/off' samples in 30s; the product peak fits with Lorentzian curve.

In conclusion, nanoparticle-cavity designs based on the coupling of LSPR and FP resonances achieved an active control on photocatalysis with tailored configurations. However, the Ti substrate exhibits instability during the annealing process at 500°C. Thus, the absorption peak is not only attributed to the resonance. To improve selectivity behavior, it is proposed to substitute Ti with a high-temperature-resistant material, such as Au.

Abstract: This research establishes that fullerene can be efficiently reduced by hot electrons in a Plasmonic-Fabry-Perot coupled system, emphasizing the pivotal role of hot electrons generated by localized surface plasmons. The study highlights the intricate dynamics among nanoparticle size, hot electron generation, and photoreduction efficiency in plasmon-driven processes. The findings offer a promising avenue for controlling chemical reduction processes and optimizing plasmonic catalysts, with implications for diverse applications like photocatalysis.

Summary: Disordered plasmonic arrays of Au nanoparticles (NP) were fabricated on Si-SiO2 substrates using thermal evaporation and annealing. The particle size distribution was evaluated by analysis of SEM images, which revealed average radii of 4nm, 6 nm, 8 nm, 10 nm and 15 nm, respectively, obtained by changing the initial thickness of the Au film (Figure 1(a)). UV-Visible spectroscopy was used to characterize the fabricated Au NP arrays for their absorption properties (Figure 1(b)). The reference Si-SiO2 substrate reveals a strong peak in the absorption spectra associated with the SiO2 layer present in the substrate that acts as an anti-reflection coating supporting Fabry-Perot (FP) modes. In Au NP arrays, a strong absorption in the visible region occurs due to surface plasmonic resonances of the Au NPs. As gold particle size increases, the absorption peak undergoes broadening and shift towards longer wavelengths, indicating changes in plasmonic resonance conditions. Fullerene C60 was deposited through thermal evaporation onto Au NP arrays and onto a Si/SiO2 substrate, serving as a control sample for measurement comparison. The introduction of the C60 layer caused a redshift and broadening of the absorption peak in the reference Si/SiO2 substrate due to the changes in the dielectric environment (Figure 1(c)). The absorption peaks of the NP arrays showed significant splitting when the C60 layer was present. The observed peak separation resulted from the strong coupling between LSPR and FP modes in the altered dielectric environment produced by the C60 layer. Theoretical studies reveal that Fullerene C60 can undergo a reduction process of up to six electrons due to its triply degenerated LUMO[1]. To monitor this multi-electron reduction using the Au–C60 systems, in-situ real-time Raman measurements were performed. Temporal evolutions of the control and AU NP arrays with different radii were taken for 300s upon irradiation with an excitation wavelength lext = 633 nm and 0.66 mW of power. The measurements were performed at -100^{o}C to reduce the intrinsic C60 photopolymerization process. No indications of photo-polymerization or electron reduction were observed in the control as evidenced by the absence of newly emerging peaks. In contrast, in the samples containing Au NP arrays under the same conditions, distinct new peaks emerge. These new peaks can be confidently associated with 1, 3, and 6 electron reductions of C60 (Figure 1(d)). The clear emergence of these peaks strongly suggests that C60 molecules undergo multiple electron reductions, a process facilitated by the presence of plasmons associated with the Au NP arrays. Quantitative analysis of the photoreduction yield at each NP radii clearly demonstrate a strong dependence of yield on NP size(Figure 1(e)). Specifically, the 6 nm NP array exhibits the maximum yield for total electrons reduced, while conversely, the 15 nm array demonstrates the lowest yield. This observation underscores the significant influence of nanoparticle size on the efficiency of C60 photoreduction. The wavelength dependence study further highlighted higher overall yields and proportionally more multiple electron transfers at shorter wavelengths, particularly for radii in the middle range of the investigated radii. To gain insights into the observed trends in the

results, comprehensive full-field three-dimensional optical simulations were conducted for the nanoparticle (NP) arrays, incorporating experimentally obtained parameters. The optical simulations were employed to calculate average near-field enhancements and hot electron generation rates for each nanoparticle radius. This analysis aimed to discern the specific plasmonic effects responsible for the observed photoreductions. A comparative analysis of these calculations clearly demonstrates the substantial role played by hot electrons in the reduction of C60, overshadowing the impact of near fields. The discerned trend in yields for each nanoparticle radius can definitively be associated with the quantity of generated hot electrons. In conclusion, this study employing a Plasmonic-Fabry-Perot (Plasmonic-FP) coupled system clearly demonstrates that the multi-electron reduction of C60 can be effectively facilitated through the leveraging of hot electrons. Furthermore, it underscores the intricate interplay among nanoparticle size, hot electron generation, and photoreduction efficiency in plasmon-driven processes. This emphasizes the significance of experimental validation in understanding these complex dynamics. By harnessing the plasmonic effects induced by the interaction between light and metallic nanoparticles, the study unveils a promising avenue for precisely controlling and enhancing chemical reduction processes. This insight not only deepens our understanding of plasmon-driven reactions but also opens up new possibilities for the design and optimization of plasmonic catalysts with implications for various applications in fields such as photocatalysis.

Abstract: The model is implemented using Maple to assess open-circuit voltage, short-circuit current density, conversion efficiency, and fill factor for a ZnO(window)/CdS(buffe)/ CZTSSe(absorber) solar cell. The varying thicknesses of Buffer layer (w_n) is considered in the calculations. The outcomes reveal that w_n leads to a significant enhancement in all performance indicators.

Keywords: CZTSSe, solar cell, MAPLE, high performance

The advancement of thin-film solar cells has prompted researchers to explore various materials to enhance conversion efficiency, reduce the use of hazardous raw materials, or lower manufacturing costs. One approach involves the utilization of simulation tools, which permit the manipulation of solar cell materials, parameters, dimensions, and other variables to assess the cell's performance metrics without material wastage. This article introduces a mathematical model designed for thin-film solar cells based on Copper zinc tin sulfo-selenide (CZTSSe). Solar cells based on CZTSSe is intensively studied as all components are abundant in nature [1-3]. In this work we want to understand the efficiency of the cell using Maple program. The proposed structure is shown in figure 1.

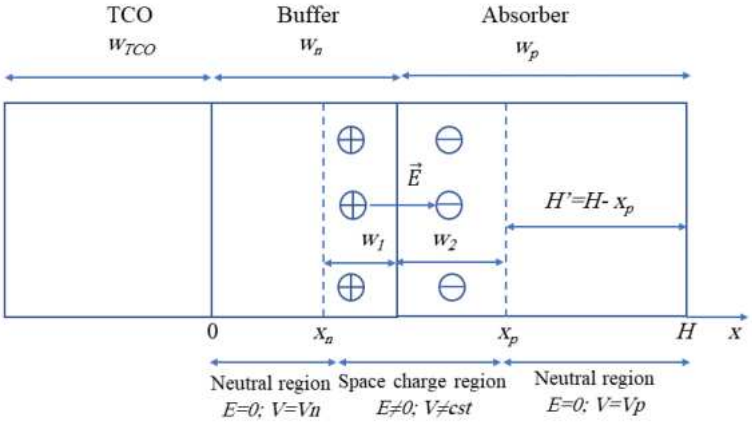

Fig 1: the proposed solar cell structure

The total photo current density is defined as follows:

$$J_{ph} = \int_{\lambda_1}^{\lambda_2} J_{ph}(\lambda);\ \ where\ Jph(\lambda) = Jp(\lambda) + Jn(\lambda) + Jzce(\lambda) \qquad (1)$$

Photocurrent $Jph(\lambda)$ is defined as the sum of the current density due to the holes in N region ($Jn(\lambda)$), the current density due to the electrons in the P region ($Jp(\lambda)$), and the current density in the space charge zone ($Jzce(\lambda)$).

The three Solar cell characteristics that describes its performance are: the open-circuit voltage (*Voc*), the fill factor (*FF*) and the power conversion efficiency (η) as defined in equation (2)

$$V_{oc} = \frac{kT}{q}\ln\left(\frac{J_{ph}}{J_0}+1\right); FF = \frac{P_m}{V_{oc}I_{sc}};\ \eta = \frac{P_m}{P_i} \qquad (2)$$

where *Jo* is the dark current density, I_{sc} is the cell short-circuit current, P_m is the maximum power and P_i is the incident power. The simulations are performed as function of the width w_n. Results are given in figures 2.

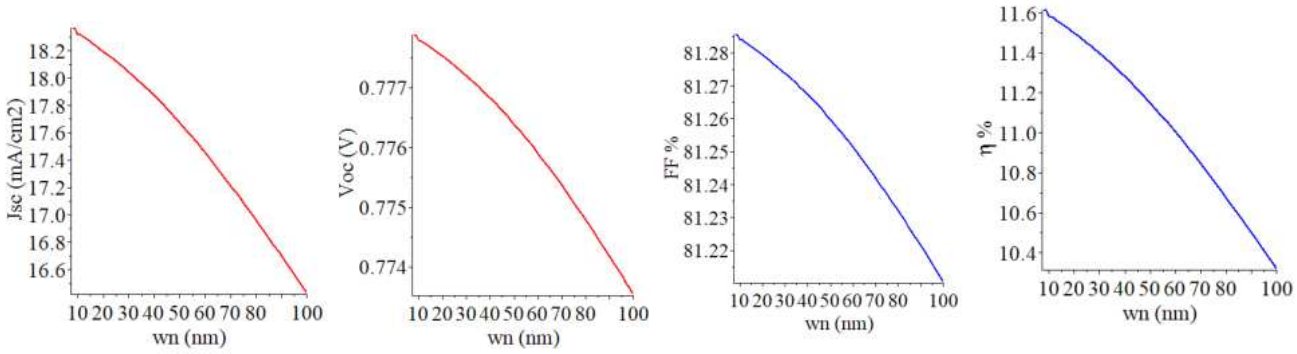

Fig 2: effect of w_n on solar characteristics

Fig. 2 shows the effect of the thickness *wn* of the CdS buffer layer on the cell performance for: *EgCdS* = 2.42 eV, *EgCZTSSe* = 1.13 eV, *wZnO* = 200 nm and *wp* =3µm. The breadth of the space charge area, known as w1, is 12.6 nm. Given that the buffer layer's maximum width, wnmax, is 100 nm, which exceeds w1, the buffer layer comprises not only the space charge area with a width of w_1 for $w_n < w_1$ (where x_n equals 0), but also a secondary neutral zone with a width of $x_n = w_n - w_1$ for $w_n > w_1$. Fig. 2 shows that if $w_n < w_1$, the cell's performance is unaffected. However, after wn surpasses w_1, the neutral zone effect kicks in, marginally reducing the current and, as a result, efficiency. This effect is caused by the minority carriers (holes) in the N layer (CdS) having a shorter diffusion length than minority carriers (electrons) in the P layer (CZTS). As a result, increasing the thickness of w_n causes more photon absorption in the N layer before it reaches the P layer, lowering absorption there. As a result, it is preferred that w_n stay equal to or smaller than w_1. Furthermore, it is important to note that the thickness of the buffer layer, w_n, has no major effect on the cell's performance. While this may appear insignificant at first, it confirms the previous finding. However, this does not indicate that the buffer layer should be removed, as its role in creating the electric field within the space charge zone is critical to junction formation.

Research on the enhancement of photocatalytic activity of bismuth-based materials by plasma effect

Derek Hao*

School of Science, STEM College, RMIT University, Melbourne, 3000 Australia
*Corresponding author: derek.hao@rmit.edu.au

Abstract: The study investigates the enhancement of photocatalytic activity in bismuth oxide material through plasma effect. The research explores the preparation of C/Bi/Bi_2O_3 composite photocatalyst. The reduced particle size and plasma effect of bismuth increase the photocatalytic efficiency, offering promising applications in environmental remediation and energy conversion.

In recent years, bismuth-based materials have made significant advances in the field of photocatalysis, which is the acceleration of photoreaction in the presence of a catalyst.[1] These materials are particularly interesting due to their unique properties including the adjustable band structure and light absorption, good stability and non-toxicity, good photocatalytic activity, etc.[2] More importantly, bismuth nanoparticles can exhibit surface plasmon resonance, which can be employed to improve the photocatalytic activity of materials.[3]

Compared with other Bi-based photocatalysts, α-Bi_2O_3 is the most common Bi-based photocatalyst with a lot of advantages. For instance, it has a narrow band gap which can be excited by visible light, moreover, α-Bi_2O_3 is nontoxic and easy-prepared. However, the band gap around 2.7 eV indicates that α-Bi_2O_3 can only utilize a small amount of solar energy.[4,5] Meanwhile, the grain size of α-Bi_2O_3 obtained by calcination method is often too large for interface reactions. Herein, as shown in Figure 1, a new C/Bi/Bi_2O_3 composite photocatalyst was synthesized through an uncomplicated, single-step process utilizing EDTA-Bi as the starting material. This composite catalyst demonstrated superior performance in photodegradation of 2,4-dichlorophenol compared to pure Bi_2O_3, under both simulated sunlight and visible light. The presence of metallic Bi and residual organic carbon in the composite not only boosts light absorption but also promotes the swift separation of photo-induced charge carriers, leading to enhanced photocatalytic efficiency. Additionally, this research introduces an easy-to-implement technique for crafting C/Bi/Bi_2O_3 composites, offering a practical approach for enhancing the photocatalytic activity of composite materials.

Abstract: Renewable energy and waste water treatment require advanced nanoscale platforms. Localized Surface Plasmon Resonances (LSPR) show promise. Here is proposed a self-organized method creates glass nanorippled templates for gold nanowire growth, enhancing photocatalysis and electrode performance. Plasmonic NWs extend absorption, offering potential for scalable solar energy conversion and large-area photonics.

Photochemical reactions, such as photocatalysis and water splitting, are of great since they can promote molecular degradation of organic pollutants[1,2], or energy storage via hydrogen production in view of renewable energy conversion[3]. While large band gap semiconductor oxides like TiO_2 exhibit robust photocatalytic activity and chemical stability, their limited absorption of solar light, primarily confined to the ultraviolet (UV) spectrum (5% absorption), poses a challenge for efficient light utilization. A promising approach to improve the functionalities of such electrodes in the visible range is based on the excitation of Localized Surface Plasmon Resonances (LSPR) in nanoparticles. Specifically, LSPR facilitates the strong confinement of incident light within a subwavelength volume, thereby enhancing light scattering and absorption cross sections. These properties have garnered increasing interest for their potential application in photochemical processes, particularly in waste water treatment and energy storage through the water splitting process. Notably, LSPR can directly influence photochemical reactions through its local field enhancement and the injection of "hot electrons." Moreover, it can be coupled with another photocatalyst such as TiO_2 to further enhance its efficacy.
However, for this kind of applications is crucial to develop fabrication techniques that are usable over large-areas. To address these challenges, we have developed a self-organized method[4,5] capable of producing glass nanorippled templates spanning centimeters squared, with scalability up to meters squared. These templates serve as a substrate for the growth of laterally separated gold nanowires. This unique system holds promise as both a standalone photocatalyst and a functionalized electrode.
In the former application, we utilized this sample in a photochemical reaction involving the photobleaching of Methylene Blue (MB)[2]. Specifically, using a monochromatized and polarized illumination, we observed an higher MB's photodissociation rate at the wavelength at which the LSPR is tuned in resonance with the MB's maximum optical absorption. This observation is pivotal in demonstrating the active role of plasmonic resonance in the photodissociation process and optimizing the fabrication of plasmonic substrates for the photodissociation of colored dye molecules. Therefore, these findings underline the potential of nanophotonics solutions in environmental applications such as waste water treatment.
Regarding the use of this system as electrode we deposit an ultra-thin film of TiO_2 on the top of the NW matrix and we use this kind of system as electrode for an Oxygen Evolution Reaction (OER)[3]. In this setup, the Au NW arrays serve dual purposes: as a transparent conductive layer and as a plasmonic medium, resonantly enhancing

the photoconversion efficiency of a reference photoelectrochemical OER at visible photon energies significantly lower than the TiO_2 band gap. A spectrally selective and polarization-dependent detection of the photocurrent demonstrates the key role played by the plasmonic NWs that promote both polarization-sensitive optical absorption, via resonant near-field enhancement, and hot-carrier injection over a broader visible spectral range. This extension surpasses the band gap of the TiO_2 layer, yielding a notable gain of approximately 3.8 within the visible spectrum. These results qualify the hybrid Au NWs-TiO_2 as a promising and scalable self-organized platform for solar energy conversion via photochemical reactions and pave the way for large-area photonics and energy storage applications.

Abstract: Chemically synthesized plasmonic nanoparticle colloid templated self-assembly onto soft lithography replicated elastomer templates is a well-established method for originating 1 cm^2 scale metasurfaces. Regular noble metal nanoparticle arrays couple the scattered localized plasmon light into high-Q surface lattice resonances serving in nanolasing, Raman enhancing, and photocatalysis.

Precise average size control, high monodispersity, and reproducibility of chemically synthesized plasmonic nanoparticles enable their applications for photonic devices which are originally made employing top-down methods [1-2]. Templated nanoparticle self-assembly from concentrated nanoparticle colloids is an established method for the manipulation and deposition of nanoparticles into well-defined positions originating desired photonic coupling and controlled local field enhancements [2-4]. Regular sub-wavelength spaced noble metal nanoparticles arrays can diffractively couple the scattered light from broad localized surface plasmons (LSPs) into narrow and high-Q resonances termed plasmonic lattices or surface lattice resonances (SLRs) [2-4]. The wavelength taylorability of SLR positions rises from the size-dependent LSPR coupling with the pitch-determined Rayleigh's anomaly [2-4]. The laterally confined light can act as an optical resonator for a dye nanolaser [5,6], can confine the electromagnetic radiation for desired wavelength Raman enhancement [4], and can contribute to efficient solar water splitting by metasurface photoelectrodes [7]. Electron beam lithography defined master replication with soft lithography into elastomer deposition templates act as plasmonic metasurface carrier for direct application or as a transfer carried for integration into more complex photonic structures.

*corresponding author: joel.loh@manchester.ac.uk

Abstract: Metal-based photo-absorbing metamaterials can achieve electromagnetic field amplification and broadband absorption throughout the visible spectrum by reaching an effective refractive index similar to that of air. For instance, a ZnO/Cu metamaterial surface comprising periodically arranged nano-cubes demonstrates near-perfect 97% absorption from 350 to 650 nm. By having an index below 1, the plasmonic electric field expands to the entire visible spectrum, which enhances light-to-dark adsorption of CO_2 gas and with angular invariance. Fourier Transform Infrared Spectroscopy reveals additional intermediate species, suggesting new adsorption and reaction pathways.

Summary: Figure 1 shows the cross-sectional microscopy of 90nm copper / 10 nm ZnO nano-cubes on a gold layer [1]. The optical absorption spectrum of the meta-surface is wider and higher than that of a nanoparticle film. For randomly distributed nanoparticles, most absorption is via internal scattering of incident light, with a copper plasmonic absorption edge at 600nm. For the meta-surface, the edge is extended to 650nm (**Figure 1**). To show the difference in the underlying EM mechanism, we show the results associated with the conventional effective medium theory and the boundary sheet theory. **Figure 2** shows the real and imaginary component of the index, and the calculated absorption spectrum of the meta-surface nano-cube array and periodicity, using the MG effective medium theory. The absorption spectrum is similar to that of the nanoparticle film but not the meta-surface, and while the refractive index is close to 1, it is still high enough to induce reflection. A different refractive index theory is needed.

Using the boundary sheet theory we calculated that the meta-surface has an index real component below 1 and imaginary component near or below zero (**Figure 3**). This means that the metamaterial scatters or reflects minimal light because light effectively does not see any scattering medium. This is also effective at various incident angles of light- showing the metamaterial is a perfect absorber at all angles (**Figure 4**).

When a CO_2 gas is passed over the meta-surface, its chemisorption profile under light and dark is different than that of a copper nanoparticle film. The in-situ FTIR spectroscopy showed a large increase in absorption in the 1050−1220 cm^{-1} band under 1 sun illumination (**Figure 4**), which is associated with adsorbed methoxy (*CH_3O) or gaseous CH_3OH species. By contrast, the particle film showed relatively small absorption changes in the same band. This separate hydrogenation pathway suggests an additional indirect charge transfer that is present in the meta-surface, even though the nanoparticle film should also exhibit plasmonic effects. This is revealed by the electric field intensity spectrum (**Figure 5**), which showed that while a nanoparticle film only shows strong plasmonic fields at the resonance wavelength of ~600nm, the plasmonic field in the meta-surface covers 350nm to 650nm. Such a range of plasmonic energies can likely enhance the adsorption of gas molecules through an energy ladder of charge injection.

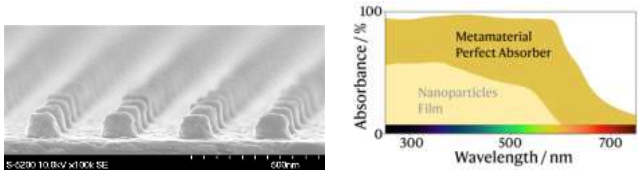

Figure 1. The cross-sectional microscopy image of the meta-surface (left). The optical absorption spectra of the fabricated meta-surface and uniform ZnO / Cu film (right).

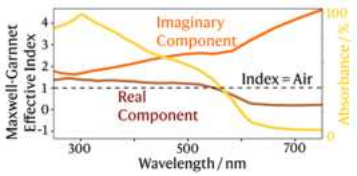

Figure 2. Effective medium theory shows the real and imaginary components of the refractive index of a Cu layer with a low volumetric filling ratio. Also shown is the simulated absorption spectrum of the Cu layer, which does not match the experimental absorption spectrum.

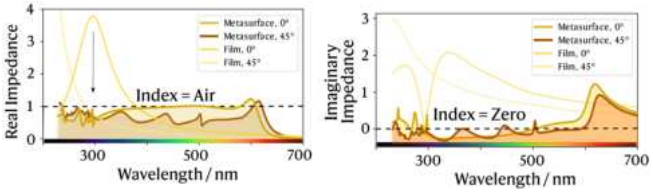

Figure 3. The Boundary Sheet theory shows the real and imaginary components of impedances of the meta-surface and ZnO / Cu film. The meta-surface impedance shows minor changes in profile whereas the film shows significant changes both across the spectrum and incident angle.

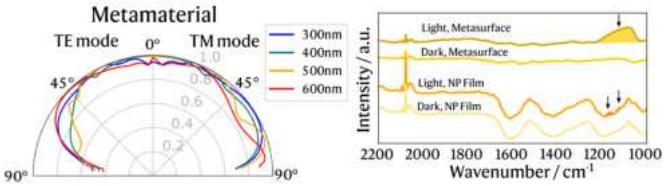

Figure 4. Polar plots of the meta-surface under a range of incident angles at selected wavelengths of 300, 400, 500, 600 nm. Fourier transform infrared spectra of the meta-surface and quartz fiber surface coating under 250 °C temperature and CO_2 and H_2 flow, compared between under dark and light conditions.

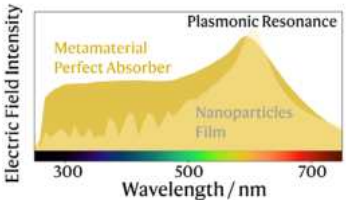

Figure 5. Average electric field intensities between the nano-cubes at the optimal periodicity, and nano-cubes with random periodicities, such that it is considered a nanoparticle film

Plasmonics and nano-optics

A Direct Approach towards Nanoscale Mapping of Plasmonic Heat Generation in Nanostructures

Serene Pauly[1*], and Dr. Amit Kumar[1]

[1]Queen's University, Belfast, UK
[*]Email: spauly01@qub.ac.uk

Abstract: This work focuses on direct visualization and optimization of nanoscale plasmonic heating in metallic nanostructures. Through integration of scanning thermal microscopy with laser-enabled plasmonic excitation, our methodology allows for precise measurement and analysis of localized heating effects. Additionally, the study examines wavelength, and morphological effects on influencing the thermal response.

Data demands have been predicted to grow 40% annually and one of the key players to make an impact is heat assisted magnetic recording (HAMR) with increased storage density up to 1 Tb/in^2, surpassing today's hard disk drives (HDD) [1]. One of its main components is a near field transducer (NFT) whose design is based on excitation of surface plasmons nanostructure to produce sub-diffraction limited thermal spot. A major bottleneck associated with nanoscale light confinement is the significant joule heating produced [1][2]. As a result, the performance and dependability of NFTs will decline, and plasmonic nanostructures will steadily deteriorate. Therefore, it is essential to directly measure the elevation of nanoscale temperature as a function of light intensity since this will lead to a comprehensive understanding of thermal distribution. While the topic has been explored from different perspectives for plasmonic response and arising thermal effects, most of this work focuses on macroscopic measurement of heat whereas plasmonic mediated heating is a nanoscale phenomenon. Our work combines different strands of the problem together and develop a holistic approach that allows direct visualisation of plasmonic-mediated thermal transport at nanoscale resolution. One of the major challenges in the field of thermal plasmonics, as mentioned in several publications [4] [6] is the need to directly quantify light-induced heat with nanoscale resolution, however much of the present literature has macroscopic temperature measurement utilising far field methods such as fluorescence microscopy, Raman spectroscopy, and others [6] [4]. Hence, our work aims to fill this gap in literature by investigating thermal distribution in nanometric plasmonic structures at high spatial resolution. The work consists of a novel method to visualize plasmonic-mediated thermal transport at a nanoscale resolution using scanning thermal microscopy. SThM is a variant of an Atomic Force Microscopy (AFM) which consists of a nano-thermocouple probe operating on passive mode. In passive mode, the probe functions as a temperature sensor and senses sample surface temperature distribution with 10 nm spatial resolution [3] and thermal sensitivity of 10 mK. Within this context the key objective we have achieved are 1) optimised plasmonic coupling to achieve wave vector matching by tilting the direction of illumination 2) direct measurement of temperature changes using SThM 3) replicate HAMR conditions in terms of plasmonic nanostructures. The SThM setup for thermal mapping is shown in broad strokes in Fig. 1, together with the related temperature map.

In pursuit of a comprehensive approach, the present study employs COMSOL simulations as a predictive framework to elucidate temperature distribution patterns as a function of structural morphology. This computational methodology facilitates an in-depth exploration of thermal dynamics within the structure, enabling the identification and characterization of hotspots. The utilization of COMSOL simulations affords a robust and quantitative means to analyze the thermal behavior of the system, providing valuable insights into the intricate interplay between morphology and temperature distribution. This study is a good starting point for significant advancements in the study of fundamental

physics related to thermal signatures that are produced by plasmonic responses.

Abstract: We inversely design reflective Aluminum gratings for narrow-/wide-linewidth TE/TM/unpolarized perfect absorption around 1.06μm. Expanding the widely studied P-polarization plasmonic case, we highlight the achievability of perfect S-polarization absorption in the simplest 1D geometry without extra materials. Optical and thermal measurements of the absorption of a large-area fabricated design match simulations.

The physical mechanisms behind enhanced photo-absorption in metallic reflection gratings, initially linked solely to excitations of surface plasmon polaritons (SPP), have been extensively studied and proven complex [1]. Under P-polarized incidence, in addition to SPPs, the modal mixture can comprise standing waves and cavity modes commonly referred to as localized SPP (LSP modes) and geometrically induced surface modes labeled spoof surface plasmons. Simple 1D metallic grating geometry does not offer versatile coupling and confinement mechanisms for S-polarized incidence, and thus, such reports are uncommon. Relevant studies mainly include designs with additional dielectric layers, smooth or periodic, to offer more physical complexity. Aluminium (Al) is the most prevalent metal, and due to its many benefits, Al and its alloys are essential for almost every industry, e.g., transportation, packaging, construction, electricity, machinery, etc. In the past decade, high-power fiber lasers with superior beam quality have become accessible and affordable. They are used in many applications, such as material processing, wireless power transfer, laser guidance and designation, satellite optical communication, and defense-related laser systems. Owing to their superior performance, Ytterbium (Yb)-doped fiber lasers, centered around 1.06 μm, dominate the high-power market nowadays. With such applications in mind, here we investigate the absorption enhancement of bulk Al around λ_0=1.065μm. Also, we achieve perfect S-polarized absorption in the simplest 1D geometry without adding material complexity. Such geometry can potentially be patterned remotely on large scales, e.g., with femtosecond pulsed lasers, and has the benefit of possible single-step fabrication.

The general design and its dimensions, i.e., period Λ, grooves width a, depth h, and the polar incidence angle θ, are shown in Fig. 1(a). The S- and P-polarization correspond to an incident electrical field, $\mathbf{E}_i$ perpendicular and parallel to the incident plane (xz), respectively. Using an in-house numerical EM simulation and optimization tool [2], we optimize the dimensions of several designs to maximize $A(\lambda_0)$ in TE, TM, and unpolarized irradiations. Here, we detail the properties of a design optimized for S-polarized operation. Unlike the P-polarization case, there is no transverse (along $\hat{z}$) confinement mechanism under S-polarization incidence. Thus, the groove should be high enough to fully encompass the mode distribution to achieve perfect absorption. This notion is demonstrated in Fig. 1(b), in which we plot a scan of the TE-polarized $A(\lambda)$ of an optimized design, with dimensions Λ_o=0.68 μm, a_o=0.517 μm, and h_o=1.836 μm, for a span of h. Note that this design, optimized while limiting Λ_o to inhibit reflective diffraction orders for θ<35º, shows low $A(\lambda)$ in the simulated spectrum $\forall h$<1 μm.

It is apparent that coupling to confined longitudinal modes (along $\hat{x}$) of the symmetrical MDM Fabry–Pérot resonant cavity propels the absorption enhancement. Considering perfect mirrors, such modes resonate according

to $2n_dk_0a=2\pi m$ with n_d- refractive index of the dielectric, k_0- wavenumber, and m- longitudinal mode order. Assuming that the additional optical phase accumulations due to the non-ideal metal are negligible, the resonant condition, for $n_d=1$, m=1, will be satisfied close to $a_{FP}\approx\lambda_0/2=0.5325$ μm that matches $a_o=0.517$ μm. Fig. 1(c) shows a comparison of $A(\lambda)$ for h_o and $h_1=2.6$ μm, marked with a dashed blue line in Fig. 1(b). The former shows a global $A(\lambda_0)>99.98\%$ maximum and additional local maxima at $\lambda_1=0.966$ μm. For h_1, the absorption peaks shifts $\lambda_0\rightarrow\lambda_{0d}=1.083$ μm with $A(\lambda_{0d})=83.46\%$, and $\lambda_1\rightarrow\lambda_{1d}=1.026$ μm with $A(\lambda_{1d})=98.48\%$. In Figs. 1(d)-1(f), we plot the color map distribution of $|\mathbf{E}|$ for h_o- Fig. 1(d) and h_1- Figs. 1(e)-1(f) under TE-polarized incidence at wavelengths λ_0, λ_{0d}, and λ_{1d}, respectively. The distributions in Figs. 1(d)-1(f) implies that the absorption peaks correspond to the laterally confined modes with m=1. Specifically, Figs. 1(d) and 1(e) depict optimal and non-optimal, due to h, coupling to TE_{10}, respectively, and Figs. 1(f) corresponds to close to optimal coupling to TE_{11}.

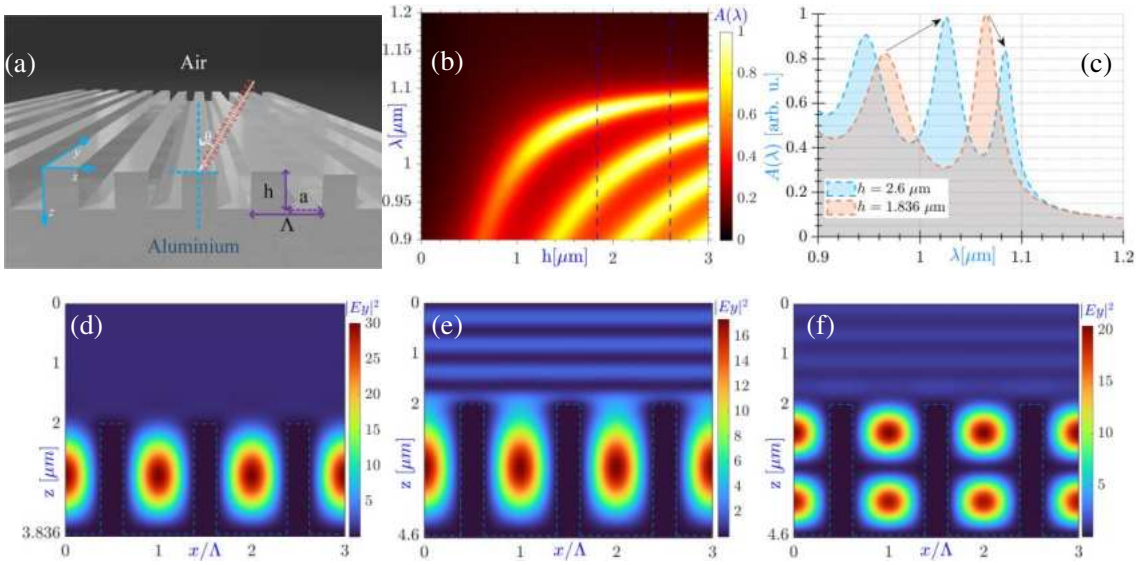

Fig. 1. (a) 3D illustration of the design schematic and reference frame as described in the text; TE polarized $A(\lambda)$ for $\Lambda_o=0.68$ μm, $a_o=0.517$ μm, and (b) a span of h and (c) $h_o=1.836$ μm, $h_1=2.6$ μm marked with a dashed blue line in (b); (d)-(e) TE-polarized $|\mathbf{E}|$ distribution inside and near the design for (d) h_o at λ_0 and (e)-(f) h_1 at λ_{0d}, and λ_{1d}, respectively.

We fabricated a 1 cm^2 sample of another design, optimized for unpolarized incidence, and comprehensively measured its $A(\lambda)$ at near-to-normal Gaussian-beam incidence. The spectral absorption, derived from reflection, was measured using a super continuous laser source and a spectrum analyzer. The single-frequency absorption was measured both optically and thermally using an in-house linearly polarized Yb-doped photonic crystal fiber laser source with ~0.2 nm linewidth at $\lambda_0=1065$ nm. In the thermal experiments, the absorption was numerically derived from the EM-induced heating of the sample, measured using thermocouples. Taking into account a scattered reflection pattern that was carefully investigated, the optical and thermal measurements agreed well with the simulations of the fabricated design, which experimentally showed more than 9.5- and 6-fold absorption enhancement over bulk Al in S- and P-polarization, respectively. The Al prevalence and progress of fiber-based optical sources, around 1.06 μm, promote the proposed designs as promising candidates for many applications.

Analyzing Absorption Mechanisms of Plasmonic and Dielectric Surface Lattice Resonance Embedded in Absorptive Medium

Joshua T. Y. Tse[1*], Shunsuke Murai[1], and Katsuhisa Tanaka[1]

Abstract: In this work, we present an analytical model based on the temporal coupled-mode theory that describes different absorption pathways of surface lattice resonance with absorptive nanoparticle array and index-matching layer. Each component of absorption is further analyzed to reveal general guidelines on optimizing nanoparticle arrays for photoluminescence enhancement.

Plasmonic nanoparticles which support localized surface plasmon resonance (LSPR) were known to possess extraordinarily strong light localization and EM field enhancement near the vicinity of the nanoparticles. When the nanoparticles are arranged in a periodic structure, it gives rise to a new type of plasmonic-photonic hybrid mode called surface lattice resonance (SLR). SLR retains the strong light confinement and field enhancement properties of LSPR, while greatly improving the low Q-factor of LSPR. We utilize such properties of SLR and explore the potential of SLR in enhancing the absorption efficiency in photoluminescence processes [1,2].

In our previous work, we have established a modified coupled-mode theory (CMT) that describes the SLR supported on TiO_2 nanoparticle arrays embedded in an absorptive index-matching layer [3]. We generalized the well-established lossless CMT by introducing a non-resonant absorption factor for the index-matching layer to modify the excitation and decay of the SLR. Yet, this modified CMT is incompatible with plasmonic nanoparticle arrays which exhibit intrinsic ohmic absorption. Therefore, we generalize the modified CMT to utilize the strong light-matter interaction enhancement provided by plasmonic nanoparticles. We generalize the modified CMT by separating the absorptive decay rate Γ_{abs} and the non-resonant absorption A_0 into components contributed by the fluorescent dye (*dye*) and the nanoparticle (*NP*) respectively, denoted as $\Gamma_{abs} = \Gamma_{abs,dye} + \Gamma_{abs,NP}$ and $A_0 = A_{0,dye} + A_{0,NP}$. Under this formulation, we can divide the total absorption of the system into the contributions between the fluorescent dye and the nanoparticle, that is $A = A_{dye} + A_{NP}$, where the two components are

$$A_{dye} = A_{0,dye} + (1 - A_0)\frac{2\Gamma_{rad}\Gamma_{abs,dye}}{\Gamma_{tot}^2}\frac{|\langle \kappa^* | s_+ \rangle|^2}{\langle s_+ | s_+ \rangle} \quad (1)$$

$$A_{NP} = A_{0,NP} + (1 - A_0)\frac{2\Gamma_{rad}\Gamma_{abs,NP}}{\Gamma_{tot}^2}\frac{|\langle \kappa^* | s_+ \rangle|^2}{\langle s_+ | s_+ \rangle} \quad (2)$$

at the resonant wavelength of the SLR, where Γ_{tot} is the total decay rate and Γ_{rad} is the radiative decay rate of the SLR, $|s_+\rangle$ is the incident wave and $|\kappa\rangle$ are the in-coupling constants.

The modified CMT is verified by FDTD simulations with nanoparticle arrays with the geometry illustrated in Fig. 1(a), where Al nanocylinders are placed on a transparent substrate (n = 1.46) and are covered by an absorptive index-matching layer (also n = 1.46) of thickness t = 280 nm. The nanoparticles have diameter D = 90 nm, height H = 100 nm and the period P of the square lattice is 380 nm. The extinction coefficient κ of the index-matching layer is modulated to simulate the absorption introduced by absorbers randomly distributed inside the index-

matching layer at various concentrations. The total absorption is calculated by $A = 1 - T - R$, where T is the transmissivity and R is reflectivity of the nanoparticle array. The divergence of the Poynting vector inside the nanoparticle is integrated to obtain A_{NP}, and A_{dye} is calculated by $A_{dye} = A - A_{NP}$. As shown in Fig. 1(b), the modified CMT accurately predicts the total absorption as well as by dye and by nanoparticle using the parameters from spectral fitting.

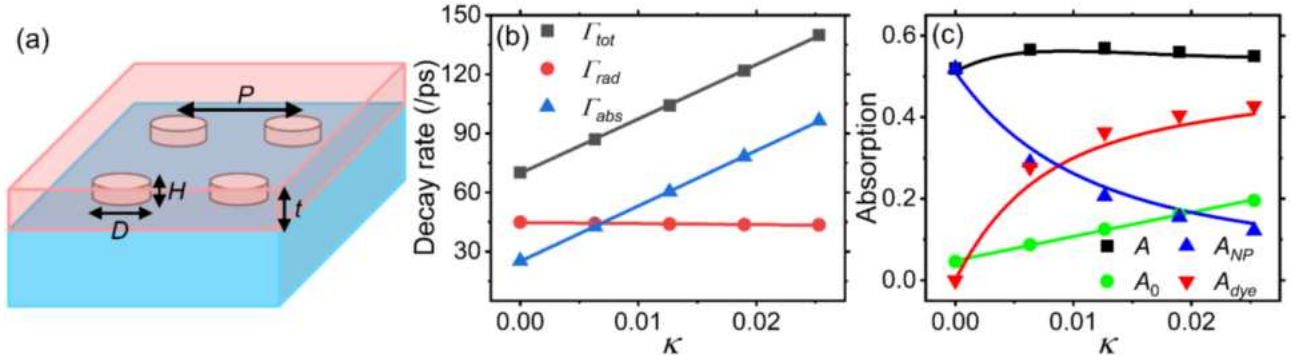

Figure 1. (a) The illustration of the nanoparticle array used in simulations. (b) Γ_{tot}, Γ_{rad} and Γ_{abs} are plotted as a function of κ. (c) The simulated A, A_0, A_{dye} and A_{NP} are plotted as a function of κ. The symbols represent simulated results and the solid lines are the CMT predictions.

We further analyze the origin of Γ_{abs} and A_0 by comparing nanoparticle arrays with different geometrical parameters. We discovered that $A_{0,dye}$ originates from the absorption of the index-matching layer without nanoparticles and $A_{0,NP}$ originates from the absorption cross section of LSPR of the individual nanoparticles. More importantly, we found that $\Gamma_{abs,dye}$ correlates with the nearfield intensity confined within the fluorescent index-matching layer normalized to the total nearfield intensity, while both the material choice and skin depth of the nanoparticle contributes significantly to $\Gamma_{abs,NP}$. These insights provide guidance on optimizing SLR for photoluminescence enhancement applications. In particular, lossless dielectric nanoparticle arrays have a distinct advantage in enhancing efficient energy transfer towards fluorescent dye molecules due to the near-zero $A_{0,NP}$ and $\Gamma_{abs,NP}$. We can also infer from $\Gamma_{abs,dye}$ the spontaneous emission enhancement efficiency, using the Lorentz reciprocity theorem and the relation of $\Gamma_{abs,dye}$ with the nearfield intensity. The significantly larger $\Gamma_{abs,dye}$ on plasmonic nanoparticle arrays would induce a much stronger Purcell effect for directional emission enhancement with SLR, therefore making them a superior choice over purely dielectric nanoparticle arrays.

Spin angular momentum of enhanced electric fields around a plasmonic nanostructures excited by circularly polarized light.

Abstract: We evaluated the spin angular momentum (SAM) in the electromagnetic field around plasmonic nanostructures excited by circularly polarized light. We revealed that the enhanced electromagnetic field can possess unidirectional SAM and their direction can be reversed depending on the resonance mode.

Circular dichroism (CD) spectroscopy, a technique that detects differences in the absorption coefficients of left- and right-handed circularly polarized (CP) light, is a powerful tool in materials science for structural analysis. A major challenge in CD spectroscopy is the inherent weakness of the CD signal resulting from chirality. Therefore, improving the detection accuracy of these signals is an important and ongoing challenge [1].

In chemical reactions with low signal-to-noise ratios of the observables, localized surface plasmon (LSP) is often used to enhance the electromagnetic field intensity. In particular, lattice resonance with periodically arranged nanoscale metal structures can increase the electric field intensity in the vicinity of the structure by several orders of magnitude and is widely used for signal enhancement in absorption measurements [2]. However, plasmonic structures, such as nanorods, do not always maintain circular polarization in the enhanced electromagnetic field. Therefore, it is not appropriate to directly apply plasmonic structures optimized for electric field enhancement to observation techniques that require the circular polarization of light, such as CD spectroscopy. In this study, we have analyzed the enhanced electromagnetic field of plasmonic structures excited by CP light using finite-difference time-domain (FDTD) simulations (Ansys Lumerical).

Figure 1 (a) shows a schematic of the FDTD simulation model used in this study. A plasmonic structure made of Au with a thickness of 50 nm was placed in a vacuum and circularly polarized light is normally injected from a plane wave source. Circular disk and square structures were targeted, and both antenna-type and aperture-type structures were evaluated. From the electromagnetic field, a physical quantity corresponding to circular polarization, the spin angular momentum (SAM), $\boldsymbol{S}$, is calculated using $\boldsymbol{S} = (1/4\omega)\mathrm{Im}(\epsilon \boldsymbol{E}^* \times \boldsymbol{E} + \mu \boldsymbol{H} \times \boldsymbol{H})$ [3]. Here, $\boldsymbol{E}$, $\boldsymbol{H}$, ϵ, μ, and ω are electric field, magnetic field, permittivity, permeability, and angular frequency, respectively. The asterisks signify their complex conjugates. Figure 1 (b,c) show the S_z components at $\lambda = 1200$ nm in a circular disc/aperture structure with a radius of $r = 250$ nm. Each value is normalized by the S_z of the incident CP light, calculated with the model without the plasmonic structure.

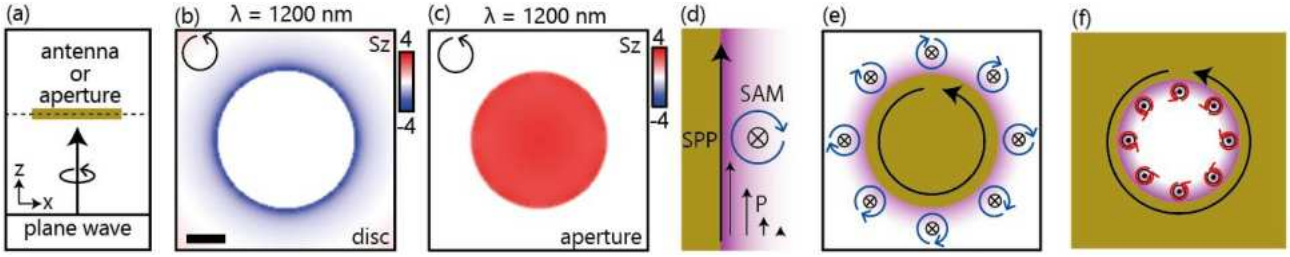

Figure 1 (a) Schematic of the FDTD simulation model. (b,c) Spatial distributions of Sz components near the plasmonic structures, normalized by the Sz components of the incident light. (d) Schematic of the SAM of the SPP on the (d) planer metal surface, (e) nano disc excited by CP light, and (f) nano aperture excited by CP light.

The sign reversal of the S_z outside the nanoantenna and inside the aperture can be explained as follows. The SAM of an electromagnetic field is proportional to the rotation of the Poynting vector, expressed as $\boldsymbol{P} = (1/2\omega^2)\nabla \times \boldsymbol{S}$ [3]. Surface waves, such as surface plasmon polaritons (SPPs), which decay exponentially from the interface, have a SAM oriented perpendicular to their propagation direction, as shown in Fig. 1 (d) [3]. In a circular structure excited by CP light, a plasmon mode is formed in which the direction of rotation is defined by the handedness of the CP light. Therefore, for nanodiscs where the evanescent field decays outwards and for apertures where the evanescent field decays inwards, the direction of the associated SAM is opposite, as schematically illustrated in Fig. 1 (e,f).

We then calculated the S_z for the square nano apertures. At a long wavelength ($\lambda = 1600$ nm), the associated S_z is positive, similar to that of the circular aperture. From the H_z distribution obtained at the same observation plane (top panel of Fig. 2 (b)), we can confirm that the dipole mode is excited at the aperture. Additionally, by calculating the Poynting vector, which represents the energy flow of the electromagnetic wave, we can confirm that the energy flow of the plasmon mode at the inner wall surface is in the same direction as the handedness of the incident CP light, i.e., counterclockwise (bottom panel of Fig. 2 (b)). The path of the charge movement for one oscillation period of the dipole mode is schematically illustrated in Fig. 2 (c).

On the other hand, in the short wavelength region ($\lambda = 750$ nm), the sign reversal of S_z near the inner wall surface is observed (Fig. 2. (d)). This non-intuitive sign reversal is because the one higher-order bright mode excited in the square structure by CP light is a negative hexapole mode [4]. The H_z distribution and Poynting vector plotted in Fig. 2 (e) corroborate that the excited mode is the hexapole mode, and the direction of energy flow is clockwise, opposite to the handedness of the incident CP light. The charge movement in the negative hexapole mode is schematically shown in Fig. 2 (f).

From these calculations, we have concluded that exciting the plasmonic structure with CP light produces a near-field with SAM in the vicinity of the plasmonic structure. Furthermore, our results reveal that the direction of the SAM can be controlled by selecting either a nano-antenna or an aperture, and by choosing which mode to excite, through appropriate design of the plasmonic structure.

Abstract:. *We present a new method that gives an exact and complete description for the quantum emitters coupled to non-Hermitian photonic devices, via the pseudomode transformation. Using this method, we obtain the non-Markovian quantum dynamics for a quantum emitters coupled with a silicon spherical particle.*

In recent years, quantum emitters have been coupled to increasingly more complex photonic systems, such as photonic crystals, for optical switching and photon generation, and nanoplasmonic devices for molecular sensing. These systems are usually non-Hermitian due to radiative and material losses, presenting a significant challenge for their quantized description, with issues arising for decomposing and normalizing the photonic modes, mode divergence, creating canonical field operators and mode mixing [1, 2].

Here, we present an exact and complete method that gives a quantized description of open, non-Hermitian photonic systems, that efficiently radiate energy to the far-field [3]. The complete electromagnetic field with its continuous spectrum is first quantized by a suitable mode expansion. The quantized continuum is then transformed into a discrete set of pseudomodes [4] which give a non-Hermitian description of the system, and correspond one-to-one with the classical photonic solutions. The discreet pseudomodes, $\boldsymbol{v}_{\xi n}(\boldsymbol{r})$, are obtained from the continuum modes $\boldsymbol{u}_{\boldsymbol{\xi}}(k, \boldsymbol{r})$ (which are solutions to the Helmholtz Equations), via the transformation:

$$\int_0^\infty k dk\, \rho(k) \boldsymbol{u}_\xi(\boldsymbol{k}, \boldsymbol{r}) \boldsymbol{u}_\xi(\boldsymbol{k}, \boldsymbol{r}') e^{-ick\tau} = \sum_n z_{\xi n} \boldsymbol{v}_{\xi n}(\boldsymbol{r}) \boldsymbol{v}_{\xi n}(\boldsymbol{r}') \Theta(\tau - \Delta_t(\boldsymbol{r}, \boldsymbol{r}')) e^{-icz_{\xi n}\tau}$$

where $z_{\xi n}$ are the poles of the radial equation $\rho(k)$ and (ξ, n) their corresponding quantum number, and Θ is a step-wise function [3]. This transformation arises naturally from the fundamental quantum equations of motion. We then employ this method for an example of a quantum emitter (QE) coupled to a spherical silicon particle of radius $1\mu m$. Classically, the spherical particle can be described in a continuum frequency space using vector

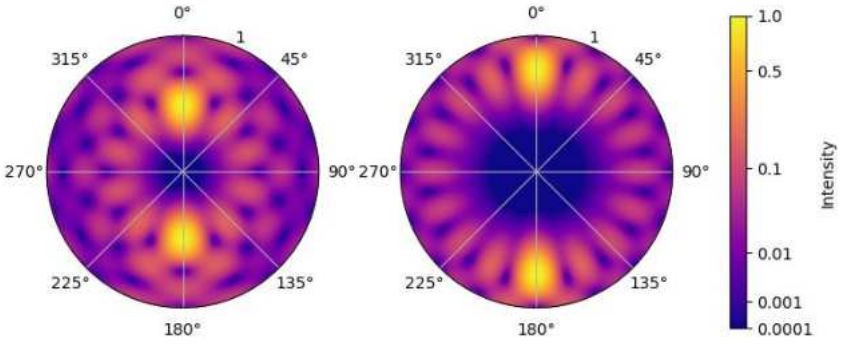

Figure 1: The intensity distribution of the Pseudomodes of the two most dominant modes of a silicon sphere of r=1um at 1550μm: left is the (l = 5,n = 4) mode and right the (l = 8, n = 3) mode.

spherical harmonics, which are readily quantized. From this we show that there is a one-to-one correspondence between the Mie modes and our derived pseudomodes, with identical angular components but a differing radial component. In Figure 1 we plot two such pseudomodes that are almost degenerate for this system: (l = 8, n = 3) and (l = 5, n = 4) (where l and n are the angular and radial mode indices).

Significantly, the pseudomode transformation method does not require the Markovian approximation, and thus allows us to also obtain non-Markovian dynamics for radiative non-Hermitian system. We do so using more than 1000 pseudomodes and demonstrate the results (in Figure 2) for dipole moments of $d = 100$ and $10000\,D$. We note that the (8,3) mode strongly couples to the quantum emitter displaying clear Rabi oscillations. However,

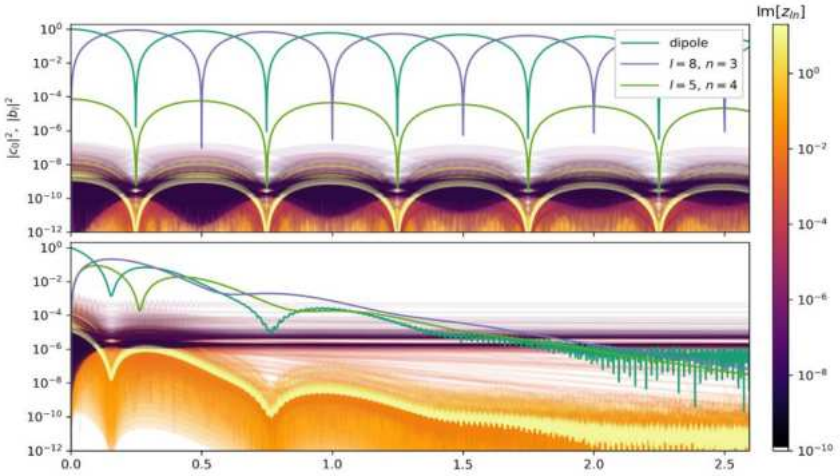

Figure 2: The Quantum Dynamics of a quantum emitter coupled to a dielectric silicon sphere. The dominant modes are (8,3) and (5,4) and dipole moments of 100 D (top) and 10000 D (bottom) were chosen for the quantum emitter. Note that the strongly coupled (8,3) mode is out phase with the dipole forming rabi oscillations, but the radiating (5,4) mode remains in phase. Also note the Markovian nature of the weakly coupled modes in the shaded purple regions which retain knowledge of their initial states.

the more radiative (5,4) mode is comparatively less strongly coupled but is in phase with the quantum emitter. The remaining modes, (demonstrated through the shaded regions on the plot) cause a lamb shift (δw_0) on the quantum emitter and an additional decay rate given by $-Re(\delta\omega 0)$. Therefore, our method reveals that non-Markovian dynamics arise for all weakly radiating modes, regardless of coupling strength and frequency. This is explicitly clear in the $d = 10000D$ case as the purple shaded pseudomodes do not oscillate in phase with the quantum emitter and continue to exchange energy with the mode even at times far from the initial decay of the emitter.

In conclusion, we present a method for the exact and complete second quantization of non-Hermitian photonic systems, through the pseudomode transformation. We use the method to demonstrate non-Markovian dynamics for a QE coupled to a spherical Silicon sphere, which are often ignored.

Abstract: Arrays with multipartite unit cells can be engineered to support lattice resonances with exceptional properties. Here, we show the excitation of out-of-plane lattice resonances at normal incidence in a bipartite array of metallic nanostructures. Furthermore, we analyze a metallo-dielectric array exhibiting a lattice resonance with perfect absorption.

Periodic arrays of nanostructures can present **collective modes commonly known as lattice resonances**. These modes emerge from the coherent interaction between the constituents of the array, resulting in strong responses with narrow spectral profiles. Motivated by their unique properties, periodic arrays are being exploited in a wide range of applications, including nanoscale light-emitting devices, ultrasensitive biosensors, and light-to-heat transducers [1].

The properties of lattice resonances are strongly dependent on the geometry of the unit cell. In particular, **multipartite arrays** with more than one particle per unit cell result in the **hybridization of lattice resonances** [2], which give rise to exceptional properties such as super- and subradiant behaviors [3]. Most of past theoretical works on lattice resonances in multipartite arrays have focused in the interaction between the electric dipoles, thus neglecting the magnetic response of the system. However, arrays with complex unit cells supporting both an electric and a magnetic response present a rich behavior that is yet to be explored.

Here, we extend the hybridization model to **account for the magnetic response** of the array and study two different arrays with complex unit cells in which the magnetic response plays a crucial role. First, we explore the **excitation of out-of-plane lattice resonances at normal incidence** in periodic arrays of metallic nanostructures [4]. These modes are characterized by a dominant component of the dipole perpendicular to the plane of the array. Due to the transversality condition of the electromagnetic field, it was assumed that out-of-plane modes can only be accessed at oblique incidence. Nevertheless, we show that, by exploiting the **interaction between the electric and magnetic dipoles** of the array, it is possible to excite an out-of-plane lattice resonance at normal incidence with an extremely high quality factor (see Figure 1).

Furthermore, we also study the emergence of lattice resonances with perfect absorption in metallo-dielectric arrays [5]. It is well-known that two dimensional arrays of electric dipoles can only absorb up to half of the incident light. This poses a strong limitation on their usage for certain fields such as thermoplasmonics. Here, **by spectrally overlapping two electric and magnetic lattice resonances, we achieve a lattice resonance with perfect absorption (>0.99)**. Unlike other approaches to achieve perfect absorption, our method achieves an

extremely narrow resonance with a high dependence on the incident polarization, which can be employed as a polarization selective filter, among other applications. This work sheds light on the excitation of lattice resonances in arrays with complex unit cells presenting both an electric and a magnetic response.

Abstract: Precise control of localized surface plasmon resonance (LSPR) wavelengths has been highly demanded for the practical use of metallic nanostructures in various nanophotonic devices. In this study, we demonstrated anisotropic control of the LSPR wavelengths of gold nanoparticles on a graphene substrate, achieved by uniaxially stretching the graphene.

In this study, we demonstrated active control of localized surface plasmon resonances (LSPR) of gold nanoparticles on stretched graphene by inducing a change in the dielectric constant (refractive index) of graphene through the application of uniaxial stress to graphene. As shown in Figure 1(a), gold nanoparticles (100 nm in diameter) were monodispersed and adsorbed on graphene placed on a stretchable polymer (PET: Polyethyleneterephthalate) film. Figures 1(b) show dark-field optical images of gold nanoparticles before and after uniaxial stretching of the graphene substrate, respectively. The gold nanoparticles moved in the stretching direction, and the scattering color changed from orange to green. The dark-field scattering spectra of the nanoparticles show that the LSPR wavelength blue-shifts from 585 nm to 550 nm before and after stretching (Fig. 1c). This is attributed to the uniaxial stress on the graphene underlying the gold nanoparticles, which changed the dielectric constant of the graphene. Furthermore, the LSPR wavelength of the gold nanoparticles on the stretched graphene was found to be dependent on the incident polarization direction. This is attributed to the anisotropy of the dielectric constant in the graphene plane between the stretching direction and its perpendicular direction.

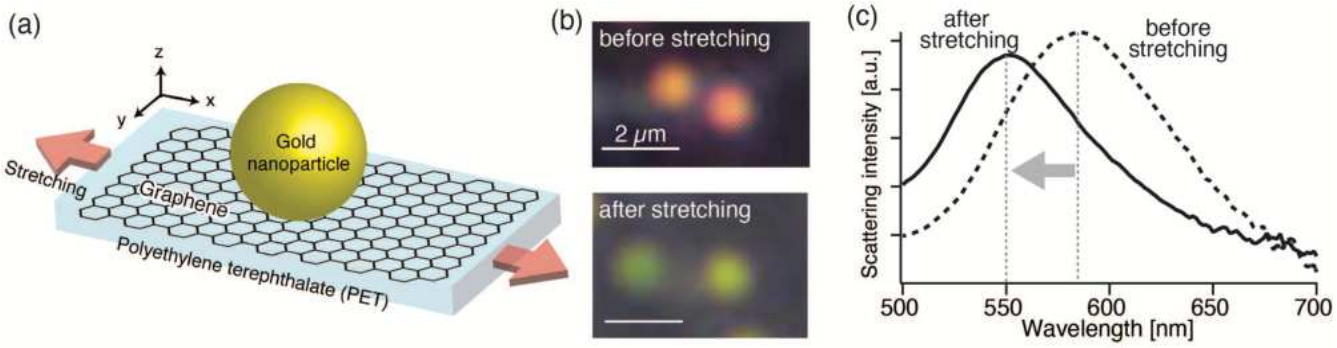

Figure 1 (a) Schematic of gold nanoparticles adsorbed on a stretched graphene substrate. Uniaxial stretching of graphene changes the dielectric constant in the graphene plane and modulates the plasmon resonance properties of the gold nanoparticles. (b) Dark-field optical images of the gold nanoparticles before and after stretching. (c) Dark-field scattering spectra of the gold nanoparticles before and after stretching.

High-Q and Small Size Cavity with Mie Scattering Mirror

Bokyung Kim [1], Seokhyeon Hong [1], Youngsoo Kim [1], Seung Hyeon Hong [1], Juhan Lee [1] and Soon-Hong Kwon [1*]

Abstract: We propose a new Mie scattering based two-dimensional resonator. Using strong backscattering based on Kerker condition, resonators have a physical size on the order of a wavelength and can achieve quality factor(Q) values up to 120,000.

Photon localization technology is actively researched in the development of optical waveguides, metasurface s, resonators, and light sources, and is related to future industries such as 3D imaging, VR and AR, and holograp hic displays. Notably, resonators, which are structures capable of trapping photons at or below the wavelength of light, are core in light localization research. Photonic crystal resonators, microdisk resonators, surface plasmon resonators, and BIC(bounded states in the continuum) resonators are studied for light localization, and each physical principle captures light based on photonic-bandgap, total reflection, surface plasmon, and BIC. The surface plasmon resonators have the advantage of small physical size, but inevitably suffer from metallic absorption loss. Photonic crystal, microdisk, and BIC resonators have the advantages of small mode sizes and high order Q-factors, but the considerably large physical size are required to build up large enough photonic bandgap, TIR, or quasi-infinitely periodic structure. The large physical size would be the critical limitation to develop highly integrated photonic circuits.

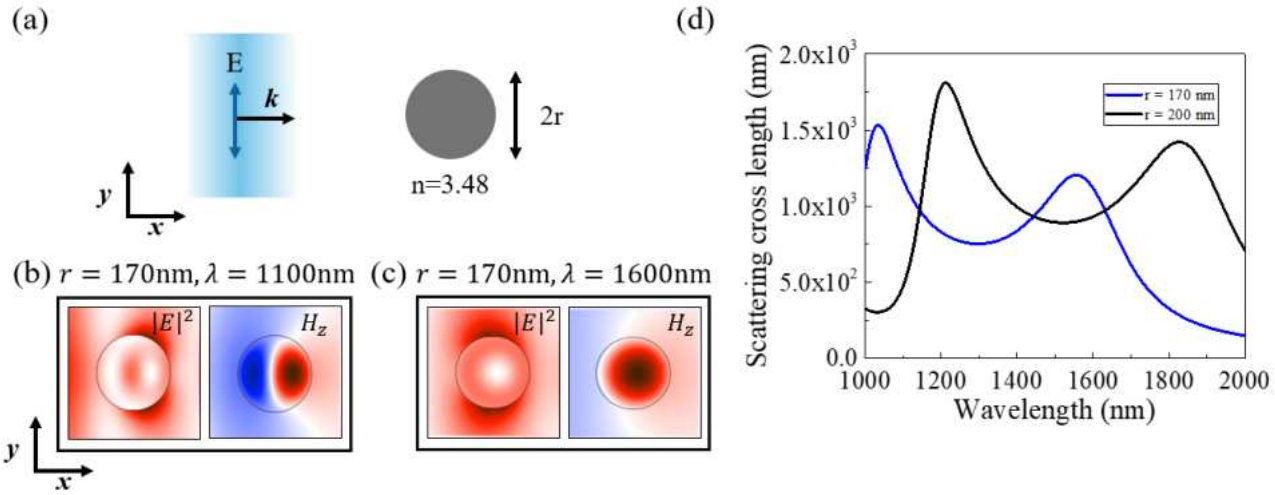

Figure 1 (a) Linearly polarized light is scattered by an infinitely long cylinder. **(b-c)** Mode profiles of an electric dipole (ED) and magnetic dipole (MD) modes. **(d)** Scattering crossing lengths of the infinitely long cylinders for different radii.

We propose a high-Q resonator with a wavelength-sized cavity based on Mie scattering. Mie scattering is a type of interaction between light and matter, occurring when the size of matter is comparable to the wavelength of light. It is analyzed through multipole analysis, and strong resonances occur in structures where electromagnetic dipoles are formed[1]. By examining the scattering pattern, we can identify points corresponding to the Kerker condition, where the electric and magnetic dipoles overlap, leading to strong backscattering due to the interference of two dipoles[2].

Using Mie scattering based conditions, we design a two-dimensional resonator consisting of a center cylinder and surrounding larger cylinders, as shown in Figure 2. The center cylinder has a radius of 170 nm and exhibits the magnetic dipole at a wavelength of 1580 nm. And the surrounding cylinders with a radius of 200 nm has the optical property of strong backscattering at 1580 nm due to the overlap of ED and MD modes. As results, the lights of the magnetic dipole mode excited at the center cylinder can be confined by the strong backscattering from the surrounding larger cylinders. The number of the surrounding cylinders was varied from 4 to 10 while the distance from the center is kept to be equal. The center of each structure was fixed, and the distance from the center to the outer structure was also investigated to determine the wavelength of light trapped inside and the Q-factor. When the number of outer cylinders was 8, lights with a wavelength of 1580 nm was trapped, showing a high Q-factor of 120,000.

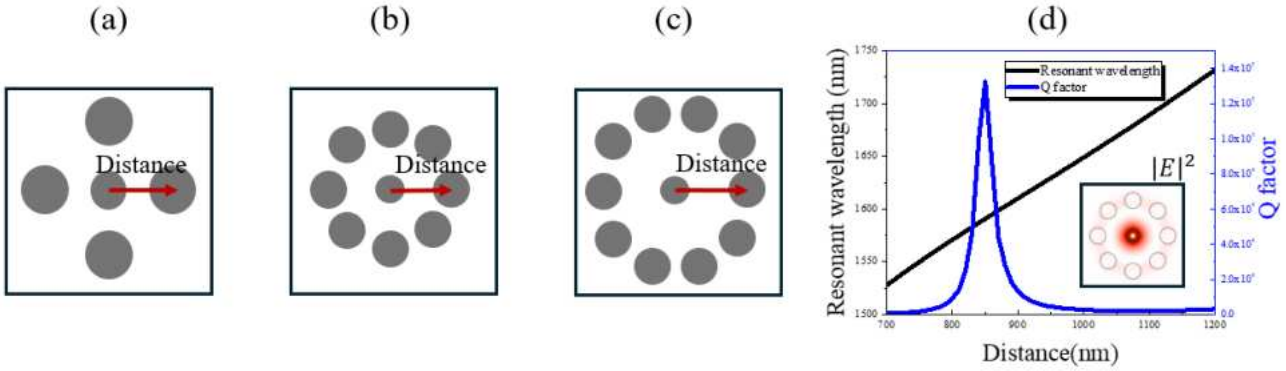

Figure 2 (a-c) Mie scattering resonators when the number of the outlying cylinders are 4, 8, and 10, respectively. **(d)**Q factor and resonant wavelengths as functions of the distance between the cavity center and the surround cylinders when the number of surrounding cylinders is 8.

To verify the feasibility of the design, the resonant wavelength and the Q-factor were calculated as the radius of the center cylinder changes. The strong drop in Q factor values as the radius of the center changes indicates that the formation of a magnetic dipole in the center is critical to performance.

Due to its compact physical size and straightforward dielectric-based design, it finds applications in nanolasers, optical switching devices, optical sensors, and optical waveguides. Particularly, it enables the realization of high-density photonic integrated circuits with remarkably low power consumption. The advancement of these photon-based devices is intricately linked to ultra-low power, small size, and ultra-fine photonic device technology, positioning them as pivotal technologies for the information society.

Abstract:
Photonic memories based on phase change materials have recently attracted much attention, but mostly require rare materials. Here, we demonstrate that silicon nanostructures exhibit laser-induced phase change, through a confocal micro-spectroscopy setup, leading to clearly bistable states with 80% scattering modulation The results are promising for silicon-based all-photonic memories.

1. Introduction:

Current computing technology based on the von Neumann architecture faces its physical limitation, known as the von Neumann bottleneck. The performance of computers is nowadays restricted by the speed of the information transfer between the central processing unit (CPU) and memories instead of the CPU computational capacity. Besides, as electrons move faster along circuits, a larger amount of energy is dissipated in the form of heat[1]. To further increase the speed of the information transfer and avoid energy loss, all-photonic computing is one of the best options due to its high speed[2], low energy loss[3,4,5], and wavelength-division multiplexing[5,6].

For all-photonic computing, photonic memories are one of the most critical elements. To achieve binary/multi-level memories, phase-change materials (PCMs) are usually considered because of the distinct difference in the refractive index between the two phases and their non-volatile nature. Among the PCMs, germanium-antimony-tellurium (GeSbTe or GST) is commonly used owing to its high repeatability[6] and large contrast[7] between amorphous and crystalline states. However, the scarcity of the material escalates the fabrication costs. Besides, most GST-based photonic memories require additional resonator design[6,7,8,9], which increases complexity and costs in the fabrication process. Maintaining a consistent composition of GST throughout the entire domain also proved challenging.

Here, we demonstrate that silicon-based nanostructures have the potential to achieve photonic memories based on laser-induced phase change. The nanoparticles can be reversibly amorphized and crystallized by sub-nanosecond laser irradiation. The advantages of using silicon include its abundance on Earth, mature nano-fabrication with mass production, as well as nanoscale Mie resonance that strongly confines the electromagnetic field, thus mitigating the need for additional resonators.

2. Photonic memories based on silicon nanoparticles

The experimental setup is based on a confocal laser scanning microscope, as shown in Figure 1(a). We used a pulsed laser with 0.1ns pulse width to induce the phase change of crystalline silicon nanoblocks (SiNBs). The corresponding scattering intensity variation was detected by a photomultiplier tube (PMT). In the same setup, an LED white light and

a spectrometer are employed to measure the back-scattering spectrum of the SiNB before and after phase change.

Figure 1(b) is an experimentally acquired scattering intensities from an isolated SiNB, whose size is 210x210 nm^2, with a height of 150 nm. When the input intensity increases from zero (solid line), the scattering intensity initially increases linearly. Intriguingly, at ~0.1mW/μm^2 excitation, a sudden drop of scattering appears, with 80% intensity modulation. This represents the transition from "ON" to "OFF" state. On the other hand, by decreasing input intensity from the "OFF" state (dashed line), the scattering intensity keeps reducing until ~0.04mW/μm^2, where an 80% sudden increase is observed. The steep variation between the "ON" and "OFF" states clearly forms a hysteresis curve, manifesting the potential for photonic memories.

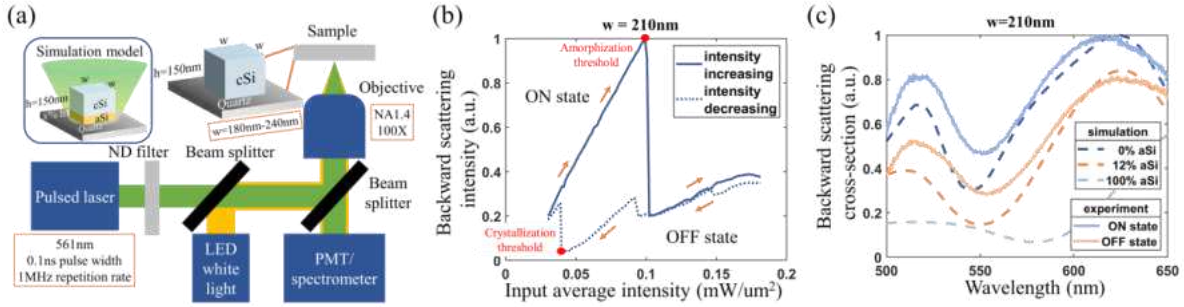

Figure 1. (a) Experimental setup for scattering detection from a SiNB. The width of SiNBs ranges from 180nm to 240nm, and the height is 150nm. The simulation model with different amounts of amorphous silicon is shown in the inset; x is from 0 (fully crystalline) to 100 (fully amorphous). (Abbreviation: cSi: crystalline silicon, aSi: amorphous silicon). (b) Experimentally measured relationships between input and scattering intensities from a SiNB of 210nm width. The solid and dashed lines are obtained by increasing and decreasing the input intensity. (c) Comparison of the experimental (solid lines) and simulated (dashed lines) spectrum.

To investigate the mechanism behind the unexpected scattering state transition, we measure the spectrum at "ON" and "OFF" states respectively, as shown in the solid lines of Fig. 1(c). Two Mie resonant peaks are found, at 520 nm and 620 nm respectively. Comparing the "OFF" spectra over the "ON" one, the 520-nm peak exhibits a blue shift, while the 620-nm peak shows a red shift. We assume the underlying mechanism is due to the phase change of silicon via pulse excitation[10], so we built a model to simulate partial amorphization on a SiNB, as shown in the inset of Fig. 1(a), where a thin layer becomes amorphous (x% aSi thickness) and the rest remains crystalline. The dashed lines in Fig. 1(c) present the simulation results. When there is no amorphous silicon (0% aSi), the blue dashed curve has two peaks that agree well with the "ON" state experimental results. Notably, when we increase the percentage of layered aSi in simulation, the spectrum displays similar blue and red shifts for the two peaks, and the best fit versus the "OFF" state measurement is found at 12% amorphous layer thickness. That is, the crystalline SiNB is partially amorphized at ~0.1mW/μm^2 (amorphization threshold) when input intensity is increasing at the "ON" state; on the other hand, it is "re-crystallized" at ~0.04mW/μm^2 when input intensity is decreasing at the "OFF" state. The controllable and reversible phase change of silicon nanostructures, as well as the clear bistable transition, lay a solid foundation for future photonic memory applications.

Hybrid full-space metalens for ultraviolet light

B. Idesová[1,2*], F. Ligmajer[1,2], O. Červinka[1,2] and T. Šikola[1,2]

[1]Central European Institute of Technology, Brno University of Technology, Czech Republic

Abstract: Conventional optical elements used nowadays are bulky and heavy, while metasurfaces offer a promising solution allowing for miniaturization and multifunctionality. In this work, we use hybrid nanostructures made of hafnium dioxide and aluminium to fabricate a metalens operating both in reflection and transmission simultaneously for a wavelength of 325 nm.

Great attention has been drawn to the manipulation of ultraviolet (UV) light because of its application in the telecommunication and consumer electronics industry, where extreme-UV lithography is a primary workhorse. However, absorption and tight precision constraints set limits on the fabrication of optical components, such as lenses, suitable for this part of the spectra. Nanophotonics offers a solution in the form of metasurfaces which can manipulate the amplitude, phase and polarization of the incident light by engineering its building blocks [1]. Moreover, metasurfaces are lightweight, compact and multifunctional [2], following the nowadays popular trend of miniaturization in not only the electronics industry.

With optical applications in mind, where low absorption is a key requirement, dielectric metasurfaces are mainly used because of their significantly lower losses compared to metallic metasurfaces based on plasmonic resonances [3]. In literature, UV metasurfaces are mostly explored or proposed on material platforms composed of oxides (HfO_2, Nb_2O_5, Ta_2O_5, ZnO) and nitrides (AlN, Si_3N_4) [4]. These materials are not mouldable like, e.g., the traditional fused silica, but they still offer large bandgaps which prevent UV light absorption. All of these materials were so far used for metasurfaces operating in transmission, meaning they were able to manipulate the transmitted light only. Recently, Jiang et al. [5] theoretically explored and proposed a metasurface which could project two distinct holograms simultaneously yet independently, both in reflection and transmission, a so-called full-space metahologram. Their main thought was to use two materials – Nb_2O_5 and MgF_2. MgF_2 is usually used for antireflective coatings in the optical industry. However, nanostructuring such a material presents a great challenge since it

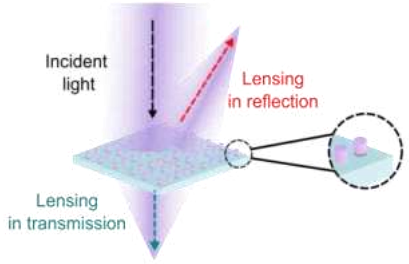

Figure 1: Schematics of a full-space metalens.

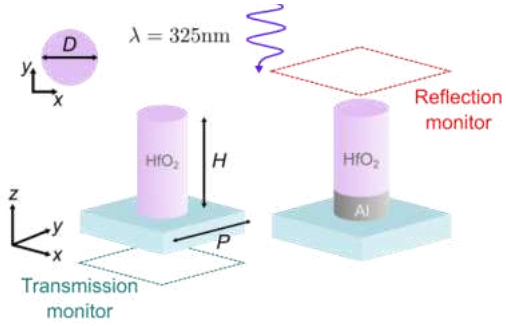

Figure 2: Two types of building blocks: pure HfO_2 operating in transmission and hybrid Al+HfO_2 operating in reflection.

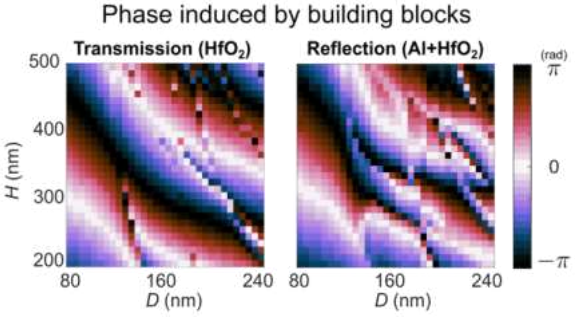

Figure 3: Phase induced by respective building blocks calculated using RCWA simulations for varying height *H* and diameter *D*.

is very hard and non-reactive, preventing the possibility of reactive etching.

In our work, we demonstrate a metasurface capable of lensing both in transmission and reflection simultaneously yet independently as is schematically shown in Figure 1 using CMOS-compatible materials. Such a metasurface could find an application as a controlling device for laser stability, in on-chip UV photodetectors and UV LiDAR systems. To achieve simultaneous operation in reflection and transmission, we utilize two types of nanostructures. The first one is composed of pure HfO_2 for its large bandgap of 5.7 eV and the second one is composed of HfO_2 and Al, forming a hybrid nanostructure (See Figure 2). In this hybrid nanostructure, Al serves as a backside mirror to ensure high reflectivity of the incident light.

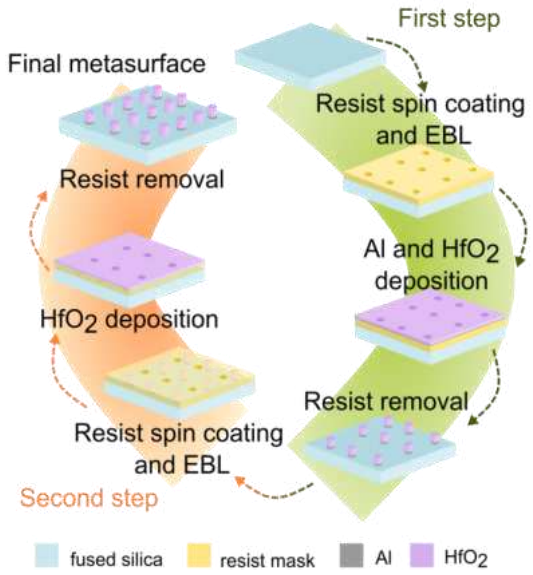

Figure 4: Schematics of two-step lithography fabrication of hybrid metasurfaces from two types of building blocks – pure HfO_2 and hybrid Al+HfO_2.

In the first step, we used rigorous coupled-wave analysis (RCWA) simulations to estimate the amplitude and phase change induced by each type of building block for varying heights H and diameters D and constant Al thickness 30 nm (See Figure 3). In these simulations, we set periodicity P = 250 nm while illuminating nanostructures with a plane wave of a wavelength of 325 nm. The transmissivity for pure HfO_2 nanostructures was close to unity, while the reflectivity of the Al+HfO_2 nanostructures was sustained above 0.8 for nanostructures with diameters greater than 150 nm. The final metasurface was composed of interposed arrays of pure and hybrid nanostructures mimicking the lens profile. Such a full-space metalens was fabricated using two-step electron beam lithography whose workflow is schematically shown in Figure 4. This approach allows for the deposition of HfO_2 and Al directly into the precisely patterned resist mask, using atomic layer deposition and electron beam evaporation, respectively. Finally, the full-space metalens characterization was done by measuring the intensity profile of the focused spots, quantifying its focusing efficiency in our custom-built optical setup.

Abstract: We introduce a novel metalens capable of generating a 10x10 multifocus array with high NA, unlike conventional low-NA microlens arrays. This method enhances imaging speed and quality, promising advancements in various imaging applications with superior resolution and efficiency.

As imaging technologies employing microlens arrays advance in the field, there is an increasing demand for optical components capable of generating multifocus. However, augmenting the number of focal points while maintaining a high numerical aperture (NA) presents a significant challenge. And also previous multifocal research had increased the number of focal points up to 50, but faced limitations on uniformity, resolution, positioning, and short focal distances [1,2]. In this study, we propose a novel approach for creating a multifocus array using a single metalens. Metalens are composed of meta-atoms with subwavelength dimensions. By manipulating the arrangement of these meta-atoms, we can freely modulate phase, an advantage we harnessed to achieve multifocus. In contrast to conventional microlens arrays, which typically have a low NA of around 0.3, our designed metalens maintains a high NA while accommodating an array of up to 10x10 focal points.

We designed the metalens phase profile and conducted simulations for multifocus generation using Rayleigh-Sommerfeld optical propagation.

$$\psi(x,y) = -\frac{2\pi}{\lambda}\sqrt{\left(x + x_{shift}\right)^2 + \left(y + y_{shift}\right)^2 + f^2\Big)} - f \qquad (1)$$

In this phase profile equation (1), x and y represent the spatial coordinates. λ is the wavelength of the incident light, f is focal length, and x_shift, y_shift indicate the desired shift in the coordinate focal position.

Additionally, Rigorous Coupled-Wave Analysis (RCWA) electromagnetic wave simulations were performed to develop a comprehensive meta-atom library. Silicon Nitride (SiN) was chosen for lens fabrication to function effectively in the visible light spectrum, with circular-shaped meta-atoms used to ensure polarization independence. We focused on optimizing the metalens for the specific wavelength of 532 nm.

To optimize its performance, we conducted simulations varying the NA, focal distance, and the lens size. To assess the lens's effectiveness, we measured resolution, Signal-to-Noise Ratio (SNR), and the uniformity of brightness. Our simulation results demonstrated that each focal point maintained uniform intensity and consistent size. The resolution achieved met the diffraction limit, and ensuring uniformity and high-quality imaging across the entire lens. Additionally, our multifocus metalens has achieved a variety of beam shapes array through a flexible design approach.

This technique significantly improves imaging applications without compromising image quality, offering a substantial advantage over other imaging method. With its high-resolution maintenance and multifocus capabilities, we expect that our research will be applicable in a diverse range of imaging fields, leading to advancements across various domains.

Abstract: We demonstrate a proof-of-concept localized surface plasmon resonance (LSPR) sensor device using high-density gold nanoparticle (AuNP) arrays on porous anodic aluminum oxide (PAAO) substrates. Refractometric sensitivity of approximately 100% relative intensity change per refractive index unit (RIU) was achieved in measurements of optical scattering in an off-resonance wavelength band.

Capillary force assisted convective deposition of colloidal nanoparticles on PAAO has enabled low-cost production of high density (≈100 μm^{-2}) non-close-packed (NCP) arrays of gold nanoparticles (AuNP) (fig. 1 inset). The considered metal-insulator-metal (MIM) structure consists of bulk Al substrate, PAAO membrane and AuNP array. Tuning the PAAO layer thickness in the optical subwavelength range can enhance the LSPR signal amplitude by constructive interference of the scattered light by AuNP and their reflection at the PAAO-Al interface [1]. Specifically, for 60 nm diameter AuNP, PAAO thickness ≈300 nm the scattering is maximized at ≈575 nm wavelength. While LSPR sensors commonly function by detecting resonance wavelength shift in response to changes in refractive index (RI), an alternative approach to detection involves measuring signal intensity in an off-resonance band. Specifically, this can be done at longer wavelengths where the intensity decreases to approximately half of its maximum value.

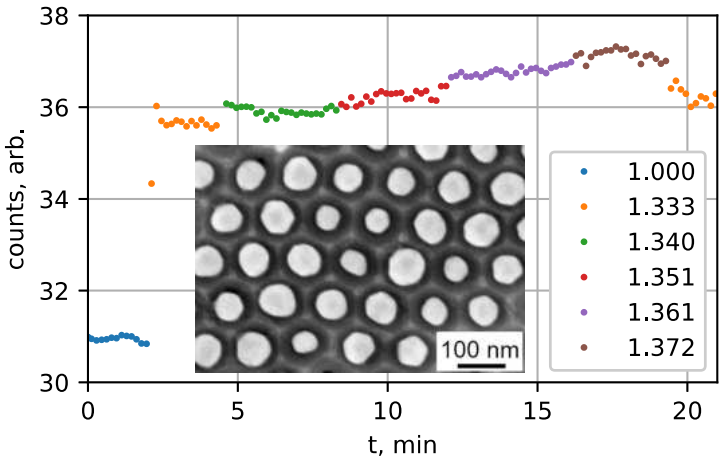

Figure 1. Integrated scattering intensity in the orange-red spectral range (≈610-630 nm) in media with different refractive indices, air n=1.000, water n=1.333 and 4%, 10%, 16%, 22% solutions of NaCl with RI values listed data point labels. Inset: 60 nm diameter AuNP on PAAO template.

PAAO was produced through a two-step anodization process of bulk aluminum substrates in a 0.3 M oxalic acid electrolyte at a 40 V potential [2]. The electrochemical cell was equipped with an optical window, enabling

real-time monitoring of PAAO layer thickness via reflective interference spectroscopy [3]. AuNP with a nominal diameter 60 nm (Sigma-Aldrich 753653) were deposited on PAAO by immersing the anodized substrate into the colloidal suspension and gradually withdrawing it at a rate of 0.1 μm/s. When subjected to angled illumination by a broadband visible light source (white light emitting diode, 3 W, 2700 K, 150 lm, PHILIPS), the Al-PAAO-AuNP MIM structure exhibited bright green-yellow colors visible to the naked eye. The sample was placed within a fluidic cell, enabling the measurement of scattered light by the MIM system in various RI media (NaCl solutions). The scattered light was collected without any lenses from an area with $\approx$5mm diameter by a multimode optical fiber, 200 μm core diameter, 0.22 numerical aperture at a $\approx$1cm distance from the sample surface. The collected light was analyzed using a miniature spectrometer (Ocean Optics USB4000). Instead of measuring the peak wavelength shift, we integrated the intensity in a narrow off-resonance band where scattering intensity is reduced by approximately one half of the maximum value.

The integrated scattering intensity is shown as a function of time in figure 1. The liquid cell was initially filled with air, then water, followed by increasing NaCl concentrations every $\approx$4 minutes, and finally with water again. Although the steps of intensity levels between measurements in different concentrations are somewhat fuzzy, most likely due to solution mixing and incomplete replacement, it is still possible to evaluate the sensitivity of such a sensor. Considering that the RI change $\Delta n=0.04$ between water and maximum concentration leads to intensity change from $\approx$35.5 to $\approx$37.0 counts in arbitrary units, the sensitivity exceeds 100 %/RIU by a good margin.

This study demonstrates the potential of PAAO based MIM structures for high-brightness LSPR sensing. Due to the large number of AuNP per surface area in NCP array without aggregation, the system has large total scattering cross-section while preserving LSPR resonances. This enables significant simplification of optical components in practical LSPR sensor systems.

Abstract: This work reports on an integrated plasmo-photonic bimodal interferometer with 1.233 nm/℃ sensitivity.

Photonic temperature sensors compared to other techniques relying on different physical mechanisms, exhibit superior performance demonstrating high sensitivity to temperature variations, wide temperature range, stability, and immunity to electromagnetic interference [1-3]. While early prototypes were based on fiber solutions [4], photonic integration enabled the miniaturization of these sensors without compromising their performance. Meanwhile, the field of plasmonics has attracted attention for its ability to offer compactness and extreme light confinement, enabling a diverse range of applications [5]. In this work, we propose an integrated plasmo-photonic bimodal interferometric sensing platform that leverages the advantages of both technologies, achieving an experimental temperature sensitivity of 0.563 nm/℃ with an air-cladded sensing area. This value increases to 1.233 nm/℃ by utilizing water instead of air, taking advantage of the higher thermo-optic coefficient (TOC). In principle, the proposed sensor can operate at different temperature ranges by using materials with different thermal properties on top of the sensing area.

Figure 1(a) shows a 3D conceptual schematic of the plasmo-photonic bimodal interferometric device that serves as a temperature measurement platform. The photonic part consists of cladded polymeric SU8 waveguides with dimensions of 1.8 (H) x 1.5 (W) μm^2. The SU8 waveguide is thinned to 0.9 μm for a 75 μm long distance, and an Aluminum (Al) metal stripe with dimensions of 80 nm (H) x 7 μm (W) is deposited to form a cavity that can be left empty or host thermo-optically sensitive materials in gas or liquid state. Two metal/insulator interfaces are formed at the top and bottom surfaces of the metal stripe, capable to support surface plasmon polariton (SPP) modes. These modes propagate along the two metal surfaces and interfere at the output photonic waveguide,

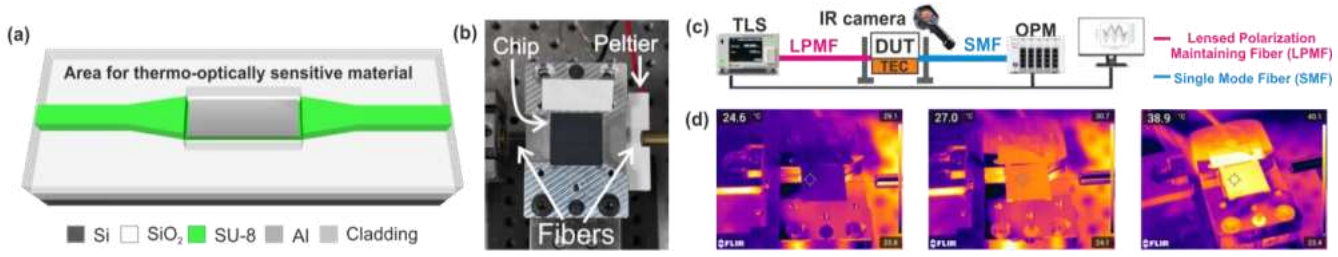

Figure 1: (a) 3D conceptual design of the plasmo-photonic bimodal interferometric temperature sensing platform. (b) Image of the DUT and TEC configuration. (c) Schematic of the experimental setup. (d) Thermal images at three different temperatures, 24.6 ℃, 27℃, 38.9 ℃, demonstrating the thermal change during this heating scheme.

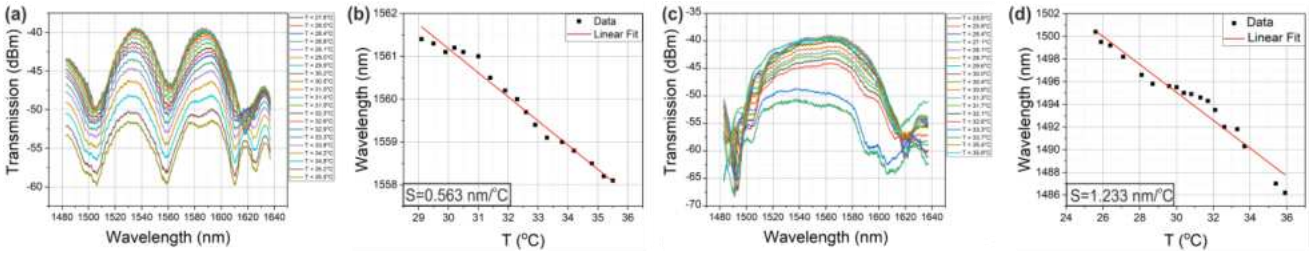

Figure 2: (a) Experimental spectral response of the temperature sensing platform under air conditions. (b) Least squares linear fit of the wavelength dip shift vs. temperature change, revealing an experimental sensitivity of 0.563 nm/℃. (c) Experimental spectral response of the temperature sensing platform filled with water. (d) Least squares linear fit of the wavelength dip shift with the temperature change, in the presence of water, showing an experimental sensitivity of 1.233 nm/℃.

realizing a single-arm interferometer. A more detailed description of the sensor and its operation as a refractive index sensor is given in [6,7]. Any temperature variation on the sensor chip will lead to changes of the refractive indices of the materials, that will alter the effective indices of both SPP modes. Therefore, an intense wavelength shift of the interference dips at the sensor output will be recorded.

The sensor chip was heated by a Peltier module located directly under the chip holder as shown in Figure 1(b), while the temperature was measured at the chip surface with an IR thermal camera. Figure 1(c) shows the experimental setup employed to perform the measurements consisted of a tunable laser source (TLS) and an optical power meter (OPM). The response of the sensor was first investigated with air acting as the medium on top of the plasmonic waveguide, in a temperature range from 27.6°C to 35.5°C. By analyzing the recorded spectral response of Figure 2(a), an experimental sensitivity of 0.563 nm/°C was calculated, as can be seen in Figure 2(b). Subsequently, a drop of water was injected into the thermo-optically sensitive material region exploiting the relatively higher TOC of water compared to air and the experiment was repeated for a temperature range from 25.6°C to 35.9°C, as presented in Figure 2(c). The linear fitting of the data in Figure 2(d), revealed an experimental sensitivity of 1.233 nm/°C confirming the sensitivity improvement of the sensor versus the TOC.

In summary, an integrated plasmo-photonic interferometer is experimentally evaluated for temperature sensing with high precision. The sensitivity of the device is directly related to the TOC of the material on the sensing area as confirmed by air and water measurements. The proposed temperature sensor is capable to support operation at different temperature ranges by placing liquids with diverse thermal properties on the plasmonic surface.

Abstract: In this work we propose a self-referenced plasmo-photonic refractive index sensor configuration, integrated on a polymer platform, to compensate for the effect of temperature.

Integrated plasmo-photonic sensors leverage the enhanced sensing credentials of plasmonics with the low-loss characteristics of photonics paving the way for powerful sensing devices with small footprint. On top of that, when integrated in polymer-based photonic platforms, they can offer lower-cost and faster fabrication [1,2]. However, due to the high thermo-optic coefficient of polymeric materials, temperature-induced variations become more prominent and limit the sensor performance. To date, several works have reported methods to compensate the effect of temperature on optical refractive index (RI) sensing. However, most of them consider fiber-based sensors while the respective works on integrated photonic circuits are limited to Si-based platforms [3,4], leaving room for further investigation on polymeric integrated devices.

In this work, we propose an integrated self-referenced scheme to compensate for the effect of temperature variations and improve the performance of the Aluminum-on-SU-8 bimodal plasmo-photonic sensor reported in [1]. The proposed self-referenced sensor is realized by cascading an SU-8 Bragg grating after the bimodal interferometer, as illustrated in the 3D schematic representation of Fig. 1(a). The bimodal sensor consists of an Aluminum stripe with 75 μm length located between two access SU-8 waveguides and on top of a thinner SU-8 layer. The working principle and the experimental evaluation of the sensor have been shown in detail in [1,5]. The Bragg grating has been placed at the bimodal sensor output to serve as a reference by tracking temperature variations. Opting for a narrow Bragg grating resonance at the edge of the sensor spectral response, a period of 520 nm and waveguide widths of $W_1 = 7$ μm and $W_2 = 6.1$ μm have been selected after numerical simulations.

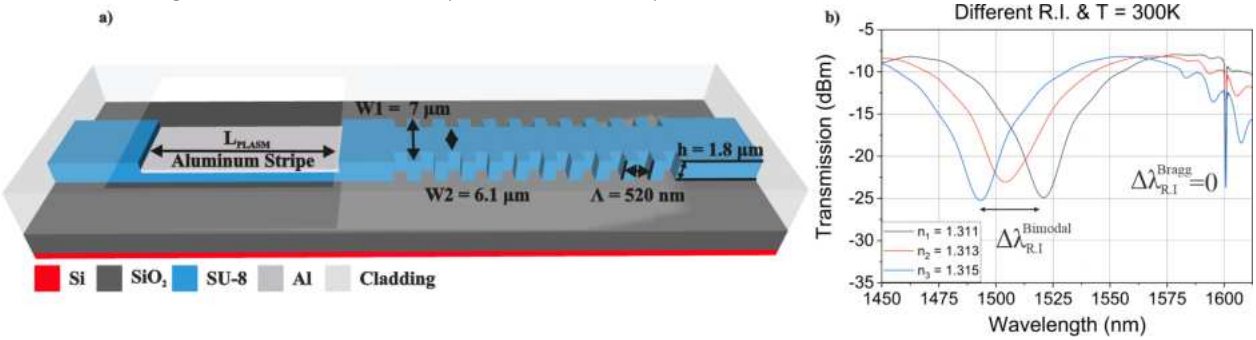

Fig. 1. (a) 3D schematic layout of the self-referenced bimodal plasmo-photonic sensor. (b) Spectral responses at constant temperature when mediums with different RIs are applied on the sensor surface.

The spectral response of the proposed configuration consists of two parts: (i) the sensor spectral response

comprising wavelength dips due to the bimodal interference and (ii) a sharp wavelength dip due to the Bragg grating resonance, as can be seen in Fig. 1(b). The simulated spectral responses of the proposed configuration when mediums with different RIs are applied on the sensor surface at a constant temperature are illustrated in Fig. 1(b). As can be observed, the RI changes cause a wavelength shift to the bimodal dips ($\Delta\lambda_{RI}^{Bimodal}$) revealing a sensitivity of 6078 nm/RIU, which is close to the experimentally reported values of [5], while the Bragg grating resonance remains unaffected by these changes due to being covered with cladding ($\Delta\lambda_{RI}^{Bragg} = 0$) making it ideal for a reference structure. Fig. 2(a) shows the respective simulated spectral response when the configuration is exposed to different temperatures and considering that a material with the same RI is applied on top of its surface. As can be observed, both parts of the transfer function are affected by variations in temperature with the bimodal sensor and the Bragg exhibiting a temperature sensitivity of 687 pm/K and 111pm/K, respectively. From these results, we can extract the calibration curve of the proposed self-referenced sensor shown in Fig. 2(b) which correlates the thermal shift of the bimodal dip ($\Delta\lambda_{\Delta T}^{Bimodal}$) with the thermal shift of the Bragg resonance ($\Delta\lambda_{\Delta T}^{Bragg}$) cancelling the factor of temperature.

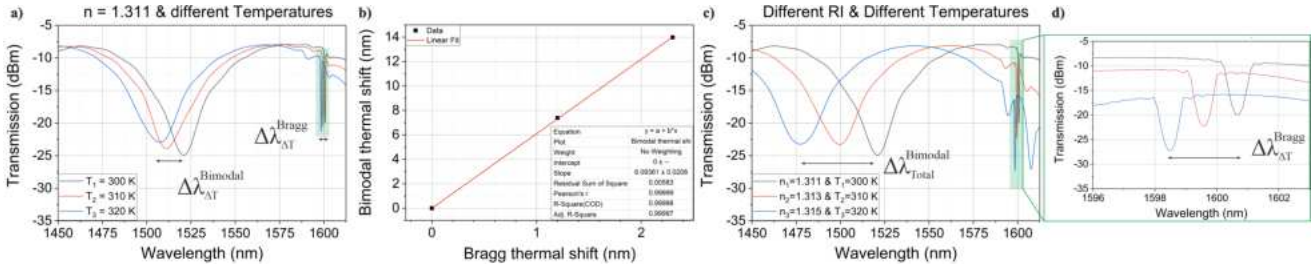

Fig. 2. (a) Spectral responses and resonances shifting for different temperatures. (b) Calibration curve. (c) Spectral responses and resonances drifting for different RIs and different temperatures. (d) Magnified view of the Bragg resonance drift.

Figure 2(c) shows a practical example of how the bimodal dips are shifted when both RI and temperature changes occur, while Fig. 2(d) presents a zoomed in view of the Bragg resonance shifts that are affected only by temperature. Measuring this $\Delta\lambda_{\Delta T}^{Bragg}$ and using the calibration curve of Fig. 2(b), we can define the shift of the bimodal dip due to the temperature change and subtract it from the total shift. For example, the $\Delta\lambda_{Total}^{Bimodal}$ corresponding to the black and blue curves of Fig. 2(c) is 40.21 nm, while the $\Delta\lambda_{\Delta T}^{Bragg}$ equals to 2.3 nm corresponding to the $\Delta\lambda_{\Delta T}^{Bimodal}$ value of 13.98 nm according to the calibration curve. By subtracting this value from the $\Delta\lambda_{Total}^{Bimodal}$, we find that the pure $\Delta\lambda_{RI}^{Bimodal}$ equals to 26.23 nm which is in good agreement with the value of 26.7 nm calculated from Fig. 1(b).

Therefore, the proposed polymer-based self-referenced sensor can effectively compensate for the temperature-induced wavelength drift hence eliminating a major flaw of polymer sensing platforms enhancing their resolution.

Abstract: Chemically synthesized gold nanoparticles were self-assembled on a template and transferred onto TiO_2 layer. The photoelectrochemical performance and spectral response of high-Q surface lattice resonance demonstrating electrode was compared with the counterpart containing random particles originated by dewetting of thin film and having broader localized surface plasmon resonance.

Recently plasmonic photocatalysis utilizing solar power for fuel generation has become an intensely growing field. The possibility to synthesize a variety of noble metal nanoparticles, *i.e.* gold, silver, platinum, etc. having different morphologies opened new paths for investigation. The most common approach is to use metal nanoparticles together with TiO_2-based materials to enable effective charge carrier separation and tune the optical response of the structure from UV to the longer wavelength regions (visible and IR) [1-2].

One of the needs for effective catalysis is to have controllable nanoparticle distribution on the surface. Colloidal nanoparticles can be deposited on solid TiO_2 surface creating active catalytic sheets [2]. The problem here is that nanoparticles tend to agglomerate on the surface if nanoparticle surface is not functionalized. Templated nanoparticle self-assembly [3] or deposition of monolayer from liquid-liquid interface can solve this problem without additional functionalization of particle surface. Ordered array of noble metal nanoparticles has additional advantage – surface lattice resonance that was shown to increase the electromagnetic field enhancement in a controlled way [3] and such photoelectrodes could also contribute to higher efficiency in solar water splitting at certain wavelength bands [1]. The water splitting performance and spectral response of regular gold nanoparticle array photoelectrodes carrying photonic modes were compared with TiO_2 nanoparticles formed by dewetting gold films.

This project has received funding from the Research Council of Lithuania (LMTLT), agreement No. S-MIP-23-93.

Abstract: This study aims to enhance the fluorescence of novel azulene-tetrazole derivatives using a platform based on plasmonic metasurfaces with the aim of developing new biosensors. We focus on two important azulene-tetrazole derivatives. We investigate the effect on fluorescence of gold, silver or aluminum nanostructures on silicon or glass substrates.

Azulenes are non-alternating aromatic compounds that possess unique properties due to the presence of an electron-rich five-membered ring and an electron-deficient seven-membered ring. They are well known for their distinctive color and fluorescence properties, which have been used to develop chemical sensors and dosimeters with distinct colorimetric and fluorescent responses [1]. Also, azulene-derivatives have applications in engineering, optoelectronics [2] and medicine, for anti-inflammatory, antibacterial, anti-diabetic and anti-retroviral therapy [3]. An interesting class of azulene derivatives are the tetrazole-substituted azulenes, which combines the properties of azulenes with those of tetrazoles [4]. The tetrazole class has applications in biochemistry and medicinal chemistry. They are used as biologically active compounds and drugs, and have potential for developing new biologically active substances [5]. Due to the relatively low quantum yield of azulene fluorophores [6], it is necessary to increase their emission efficiency in order to develop more efficient sensors. Therefore, it is crucial to investigate the potential for fluorescence enhancement (FLEN) in azulenes. One promising method for increasing fluorescence is to use a metasurface platform. Metasurfaces are arrays of nanostructures smaller than the wavelength, which can manipulate electromagnetic waves and allow precise control of the properties of light and other forms of electromagnetic radiation [7]. Metasurfaces have been used in advanced sensing and medical diagnostics, with the potential to overcome the technical drawbacks of traditional sensor technologies [8]. Here, we investigated the FLEN of new azulene-tetrazole (**Az-Ta**) derivatives using a low-cost metasurface-based platform consisting of randomly distributed metal aggregates. Our aim is to develop new and selective fluorescence biosensors based on metasurface structures.

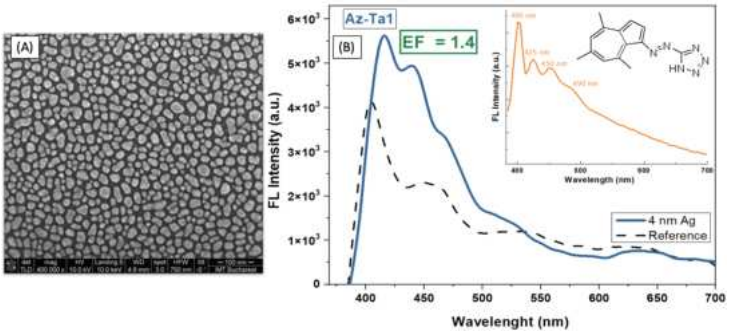

Figure 1. SEM micrograph of Ag metasurface and **Az-Ta1** fluorescence intensity in the presence of Ag metasurfaces compared to reference (bare silicon); inset shows the chemical structure of **Az-Ta1** and the fluorescence emission spectrum of **Az-Ta1** solution in ACN.

We analyzed the fluorescence emission of two azulene-tetrazole derivatives: (E)-5-((4,6,8-trimethylazulen-1-yl)diazenyl)-1H-tetrazole (**Az-Ta1**) and (E)-5-(azulen-1-yldiazenyl)-1H- tetrazole (**Az-Ta4**) dispersed in acetonitrile (ACN). For this study we used gold (Au), silver (Ag) and aluminium (Al) nanostructures patterned on a silicon or glass substrate. The metallic nanoaggregates were fabricated by electron beam evaporation of discontinuous layers 4 nm thick (mass equivalent) (Fig. 1A and Fig. 2A) and Az-Ta has been coated on top of the metasurface.

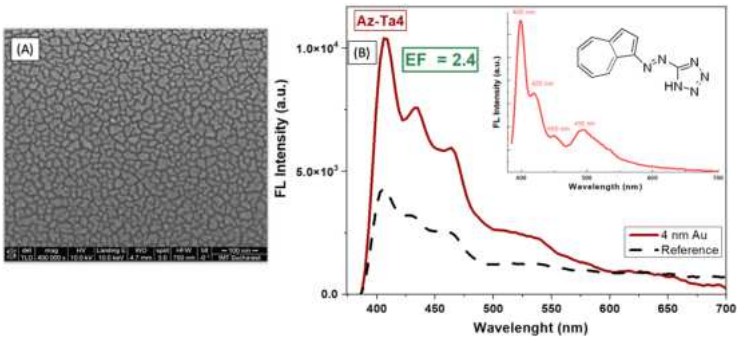

Figure 2. SEM micrograph of Au and **Az-Ta4** fluorescence intensity in the presence of Au metasurfaces compared to reference (bare silicon); the inset shows the chemical structure of **Az-Ta4** and the fluorescence emission spectrum of **Az-Ta4** solution in ACN.

As the studies are still in their beginning stages, in this summary we present the best preliminary results obtained. We observed that the random metasurfaces provide a significant enhancement of the fluorescence of the azulene-tetrazole derivatives. The best result for of FLEN **Az-Ta1** was obtained on Ag/silicon metasurfaces with an enhancement factor (EF) of 1.4, as shown in Fig. 1. **Az-Ta4** exhibited the highest fluorescence enhancement on Au/silicon metasurfaces, with an enhancement factor of 2.4, as can be seen in Fig. 2.

Abstract

We present the acoustic manipulation of 2D structures of metallic nanoparticles and their use for localized surface plasmon resonance (LSPR) sensing, creating a unique LSPR scanning system. The movable nanoparticle monolayers were patterned using standing surface acoustic wave (SSAW) tweezers. We validated their functionality for refractive index sensing.

1. Introduction

Optically active nanoparticles (NPs) have been used extensively to generate plasmonic-enhanced optical components (e.g. in LSPR or Raman applications) [1], although in such cases the particles most often remain static, requiring the sensed moieties and material structures to be built up on or bound to the particles themselves, so limiting the applicability of the techniques on native, unmodified structures (such as those in imaging applications). The ability to manipulate and pattern these particles in real-time, and in an arbitrary fashion, may open up research avenues for new sensors and devices. Surface acoustic waves (SAW) may be an answer to this problem. SAW devices have previously been used for contactless microparticle manipulation and alignment [2] in applications for patterning, separation, and mixing of particles and biomaterials. Z. Mao *et al.* reported the focusing and enrichment of nanometer scale particles by using travelling SAW [3] whilst H. Sazan et al [4] were able to form microstructures of silver NPs using standing SAW. R. Habibi et al [5] demonstrated NP collection using a microparticle bed in a microfluidic chamber, utilizing acoustic resonances and scattering forces to attract NPs in a specific location. Here we use SAW to manipulate 2D plasmonic AuNP monolayers in a contactless manner and demonstrate their use for label-free localized LSPR sensing.

2. Monolayer preparation

AuNPs were washed in DI water by centrifugation at 16,000 and 7,500 rpm for 25 and 10 minutes for 15 and 30 nm, respectively. Following previous reports [6], 1 ml of Hexane was then added to create an oil-water interface. 2 ml of Ethanol was subsequently added, which acts to form a monolayer of NPs at the oil-water interface. The Hexane was completely evaporated over 10 hours, resulting leaving the monolayer of NPs at the air-water interface (Figure 1).

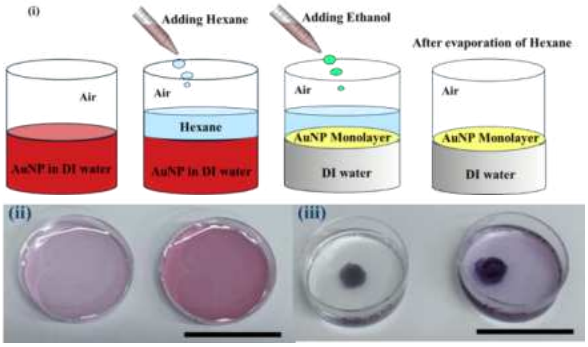

Figure 1: (i) Steps to form a monolayer of AuNPs, illustrated in pictures (ii-iii) of 30 (left) and 15 nm (right), before (ii) and after (iii) adding hexane and ethanol. Monolayer size is ~1cm., (scale bar: 3 cm)

2.1. Characterization

Glass cover slips (18x18 mm) were coated with 10 nm of Ti-Au (using a plasma coater) before being observed in scanning electron microscopy (SEM). Figure 2 shows closed packing of a 2-dimensional monolayer of gold nanoparticles. Two different approaches were explored to transfer the monolayer for characterization with SEM: top lift up and glass capillary method [7]. The results confirm the monolayer remains intact after transfer.

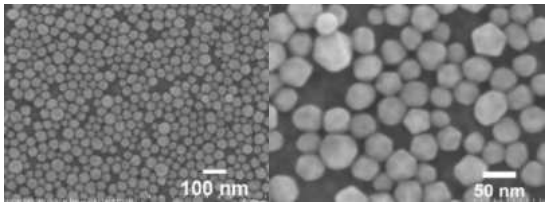

Figure 2: SEM images of AuNP monolayers at two magnifications.

3. SAW manipulation of AuNP monolayer

A pair of interdigitated transducers (IDTs) was used to generate SSAW, comprising 30 pairs of electrode "fingers" of 130 µm, leading to a resonant frequency at 30 MHz, with a 1 mm aperture. IDTs were fabricated as described previously [8] on 128^0 Y-cut 4-inch lithium niobate ($LiNbO_3$) wafer using photolithography. PDMS chambers were prepared by mixing monomers with curing agents in 10:1 ratio and polymerized at 70ºC for 2 h. The 1 mm square PDMS chamber was plasma bonded over the SAW device.

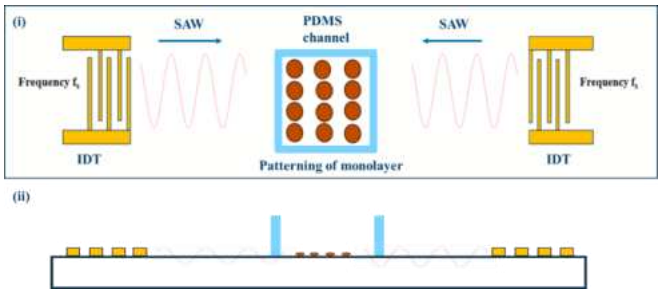

Figure 3: Schematic diagram to ilustrate the SSAW manipulation of 2D monolayers in a PDMS chamber (i) top and (ii) side view. Surface deformation are in the order of nm.

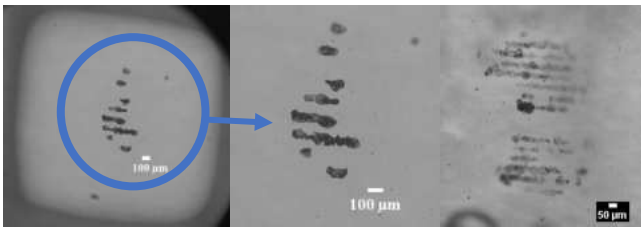

Figure 4: SAW manipulation of AuNP monolayer in a PDMS chamber: (i) and (ii) 15 nm AuNPs, and (iii) 30 nm AuNP. The monolayer fragments align on the SAW nodes due to the radiation force [8], spaced by 65µm, half wavelength of the acoustic waves. By changing the phase or frequency, the monolayers can be moved along the surface to scan it.

One pair of IDTs was connected to an RF signal generator to generate standing-SAW (S-SAW) at a resonant frequency of 30 MHz with an applied power of -20 dBm. The AuNP monolayers from the air-liquid interface was transferred by into a PDMS chamber. Initially, when the SAW was OFF, the monolayers were freely floating in DI water. Upon actuating the S-SAW, NPs moved towards the pressure nodes forming structured lines (due to the gold particles acoustic properties, leading to a positive acoustic contrast factor) – Figure 4. The spacings between lines are 65 µm which is equivalent to half of the propagating wavelength.

3.1 LSPR sensing with gold monolayer

The plasmonic effect of arrays of metallic nanoparticles is sensitive to the surrounding medium optical properties. If the interparticle distance is reduced, then a red shift with broadening in the spectra is visible. The monolayer represents a perfect example for aggregated NPs which leads to broadening of the spectra and red shift at the same time [9, 10]. We used different refractive indices in the solution to illustrate the functionality of the monolayers as LSPR sensors. Figure 4 shows that with increasing refractive index (RI, created with 1%, 2%, 3% and 4% concentration of NaCl), a red shift in the spectra is observed. Results show that the absorbance peak was red shifted as the RIs increased (figure 5). All experiments were performed in triplicate. Smoothing of data and normalization was performed to reduce noise.

4. Conclusions

We successfully demonstrated the manipulation of 2D AuNPs monolayers using SSAW, and used them for RI sensing using LSPR. Future work will focus in implementing a robust scanning control and explore RI sensitivity for different SSAW actuation.

Optical response of Smooth and rough Mono and bilayers of plasmonic materials

J. A. Polito-Lucas[1] and Ana L. González[1*]

[1]Institute of Physics, Benemérita Universidad Autónoma de Puebla, México

[*]corresponding author: ana.gonzalezron@.correo.buap.mx

Abstract: Rough thin films were modeled using DDA and patterns composed by hemispheres and hemi ellipsoids. The reflected, transmitted and absorbed light of these rough films are compared with that of a real roughness pattern obtained by AFM. Smooth and rough mono- and bilayers of plasmonic materials and nitrides are presented.

Summary

Au and Ag are superb nanoscale plasmonic materials due to their surface plasmon properties in the visible region. However, they have a disadvantage, their optical efficiency spectra are strongly reduced and broadened in intensity due to the dispersion phenomenon caused by electron confinement, this has been observed in thin films with thickness less than 12 nm [1], above this thickness the bulk response is recovered. On the other hand, plasmonic thin films of Nb have shown that size quantum effects are relevant for films with thickness less than 20 nm. The latter may favor Nb over Ag and Au for both plasmonic and photonic applications [2,3].

In this work we have investigated the effect of thickness and roughness on the optical response of thin films. Thin film surfaces with uniform roughness were modeled using the Discrete Dipole Approximation (DDA). The theoretical basis of the DDA are explained in detail in [4]. Briefly, a unit cell of N dipoles (TUC) is periodically repeated along the *yz* plane to create an infinite film, see Figure 1. The polarizability of each dipole is calculated using the Lattice Dispersion Relation [5], which requires the dielectric function of the material, the polarization state of the incident wave plane and the dipole-dipole separation distance, d. DDA calculates the scattered electric field, the Mueller matrix and the reflection and transmission coefficients of the films mimicked by the array of dipoles.

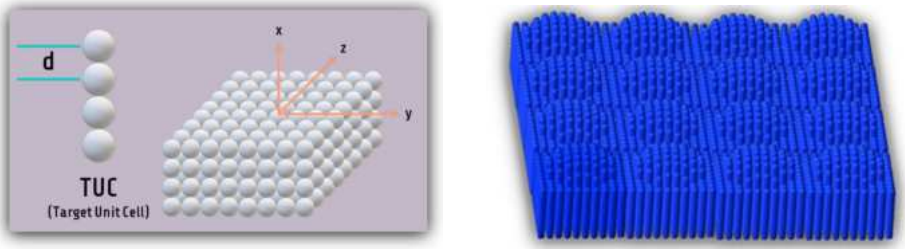

Figure 1. *Left.* Scheme of a column of N dipoles (each one represented by a small sphere) which is repeated along the *yz* plane to mimick a thin film with a smooth surface. d is the separation distance between adjacent dipoles. *Right*. TUC of dipoles repeated periodically to represent a film with a rough surface of hemispherical patterns.

The optical response of films with rough patterns composed by hemispheres (SS) and hemiellipsoids (SE) is compared with that of a real roughness pattern obtained from AFM topography images. In Figure 2 the reflected light of an Ag thin film with a thickness of 50 nm is shown. There, the roughness (h) has been varied from 0 to 25

nm. In the calculations, h is the length of the axis of the hemisphere or hemi-ellipsoid perpendicular to the film surface. The right panel of Figure 2 shows the calculated reflectance of an Ag film with a rough surface that replicates the topography observed in a niobium thin film deposited by magnetron sputtering. For this film, the reflectance was calculated using three TUCs whose size is represented by Zone A, Zone B and Zone C. As we can see, the reflectance is very similar due to the uniform roughness along the sample.

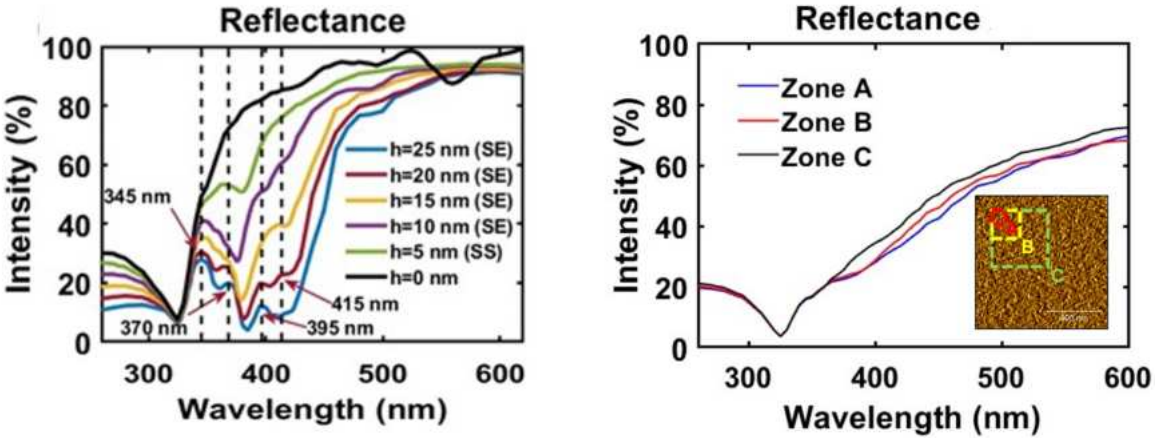

Figure 2. Light reflection of an Ag film with different roughness. *Left.* The roughness was obtained from hemispherical and hemi-ellipsoidal patterns. *Right*. The roughness was created from a real pattern observed from an AFM image of a thin film of niobium.

Reflected, transmitted and absorbed light of smooth and rough mono- and bilayers of Ag, Au, Nb, Ti and other materials were calculated.

Abstract: We report high Q surface lattice resonances using plasmonic transition metal nitride nanoparticle arrays, which possess a high-quality factor (Q-factor) that is sensitive to the surrounding environment of the nanoparticle structure. We intend to utilize this plasmonic nanostructures for future design of high temperature enable optical sensing systems.

Surface lattice resonances (SLRs) as an alternative optical cavity are widely investigated owing to their high Q-factor, which is indicative of strong light confinement [1]. SLRs also exhibit pronounced field enhancement, supporting strong light-matter interactions [1]. Notably, most of the SLR's designs are based on noble metals such as gold or silver [1,2,3]. However, those noble metals are unstable at high temperatures, which gave rise to the idea of designing an SLR cavity that can be tailored to high-temperature surroundings. Here, we demonstrate high Q SLR using plasmonic transition metal nitrides, renowned for their high melting temperatures as refractory plasmonic materials [4]. Employing Finite-Difference Time-Domain (FDTD) simulations, we design SLRs using titanium nitride (TiN) and hafnium nitride (HfN), and ascertain their SLRs modes within the infrared spectrum. By combining the inherent advantages of SLRs, particularly their sensitivity to the refractive index of the environment and the refractory properties of transition metal nitrides, we could pave the way to high-temperature functional sensing devices that operate in the infrared.

Figure 1(a) depicts the scheme of the system we designed, which is composed of TiN (HfN) nanoparticle arrays with a periodicity of 1045 nm (1070 nm), a diameter of 230 nm (220 nm), and a height of 250 nm (230 nm) on SiO_2 substrate. Figures 1(b) and 1(c) show the calculated transmission spectra *via* FDTD simulations. The result reveals the SLR mode of TiN (HfN) occurs at 1470 nm (1568 nm), with a Q-factor of 81 (148). The results indicate that SLR modes exhibit sharp dips within the infrared range. In addition, Figures 2(a) and 2(b) demonstrate how we can tune the SLR mode by varying the refractive index of the surrounding medium. This wavelength-tunable property inspires the design of sensors tailored for the infrared range. Due to the refractory properties of transition metal nitrides [4], We intend to utilize this plasmonic nanostructure for the future design of high-temperature optical sensing systems.

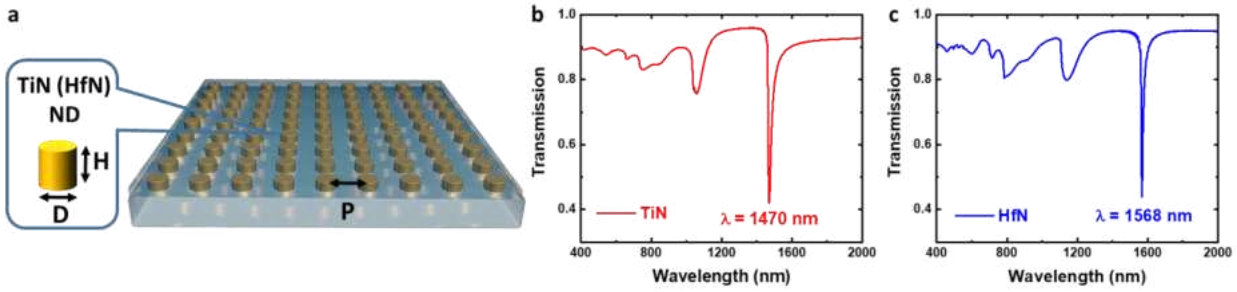

Figure 1. TMN-based SLR nanostructure and their optical properties. (a) Schematics of TiN (HfN) nanoparticle arrays to form surface lattice resonances. (b) calculated transmission spectrum of SLR mode from TiN nanoparticle arrays. (c) calculated transmission spectrum of SLR mode from HfN nanoparticle arrays.

Abstract: We report a broadband gap-plasmon-enhanced superconducting single-photon-detector using NbN superconducting microstrip integrated with silver nanocubes to form gap plasmon resonances from 440 nm to 640 nm. The nonlinear photoresponse is attributed to the gap-plasmon-induced heating that breaks the superconducting state to normal, an impressive detection efficiency of 98% was achieved.

Superconducting single photon detectors (SSPDs) [1,2,3] have many advantages, such as low dark noise, low time jitter, and a wide detection range. However, achieving high detection efficiency with traditional SSPDs for visible light detection is not easy. To overcome this difficulty, we designed a superconducting NbN microstrip photon detector integrated with plasmonic nanostructures to enhance detection efficiency. Here, we demonstrate a superconducting single-photon detector by coupling an NbN-based superconducting microstrip with different sizes of silver nanocubes plasmonic resonators. To achieve high detection efficiency, we designed different Ag nanocube arrays and excited the gap plasmon resonances at wavelengths of 640 nm (red), 510 nm (green), and 440 nm (blue), using the Finite-difference time-domain (FDTD) method to simulate gap plasmon resonances at these wavelengths. In our previous results, the gap-plasmon-enhanced SMSPD enhanced detection efficiency from 62% to 98% at 532 nm [4]. We will discuss the working mechanisms and potential applications of broadband gap-plasmon-enhanced SSPD in the entire visible region.

Fig. 1 displays the properties of the NbN film. Fig. 1(a) presents the NbN film sample. The ellipsometry results plotted in Fig. 1(b) reveal that the wavelength region above the epsilon near zero (ENZ) covers the visible range. Therefore, we can use the plasmonic property of NbN in the visible range to design a metal/insulator/metal structure as gap-plasmon. Fig. 1(c) depicts an AFM image indicating that our NbN films have an atomically smooth surface with a root-mean-square (RMS) roughness of approximately 0.3 nm. Fig.1(d) illustrates that the metal-superconductor transition temperature (Tc) of NbN films is about 12 K, which was measured by superconducting quantum interference devices (SQUIDs). Fig. 2 showcases that the designed plasmonic nanostructure on an NbN superconducting microwire (4 μm). Fig. 3 presents Finite-Difference Time-Domain simulations of the electric field intensity at wavelengths of 510 nm and 640 nm.

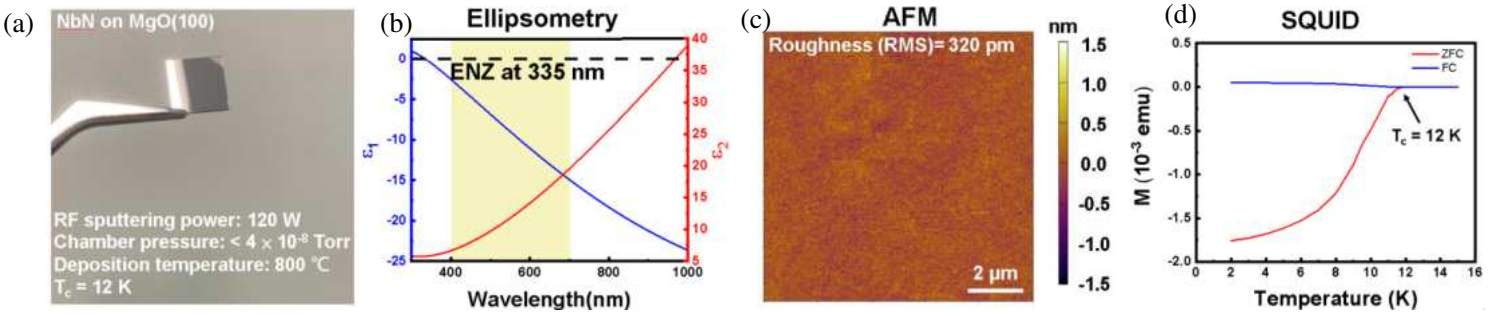

Figure 1. Characterization of NbN film. The measurement of (a)Sample of NbN film, (b)Ellipsometry, (c)AFM, (d)SQUIDs.

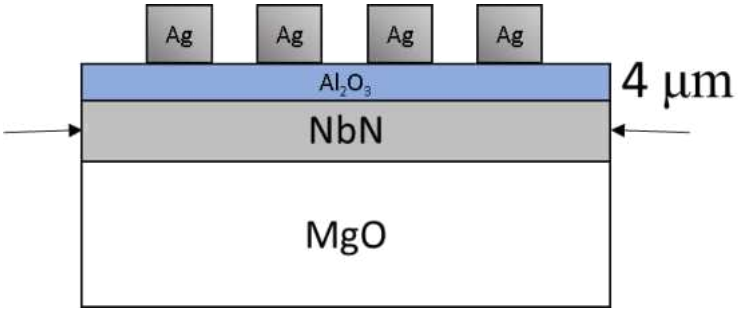

Figure 2. Schematic of the gap-plasmon-enhenced SMPD, featuring Ag nanocubes on NbN microstrip photodetectors capped with 5-nm Al_2O_3. Highly-Sensitive Broadband SMPD can be achieved by tailoring the size of silver nanocubes.

Abstract: Phase-change materials (PCMs) provide a specific combination of properties. The binary semiconducting chalcogenide Sb_2S_3 is consider one of the promising candidates, especially its intrinsic high refractive index, low loss and wide bandgap properties, in near infrared (NIR). Here, the Sb_2S_3 transformation from amorphous to crystal state embedded between the distribute Bragg reflector (DBR) and metal layer. At the interface between DBR and metal layer in specific parameter, Phase-change Tamm plasmon–polariton (PC-TPP) resonance could be produce. The PC-TPP resonance has a 70 nm modulation wavelength. Also, the resonance achieves around 100 nm-shifted in NIR at the proper incident angle.

Key Words-- *Sb_2S_3, distribute Bragg reflector (DBR), Phase-change materials (PCMs), Tamm Plasmon Polaritons metasurface (TPP), High Refractive Index (HRI)*

1. Introduction

Phase-change materials (PCMs) has been widely applied in switchable electronic and photonics [1-5]. The crystal phase of vanadium dioxide (VO_2) was changed from monoclinic state near 340 K. Also, the working system of germanium-antimony-tellurium (GST) was above 380 K at communication wavelength. However, these two PCMs have a high extinction coefficient around 0.5 and 2.0 in visible, respectively [6]. Here, the binary semiconducting chalcogenide Sb_2S_3 has bandgap 1.8 to 2.1 eV to move the absorption band-edge in visible. Meanwhile, the high refractive index of Sb_2S_3 could be tuned from 3 to 4 at around 650 nm. And, its extinction coefficient was below 0.5 after 600 nm in both states.

One of the plasmon resonance was theoretically demonstrated at the surface photonic crystal and metals, called Tamm state. Between distributed Bragg reflector and metal layer, it has the strong confinement at the interface, known as Tamm plasmon polariton (TPP) [7, 8].

In this research, Sb_2S_3 was used as function layer in the TPP structure. After annealing process, the modulable wavelength was demonstrate around 70 nm. The analysis of angle-dependence resonance also was proved close to 100 nm in proper incidence light. In the future, the optical signal would be encoded to electrical signal, called photocurrent. It was shown that our design would be added in LiDAR [9], sensor [10].

2. Results and discussion

The finite-difference time-domain (FDTD) method has been used to calculate the Phase change Tamm plasmon–polariton (PC-TPP) resonance with normal light incidence in NIR. In this modeling setup, the DBR unit cell consist of two layers 145 nm silica and 95 nm TiO_2 with several pairs, as shown in Figure 1 (a). With the specific Sb_2S_3 and gold thickness, the PC-TPP resonance could be achieved 70 nm modulation after Sb_2S_3 annealing from amorphous to crystal state, as shown in Figure 1 (b). The optical constants of Sb_2S_3 were taken in the visible spectra range from, as shown in Figure 1 (c). It was shown phase change material Sb_2S_3 has the HRI and low extinction coefficient property, compared to commercial material, silicon, in NIR.

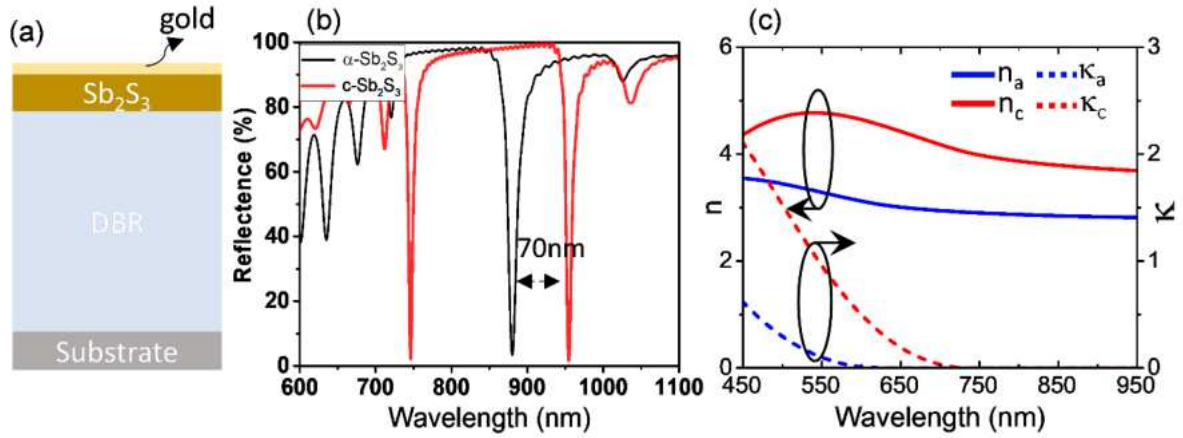

Figure 1 (a) The structure of Sb_2S_3 TPP device. (b) The TPP resonance shifted from 870 nm to 960 after transformation state. (c) The real optical constant of the α–and c- Sb_2S_3 after annealing.

Further, the simulated PC-TPP reflectance spectrums were calculated with different Sb_2S_3 thickness in NIR, depicted in Figure 2. In Figure 2 (a, b), the dashed line was illustrated that design was with 30 nm gold and 130 nm Sb_2S_3 and applied at 870 nm. After annealing process, the resonance was tuned to 960 nm. This design could be easily used in NIR spectrum from 750 nm to 950.

In addition, the angle-dependent TPP resonance was theoretically investigated in Figure 2 (c, d). In amorphous state, the TPP resonance was tuned from 960 nm decreases to 780 nm at the normal and tilt 60 degrees incident light, respectively.

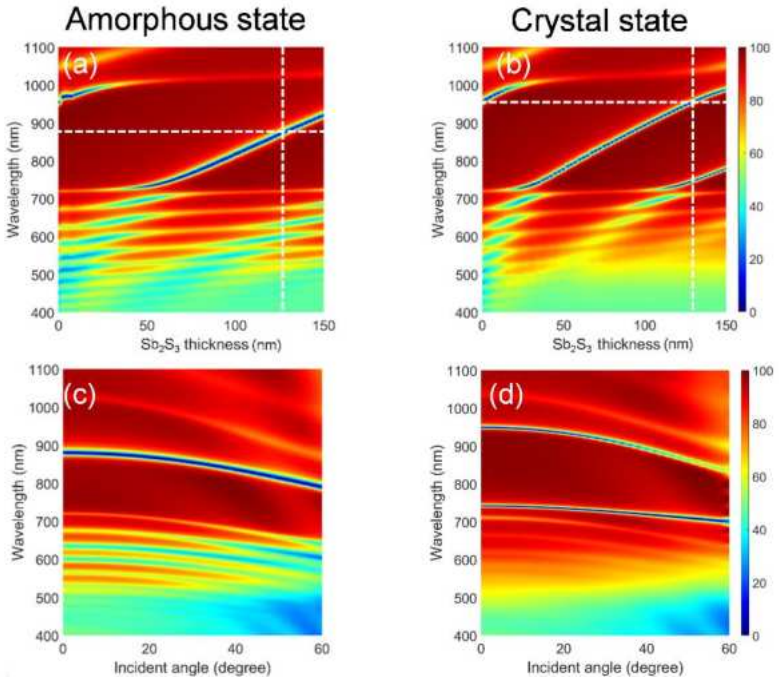

Figure 2 Reflectance spectrum of simulated parameter tuning of PS-TPP of Sb_2S_3 thickness(a) α–and (b) c- state. 130 nm Sb_2S_3 at the proper incident angle in PC-TPP structure (c) α–and (d) c- state.

3. Conclusions

In summary, the PC-TPP resonance has a 70 nm modulation wavelength. The angle-dependent resonance was demonstrated around 100 nm-shifted in NIR spectrum.

Abstract: Two-dimensional gold with a single-crystal structure is highly desired for upcoming technologies. In this work, we demonstrate the fabrication of large-area (>10^4 μm^2), two-dimensional single-crystal gold using a chemical etching approach with an atomic-level precision, and its use for the realization of ultrathin plasmonic structures with low loss.

Two-dimensional (2D) single-crystal gold (<5 nm) is an attractive material due to its capability of extreme optical confinement via the excitation of surface plasmons[1], which is of great interest for the study of light-matter interactions at nanoscale and the development of ultrathin nanophotonic devices including ultrafast optical modulators and high-sensitivity optical sensors. However, unlike materials with layered crystal structures, gold cannot be directly exfoliated into 2D layers from its bulk crystal. Wet-chemical approaches have been extensively utilized to fabricate low-dimensional metals, but the synthesis of 2D gold (usually less than 1 μm in lateral size) with a large area remains extremely challenging due to the concurrent increase in the thickness and lateral size[2,3]. Here, we introduce an atomic-level-precision etching approach to fabricate 2D gold flakes (2DGFs) with large size (100s of μm) and thickness down to 2 nm, and demonstrated the fabrication of ultrathin plasmonic structures with low-loss[4].

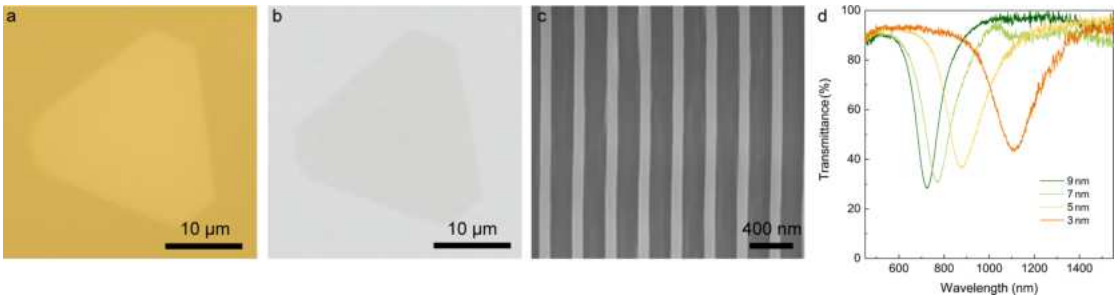

Fig. 1 a,b, Optical micrographs of a 2DGF with a thickness of 2.5 nm, taken in reflection (a) and transmission (b). **c**, Scanning electron microscopy image of a nanoribbon array fabricated with a 2DGF with a thickness of 3 nm. **d,** Transmission spectra of nanoribbon arrays fabricated with 2DGFs for various nanoribbon thicknesses (w = 100 nm).

2DGFs were fabricated by chemical etching of chemically-synthesized large-area single-crystal gold flakes[5] with a large thickness (~20 nm). During the etching, the thickness of the gold flakes can be controlled with an atomic-level precision while keeping the lateral dimensions essentially unchanged. Figure 1a and 1b show optical micrographs of an as-fabricated 2DGF with a thickness of 2.1 nm, which is almost transparent due to its thin thickness (Fig. 1b). By using electron-beam lithography and reactive ion etching, 2DGFs can be patterned into ultrathin nanoribbon arrays, as shown in Fig. 1c. A strong resonance dip (Fig. 1d, orange line) can be observed in its transmittance due to the excitation of a dipolar localized surface plasmon mode, which is difficult to be realized with sputtered gold. The resonance dip is blue shifted dramatically from 1115 to 724 nm with the increase of the nanoribbon thickness from 3 to 9 nm.

In conclusion, we have demonstrated the fabrication of 2D single-crystal gold and its use for low-loss nanoplasmonics. The results hold great potential of nanoscale light-matter interactions for fundamental studies, and also provide an attractive platform for the development of ultrathin optoelectronic, plasmonic and quantum devices.

email: cytai@dop.ncu.edu.tw

Abstract: High density molecular traps are realized by metastructures with intertwined Fibonacci spirals. Depending on the chirality of incident light, traps are switchable following either clockwise or counterclockwise spirals. The associated trapping potential is larger than $10k_BT$ with incident intensity I=15 mW/μm^2 showing capability to stably trap molecules at room temperatures.

Mother nature has been teaching us in a variety of aspects. For instance, phyllotaxis adapted in some plants makes the most efficient capture of light. Inspired by this, in this work, a sunflower seed like pattern [1] is adopted which enables the construction of dense molecular traps on a chip. Essentially, Vogel's model is utilized to construct clockwise (CW) and counterclockwise (CCW) intertwined spirals [2], forming spatially separated molecular traps switchable by right/left circularly polarized (R/L CP) incident light. In order to produce resonance in the visible wavelength range, here we use Au nanorod (NR) as the building block with the geometric parameters as follows: height h=10 nm and diameter D=40 nm sitting atop SiO_2 substrate. The center-of-mass of each NR is specified by the polar coordinates (r_n, ϕ_n) where $r_n=kn^{1/2}$ and $\phi_n=n\phi$. The scaling factor k characterizes the distance between neighbouring NRs, and n stands for the sequence number of a NR, counting from the central NR (n=1). Setting the divergence angle $\phi=137.508°$ (the golden angle) with k=32, and a total number of NRs to n=141, the metastructure with two intertwined spirals with opposite chirality is mathematically generated, which gives the highest packing efficiency. Essentially, CW/CCW spirals consist of collections of the nearest/next nearest NRs, corresponding to NRs with sequence number coincident to the Fibonacci sequences with Δn=13/21.

The scattering spectrum is modelled by a finite difference time domain simulator, Lumerical. The material parameters are extracted from literatures [3-4]. Perfect matched layers (PML) are deployed outside as boundaries and a spatial grid size of 1 nm is used so as to obtain results with high accuracy. Fig. 1(a) indicates that the primary resonant wavelength is located at λ=675 nm, regardless of the incident polarizations. Slightly detune the wavelength to the shoulder peak, i.e., λ=700 nm, enables one to observe mode splitting. As shown in Fig. 1(b-c), the hot spots of the electric field distribute predominantly in the gaps between NRs of the CCW/CW spirals subject to L/R CP polarized light incidence, respectively.

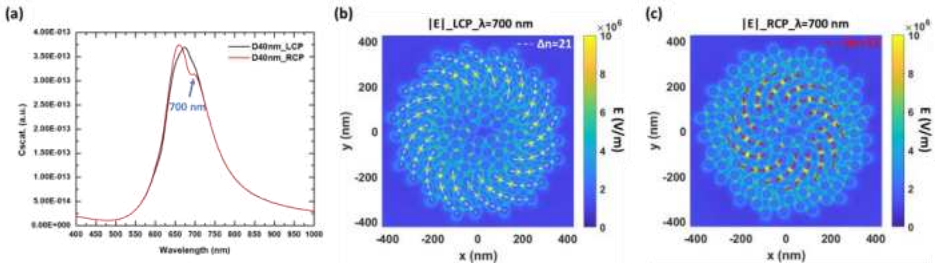

Fig. 1. (a) Scattering spectrum of the designed metastructure. (b/c) Near field electric field distributions excited by L/R CP light at λ=700 nm, respectively. The simulation is conducted at an incident intensity of I=1 mW/μm^2.

Next, to assess the trapping capability, the optical chirality and the associated trapping potentials are calculated, according to equations (1-2). We consider a hybrid configuration, i.e., a 10 nm Ag nanosphere decorated with a molecule

with R/L handedness, designated as Ag-R/L enantiomer here. The resultant electric-/magnetic-/chiral- polarizabilities (α/β/χ) are calculated following [5] with chiral parameters κ=±1. Fig. 2(a-d), depict the calculated optical chirality C, their mutual difference ΔC, and the relative trapping potentials (at z=15 nm above the structure) under L/R CP incidence at λ=700 nm with I=15 mW/μm^2. It is clear in evidence that switchable molecular traps are successfully created for Ag-R/L enantiomers along CW/CCW Fibonacci spirals. Besides, as the trapping potentials are higher than 10 k_BT (k_B: Boltzmann constant) and the averaged separation between opposite traps is only 12 nm, high-density stable-trapping of molecules can be achieved.

$$C = \frac{\omega}{2c^2}\,\mathrm{Im}[\dot{E}\cdot\dot{H}^*] \tag{1}$$

$$U_{xy} = -\frac{\mathrm{Re}[\alpha]|E|^2}{4} - \frac{\mathrm{Re}[\beta]|H|^2}{4} - \frac{\mathrm{Re}[\chi]\,\mathrm{Im}[\dot{E}\cdot\dot{H}^*]}{2} \tag{2}$$

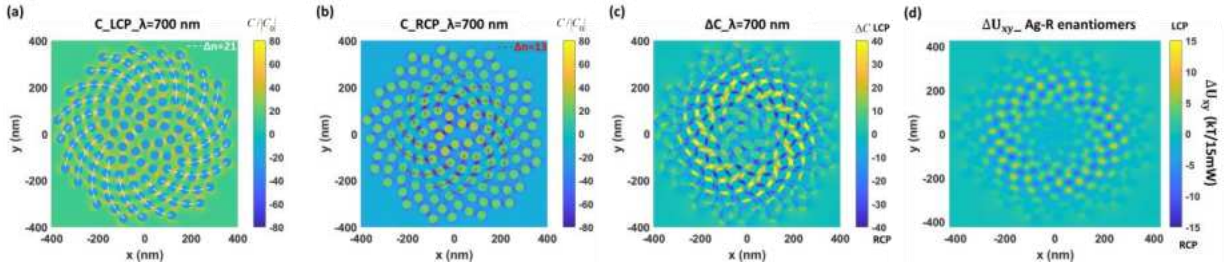

Fig. 2. Optical chirality distributions under (a) LCP, (b) RCP illuminations. (c) Differential optical chirality and (d) trapping potentials.

Regarding to signal readout, the scattered intensities evolved at successive monitoring distances are calculated. Fig. 3 (a) and (b) illustrate this, where the difference between LCP/RCP at z=50 nm is already distinguishable, as marked by the arrows. Fig. 3 (c-d) depict the differential intensities, respectively at z=20 nm, 50 nm, which once again verifies this observation. Further increase the monitoring distance only results in a minimal change of distribution with weakened intensity. This property makes the designed metastructure an efficient platform for molecular trapping and chirality discrimination with fast-readout capability.

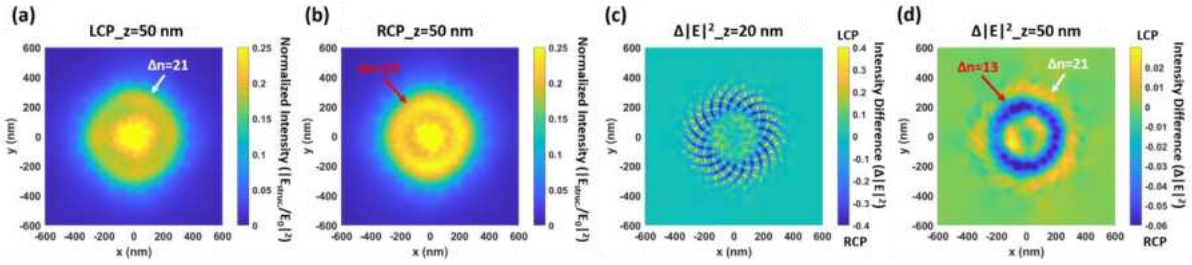

Fig. 3. Scattering patterns of (a) LCP and (b) RCP incidence at z=50nm. (c-d) Differential scattering patterns at z=20, 50 nm, respectively.

Abstract: We report the comprehensive analysis of metal-dielectric gratings with broad opto-geometric parameter range, for the angular interrogation of surface plasmonic excitation. The multi-parameter optimization of sinusoidal and rectangular grating structures yields the design coordinates for sharp resonance features in the angular reflection response of surface plasmons.

Surface plasmons (SP) are collective oscillations of the free electron plasma propagating along the metal-dielectric interface [1]. Grating coupling provides a planar, robust and scalable configuration necessary for the on-chip excitation and control of surface plasmons [2]. The grating coupled surface plasmon resonance (GCSPR) is convenient to study the plasmonic responses in either transmission or reflection mode [3], as well as for zeroth or higher order diffractions [4]. GCSPR devices for sensing and switching have been demonstrated, leveraging on the angle or wavelength interrogation of SP using shallow grooves etched on thin metal films [5], and differential measurements at fixed, small incident angles [6]. In this work, we report the comprehensive parametric analysis of angle interrogation of SP excited at the interface of a metal-dielectric grating. SP responses at steep incident angles (θ_i) for large grating modulation depths (d $\geqslant$100 nm), and varying duty cycles for sinusoidal and rectangular gratings are studied. The results show that the angular spectral features of the SPs can be precisely tuned with the control of grating geometry and the excitation wavelength.

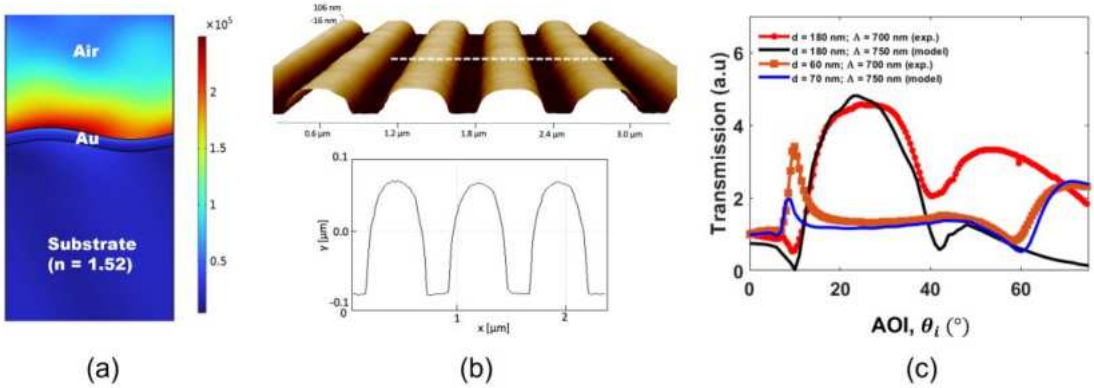

Figure 1: (a) Simulated electric field at θ_i = 11.5°, for a sinusoidal grating with Λ = 750 nm and d = 60 nm, (b) AFM image showing the 3D topography and depth profile of the optical disc-based gratings with Λ = 750 nm and d = 180 nm, and (c) Comparison of the numerical and experimental transmission response of the gratings.

To numerically evaluate the angular response, a Finite Element Method (FEM) solver in COMSOL® Multiphysics 6.0 is used. The model consists of a unit cell of a dielectric grating (n_g = 1.52) coated with continuous film (t = 50 nm) of gold, as plotted in Fig. 1(a). A periodic port placed on top of the unit cell is used to excite TM-polarized light at a fixed wavelength, $\lambda = 633$ nm. To validate this model, transmission measurements of gold-

coated gratings prepared using off-the-shelf commercial optical discs (Λ = 750 nm ; d = 180 nm) are carried out. The topography of these gratings, obtained using AFM, is shown in Fig. 1 (b). The numerical results are found to be in good agreement with the experimental transmission response of gratings, Fig. 1 (c).

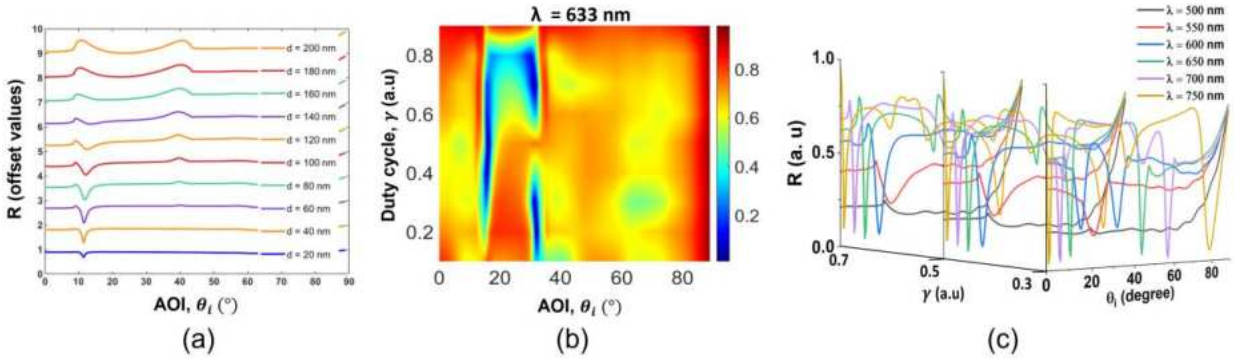

Figure 2: (a) Evolution of the SPR reflection dip with variation in grating depth, (b) 2D reflection map of the rectangular gratings for broad range of angles and duty cycle for a fixed excitation wavelength $\lambda = 633$ nm, and (c) Angular response of rectangular grating-based plasmonic excitation for wavelengths (legends) in the visible domain and for duty cycle varying from 0.3 to 0.7.

Fig. 2(a) shows that, for shallow sinusoidal gratings (d < 120 nm), the plasmonic excitation is manifested by a single narrow reflection dip. The SP response widens and includes multiple low reflection zones for deep gratings. For a fixed grating period, the FWHM of the dip is reduced from 20° to 0.75° by optimizing the grating depth from 180 nm to 60 nm. Further, the performances of metal-dielectric gratings with sinusoidal and rectangular modulation profiles are compared, for varying duty cycles (γ) and for differing excitation wavelengths in the visible and NIR regime, Fig 2 (c-d). Rectangular gratings provide extra artifacts in the angular response than their complementary sinusoidal geometries. It is evident from Fig. 2 (c) that even under weak modulation, rectangular gratings preserve the single SP reflection dip only for $0.4 \leqslant \gamma \leqslant 0.6$, but shows split reflection dips else. The dual dips are observed to be shifting contra-directionally with increase in excitation wavelength. The multi-parameter optimization of gratings in a broad geometric range yields the design coordinates wherein well-defined, narrow resonance are obtained in the angular response of SP, which is desirable for bio-sensing applications.

Modulable Chiral Plasmonic Activates via Stimulus Triggered Shape-Morphing

Yisheng He, Chunhong Ye*

School of Physical Science and Technology, Shanghai Tech University, Shanghai 201210, China

Abstract: A unique approach to fabricate chiral plasmonic materials based on helically arranged AuNSs was presented by utilizing polymeric micro-origami. The shape-morphing of the micro-origami from 2D sheets to 3D tubules induced the pre-assembled AuNS chains into 3D helices, which exhibited tunable circular dichroism signals over frequency, magnitude and handedness.

Chiral assembly of plasmonic nanoparitcles have attracted broad interest due to its unique circularly polarized light-dependent optical response, presenting great potentials for photonic and biomedical applications.[1,2] However, it still remains challenging to have a simple strategy to modulate chiroptical properties.[3] In this work, we demonstrate a facile approach to fabricate chiral plasmonic micro-structures composed of 3D helically assembled gold nanoparticles (AuNSs), which is facilitated by the shape-morphing of polymer-based micro-origami.

Gold nanospheres (AuNSs) with an average diameter of 75 ± 2 nm were utilized here. To create helical assemblies of the nanoparticles, AuNSs were aligned onto the responsive polymer-based micro-sheets through template-assisted colloidal assembly by employing unidirectional polydimethylsiloxane wrinkles as templates.[4] Closely packed AuNS linear chains with well-controlled positions and gaps were yielded on the substrate over centimeter area (Figure 1). The polymeric micro-sheets were prepared by photo-crosslinking using a 254 nm UV-light through a photomask with pre-designed rectangle-shaped openings. The chemical components of the micro-sheets are composed of temperature-responsive poly(N-isopropylacrylamide) (PNIPAM) as active layer and non-responsive poly(methyl methacrylate) (PMMA) as passive layer, respectively.

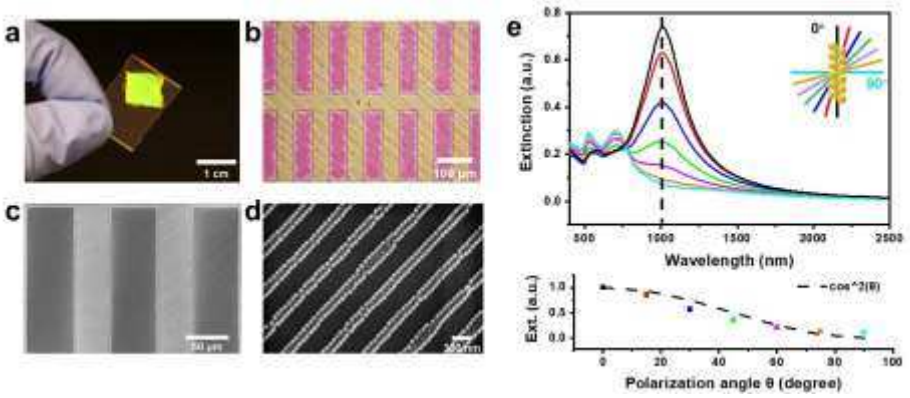

Figure 1. 2D linearly aligned gold nanospheres (AuNSs) structure and optical property. (a-d) Photography, and optical microscope, SEM micro-sheet arrays with homogeneous coverage of linearly AuNS chains. (e) Measured extinction spectra of the entire macroscopic samples within UV-vis-NIR range under varied polarization angles with respect to the axis of chains.

Upon exposure to aqueous solution with a temperature (used 0 °C) below the lower critical solution temperature (LCST, 28 °C) of PNIPAM, the 2D micro-sheets spontaneously rolled up to 3D hollow micro-tubulars. Accompanied with the shape-morphing of micro-sheets, the pre-assembled linearly AuNS chains transformed to

3D helical geometry along the internal wall of micro-tubulars (Figure 2a-c). The AuNS helices with geometrical asymmetry contributed to plasmon-based chiral material.

To quantitatively characterize the chiroptical property, 4x4 Müller matrix data were collected from spectroscopic ellipsometry in transmission mode to evaluate the circular dichroism (CD) and optical asymmetry factor (g-factor). A characteristic CD spectrum was detected with two distinct peaks and dips, as for the typical AuNS helices rolled from 30° aligned AuNSs chains with respect to the long axis of the rectangular micro-sheets (bottom of Figure 2d), whereas the AuNS chains in 2D array as control sample did not show any CD signal (top of Figure 2d). The observed different chiral response supported that chiroptical signal stemmed from the helical arrangements of the closely packed gold nanoparticles with nanometer-sized gaps. To identify the origin of the observed chiral response, the electromagnetic simulations were further carried out for double helical chains with a nanoparticle gap of 2 nm. The calculated CD spectra for left- and right-handed helical structures agreed qualitatively with the measured results with four distinctive features (Figure 2e, f).

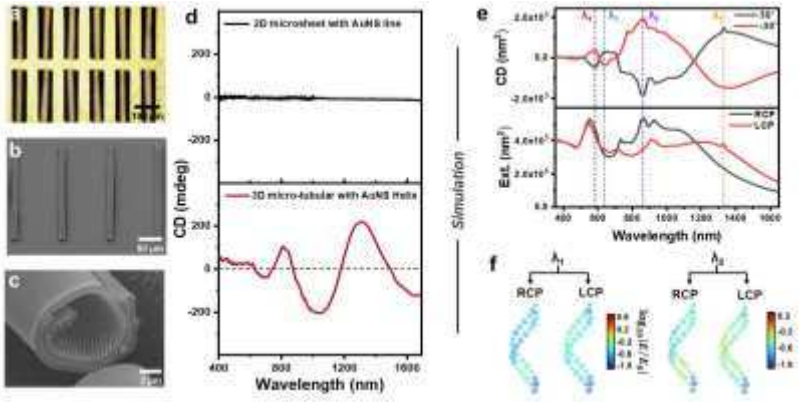

Figure 2. 3D helically aligned AuNSs and chiral optical properties. (a-c) Optical microscope and SEM imageS of the micro-tubes rolled-up from rectangular sheets covered with AuNS chains. (d) Measured CD response at different morphologies. (e) Simulated CD response and extinction cross-sections of left- and right-handed gold nanospheres chains. (f) Simulated electric field enhancement of the corresponding structures.

The micro-origami based approach for constructing 3D AuNS helix enables facile tuning and switch of the handedness. By controlling the assembly angle of AuNSs chains, the CD response frequency, magnitude and handedness can be readily tuned. CD spectra with mirrored symmetry were observed for two rolled-up AuNS helices with opposite handedness, formed by the AuNS chains with tilted angles of different signs, and all the CD spectra showed features with two distinctive dips and peaks, which was also confirmed by FDTD simulation.

Utilizing a microcone array to control the distance between a microsphere and a SERS substrate for photonic nanojet-mediated SERS

Chen-Ting Hung[1], Yan-Ru Liu[1], Yih-Fan Chen[1*]

[1]Institute of Biophotonics, National Yang Ming Chiao Tung University, Taipei 112, Taiwan, R.O.C.

Abstract: A photonic nanojet (PNJ) is a narrow and intense electromagnetic beam on the shadow side of a microsphere when illuminated by light. We fabricated a microcone array to control the distance between microspheres and surface-enhanced Raman spectroscopy (SERS) substrates, effectively utilizing the PNJ effect to enhance signals by 15 times.

The photonic nanojet (PNJ) is a subwavelength focusing phenomenon observed on the shadow side of a light-illuminated microsphere. Due to its ability to generate a sub-diffraction-limited focusing spot and an intense electric field, PNJs have found applications in enhancing surface-enhanced Raman spectroscopy (SERS) [1], increasing the intensity of fluorescent dyes, and providing super-resolution imaging. However, since the focusing spot of a PNJ is elongated and typically located a few microns away from the surface of the microsphere, to ensure effective excitation of the electromagnetic hot spots of a SERS substrate by a PNJ, we fabricated microcone arrays with different spacing and used the arrays to control the distance between microspheres and SERS substrates (Figure 1(a)). When the focus of a PNJ was on the surface of a SERS substrate, SERS signals could be significantly enhanced by the PNJ effect.

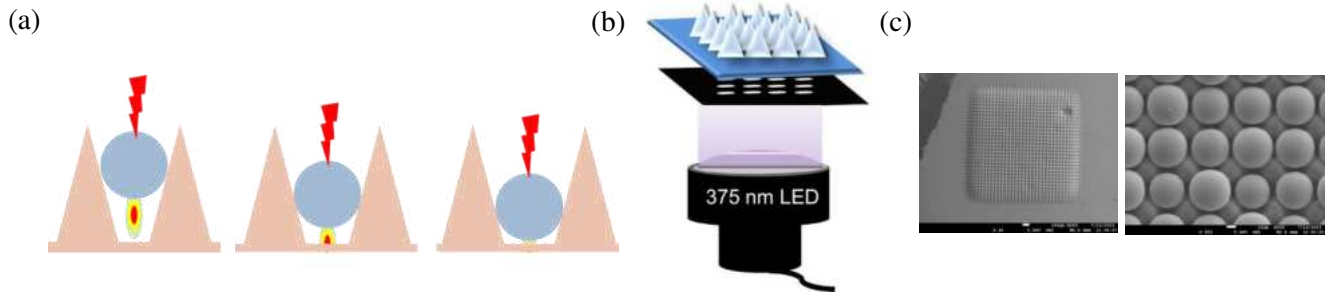

Figure 1. (a) Schematic representation of controlling the distance between microspheres and SERS substrates using microcone arrays with different spacing. (b) Schematic illustration of the fabrication of the microcone arrays. (c) SEM images showing 55 μm silica microspheres on the microcone array.

To fabricate microcone arrays, photopolymerization solution was prepared by mixing poly(ethylene glycol) diacrylate (PEGDA) and 2,2-Dimethoxy-2-phenylacetophenone (DMPA). We then used a 375 nm LED light source and a photomask with a circular hole array to cure the PEGDA solution on a glass slide [2] (Figure 1(b)). After the curing process, a microcone array was formed (Figure 1c). We utilized different photomasks with varying hole arrays to create microcone arrays with different spacing. Next, we modified the microcone arrays with (3-Aminopropyl)triethoxysilane (APTES) and 28 nm silver nanoparticles (AgNPs). Finally, we injected a

mixture of adenine and silica microspheres onto the microcone array, and SERS signals were measured using a Raman spectrometer with a 633 nm laser excitation.

We evaluated the PNJ effects of 55-μm silica microspheres on SERS by measuring 10 μM adenine using AgNP-decorated microcone substrates (Figure 2(a)). SERS spectra were obtained using microcone arrays with different spacings, as shown in Figure 2(b, c). Measurements were taken at locations where microspheres were present and absent, with each SERS spectrum in the figure representing the average of data from 5 locations. By comparing the intensities of the Raman peak at 733 cm^{-1} with and without the 55-μm microspheres, we calculated the additional Raman enhancements, as illustrated in Figure 2(d). Our results indicate a maximum enhancement of ~15 from the PNJ effect when using the 55-μm silica microsphere."

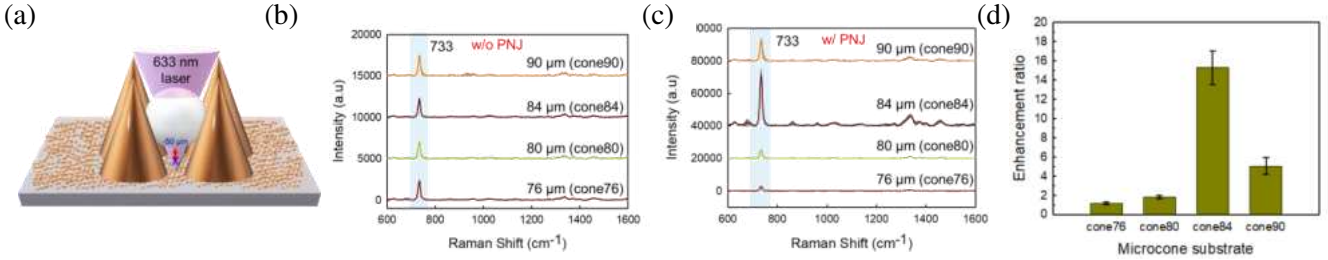

Figure 2. (a) Schematic representation of PNJ-enhanced SERS. (b, c) SERS spectra obtained using AgNP-decorated microcone arrays with different spacings. The circular hole arrays in the masks used for fabricating the microcone substrates had a diagonal distance between adjacent holes ranging from 76 to 90 μm. In the circular hole arrays of the masks used to fabricate the microcone substrates, the distance between adjacent holes diagonally was between 76 and 90 μm. Measurements were conducted (b) without and (c) with the 55 μm silica microspheres. (d) Additional Raman enhancements from the microsphere.

Abstract: In this work we investigated carrier dynamics in SHL-array on gold deposited on amorphous SiO_2. Each 140nmx220nm unit cell has a slit width of 260nm. The sample shows multiple resonance bands extending from visible to NIR region and long-lived excited carriers due to structuring induced changes in electron phonon interaction.

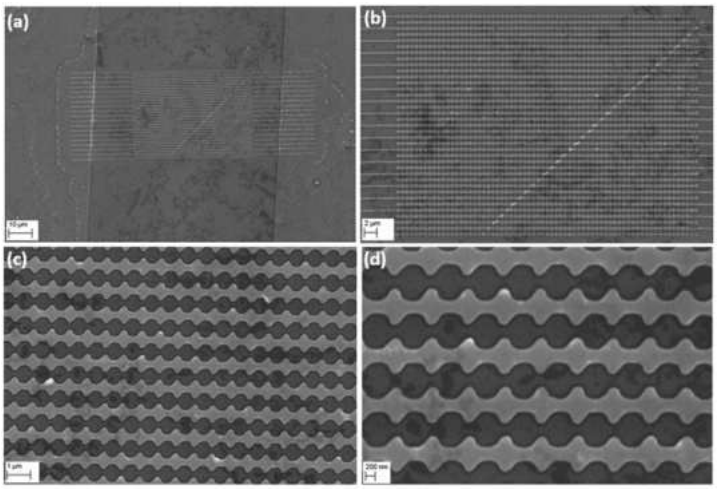

Figure 1: A SEM image of EBL fabricated structures on SiO_2 at varying magnifications.

Figure 1 shows SEM image of the SHL array at different magnifications. From figure 1(d) we can see that the edges of the H shape were over etched during fabrication which gives them a round shape. The sample was then characterized under transient absorption spectroscopy to measure the transient optical response. The sample was exited by a 410 nm pump and analysed with both visible and NIR probe. Figure 2 (a) shows a broad negative dip at 460 nm that decays in 5- 10 ps time (figure 2 (b)). This behavior is attributed to bleaching of SP resonance of 10 nm gold thin film[1]. At later delay times we see appearance of another behavior around 636 nm which stays for a longer time (100s of ps). This behavior is because of the resonant SHL. Positive ΔA signal due to excited state absorption (ESA) of carriers generated through interband transition and SPR dephasing[2]. The decay kinetics of these carriers indicate that they do not decay within the 5 ns measurement window. This suggests either a prolongation of decay induced by the structure itself or the transfer of hot carriers to the SiO_2 substrate.

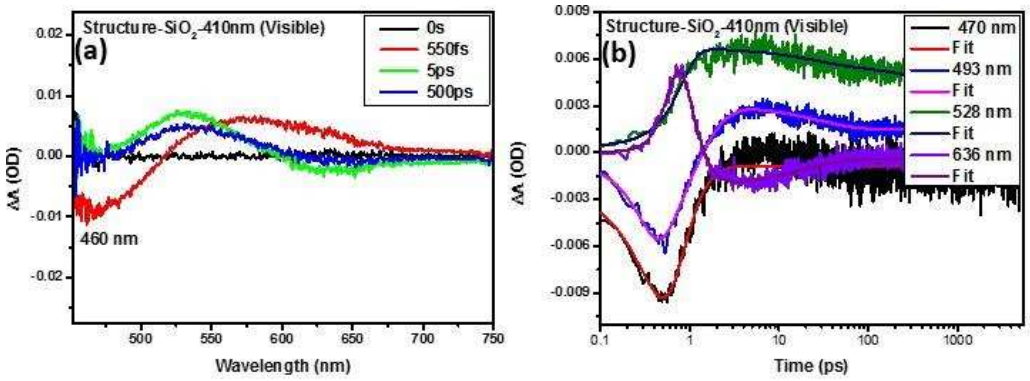

Figure 2: Transient absorption a) spectra b) kinetics of structures fabricated on SiO_2 excited by 410 nm pump and visible probe.

The transient behavior in NIR region (figure 3) show a broad negative signal extending 1150 nm to 1600 nm. The initial behavior at 750 fs is of an Au film over SiO_2. It red shifts to give a GSB at 1450 nm and ESA at 1200 nm. This behavior decays within 5 ps and a broad ESA covers the whole NIR spectra. The ESA in this wavelength region decays completely within 50 ps.

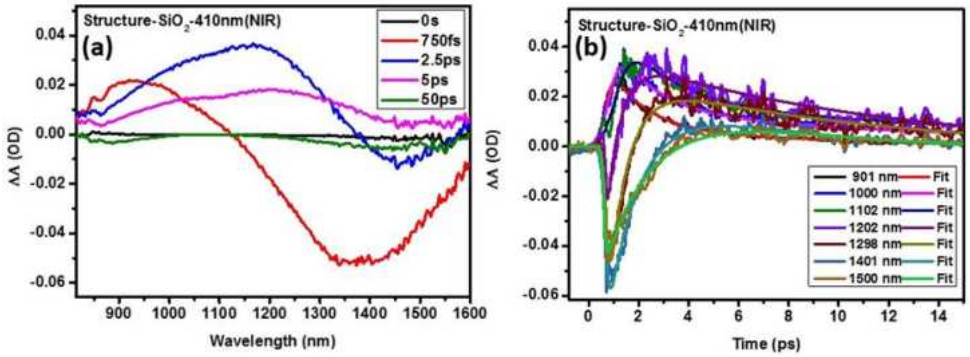

Figure 3: Transient absorption a) spectra b) kinetics of structures fabricated on SiO_2 excited by 410 nm pump and NIR probe.

The fabricated SHL structure has three resonance band centered at 460 nm, 636 nm and 1450 nm. The exited charge carrier in visible shows a prolonged decay time which is one of the crucial criteria in high efficiency solar cells and photocatalytic systems. The extended decay rate arises from unavoidable alterations in phonon interactions, induced by dimensional confinement impacting phonon modes within nanostructures [3].

The authors are thankful to the CSIR-National Physical Laboratory and TIFR, India for providing the measurement facility for this study.

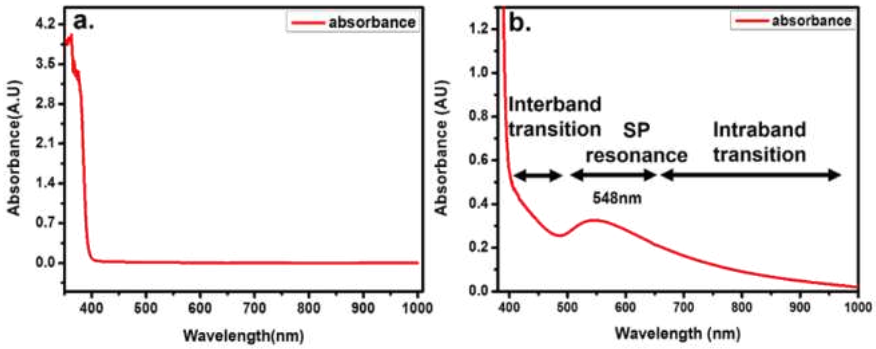
Abstract: This study demonstrates visible region nonlinear optical switching by coupling reverse saturable absorption(RSA) in STO with saturable absorption(SA) in a Gold film. SA in Gold comes from SPR bleaching, while RSA in STO from 2PA. Using a nanosecond pulsed laser(532nm), we achieved optical switching at irradiances from 2.12 to 3.0GW/cm².

Summary:



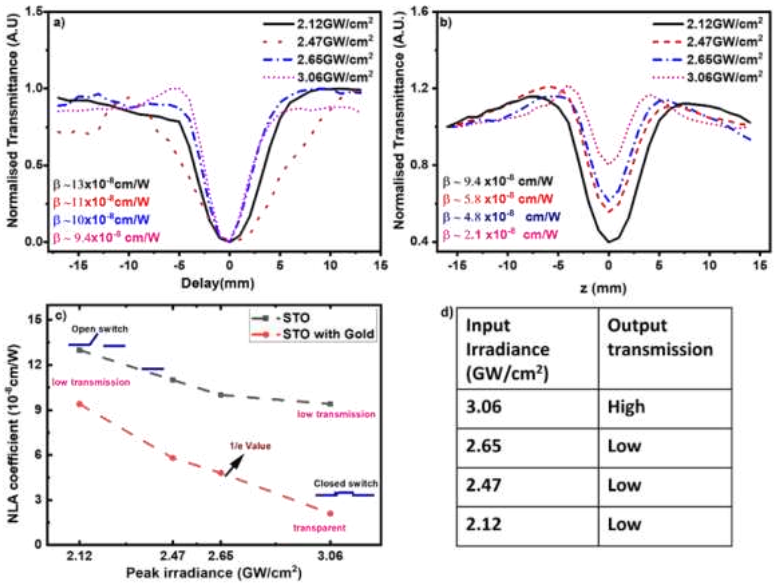


Fig. 1. *Linear absorption spectra of a) STO substrate (100) b) 11 nm Gold thin film deposited on STO through thermal vapour deposition.*

As seen from fig. 1 (a), STO shows high absorption in the UV region (below 400 nm) with the maximum transmission in the Visible and NIR range (400 nm -1000 nm). On deposition of gold film (11 nm) over STO (fig. 1(b)) we see an appearance of interband absorption from 400 nm to 500 nm, a broad SP resonance band at 548 nm and an intraband absorption tail above 650 nm [1]. The interband transitions is from filled d band to empty sp band while the intraband transitions is within the filled and unfilled orbitals of the sp-band in Au [2,3]. Through AFM the RMS (Rq) roughness of the film came out to be around 2.46 nm.

Fig. 2 represent non-linear absorption in STO and gold film deposited on STO, respectively obtained through Z-scan using 532 nm, 6 ns pulses of varying energy (2.12 GW/cm^2, 2.47 GW/cm^2, 2.65 GW/cm^2 and 3.0 GW/cm^2).

Input Irradiance (GW/cm²)	Output transmission
3.06	High
2.65	Low
2.47	Low
2.12	Low

Fig. 2. *Laser irradiance dependent variation in a) normalized transmittance of STO, b) normalized transmittance of 11 nm thick gold film deposited on STO, c) non-linear absorption coefficient (NLA) of STO and Gold over STO. The change in NLA coefficient indicates a shift in switching threshold due to introduction of gold film. d) Truth table of the optical switch thus obtained.*

The value of the non-linear absorption coefficient 'β' (listed in fig 2 (a) and (b)) corresponding to laser energy variation is calculated using following relation [17]

$$\beta = \frac{((m+1)^{1.5} * \Delta T)}{(I_o * L_{eff})} \qquad (1)$$

Where 'm' is a constant, which depends on the order of nonlinearity. For 3rd order nonlinearity, 'm' is taken as 1, ΔT = difference in peak transmittance and the least transmittance (normalized), Leff= effective sample width (cm).

As seen from fig 2 (a) STO dominantly shows RSA which is attributed to 2PA thus making it a good candidate for optical limiter or saturable absorber. For Au-STO heterostructure, we observe a competition between saturable absorption (SA) and reverse saturable absorption (RSA) as the input irradiance varies. For the value of peak irradiance > 2.65 GW/cm^2 or $\beta < 1/e^{th}$ of the initial value, the sample shows high transmission or behaves like a closed switch (low transmission). This result is summarized by the truth table shown in Fig. 2(d). For Gold film deposited on STO (Fig.2 (b)), the SA or decrease in 'β' is due to local field enhancement by SP wave of Au clusters in thin Au film.

The authors would like to thank CSIR-NPL and HCU for providing the instrumental facilities required for this work. One of the authors, Nikita Vashistha, would like to thank UGC for providing a student research fellowship.

Abstract

In this study, a novel hybrid plasmonic waveguide as near field transducer is proposed, consisting of high refractive index nanorod separated from metal by low primitivity region. The design aims to enhance mode confinement at the metal-dielectric interface by combining the benefit of both the nanorod and the plasmonic waveguide.

Keywords— HAMR, HPW, NFT, ...

Heat-assisted Magnetic Recording (HAMR) is a technology that has been developed to address the need for higher data storage capacities in hard disk drives (HDDs). The technology enables greater write densities, allowing more data or grains to be stored onto each area of the disk platter by using a laser to heat a small portion of the recording surface.[1] This reduces the coercivity below of that of the applied magnetic field from the recording head, allowing for more stable bits to be written on the disk.

HAMR technology necessitates the utilization of materials that have resistance to high temperature. One of the primary challenges in utilizing these materials to improve thermal stability; is their compatibility with the current HAMR system design. The reliability and long-term stability of refractory materials under repeated thermal cycling is a significant concern. HAMR involves the repeated heating and cooling of the recording media during the read-write process, which can lead to material fatigue and degradation over time. Ensuring that refractory materials can withstand these thermal stresses without compromising their structural integrity or performance is vital for the durability and reliability of HAMR systems.

To achieve this, the laser heat needs to be efficiently transferred to the recording media without causing excessive heating in other components of the HAMR system. The integration and deposition of refractory materials to the recording transducer and their subsequent patterning and alignment with the laser may require new fabrication techniques and equipment. These materials are known for their excellent thermal stability and high reliability, however they diminish the plasmonic performance due to their poor optical properties therefore leading to the need to explore different design avenues.[2]

Here we explore the possibility of doing HAMR using dielectric loaded plasmonic waveguides (DLPW).[3] These nano-waveguides use the dielectric (typically a non-absorptive high refractive index material) to carry the plasmons, therefore enabling low absorption losses while also guaranteeing heat spot confinement through the waveguide size. The effective refractive index that determines the propagation characteristics of the guided mode in the HPW can be calculated using:[4]

$$n_{eff} = n_r\left(1 - \frac{d_g}{d_r}[(n_r^2 - n_m^2)/(n_r^2 - n_d^2)]^{(1/2)}\right) \tag{1}$$

where n_r is the refractive index of the high index nanowire, d_g presents the separation between metal and nanorod,

d_r gives the diameter of the high index nanowire, n_m and n_c donate the refractive indices of the metal and dielectric gap respectively. A schematic of the geometry is shown in Fig (1)

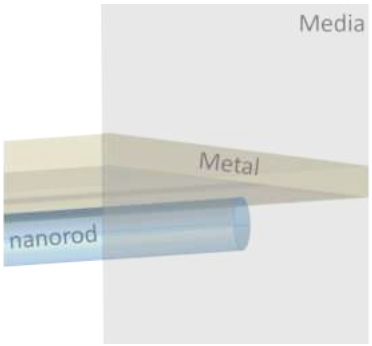

Figure 1: HPW consists of high index nanowire embedded in low permittivity dielectric, separated from the metal (ϵ_m) by a gap of SiO_2 ($\epsilon_d = 2.25$).

We will examine the heatspot confinement generated by the DLPW as well as different methods for coupling light to it and integrated to a typical HAMR head.

Abstract: In this work, we report on a high-efficiency SERS platform based on Titanium Nitride (TiN) nano and microstructures. TiN films were deposited by magnetron sputtering. The structural, and optical properties were carefully studied. SERS measurements confirmed the high SERS activity of TiN samples with good stability and repeatability.

So far, most of the SERS platforms are based on noble metals, especially gold and silver. However, the last research showed very promising optical properties of titanium nitride (TiN) nano and microstructures[1]. Such materials are mainly used in photocatalysis[2], but our last research proved excellent SERS activity in novel, non-metallic materials based on TiN[3]. In this work, we study for the first time samples having the same morphology coated by TiN and Au layers with the same thicknesses.

The Si pyramids were formed by the chemical etching of Si wafers. TiN thin films were prepared by a magnetron sputtering method. The structural properties were done by SEM microscopy. Data analysis showed that deposited Au and TiN layers are continuous and do not change the morphology of the formed Si pyramids. The optical properties were studied by UV–Vis DRS and spectral ellipsometry measurements proved the plasmonic properties of both types of materials. It was found that the SERS efficiency increased as the thickness of the deposited films increased and reached a maximum of 160 nm of film thickness. The minimal detectable amount of Raman reporter molecules (tartazine) was the same for both sample types of the SERS platform and equal to 10^{-9}M concentration. It was also proved that due to their hydrophobic properties, TiN-Si samples can be used as SERS platforms that are reversible after simple rinsing in water even in 20 cycles.

Abstract: We use surface forces to self-assemble all-silicon photonic nanocavities that confine light to air gaps at the scale of a few atoms. This relies on a new fabrication method that uses self-assembly to bypass the resolution limit of conventional fabrication and results in cavities with unprecedented figures of merit.

Enhancement of the light-matter interaction strength is a central goal in nanophotonics as it is required for building better and more compact devices or even realizing entirely new functionalities within areas such as nanolasers, optical interconnects, and quantum light sources [1]. The strongest enhancements are obtained in cavities, and while research on photonic-crystal cavities has led to very high quality factors, a common assumption in the field has been that dielectric cavities are bound to mode volumes larger than the diffraction limit. Recent developments have disproved this assumption: the diffraction limit does not apply to cavities, and dielectric bowties can confine light to arbitrarily small mode volumes limited only by the capability of the nanofabrication [2]. Interestingly, these insights are not new [3], but the experimental progress in the research on dielectric bowtie devices was for many years impeded by the extreme requirements posed on the nanofabrication.

Further miniaturization of the mode volume and thus the enhancement of the light-matter interaction requires unconventional fabrication concepts as previous demonstrations already go well below the smallest lithography features in the semiconductor industry [2]. We present a new method that combines the atomic-scale resolution of self-assembly with the scalability and circuitry of planar photonic circuits [4]. The method bypasses the resolution limit of lithography and results in dielectric cavities with unprecedented dimensions, confining light in air gaps with widths of about a few silicon atoms, as shown in Fig. 1. The new cavities feature mode volumes 100x below the diffraction limit while at the same time exhibiting quality factors 100x above the theoretical limit of plasmonics, while also being self-aligned to and efficiently coupled to a waveguide. The smallest dimension of devices obtainable with the new method is only limited by structural disorder [5].

Abstract: Tamm optical states are formed at the interface between a distributed Bragg reflector and a thin (~10 nm) layer of metal. We combine these with metasurfaces to form readily manufacturable devices for controlling light at the nanoscale with applications in lasers, single photon sources, and photodetectors.

Tamm optical states – sometimes called Tamm plasmons – are formed at the interface between a distributed Bragg reflectors and a nanoscale layer of metal (see figure 1). Unlike conventional surface plasmons, the majority of the mode is located in the lossless dielectric layer; they have a parabolic dispersion within the light cone, so can be coupled to without momentum matching; and can be excited with both TE- and TM- polarized light[1]. By laterally sculpting the metal layer, it is possible to form confined Tamm plasmons, spatially localized underneath the metal layer. These structures are highly manufacturable, using only metal deposition and a lift-off process, avoiding etching into the surface of the semiconductor and the resulting electronic defect states which cause problems with charging and non-radiative recombination in active photonics.

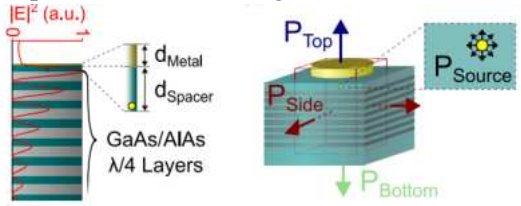

Figure 1 Illustration of a Tamm plasmon and a confined Tamm structure

In order to obtain Tamm Optical States with single mode emission, it is necessary to make very small metal structures, with implications for both classical and quantum photonics: the gain of nanolasers is limited by the small physical volume, and single photon sources face losses due to the

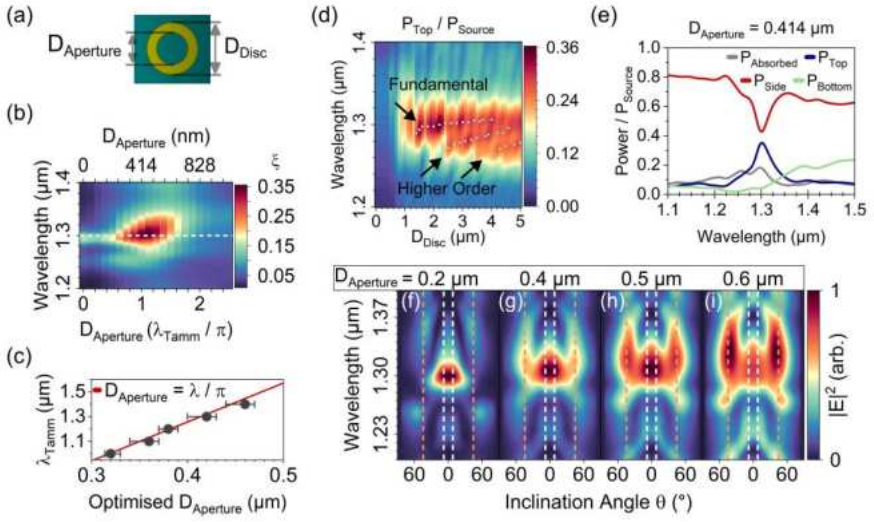

Figure 2 FDTD results for an example metasurface Tamm nanoring

metal layer as well as a deleterious effect of the lack of control of the far field, which is linked to the physical dimensions of the structure.

In this work, we combine the Tamm Optical State with the metasurface, using the readily manufacturability of the metal layer together with the ability of modern nanofabrication to sculpt the surface, decoupling the mode from the far field, and opening the door to photodetectors[2], single photon sources and lasers using the Tamm Assisted Metasurface.

As an illustrative simple example of a metasurface[3], we consider a nanoscale ring (see figure 2), using a Tamm plasmon as a stating point which is optimized for the telecommunications O band. We find that the advantage of using such a nanoring over a conventional confined Tamm plasmon is that it doubles the emission efficiency from 18% to 35%, by the mechanism of reducing the absorption.

This work is funded by Engineering and Physical Sciences Research Council under grant META TAMM (EP/X029360/1). TA acknowledges funding from the Saudi Arabian Cultural Bureau in the UK, and AS and HH acknowledge funding from the Quantum Engineering Centre for Doctoral Training.

Surface Enhanced Infrared Absorption (SEIRA) allows the resonant coupling between a plasmonic mode and a narrow resonance of an analyte. We demonstrate two different approaches for sensing PMMA and vanillin, using Cd(Zn)O nanostructures reporting enhancement factors of up to 220%.

SEIRA enables the resonant coupling between a wideband plasmonic mode upheld by a nanostructure and a narrow resonance of an analyte for detection purposes. Noble metals have been traditionally used for SEIRA, reaching absorption enhancements factors as high as 7-fold [1]. However, such materials suffer great losses in the mid infrared (Mid-IR) [2] which fuels the need to explore other material platforms suited for said part of the spectrum. Cd(Zn)O has sparked great interest lately [3] owing to its great performance in the mid-IR given by its high plasma frequency (3100–4200 cm^{-1}) and its very low losses (500–600 cm^{-1}). In this study we report two different approaches for sensing two different organic molecules, PMMA and vanillin, using Cd(Zn)O nanostructures reaching enhancement factors of up to 220%.

The first approach to be discussed is the use of self-assembled semispherical nanoparticles (NPs) made of $Cd_{0.9}Zn_{0.1}O$ grown by metal organic chemical vapor deposition (MOCVD) on a semi-insulating GaAs substrate. A series of these samples were grown at slightly different conditions yielding a varying surface coverage of NPs with an average diameter of 60 nm. Owing to their geometry and the high refractive index of the substrate, the NPs host a broad localized surface plasmon (LSP) centered at around 1750 cm^{-1} (below the plasma frequency of the $Cd_{0.9}Zn_{0.1}O$) [3] which matches the energy of absorption of the C=O bond of the PMMA molecule.

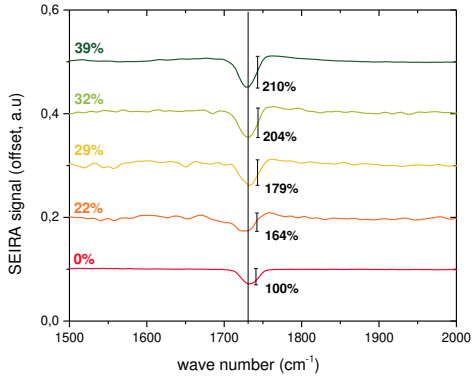

Figure 1. Enhancement of SEIRA signal with the $Cd_{0.9}Zn_{0.1}O$ NP surface coverage compared to the reference. The vertical black line indicates the absorption of the C=O bond of PMMA.

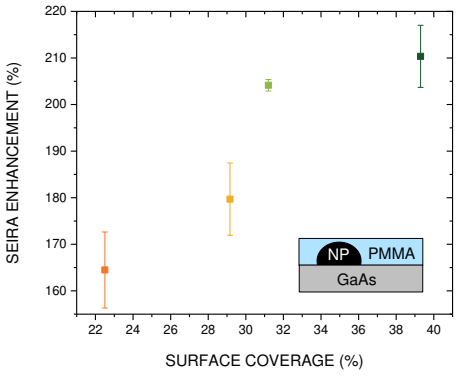

Figure 2. Vibrational signals normalized by the baseline extracted from Eiler´s algorithm. Error bars account for multiple measurements on the same sample.

A 70 nm layer of PMMA was deposited on top of the surface through spin coating and the plasmonic response of the NPs was characterized by transmittance spectroscopy using a Fourier transform infrared (FTIR) spectrometer at an angle of incidence of 45º. The interaction between the broad resonance of the NPs and the narrow vibrational absorption of PMMA are characterized by asymmetric Fano-like profiles, which are analyzed using Eiler's least square smoothing algorithm [4]. The results of the study are shown in Figure 1, where four samples with different surface coverages ranging from 22% to 39% along with a bare GaAs substrate for reference were measured. We report a SEIRA enhancement of up to 210% on the signal compared to that of the reference. Furthermore, we have observed a linear increase of the enhancement with the surface coverage (Figure 2).

For the second approach, 2 µm-pitch, 0.7 fill factor gratings were processed on $Cd_{0.9}Zn_{0.1}O$ thin films deposited on sapphire (Figure 3) featuring LSPs tailored to a frequency of 1550 cm^{-1}. This was done through a novel approach using nanolithography and dry etching never reported before on CdO/sapphire films. Owing to the geometry of the surface, when incoming light is polarized parallel to the stripes the response will assimilate that of a thin film, whereas when the light is perpendicular to stripes an LSP will appear. Two microliters of a 2 mg/ml solution of vanillin in isopropyl alcohol were drop casted on the surface of the samples and the plasmonic response was characterized using a Hyperion 3000 microscope coupled to the FTIR spectrometer. Figure 4 shows how SEIRA enhances the vanillin absorption peaks in perpendicular polarization compared to parallel polarization, where no SEIRA is acting. For vanillin's vibration at 1589 cm^{-1}, this enhancement reaches 175%.

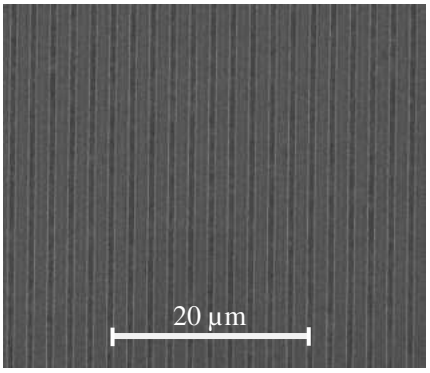

Figure 3. Scanning electron micrograph of the surface of a $Cd_{0.9}Zn_{0.1}O$ grating.

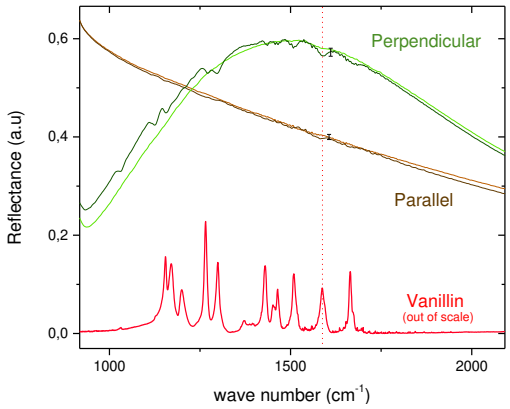

Figure 4. Reflectance spectra from a grating with light polarized parallel (brown) and perpendicular to the stripes (green). Light colored lines were measured before addition of vanillin and darker ones after. Vanillin reference in red magnified for clarity.

Abstract: Plasmonic sensors have garnered significant interest due to their ability to exhibit high sensitivities. In this work, we present the proof of concept for a plasmonic hydrogen sensor with a low detection limit at the ppm level (1.91 ppm).

The plasmon-triggered switching effect is a plasmonic phenomenon that involves two propagative orders, the 0^{th} and the -1^{st}, diffracted in reflection by a relatively deep grating [1]. The evanescent $+1^{st}$ and -2^{nd} orders respectively excite co-propagative and contra-propagative modes, where the resulting interaction between them allows for a low-loss plasmonic interaction between the two propagative orders. As depicted in Fig. 1, order oscillations yield two crossing points, WP1 and WP2, where a local angular translation is observed when the ambient medium undergoes any modification. The transducer response is then evaluated by applying a normalized differential measurement between the orders' diffraction efficiency at a fixed angle, WP1 or WP2, allowing the estimation of an angular shift with a simple light intensity measurement.

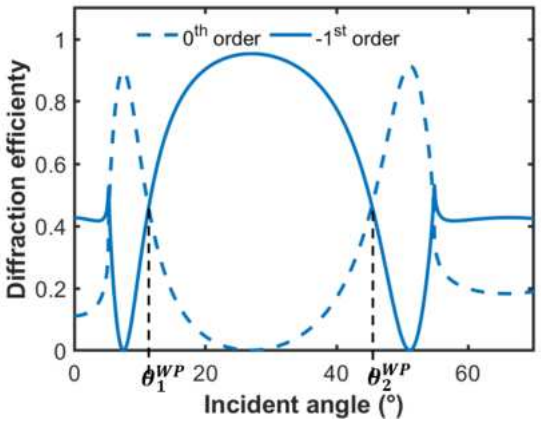

Figure 1: Computed angular responses for an ideal sinusoidal gold grating with a depth of 280 nm and a period of 935 nm in air without sensing layer

The plasmon-triggered switching effect has already shown promise in the security domain [2], biosensing [3], and the control of air quality [4]. The experimental transducer, made of a replica of a printed photoresist layer under a UV laser interference lithographic setup, was coated with a 120 nm gold layer through thermal evaporation. The measured sinusoidal grating period with a Littrow setup was 935 nm, while the depth measured through Atomic Force Microscopy was 303 nm. To adapt the transducer for hydrogen detection, a palladium sensitive layer of 10 nm was also deposited via thermal evaporation.

After an initial angular characterization of the transducer (Fig. 1), it is placed in a chamber where a controlled flow of filtered air with a defined hydrogen concentration is established. The transducer is illuminated with an 850 nm laser diode in TM polarization at WP2, where the 0^{th} and -1^{st} diffracted orders are collected simultaneously over time with two photodiodes. The ambient refractive index is also computed over time using Edlén's formula [5], through the measurement of pressure, temperature, and humidity, to differentiate the response of the hydrogen interaction from the response of the ambient refractive index of air.

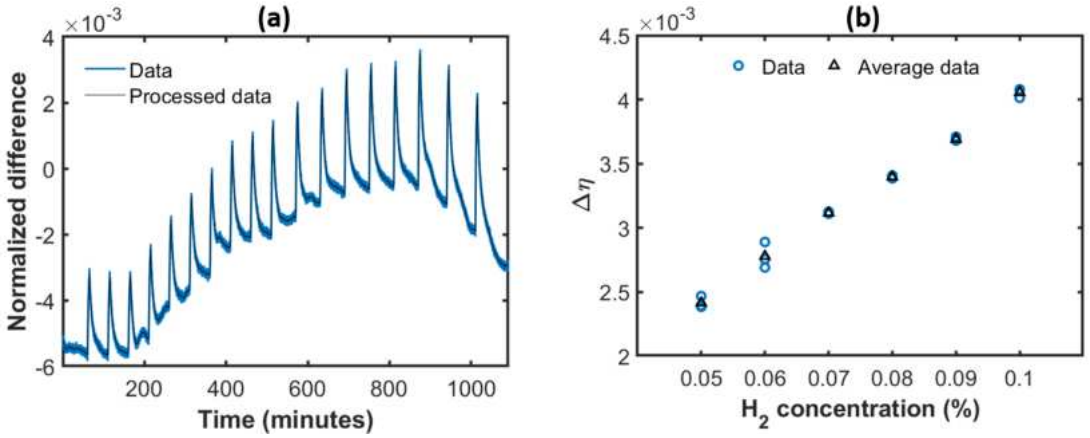

Figure 2: (a) Response to stepwise increasing H2 concentration (0.05-0.1%) composed of 3 cycle for each H2 concentration in filtered Air at room temperature with the corresponding moving average of 100 points plotted in black. (b) Measured Δη as a function of H2 concentration derived from (a) where the plotted black triangles are the average of different Δη for each H2 concentration

From Fig. 2a), the responses under hydrogen concentrations ranging from 500 to 1000 ppm show that the transducer is sensitive to hydrogen. Fig. 2b) displays the difference in the normalized difference before and after each hydrogen cycle. Responses are linear and can distinguish between different hydrogen concentrations, resulting in a detection limit of 1.91 ppm with a white noise measured at $\sigma = 2.10^{-6}$.

The authors thank the NanoSaint-Etienne platform (CNRS RENATECH+) for providing the fabrication means and NAPA company for providing the replica. Funding is provided by the French Région Auvergne-Rhône-Alpes within the framework of the CAPTHY project.

Magnetically Controllable Multimode Interference in Topological Photonic Crystals

Weiyuan Tang[1], Mudi Wang[2], Shaojie Ma[1,3], C.T. Chan[2], Shuang Zhang[1*]

Abstract: We demonstrate magnetically controllable multimode interference based on gyromagnetic topological photonic insulators that support two unidirectional edge modes with different dispersions. Herein, we successfully achieve tunable power splitting in experiments by controlling multimode interference with the magnetic field intensity or the frequency of wave.

To date, most proposed solutions for manipulating multimode interference in topological systems involve modifying the structural dimensions of channels[1-3], such as, by changing the incident channel length to change the propagation phase of the incident waves[1] or controlling the coupling strength between the incident and outgoing channels with bending angles[3]. However, the requirement for varying the geometry of the system severely restricts these techniques' practical utility. In this work, we achieve controllable multimode interference in a topological photonic heterostructure waveguide. The power splitting ratio originating from multimode interference is controlled by the propagating phase difference between two CEMs (Fig.1a), which depends on the incident frequency (Fig.1b) or magnetic field intensity (Fig.1c).

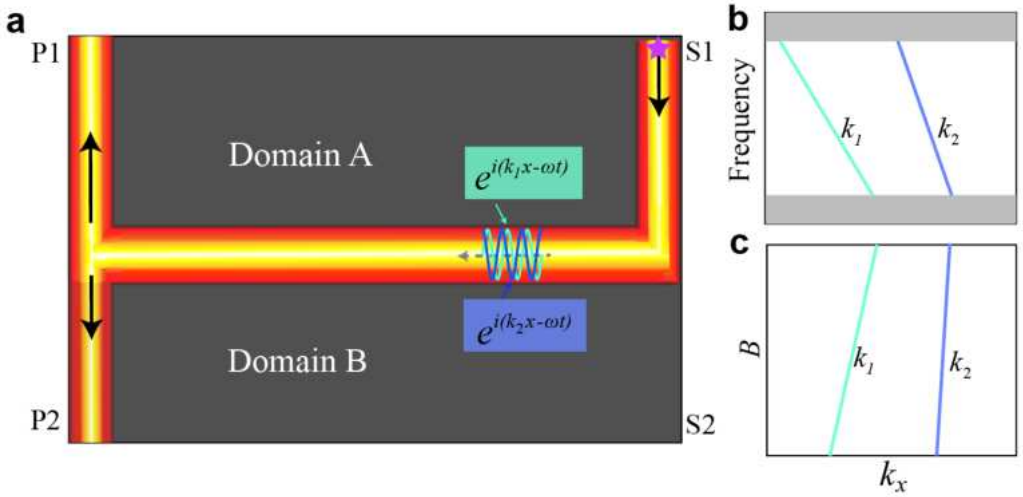

Figure 1 The proposed scheme for controllable power splitting through manipulating multimode interference. a The schematic of a H-shaped heterostructure waveguide. **b-c** The differences between the wave number of two CEMs depend on incident frequency (**b**) and the magnetic field intensity (**c**).

Based on transfer-matrix method, we develop a theoretical model to reveal the fundamental mechanisms underlying the whole course of tunable multimode interference. Then the power splitting ratios for the source being placed in channel S1 and S2 as:

$$R_{S1} = \frac{|e^{i\Delta\varphi}+1|^2}{|e^{i\Delta\varphi}+1|^2+|e^{i\Delta\varphi}-1|^2}, \quad (1)$$

$$R_{S2} = \frac{|e^{i\Delta\varphi}-1|^2}{|e^{i\Delta\varphi}+1|^2+|e^{i\Delta\varphi}-1|^2}, \quad (2)$$

where $\Delta\varphi = (k_2 - k_1)l$ is the phase difference between the mode 1 and mode 2 propagating in the same direction.

Experimentally, our waveguide system is composed of two domains, each of which is constructed by a triangular lattice of yttrium iron garnet (YIG) rods. The magnetic field is applied in positive (negative) directions to the Domain A (B). Note that Domian A and domain B possess opposite gap Chern number for the second bandgap, the interface of the two domains can support two topologically edge modes. By adjusting the distance from the magnet to the YIG rod, the magnetic field intensity can be tuned, and then the interference of the two edge modes is quantitively manipulated, leading to magnetically controllable power splitting ratios. As shown in Fig.2b, the experimental results are consistent with the simulation results. Likewise, tuning power splitting ratios of our waveguide system with the frequency of incident wave is also experimentally verified in Fig. 2c.

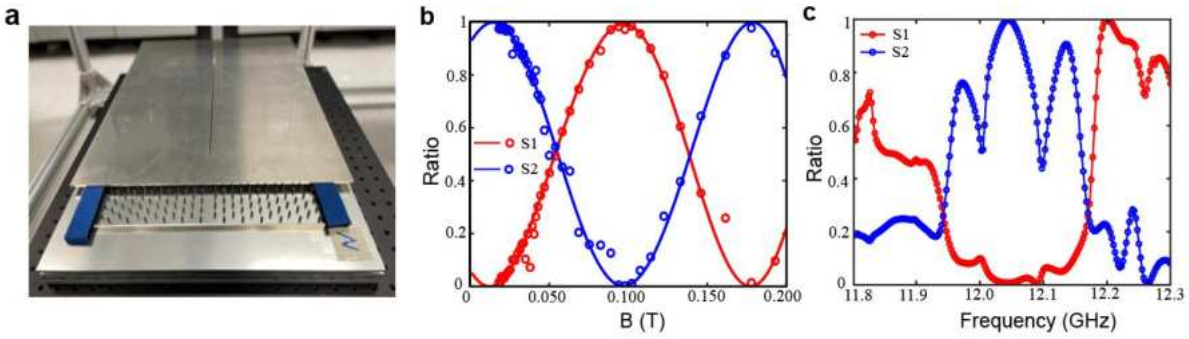

Figure 2 The experimental setup and results. a The experimental setup. **b** The measured (circle) and simulated (solid lines) power splitting ratios tuned by magnetic field intensity. **c** The measured power splitting ratios controlled by wave frequency.

Our method reveals the physical mechanism of the whole process of multimode interference in topological photonic crystal waveguides, which paves a new way for the study of multimode interference. Bedsides, the proposed topological waveguide system can provide a new technical platform for the related applications of microwave devices such as switches, signal processors, and isolation devices.

Coupled thermal and mechanical phenomena induced by the fluctuations of the electromagnetic field

J. R. Deop-Ruano[1*], and A. Manjavacas[1*]

[1]Instituto de Óptica "Daza de Valdés" (IO-CSIC), Spain

Abstract: Radiative heat transfer and Casimir interactions arise from the fluctuations of the electromagnetic field. Here, we analyze the simultaneous transfer of momentum and energy in different nanoscopic systems. In doing so, we find that the motion of the nanostructures allows us to modulate the heat transfer, and vice versa.

The **fluctuations of the electromagnetic field** are responsible for the **radiative heat transfer** between material structures [1, 2]. Another phenomenon emerging from the fluctuations of the electromagnetic fields is the **Casimir forces and torques** between neutral nanostructures, which can serve as a means to transfer linear and angular momentum in the nanoscale [3, 4]. Despite their shared physical origin, radiative heat transfer and Casimir interactions are traditionally studied independently. In the former, nanostructures are typically considered steady, while in the latter, thermalized conditions are assumed. However, as we demonstrate in our study**, Casimir interactions can exert a notable influence on radiative heat transfer, and vice versa**.

Here [5], we explore the **simultaneous transfer of energy and angular momentum** in a pair of nanostructures with different temperatures, rotating around a common axis (See Figure 1). We show that, due to the rotation of the nanostructures, **radiative heat transfer between them can be increased, decreased, or even reversed** compared to the transfer in the absence of rotation, determined solely by the temperature difference of the nanostructures. These findings unravel the **possibility of modulating radiative heat transfer between nanostructures through their motion**.

Furthermore, we study the **propulsion of Janus-like nanostructures** placed in an environment at a different temperature [6]. This type of nanostructures are characterized by having two different sides with different optical properties. Due to the unbalance in the thermal radiation produced by the two sides, the structure spontaneously accelerates as it thermalizes with the environment. We completely characterize the force and the associated motion of the structure as a function of its temperature and thickness, for different combinations of materials. In doing so, we prove the possibility **of manipulating material structures using thermal radiation**.

Our calculations rely on the fluctuational electrodynamics framework, which allows us to obtain analytical expressions for the force, torque, and power transferred between the nanostructures. This work unveils nontrivial phenomena resulting from the interplay between Casimir interactions and radiative heat transfer, paving the way for **utilizing moving nanostructures to gain control over radiative heat transfer, as well as to employ thermal radiation to accelerate and manipulate nanostructures**.

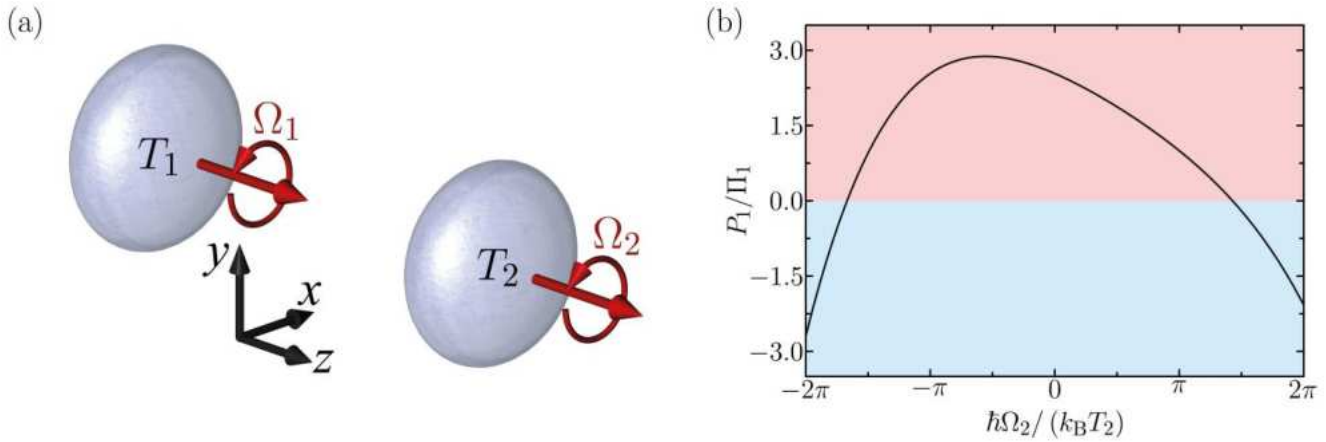

Figure 1. (a) Schematics of the system under consideration. (b) Power transferred between the nanostructures P1, normalized to the power transferred in the absence of rotation Π1, as a function of Ω2 for T1 = 1.5T2, Ω1 = πkBT2/ħ. The red (blue) background indicates positive (negative) values of the normalized power transferred.

Abstract: We present a new scheme of super-resolution imaging that can reconstruct the size, shape, position and orientation of metallic nanostructures with a precision of 5 nm, using a pump-probe method technique. This also opens a way to extract the elasticity or stiffness of the surrounding environment at the nanoscale.

Super-resolution optical microscopy has a tremendous impact in life sciences over the last decade for its ability to reveal the insights of biological processes at the nanoscale dimensions [1,2]. These methods usually rely on the optical properties of either fluorophores or nanostructures to provide super-resolution.

An alternative to light (photons) is sound (phonons) which offers sub-optical resolution as well as enabling the elasticity quantification on biological cells [3]. This is key to understand changes at sub-cellular level due to diseases (e.g. cancer).

In this talk, a new scheme of super-resolution acoustic imaging [4] will be shown by reconstructing the size, shape, position and orientation of metallic nanostructures ("nanobells) with a precision of 5 nm, using a pump-probe method technique (see Figure 1). This also opens a way to extract, for the first time, the elasticity or stiffness of the surrounding environment at the nanoscale.

Abstract: As Si_3N_4-based photonic integrated circuits emerge as a promising platform, it is important to diagnose their spatial configuration with resolution beyond diffraction limit. Here, we demonstrate a resolution enhancement of hundred-nanometer-diameter Si_3N_4 nanowires based on photothermal nonlinearity and higher order saturated excitation subtraction and detect the resonance mode inside it.

Introduction

Recently, Si_3N_4-based photonic integrated circuits (PICs) have shown a great potential in the industry[1,2]. To characterize the relationship between nanoscale structure and functional output performance, it is important to develop diagnostic tools that are able to inspect the spatial configuration of Si_3N_4-based PICs with nanometer resolution and high-speed observation, as the diameter of Si_3N_4 is getting smaller and smaller, some are even only tens of nanometers[3-6]. One of the fastest ways for such diagnosis is optical imaging. However, the resolution of an optical microscope is limited by diffraction limit.

The purpose of this study is to achieve optical resolution of Si_3N_4 nanostructures beyond the diffraction limit. Since the Si_3N_4 serve as waveguide in PICs, we start with Si_3N_4 nanowires (NWs) that resemble waveguide geometry. Previously, our group reported the resolution improvement of Si nano cubes through photothermal nonlinearity[7]. In this work, we pursue super-resolution imaging of Si_3N_4 NW with a similar strategy, whose mechanism is explained as follows: the applied laser will cause the temperature increase of the nanoparticle, which result in refractive index changes[8], leading to Mie-resonance spectrum red-shift and nonlinear scattering-excitation dependency. It is possible for Si_3N_4 NWs to exhibit strong photothermal nonlinearity around 561-nm wavelength according to the analytical solution of the Mie resonance of an infinite Si_3N_4 cylinder in vacuum. With strong nonlinear responses, enhanced resolution is achieved by adopting image post-processing methods that depend on the type of nonlinearities. Here we expect that Si_3N_4 NWs show sub-nonlinearity, so we selected the saturated excitation (SAX) subtraction method[9], achieving at least 1.36-fold resolution enhancement at an incident power of 13 mW.

Result

The sample was inhomogeneous Si_3N_4 NWs with diameter ranging from 300 to 800 nm. These NWs were randomly sprayed by acetone on a copper grid. The laser wavelength was 561 nm and its polarization was perpendicular to the NW longitudinal axis. The NA of the objective was 0.6.Fig. 1 (a) & (b) shows the scattering power dependency at the valley and peak position of wire shown in Fig. 1(d) respectively. From Fig. 1(b), sub-linear behavior starts above 17 mW, gradually toward full saturation at ~60 mW. The result of subtraction SAX for Fig. 1(b) is shown in Fig. 1(c), which shows 2-nd order nonlinearity.Fig. 1(d) is the linear backscattering image of a single NW, acquired with ~5-mW excitation power, and Fig. 1(e) is the image subtracting Fig. 1(d) from an image taken at ~17-mW. The average full width half maximum enhancement is ~1.36-fold. The theoretical value of the resolution enhancement of one SAX subtraction is $\sqrt{2}$, which is close to our result. Better resolution enhancement is anticipated by higher excitation power and higher order SAX subtraction.

Discussion

One interesting observation is that the wire image shows clear periodic peaks and all the peak positions show nonlinearity, while all the valley positions show linearity. In order to check the peaks aren't caused by the minor periodic shape change

along the wire, we first simulated the scatter intensity of wire as Fig. 2(a) shown, which shows similar periodic peaks as Fig. 1(d). One guess is the peaks are the result of the standing wave inside wire which is caused by the Mie resonance. As we all know, peak of standing wave should exist higher electric field, which leads to higher absorption. Thus, we simulated the absorption along the wire as Fig. 2(b) shows. The periodic peaks in Fig. 2(b) agrees with our guess again. Moreover, higher nonlinearity region should show higher resolution enhancement. Thus, we compared the resolution enhancement and the scattering intensity as Fig. 2(c) shows. In Fig. 2(c), we can two lines show the same peak region, which fits the guess again. Thus, we concluded that the periodic peaks are the result of the standing wave inside wire which is caused by the Mie resonance and the further checking will be done by the EELS.

Acoustic and seismic metamaterials

Design of composite mufflers based on dissipative and reactive units

Yuzhen Yang[1*], Han Jia[1], Quanquan Shi[1] and Jun Yang[1]

[1]Key Laboratory of Noise and Vibration Research, Institute of Acoustics, Chinese Academy of Sciences, China
[*]corresponding author: yangyuzhen@mail.ioa.ac.cn

Abstract: We have proposed and validated a design of a composite muffler. This design combines both dissipative and reactive units with different operating mechanisms to take advantage of the benefits offered by each structure. The result achieved a high transmission loss across a wide frequency range in a ventilation duct system.

Noise reduction in duct systems is a major issue in engineering applications, such as tunnel ventilation systems and engine exhaust systems. Acoustic mufflers have long served as the most effective devices to reduce noise in duct systems, while also allowing airflow to pass freely[1].

As the most common component of mufflers, porous sound absorbing materials (PSAM) can achieve efficient noise reduction in the middle and high-frequency range, as they can fully convert the sound energy entering the micropores into thermal energy for energy consumption[2, 3]. In this work, a common melamine porous acoustic material was used to construct the dissipative unit, which is shown as the blue part in FIG.1.

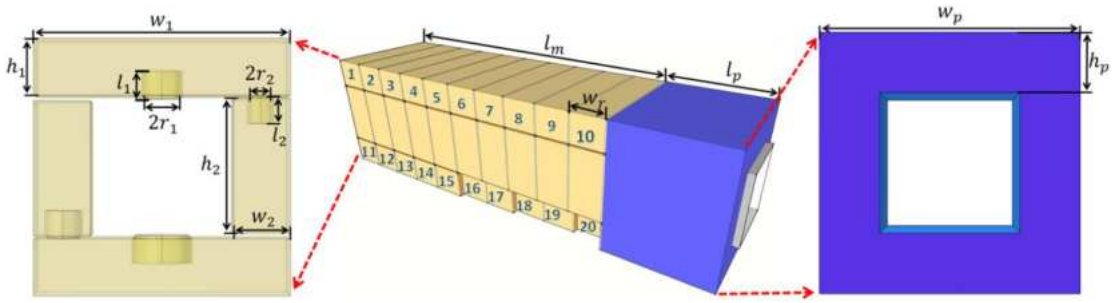

FIG.1. Schematic diagram of the composite muffler

In order to study the performance of the dissipative unit, a finite element model was built by the commercial simulation software COMSOL Multiphysics™ and the Johnson-Champoux-Allard model of porous media acoustics was chosen to characterize the PSAM in the pressure acoustics module. The thickness of PSAM h_{p} was fixed at 43 mm and the TL was calculated when the PSAM length was increased from 40 mm to 1000 mm. The cross-sectional area of the noise ventilation duct was set to 100 mm*100 mm. The TL is plotted in FIG.2.(a) as a function of length and frequency, with the black dashed line in the figure indicating the TL=20 dB contour. The results in the graph show that as the PSAM length increases, the lower frequency limit of TL greater than 20 dB gradually shifts towards low frequency. However, the lower frequency limit moves slowly in the frequency range below 1000 Hz. Based on the data in FIG.2.(a), a PSAM with a length of 220 mm was selected to construct the dissipative muffler to obtain high-efficiency noise reduction above 1000 Hz. We built a sample of dissipative muffler with a 3D printed expanded cavity and PSAM mounted inside.

The next step is to design a low-frequency noise reduction structure. Considering Helmholtz resonators are favorable for broadband noise reduction[4, 5], two order Helmholtz resonators (THR) are used for designing the reactive muffler in this work. As shown in FIG.2.(b), we extended the second cavity of the THR to the side, and this improvement not only reduces the thickness of the structure, but also makes full use of the space around the ventilation duct.

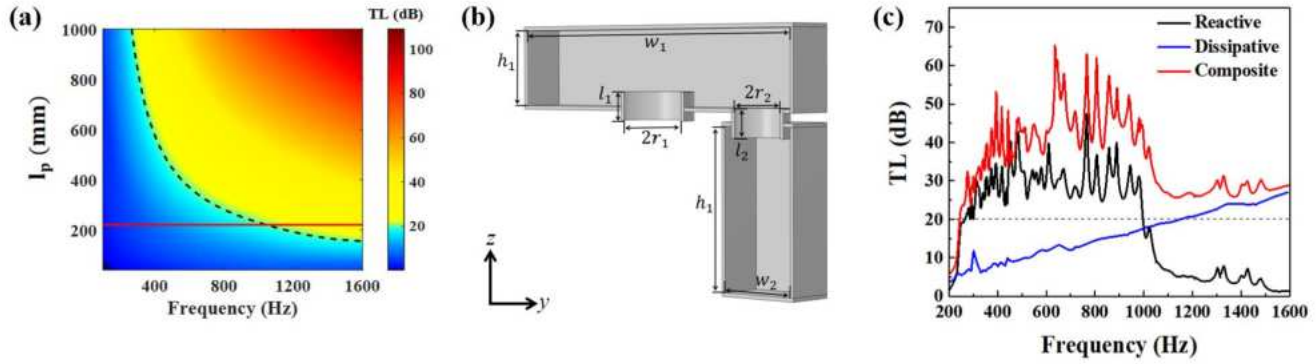

FIG.2. (a) Transmission loss of dissipative muffler constructed by PSAM. (b) Cross-section of a THR. (c) Tested TL curves for different mufflers.

After studying the sound insulation performance of THR units and the analysis of the coupling effect between units in the same cross-section, we designed a low-frequency reactive muffler consisting of 20 THR units with a total length of 522 mm. The arrangement of the 20 units was shown as the yellow part in FIG.1, where 10 units were placed on the upper and lower sides of the ventilation duct, and the annotated numbers in the figure, from 1 to 20, indicate the order in which the units were arranged from low to high resonance frequencies. The arrangment ensures that there is a significant difference between the resonance frequencies of two THRs in the same cross-section, thus eliminating the mutual coupling between the two THRs.

Finally, we attempt to combine these two types of mufflers to design a broadband and high-efficiency composite muffler, as shown in the middle part of FIG.1. Although the working mechanisms and effective frequency bands of the two are different, it is entirely possible to reduce the transmitted sound energy in a wider frequency range and to achieve broadband and higher TL by combining the two kinds of mufflers.

The measured TL curves for different mufflers are shown in FIG.2.(c), with black line, blue line and red line representing TL curves of reactive, dissipative and composite mufflers, respectively. As a reference, the 20 dB contour is marked as gray dashed line in the figure. It can be seen that, on two sides of the cut-off point around 1000 Hz, both the dissipative and the reactive mufflers alone have excellent noise reduction in the target frequency range. The TL curve of the composite muffler is above 20 dB from 244 Hz and overwhelmingly exceeds 30 dB below 1000 Hz. Therefore, the composite muffler surpasses the original effect of individual dissipative muffler and reactive muffler, which plays a positive role in the noise reduction of ventilation ducts.

Frequency-selective valley edge waveguiding in topological phononic-crystal plates

Jin-Chen Hsu[1*], Chun-Hao Wei[1], and Che-Ting Huang[1]

[1]Deaprtment of Mechanical Engineering, National Yunlin University of Science and Technology, Taiwan
[*]corresponding author: hsujc@yuntech.edu.tw

Abstract: We designed four elastic valley Hall materials composed of pillared phononic-crystal plates with two different topological modulations. By constructing distinct phase domain walls, the valley edge states emerge at different frequencies in the complete band gap. Accordingly, we can demonstrate robust zigzag waveguiding and frequency-selective channeling for elastic Lamb waves.

In the past decade, the discovery of quantum Hall, quantum spin Hall, and quantum valley Hall effects of condensed matters has inspired fascinating research direction of classical wave systems. These effects enable the creation of topological insulators (TIs) with extraordinary wave transport properties, such as defect immunity, backscattering immunity, and topologically protected edge states. However, frequency-dependent transport using topological materials has been still difficult. In this study, we demonstrate waveguiding and frequency-selective channeling for Lamb waves. We tailor a pillared phononic-crystal (PnC) plate with a honeycomb lattice to obtain the frequency band structure with a two-fold Dirac degeneracy at *K* valley. By modulating the relative height or radius of pillars to break the inversion symmetry, the Dirac degeneracy are lifted, giving rise to complete band gaps. Meanwhile, the valley Hall phase transition is induced. Consequently, two groups of distinct topological phases of the material based on radius and height modulations are obtained, respectively. Then by constructing distinct phase domain walls, the topological bands of valley edge states emerge, which could cover different frequency ranges in the complete band gaps. Finally, we are able to design frequency-selective waveguides that is immune to backscattering at sharp corners.

The designed PnC plate consists of a honeycomb array of tungsten pillars deposited on a thin lithium-niobate plate. Figure 1 shows the calculated frequency band structure for the PnC plate. the result shows that the fifth and sixth bands form a deterministic two-fold Dirac degeneracy at *K* point at 429 kHz. Then we modulate the relative height and radius (termed Δh and Δr), respectively, of the adjacent pillars of the unit cell to break the spatial inversion symmetry, the Dirac cone is lifted up, and complete band gaps are opened. Therefore, the A_h ($\Delta h < 0$) and B_h ($\Delta h > 0$) structures (and A_r ($\Delta r > 0$) and B_r ($\Delta r < 0$) structures) respectively belonging to topologically opposite valley Hall phases are obtained.

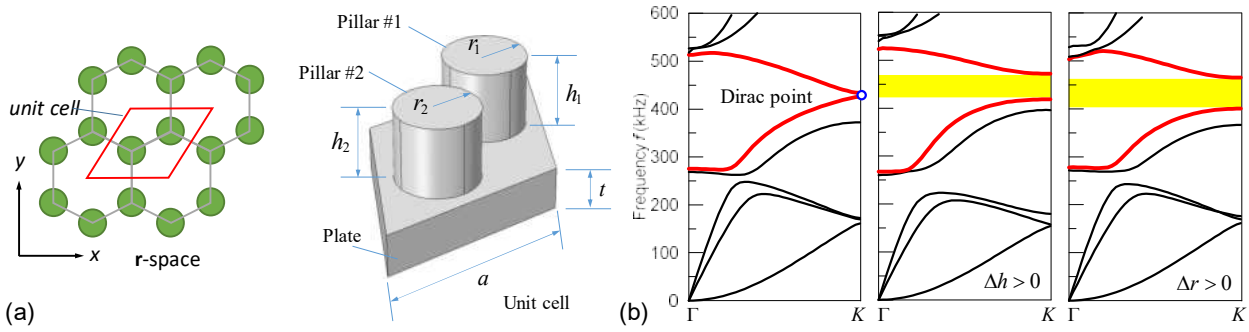

Figure 1 (a) Honeycomb lattice and unit cell. (b) Band structures of original and modulated PnC plates.

The valley Hall phase transition ensures the existence of edge state within the topological band gap and localized at the domain wall between two PnCs of different phases. Here, we combine two different PnC plates to construct the domain wall: negative phase with the A_h (or A_r) structure and positive phase with the B_h (or B_r) structure. Four combinations that yield eight different domain walls can be used, i.e., A_hB_h, A_rB_r, A_hB_r, A_rB_h and their exchange. Consequently, we can show that the projected band structures at the domain walls for the four combinations all exhibit valley edge bands covering different frequency ranges in the complete band gaps.

The most prominent feature of the valley edge state lies in the backscattering immunity to path bending. To illustrate this effect, we build zigzag domain walls and preform full-wave simulations. Three combinations, A_hB_h, A_rB_r, and A_rB_h, are illustrated. The point wave sources are excited at the chosen frequencies 446, 436, 440 kHz, respectively, at the left-end entrance. As shown in Fig. 2, valley edge states are excited and propagate along the domain walls, and the intensity of the displacement field for each combination is nearly uniform along the entire zigzag domain wall path, which indicates that no observable reflection occurs at the two sharp corners.

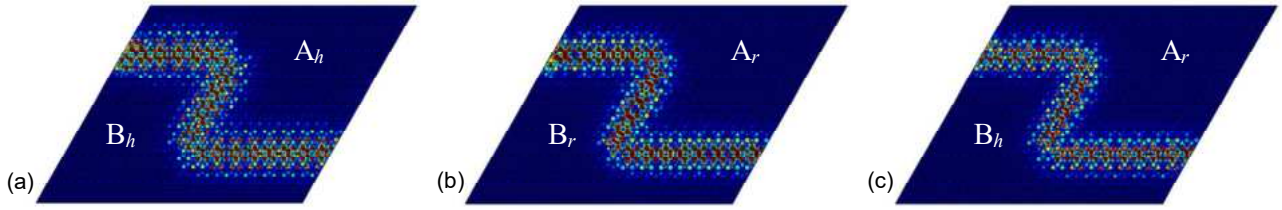

Figure 2 Transmission of valley edge states along zigzag domain wall paths composed of different phases.

Based on the four valley Hall materials, we are able to design frequency-selective topological waveguides. The design utilizes the topological edge bands of different domain walls that extend over different frequency ranges and empty topological band gaps. The waveguide consists of three sections along the horizontal direction using B_rA_r, B_hA_r and, B_rA_r combinations. Figure 3 shows the results of frequency-selective waveguiding, where a source at left entrance are excited using three different frequencies, 430, 436, and 448 kHz, respectively. When the frequency is 436 kHz, waves can freely transmit through the entire waveguide by means of the edge states supported simultaneously by the B_rA_r and B_hA_r combinations, while the other two frequencies are forbidden.

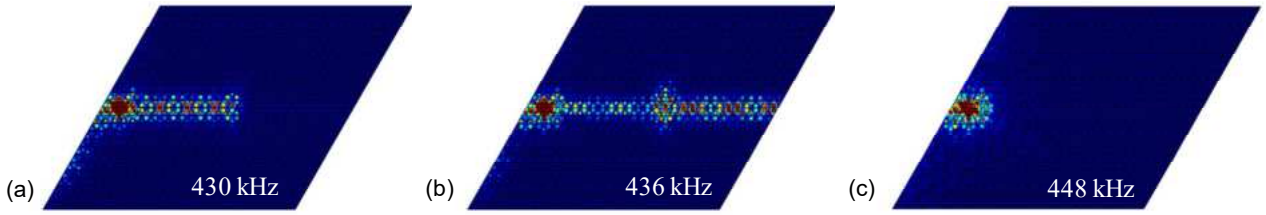

Figure 3 Result of frequency-selective waveguiding in the designed topological PnC plate.

From Air to Water: Expanding Inverse-Design Applications in Ultrasonic OAM

Chuanxin Zhang [1], Xue Jiang [1*], and Dean Ta[1]

Abstract: This study presents an inverse-design methodology for optimizing Orbital Angular Momentum (OAM) beams, enhancing ultrasonic motor performance. Utilizing an airborne 16x16 phased array and holographic lenses, we achieved significant improvements in beam uniformity and signal-to-noise ratio, demonstrating superior particle control in a constructed twisted ultrasonic motor.

Introduction and Background

Recent advancements in the field of acoustic Orbital Angular Momentum (OAM) have opened new avenues in precision acoustic applications, particularly in the development of advanced particle manipulation. Our study presents a breakthrough in this realm, employing an inverse-design methodology that optimizes OAM beams for enhanced performance.

Optimization of Phased Array in Air

Our initial focus was on air-based applications, where we used phased arrays as ideal radiating planes. Phased arrays are crucial due to their ability to control the pattern of emitted acoustic beams. This capability stems from the precise timing (phase) control of each array element. However, these arrays typically encounter limitations when employed in undersampled or sparse configurations, leading to suboptimal OAM beam performance.

Through our methodology, these phased arrays were optimized for air propagation. We incorporated a global optimization strategy, significantly improving the amplitude uniformity and Signal-to-Noise Ratio (SNR) of OAM beams. This was a crucial step towards achieving our goal of constructing a high-performance twisted ultrasonic motor.

Development of Underwater Holographic Lens for OAM

Transitioning to underwater scenarios, we employed thickness-modulated holographic lenses to manipulate acoustic fields. As reported in previous studies, under the assumption of a one-dimensional transmission line model, a critical relationship has been established between the relative phase change at any pixel position and the thickness variation of the lens. This relationship is encapsulated in the formula [1]:

$$\Delta\varphi(x,y)=(k_m-k_h)\Delta T(x,y) \quad (1)$$

However, the design and optimization of these lenses presented a unique challenge due to the three-dimensional nature of the structures and the complex physical mechanisms involved, such as diffraction within the lens material. To address these challenges, we introduced more sophisticated elements into our inverse-design methodology, allowing for a nuanced control of the acoustic field in underwater environments. The distributions of the OAM acoustic field underwater emphasize the efficacy of our approach in this more complex medium.

Ultrasonic Motor Application

The culmination of our study is the development of a twisted ultrasonic motor using inverse-designed OAM beams. This motor operates on the principle of transferring angular momentum from OAM beams to a trapped

particle, inducing rotation [2]. Our approach significantly enhanced the stability and uniformity of the particle's rotational trajectory, a critical improvement over traditional method.

We demonstrate the practical application of our methodology. The OAM beam's interaction with particles in free space is shown, highlighting the advancements in particle control. This capability is pivotal in applications requiring precise manipulation, such as targeted drug delivery or micro-assembly processes.

Conclusion

In conclusion, our study represents a significant leap in the optimization of OAM beams for acoustic applications. By employing an inverse-design methodology, we have successfully navigated the complexities of phased array optimization in air and the nuanced challenges presented by underwater environments. The resulting advancements in ultrasonic motor technology not only demonstrate the practical applications of our research but also pave the way for further exploration and innovation in the field of acoustic manipulation.

Abstract: Efficient acoustic communication across the water-air interface has always been expected in ocean explorations. However, the existing researches are mainly concentrated on the narrow-band transmission based on resonance. Here, we combined the air-based and water-based metafluids to realize an exponential gradient impedance matching layer for broadband water-air sound transmission.

The water-air GIML is shown schematically in the right panel of Fig. 1(a). The air-based metafluid is made of square solid inclusions arranged periodically in air and the water-based metafluid is made of square hollow inclusions arranged periodically in water. The corresponding impedance distribution is marked as red squares in Fig. 1(b). The red solid line and black dashed line in Fig. 1(c) show the energy transmission coefficients of equal-thickness and variable-thickness layering method, which are completely consistent. The four-layer GIML can achieve energy transmission above 0.9 in the range of 730 Hz to 1470 Hz. We further calculated the energy transmission coefficients of the impedance matching layers containing 1 layer and 2 layers, as are plotted in Fig. 1(c). The corresponding impedance distributions are shown as different symbols in Fig. 1(b). It can be seen that the transmission bandwidth is expanding with the number of layers. Therefore, we can achieve broadband transmission in a specified bandwidth by choosing an appropriate number of layers. The proposed design method can flexibly adjust the acoustic parameters in each layer of the GIML by changing their geometric parameters, which makes it possible to realize the water-air impedance matching using artificial structures.

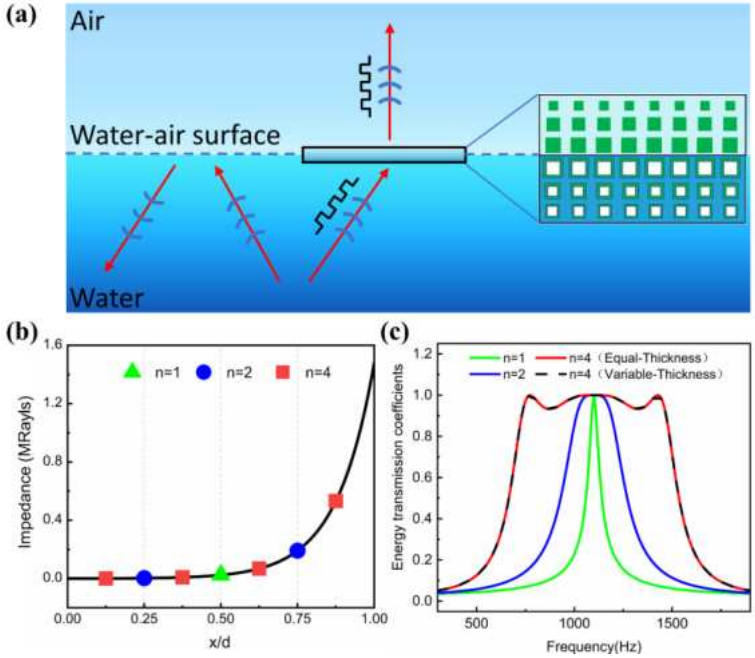

FIG. 1. (a) Schematic of water-air acoustic communication enabled by the proposed GIML. (b) The air-to-water exponential impedance distribution and the discrete impedance value including 1layer, 2layers and 4 layers. (c)

The energy transmission of the water-air GIML containing 1 layer, 2 layers and 4 layers based on equal-thickness and variable-thickness layering method.

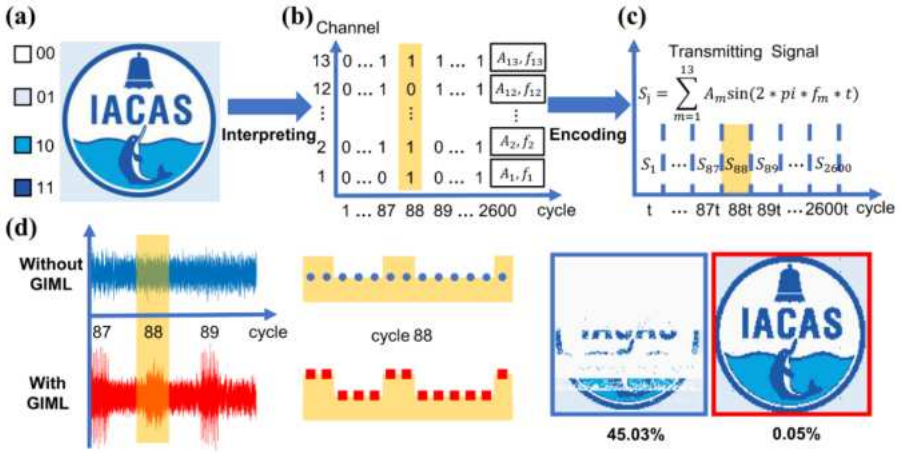

FIG. 2. (a) The transmitted picture including four different colors and 130*130 pixels. (b) The transmitted bit stream allocated to 2600 cycles and 13 channels. (c) The time-domain signal encoded by the bit stream. (d) Left panel: the received time-domain signals in 87th-89th cycle without and with the GIML. Middle panel: comparison between the target code (orange ladder) and the decoded results (circular and square) of the 88th cycle. Right panel: the received complete pictures without (blue frame) and with (red frame) the GIML. The percentages represent the bit error ratio in two cases.

With the broadband transmission enhancement ability between air and water, the proposed GIML is promising for applications in water-air acoustic transmission. Here, we use the designed GIML to realize the air-to-water acoustic communication. In this part, we aim to transmit the picture in Fig. 2(a) from air to water by frequency division multiplexing. The target picture has a size of 130*130 pixels and contains 4 different colors. The schematics of bitstream allocation and encoding are shown in Fig. 2(b) and 2(c), respectively. The bitstream is allocated to 2600 cycles. Each cycle contains 13 channels and is encoded to a time-domain signal. A time-domain sequence containing 2600 coded signals is emitted from the air and received in the water. The received signals were decoded by marking the target signal with a signal-to-noise ratio (SNR) over 20dB as "1" otherwise marking it as "0". The received transmission signals of the 87th-89th cycle are extracted and shown in the left panel of Fig. 2(d). It is obvious that the received picture through the bare interface can hardly be recognized with a bit error rate up to 45.03%, while the received picture through GIML is almost the same as the target picture with a negligible bit error rate of 0.05%. Thus, the broadband impedance matching between air and water can promote the applications in water-air acoustic communication.

optimization, as shown in Fig. 1(a), the transmission matrix takes on an anti-diagonal form, and the reflection matrix becomes nearly zero matrix, which indicates reflectionless transmission. To verify the mode conversion effect, we separately input three modes from the left side and observe the output modes. As shown in Fig. 1(c), the output modes align with our design objectives, confirming the successful mode conversion.

In summary, this study successfully achieves control over three waveguide modes under the same configuration of the complex medium. This work may have potential applications in advanced acoustic devices.

Abstract:
In this talk, I present an ultra-thin broadband acoustic metamaterial absorber for underwater acoustics. It comprises an optimal combination of Fabry-Perot resonators (FP) made of a low longitudinal sound speed tungsten-polyurethane composite that matches the water impedance.[1]

Contrary to electromagnetic waves, acoustic waves propagate in water with small attenuation.[2] Therefore, they have been exploited as an effective information carrier for underwater communications, positioning, searching, and other operations. In recent years, the emergence of acoustic metamaterials has led to new ways for manipulating sound waves. [3] However, underwater acoustics metamaterials have still not been actively pursued compared to airborne audible sound or ultrasound. The longer wavelength of underwater acoustic waves also usually implies thicker or larger devices for their manipulation. Moreover, underwater acoustic wave absorption is constrained by the causality law, which means that it requires very thick material to achieve high values of absorption.

The response of any passive materials backed by a rigid wall to an external wave must satisfy the causality constraint that relates the thickness of the sample d and its corresponding absorption spectrum $A(\lambda)$ [4]

$$d \geq \frac{1}{4\pi^2}\frac{B_{eff}}{B_w}\left|\int_0^\infty \ln[1-A(\lambda)d\lambda]\right| = d_{min}, \tag{1}$$

where B_{eff} represents the low frequency limit of composite's effective bulk modulus in the static regime and B_w denotes the bulk modulus of host medium. From Eq. (1), it can be seen that if we want to obtain thinner absorbers (i.e. smaller d_{min}) under the constraint of causality, we need to reduce the ratio of effective bulk modulus B_{eff}/B_w. For air, this is very difficult. However, for water, due to its particularly large B_w, it results convenient, and we can design as well as manufacture a composite material to achieve this goal.

In this work, we present a novel underwater metamaterial absorber made of a structured impedance-matched composite that can match the impedance of water. This absorber combines the features of being ultrathin (λ/42 at 4 kHz) as well as 'low-frequency' broadband absorption (from 4kHz to 20 kHz). Our composite is made of high-density tungsten powder dispersed in a low-modulus polyurethane (PU) polymer matrix. The resulting composite is structured into slender solid rods (**Fig. 1a**). With the pressure release boundary condition on its sidewalls, we can regard Young's modulus as its longitudinal wave modulus. This

composite material can significantly slow down the wave velocity, thereby realizing the goal of effective sound energy dissipation in the subwavelength regime. Simultaneously, reducing the composite's Young's modulus and increasing its density also ensures its impedance matching with water (**Fig. 1a**); and we can effectively increase its B_{eff}, to obtain a smaller d_{min} , while simultaneously achieving ultra-thin absorption samples. By combining the FP resonators in accordance to the integration scheme, 9 composite rods with different lengths have been combined into a unit (**Fig. 1a**), which exhibits periodical arrangement and placed on a rigid base to achieve the goal of broadband sound absorption.

Based on the above design strategy, we have successfully obtained our underwater sample (**Fig. 1b**) with ultra-thin thickness (averaged thickness only 8.9mm), realizing high sound absorption (>0.9) in the frequency range of 4-20 kHz (**Fig. 1d**), where the wavelength is much larger than its dimension. The result is demonstrated by both simulations, as well as experiments carried out in a large water pool (**Fig. 1c**). Results obtained from this work provide a novel direction for the design of underwater sound absorbers. Also, due to its ultra-thin design and broadband absorption, it has great significance in practical applications, not only in underwater sound but also in other acoustics fields.

Abstract: We propose a mechanism that can realize real-time and single-sensor ultrasonic imaging with ultra-low-cost using a disordered metasurface combined with a neural network. A single fixed sensor and a handcrafted metasurface with costs of much less than one dollar are proved sufficient to yield a high imaging quality.

Imaging using ultrasound is a frontier technique in modern science owing to its high penetration and biocompatibility, with pivotal significance in many applications ranging from crack detection to biological tissue imaging[1,2]. However, existing ultrasonic imaging technologies either allow real-time imaging but lack single-sensor imaging capability[3], or enable single-sensor imaging but do not support real-time imaging[4]. Consequently, real-time single-sensor imaging with low cost, whether in the realm of optics or acoustics, represents a formidable challenge that remains largely unresolved to this day. To overcome the above fundamental limitations, we propose and experimentally demonstrate a mechanism for real-time ultrasonic single-sensor imaging based on the coalescence of artificial structure and artificial intelligence (AI), which features fast imaging speed, low-cost fabrication, compact system size, and high imaging quality. In our proposed mechanism, a single fixed transducer emits a broadband ultrasonic signal, which passes through the object and the disordered metasurface in succession before being received by a single fixed sensor. Utilizing the rich complexity arising from the random parameter distribution and strong dispersion characteristics, a disordered metasurface can effectively encode the information of the objects' scattered field by changing the amplitude of the spectral components at every spatial point and then transmit it to a single fixed sensor. By harnessing the remarkable learning and feature extraction abilities of neural networks, the encoded signal captured by the sensor can be utilized to quickly reconstruct the geometry of the original object even in the absence of prior knowledge regarding the metasurface's internal structure and material parameters, which greatly facilitates the fabrication of the whole system. Therefore, our mechanism achieves the effects of a structurally complex and expensive phased array and multi-sensor imaging system, using only a single sensor and a piece of cheap metasurface.

Chiral and hyperbolic metamaterials

Dielectric metasurface for wave-vector variant and circular polarization dependent transmission

H. Wetter[1*], W. Gao[2], F. Rehberg[1], J. Wingenbach[1], S. Schumacher[1,3] and T. Zentgraf[1,3]

Abstract: We study a silicon metasurface consisting of sinusoidal sidewall waveguides where near-field coupling of local resonances causes negative coupling. This gives rise to fully circularly polarized radiational eigenstates that form a line in k-space. The corresponding metasurface provides wave-vector variant and spin-selective transmission.

Chiral metasurfaces exhibit unique optical properties towards circularly polarized light. Among the various metasurfaces investigated previously [1], some possess points with circular polarization in momentum space. Here, we present a metasurface in which the eigenstates of circular polarization not only occur at one point, but form a line in momentum space.

The corresponding metasurface consist of silicon waveguides on a glass substrate that are embedded in PMMA to approximately create a homogenous environment. The unit cell (see Fig. 1(a)) contains a single waveguide (SW) and double waveguide (DW) depicted in gray and blue, respectively. The sinusoidal modulation of the width enables coupling to the continuum photon states in the ambient environment thus radiation. Since the waveguides are placed in close proximity, the localized mode in the SW and the spatially odd mode in the DW couple. When these modes are degenerate, their near-field coupling results in alternating positive and negative coupling. From the real-space tight-binding Hamiltonian one can derive that this coupling pattern allows a $\pi/2$ phase delay that is crucial for circular polarization. [2]

Based on this concept, the parameters of the metasurface are tailored such that circularly polarized eigenstates emerge forming a line in momentum space (C-line). This C-line emanates from the Dirac point and possesses opposite helicity for the two energy levels (see Fig. 1(b)). The Dirac point itself presents a polarization singularity and the point at which the helicity of the C-line switches. As a result, the helicity can be switched by changing either the energy level or the sign of k_x (wave vector component along x).

This is demonstrated in figure 1(c) which shows the simulated transmission spectra for incident right- and left-polarized light (dashed and solid line, respectively) as well as for two different values of k_x (blue and black). A dip to approximately zero occurs when the incident light matches the polarization and frequency of an eigenstate. If the sign of k_x is changed, the helicity of the lower/higher frequency resonance switches. Additionally, a higher absolute value of k_x corresponds to a larger frequency difference. Both effects are consistent with the eigenstates in figure 1(b).

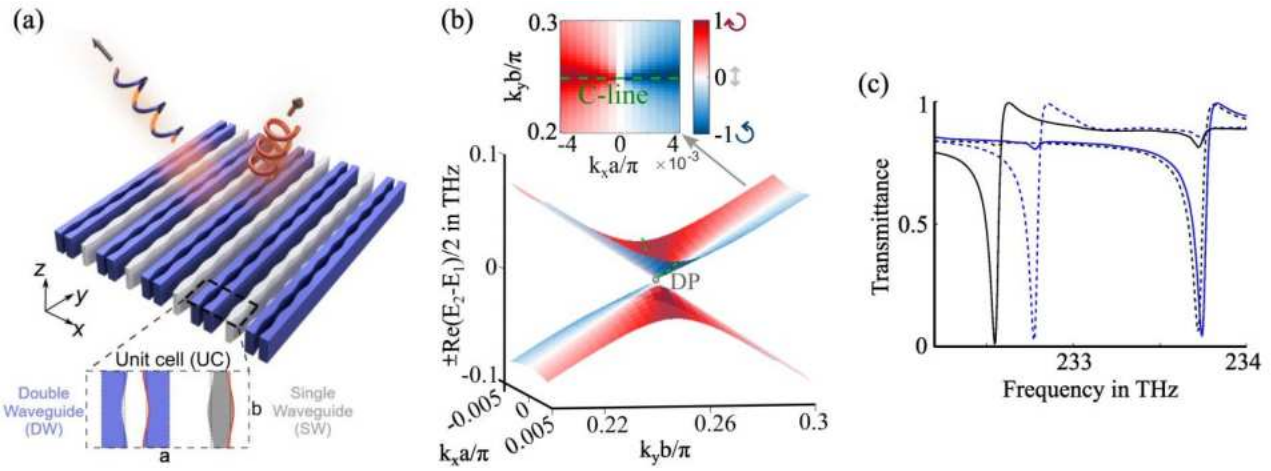

Figure 1: (a) Metasurface consisting of silicon waveguides with sinusoidal modulation and corresponding unit cell from [2]. (b) Eigenfrequencies around the Dirac point (DP). The color corresponds to the eigenpolarization of the corresponding state. Dark blue and red corresponds to left and right circular polarization, respectively, white to linear polarization and the lighter colors cover all degrees of elliptical polarization. The inset shows the eigenpolarization of the upper energy level in momentum space where the C-line is apparent. (c) Simulated transmission spectra for incident right (dashed line) and left circularly polarized light (solid line) and for $k_x a/\pi=0.08$ (blue) and -0.1 (black). For all spectra $k_y b/\pi=0.25$ holds according to the C-line.

Abstract: We present an analysis of electromagnetic surface waves localized at the interface of a one-dimensional semi-infinite photonic crystal with gyroelectric and hyperbolic layers. Starting with a single interface, we explore the influence of gyrotropy and other media parameters on the behavior of the surface modes, demonstrating non-reciprocal dispersion characteristics. In the case of multilayered structures, the investigation reveals also the existence of modes with negative group velocity and instances of high values of Goos–Hänchen Shift.

Electromagnetic Surface Waves (ESWs) have gathered attention since the work of Jonathan Zenneck in 1907. Surface modes can exist under certain conditions on a surface bounded by air, or at the interface separating two semi-infinite half-spaces. Among the most remarkable examples of ESWs there are Surface Plasmon-Polaritons (SPPs) and Zenneck Waves (ZWs). The latter can propagate along the interface between a lossless dielectric and a lossy one and, like SPPs, have a TM nature. Their most peculiar features are the attenuation in the in-plane direction – caused by absorption in the lossy medium – and a tilt of the field distribution with respect to the normal to the interface. ESWs can indeed propagate in multilayered systems, and within photonic crystals (PhC), Tamm Waves and Bloch Surface Waves[1] emerge as particularly notable examples.

When the system is subjected to an external magnetic field, thereby breaking time-reversal symmetry, certain types of media may demonstrate non-reciprocal features that significantly influence the propagation of Electromagnetic Surface Waves (ESWs). In the presence of gyrotropy, the dispersion relation of ESWs typically becomes asymmetric with respect to the reversal of the in-plane wavevector.

In this work, we present a theory describing ESWs localized at the interface of a one-dimensional PhC comprising gyroelectric and hyperbolic layers. We start by analyzing Electromagnetic Surface Waves (ESWs) localized at the interface between a Gyroelectric Material (GM) and a Hyperbolic Medium (HM)[2]. We explore the conditions for the existence of this surface mode, which are determined by the media parameters, the operating frequency, and the orientation of the principal axes of the HM (refer to Figure 1, panel A). Our findings reveal that the anisotropy of the HM leads to a tilted behavior in the field lines of the mode, reminiscent of the Zenneck Wave observed in lossy metals (as illustrated in Figure 1, panel B). Additionally, we demonstrate that gyrotropy imparts non-reciprocal dispersion characteristics to these waves. Furthermore, we numerically simulate a specific gyroelectric-hyperbolic interface, consisting of InSb and a stack of graphene layers, which is amenable to the observation of such novel modes. In this scenario, the dispersion relation along the surface is not reciprocal when the in-plane wave vector is reversed, as evidenced by the reflectivity spectra (as depicted in Figure 1, panel C). Remarkably, the propagation length of these waves can extend to several millimeters in such configurations, rendering them suitable for various applications in photonic devices.

We subsequently analyze what happens to such ESWs when the structure becomes a semi-infinite 1D PhC, composed of gyrotropic and hyperbolic layers. Our investigation reveals that, among these waves, some exhibit either forward or backward propagation characteristics, as shown in Figure 2 panel A, depending on the specific type of hyperbolic medium involved. Importantly, we demonstrate that the surface waves under scrutiny inherit key properties from both bulk plasmons and Tamm Waves, underscoring their unique potential in the realm of photonics. When gyrotropy is introduced into the system, the photonic bands are quantitatively and qualitatively

modified (as shown in Figure 2, panel B). We also provide a numerical analysis of a finite system, composed of a few dozen periods, where such effects can be found by looking at the reflection spectra. In this configuration, we show that near-zero values of the reflection coefficient correspond to non-trivial values of the Goos–Hänchen Shift (as illustrated in Figure 2, panel C).

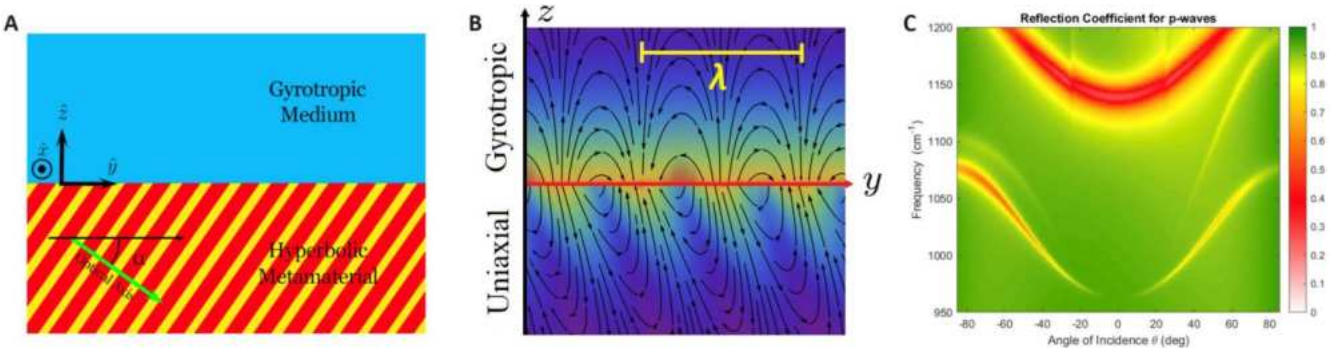

Figure 1: (A) Scheme of the GM-HM interface; (B) Typical electric field lines of a TM mode that propagates along the interface: the lines in the HM have a tilted behavior, which recalls the characteristic profile of ZWs, even though no lossy dielectric functions were involved in our theoretical calculations; (C) Simulated reflectivity spectra in the Otto configuration as a function of the angle of incidence for a realistic case including absorption: notice the non-reciprocal behavior manifested by the asymmetry between opposite angles.

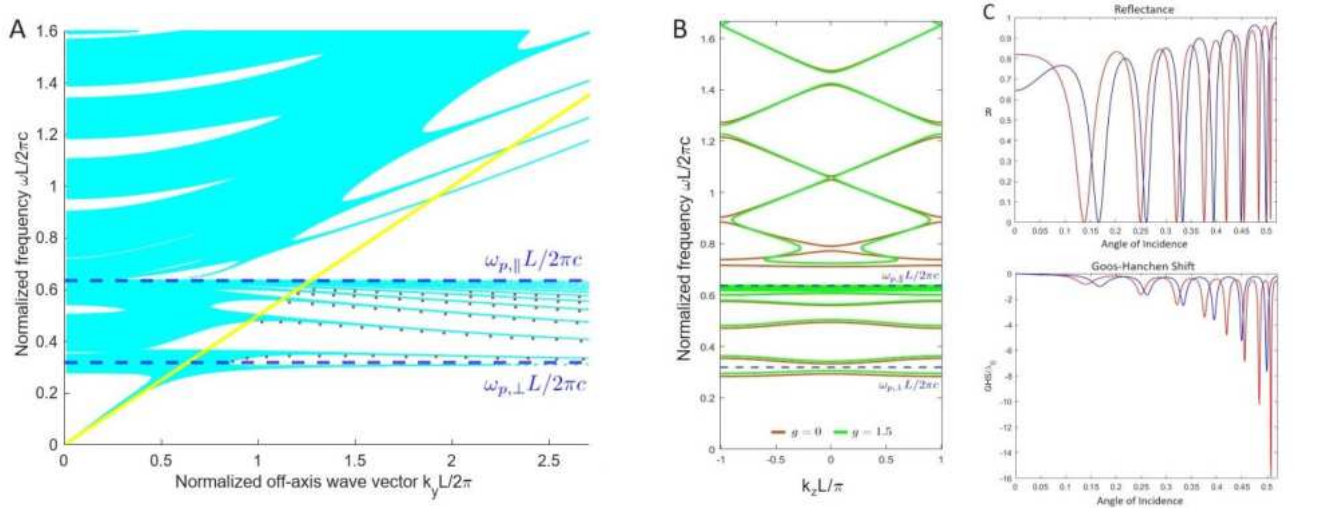

Figure 2: (A) Typical reduced band diagram for TM waves in a Gyrotropic-Hyperbolic PhC. The blue regions represent the bulk bands, the red dots represent the surface modes (propagating with negative group velocity) and the yellow line is the light line characterizing the isotropic half-space. (B) Band diagram relative to the k_y L / 2π = 1 slice in (A), where the red/green lines represent the bands without/with gyrotropy. (C) Reflectance and Goos–Hänchen Shift for a finite multilayered structure for two different values of the frequency, as functions of the incidence angle.

Abstract: We demonstrate the impact of anisotropy orientation on hyperbolic polaritons in quartz using attenuated total reflection. We reveal new insights into leaky and ghost hyperbolic polaritons, including their directional dependency and associated cross-polarization conversion. This highlights their potential to transform direction-dependent optical device development for next-generation sensing and communication technologies.

In natural crystals such as quartz, anisotropic phonon resonances in the infrared can lead to principal elements of the diagonal permittivity tensor possessing opposite signs. This, in turn, leads to hyperbolic dispersion [1]. Hyperbolic materials are great candidates for controlling light at the nanoscale, owing to their strong electromagnetic field confinement and reconfigurable anisotropy orientation. They have been shown to support surface polaritons with long-range and low-loss propagation of subwavelength information, guided waves, and negative refraction [1,2,3,4].

Hyperbolic dispersion is commonly referred to as type I when a single extraordinary component of the dielectric tensor is negative while the two ordinaries are positive, creating a two-sheet hyperboloid isofrequency contour. Conversely, when the extraordinary component is positive while the two ordinary components are negative, an open-sheet hyperbolic isofrequency contour forms, known as type II dispersion [1]. Quartz possesses two hyperbolic regions between $400\text{-}600\ \mathrm{cm}^{-1}$; a type II region between $450\text{-}480\ \mathrm{cm}^{-1}$ and a type I region between $510\text{-}550\ \mathrm{cm}^{-1}$.

Close to these frequencies, there are three wave phenomena that have recently gained significant attention: surface, leaky, and ghost hyperbolic polaritons. Surface polaritons are perhaps the simplest of these effects; being waves that travel at the surface of materials [1]. On the other hand, leaky hyperbolic polaritons (LHPs) have been classified as the hybridization between a propagating bulk mode and a surface wave, noted for their radiation leakage as well as long-range directional and sub-diffractive propagation at interfaces and ghost hyperbolic polaritons (GHPs) possess slanted phase wavefronts into the bulk of the crystal, parallel Poynting vectors to the surface, and exponential decay away from the surface. Unlike surface polaritons, which emerge when the dielectric constant is negative, LHPs [4] are typically associated with type I hyperbolic dispersion and GHPs [3] with type II hyperbolic dispersion.

Between the two hyperbolic regions in crystal quartz ($480\text{-}510\ \mathrm{cm}^{-1}$), all elements of the dielectric tensor are negative, meaning that surface polaritons are supported. To probe these experimentally, we employ attenuated total reflection (ATR) in the Otto configuration [1], where a prism is placed close to the sample surface, separated by a thin air gap. Total internal reflection occurs at the prism-air interface, allowing for the excitation of surface polaritons on the sample surface. We find that the frequencies supporting these surface polaritons between the hyperbolic regions vary significantly depending on the orientation of the anisotropy axis with respect to the crystal surface. When the anisotropy is aligned parallel with both the crystal surface and incidence plane, surface

polaritons are excited at a frequency around $505\ \mathrm{cm}^{-1}$. When rotated so that the anisotropy is perpendicular to the incidence plane (but still parallel to the crystal surface), this excitation frequency is shifted to lower frequencies around $475\ \mathrm{cm}^{-1}$.

Furthermore, we find that LHP manifests with the characteristic lenticular dispersion [4] emerging in ATR spectra, as the high-k_x modes intersect with the free-space light cone (FSLC). Close to the Epsilon-near-zero region at frequencies higher than the type-I hyperbolic region, the existence of the LHP is highly dependent on azimuthal orientation of the crystal anisotropy axis. In addition, we find that the cross-polarization conversion [2] associated with LHPs becomes significantly asymmetric if the anisotropy axis is no longer parallel to the crystal surface).

Finally, we find that for the GHPs a sharp drop in reflectivity is observed for a wide range of incident angles and azimuthal orientations, mirroring the original s-SNOM observations of this phenomenon [3]. We find that cross-polarization conversion associated with GHPs is broadly symmetric and less extreme than that due to the LHPs. When the anisotropy is tilted so that is no longer parallel to the crystal surface, the GHP excitation diminishes significantly as the reflectivity increases.

This new understanding of the anisotropy orientation's impact on quartz's reflective properties, including surface polaritons, LHPs, and GHPs at infrared frequencies, opens avenues for application in sensing and communications. Additionally, employing crystal quartz's reflective properties in the far-field simplifies access to these phenomena, offering a more accessible alternative to the complex and costly near-field methods like s-SNOM. We demonstrate the potential of utilizing these phenomena across a broad spectral range, highlighting their significance for innovative optical device development.

Abstract: Our proposed single-layer metasurface structure, integrating three dielectric cylinders based on a Mie resonator with a strong electric dipole mode. This design achieves a circular dichroism enhancement of 0.67 and an optical activity enhancement of 1.16×10^6 °/mm, confirmed through simulation to validate its tailored chiral optical effects.

Chiral structures lacking inversion symmetry (cannot be superimposed) exhibit optical properties such as circular dichroism and optical activity. Consequently, chiral structures are being studied to produce thin waveplates, circular polarizers, and chiral sensors [1].

Mie scattering occurs when the size of the structure is comparable to the wavelength of light, leading to strong Mie resonance, such as electric dipole (ED) and magnetic dipole (MD) modes. Dielectric-based Mie resonators have good responsivity with negligible absorption losses. Therefore, recent research has focused on metasurfaces to control the spectral, wavefront and polarizations [2-3]. Mie resonance-based dielectric chiral metasurfaces typically feature multi-layered or complex shapes to achieve high reactivity [4-5]. In contrast, we propose a metasurface consisting of three dielectric cylinders with ED modes, demonstrating high chirality despite its simple and single-layered structure.

As shown in Figure 1. (a), our chiral metasurface consists of three cylinders of different radii, which we refer to as C1, C2, and C3 in order of increasing radius. These cylinders (n=3.48) are arranged in an equilateral triangle configuration on a substrate (n=1.45) in a counterclockwise direction, with the cylinders organized by increasing radius. All cylinders exhibit ED modes at distinct wavelengths. When considering C1, C2, and C3 in order of increasing radius, cylinders C1 and C3 demonstrate ED resonant wavelength at 1400 nm and 1600 nm, respectively, relative to the target wavelength of 1500 nm C2, as depicted in Figure 1. (b). As indicated in Figure 3. (c), the ED phase of each cylinder increases with the radius, leading to varying responses to LCP and RCP light.

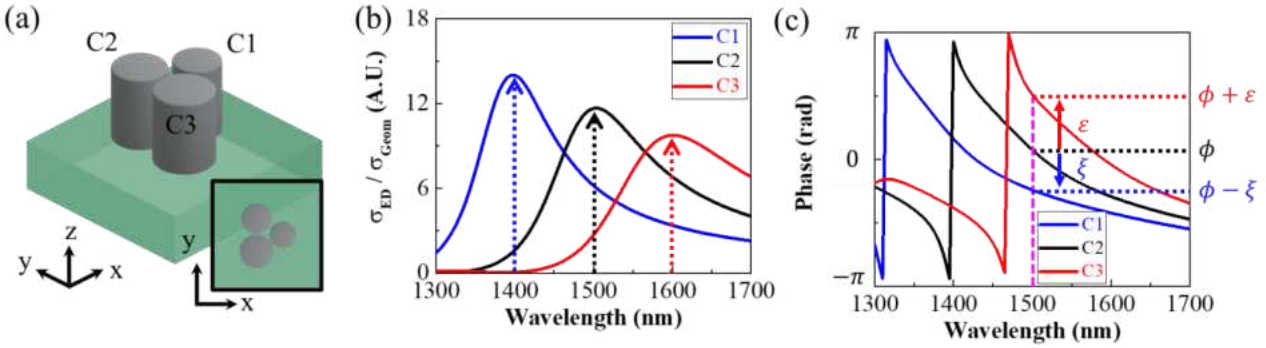

Figure 1. (a) Schematic diagrams of a chiral unitcell, each featuring three dielectric cylinders (C1, C2 and C3) with different radii above the substrate. (b) Normalized electric dipole (ED) scattering cross-section and (c) ED phase of each cylinder as function of incident wavelength.

The optical chirality of our chiral metasurface can be observed in Figure 2. Panels (a) and (b) illustrate the transmittance when LCP and RCP light are incident on the cylinder from the substrate (+z direction) and show the difference between them. Transmittance differences are observed between 1400 nm and 1600 nm, corresponding to the resonance wavelength of each cylinder, with a maximum variance (Circular dichroism) of about 0.67 at 1520 nm, near the target wavelength. Figure 2. (c) shows the variation in polarization angle and ellipticity of the transmitted wave when a linearly polarized (Ex) field is incident in the +z direction. Similar to the previous result, we can observe that the value varies between 1400 nm and 1600 nm, and we confirm that the maximum optical activity of our chiral metasurface is equal to 1.16×10^6 °/mm.

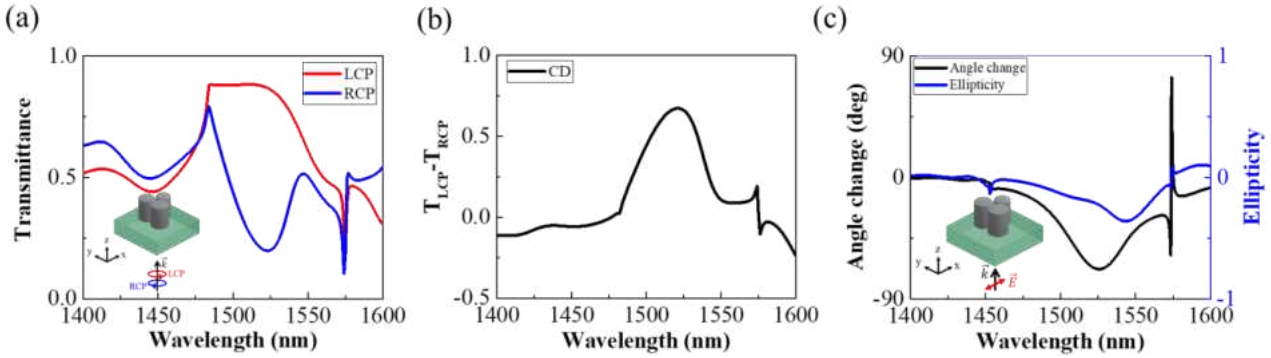

Figure 2. (a) The transmittance, (b) its difference (circular dichroism; CD) and when the left and right polarized light are incident on a chiral metasurface in the +z direction. (c) The change in polarization angle and ellipticity of the transmitted wave when linear polarized (Ex) planewave is incident.

We enhanced the chirality by arranging three dielectric cylinders in a counterclockwise direction, each with sequentially increasing resonance wavelengths of the ED, consequently altering the effective index of the structure effective index of the structure along with the direction of circular polarization. Despite being a single-layered dielectric structure, our chiral metasurface exhibits strong chirality, and we anticipate its potential applications as an ultrathin circular polarizer filter, chiral censor, and waveplate. Additionally, it is expected that adjusting the direction, shape, number, and spacing of the multi-cylinder structure within the unit cell can provide further flexibility.

Unidirectional mode excitation due to magnetochiral effects

Hiroyuki Kurosawa[1*], Keisuke Itoh[2], and Tetsuya Ueda[1]

[1]Kyoto Institute of Technology, Japan

Abstract: A numerical study shows that a single metamolecule with magnetism and chirality exhibits unidirectional mode excitation in a waveguide at microwave frequencies. The directionality has a linear response to the magnetization and the chirality, indicating that the anisotropy of the mode excitation originates from the magnetochiral effects.

Broken symmetry plays a crucial role in physics. Broken time and space inversion symmetries are given by magnetism and chirality, and coupling between them brings about magnetochiral (MCh) effects known as directional dichroism for unpolarized waves [1, 2]. The MCh effects in natural materials are generally very weak but metamaterials strongly enhance the effects [3, 4]. In previous studies, the MCh effects in metamaterials are characterized by the difference in transmittance due to the directional dichroism for unpolarized waves. Due to reciprocity, the absorption is equal to the emittance, indicating that it is possible to control the radiation direction of an emitter by the MCh metamolecule. However, the directional radiation due to the MCh effects has not been demonstrated up to now. In this work, we demonstrate that an MCh metamolecule incorporated with a microwave source exhibits directional waveguide mode excitation.

Figure 1(a) shows the schematic of the metamolecule comprising of three dielectric cubes and a ferrite rod. The cubes are spirally arranged and give chirality, whereas the rod is under an external magnetic field along the z-axis and gives magnetization. This metamolecule is placed at the center of a WR-187 waveguide and its transmission characteristics are calculated by numerical simulations. Figure 1(b) shows the calculated transmittance under the external magnetic field of +390 mT. There are dip structures corresponding to the cavity modes of the cubes. We focus on the lowest mode around 3.97 GHz. The depth of the dip depends on the propagation direction of the waveguide mode, which originates from the directional dichroism. A magnetic

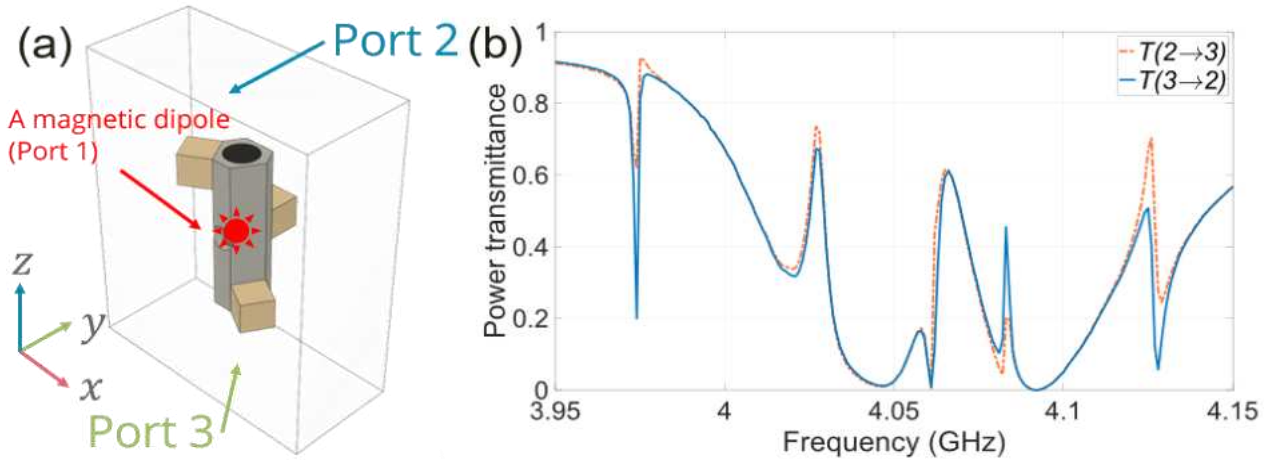

Fig.1: (a) A schematic of the metamolecule. (b) Power transmittance of the metamolecule in the waveguide.

dipole oscillating along the *x*-axis is placed at the center of the metamolecule. We evaluate the anisotropy of the waveguide mode excitation by integrating the absolute value of the z component of the Poynting vector over Ports 2 and 3. Figure 2(a) shows the radiation power spectra. Around the frequency of 3.94 GHz, the power spectra have a peak that corresponds to the sharp dip in the transmittance. There is a significant difference in the radiation power.

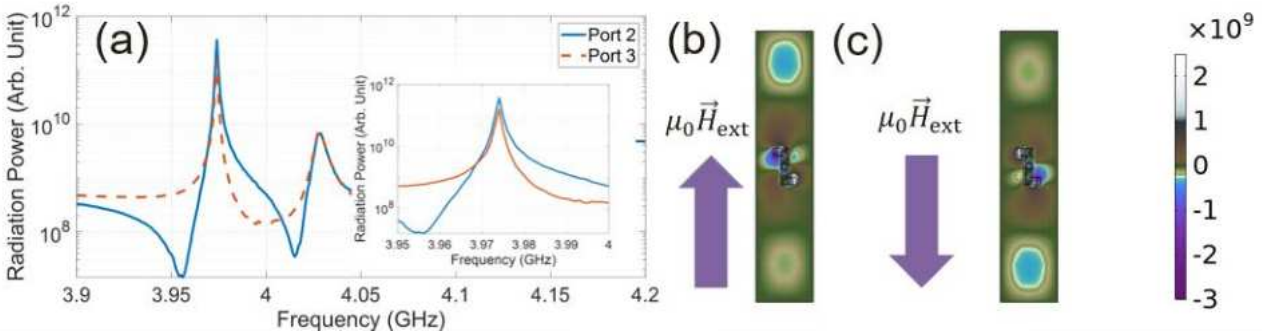

Fig 2: (a) Radiation power spectra of the metamolecule. Electric field distributions at 3.974 GHz under positive (b) and negative (c) external magnetic bias field.

To confirm that the mode excitation is directional, we show the field distributions in the waveguide. Figure 2(b) shows the electric field distributions at 3.97 GHz, where the difference in the radiation intensity is maximum. The metamolecule excites the waveguide mode of TE_{10} and there is a large difference in the excitation intensity between the propagating and counter-propagating modes. The field distribution pattern is reversed following the reversal of the direction of the external dc magnetic field (Fig. 2(c)). We also confirm the reversal of the pattern following the switch of the chirality of the metamolecule from right to left (not shown). These features indicate that the anisotropy of the mode excitation has a linear response to the magnetization and the chirality, and the directional mode excitation originates from the MCh effects.

In summary, we have demonstrated unidirectional mode excitation by a single MCh metamolecule in a waveguide. The metamolecule comprises spirally arranged dielectric cubes giving chirality and a ferrite rod giving magnetization, exhibiting the MCh effects. Due to reciprocity between absorption and emittance, the radiation power from the magnetic dipole in the metamolecule depends on the propagation direction. The field distribution of the waveguide mode has a linear response the magnetization and the chirality, indicating that the directional excitation of the waveguide mode originates from the MCh effects. This study paves the way for the control of directional excitation of a waveguide mode by a single MCh metamolecule.

Abstract: This paper introduces an end-to-end design framework for constructing a broadband achromatic metalens, corrected across 5 equispaced frequencies within the long-wavelength infrared (LWIR) spectrum (8 μm to 12 μm). We combined nanophotonic hardware with computer-vision reconstruction networks, realizing a mean absolute error (MAE) of 0.035 over test dataset.

Flat-optic metalenses offer advantages over conventional lenses, including reduced physical dimensions, minimal optical absorption, and highly customizable amplitude, phase, and polarization [1,2]. In designing achromatic metalenses, traditional approaches predominantly optimize the structure guided by numerical objectives such as focusing efficiency, modulation transfer function (MTF), field of view, and depth of field [3,4]. However, these methods fall short of considering the critical aspect of an imaging device, that is, the image quality. In response to this issue, recent studies have adopted end-to-end methodology to include image post-processing techniques in the design cycle [5]. As the optimization objective is set as the pixel loss of the scene and processed image, these systems are able to retire non-intuitive metalens building blocks and improve the imaging performance.

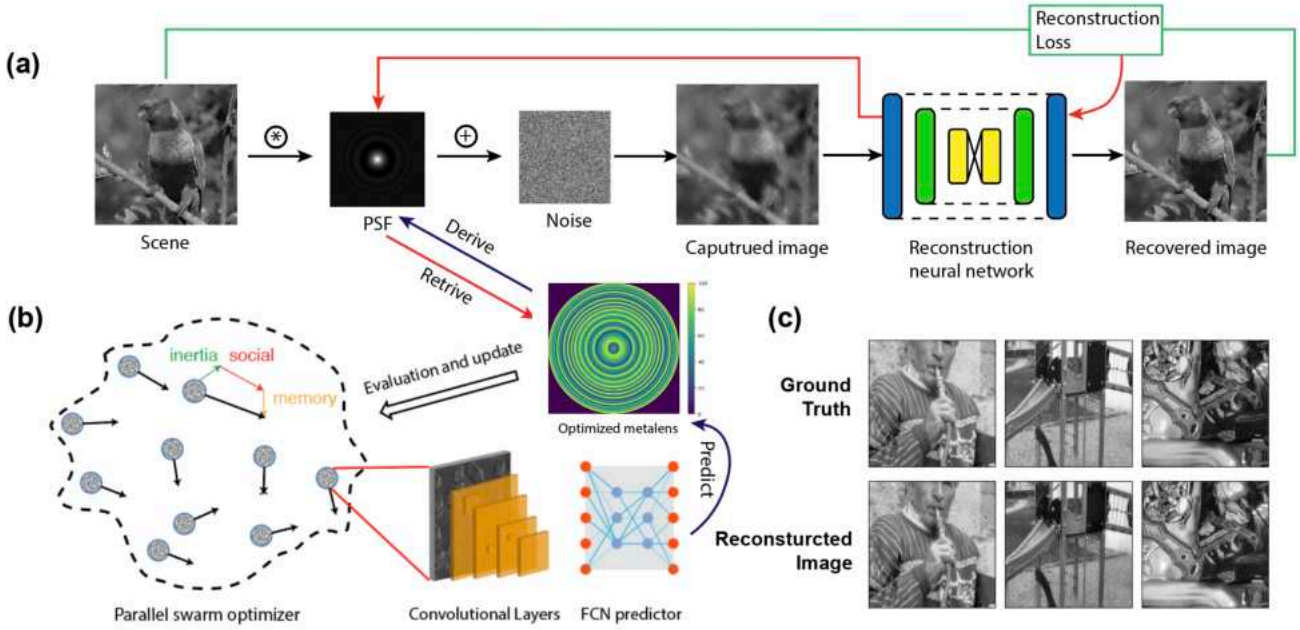

Fig.1. (a) The proposed end-to-end metalens optimization framework. (b) Parallel swarm optimized for the design of nanophotonic structure. (c) Examples of the input test image and the reconstructed output.

One challenge of current end-to-end metalenses is the trade-off on computational efficiency over simulation precision. Simplified models such as the P-B phase [6] or polynomial fitting [7] are frequently used in current metalens studies, and that often causes a drop between the design and the physical world. This work addresses the challenge by building a first-principle end-to-end design framework. Figure 1a shows the workflow of the proposed framework. We employ a unique combination of universal light encoders and finite-difference time-domain (FDTD) simulations to inversely design complex metasurfaces. During each step of optimization, we simulate the light propagation via convolving the point spread function (MTF) calculated from the metalens phase response. A sensor then captures the intensity patterns and transfers them into digital data. We train a reconstruction network based on the U-net backbone that first extracts essential features of the sensor image and reconstructs the scene image. The model defines MAE reconstruction loss indicating the similarity between the network output and the original scene. The loss is propagated through the reconstruction network, the PSF, and the metalens phase profile at the end of each step.

Illustrated in Fig.1b, we employ a parallel swarm-based open-source inverse design software ALFRED [8]. To accelerate the parallel swam search, we trained a phase prediction network on 60000 FDTD simulation results to generate phase delay data on the evolved nanostructures. The model is optimized on 5 equispaced wavelengths from 8 µm to 12 µm. Figure 1c visualizes the imaging performance after 1500 steps of training. The framework achieved an MAE = 0.035 over the test dataset.

Free-form inverse design of dynamically tunable metamaterial absorber for Mid-Infrared applications

Ram Prakash S[1*], Aastha Jain[1], Rajesh Kumar[1] and Anirban Mitra[1]

[1]Depratment of Physics, Indian Institute of Technology Roorkee, Uttarakhand, India
[*]Corresponding author: rprakashs@ph.iitr.ac.in

Abstract: This work presents a free-from inverse design of a dynamically tunable metamaterial absorber using a phase change material. The proposed inverse design is based on a neural-adjoint optimization method using a Wasserstein generative adversarial neural network (WGAN) to predict tunable metamaterial design for the desired absorption spectrum in the mid-infrared region.

Introduction

Designing a tunable metamaterial absorber in the mid-infrared region is crucial due to its application in molecular detection, chemical sensing, thermal imaging, and heat scavenging [1]. Chalcogenide phase change materials (PCM) are very attractive for use in MIR photonic applications due to their non-lossy nature in this regime. Furthermore, PCMs such as $Ge_2Sb_2Te_5$ (GST) show very refractive index contrast with phase change [2]. Thus, the absorption spectra can be dynamically tunable by incorporating GST in the metamaterial absorber structure. The inverse design of the nanophotonic structures is a much-needed technique for fast and accurate prediction of the design parameters for a desired spectral response. Recently, deep learning techniques have shown great promise for the inverse design of metamaterials for various photonic applications [3]. In this work, we present a deep learning-assisted free-form inverse design of a tunable metamaterial absorber operating in the MIR region.

Results and Discussion

The metamaterial absorber structure comprises a top gold periodic nanostructure and a bottom Au mirror. GST is used as the spacer layer. The phase change of GST is used to achieve the dynamically tunable MIR absorber. The period of the unit cell is fixed at 3 um, and the thickness of GST is 140 nm. The top nanostructure layer is divided into an 8X8 symmetrical grid, with each cell taking a random value of 0 or 1. Here, 0 means the presence of Au, and 1 means vacuum. The thickness of the top Au nanostructures is taken to be 200 nm. The finite difference time domain method (FDTD) is used to get the reflection spectrum of the metamaterial absorber [4]. Overall, we simulated 13,000 random nanostructure designs and their corresponding reflection spectrum for the training of the deep neural network. The dataset consists of absorption spectra of a given random design when GST is in the amorphous and crystalline phase.

The full inverse neural network (INN) encompasses two networks: 1) The forward network maps the design to the optical response, i.e. the absorption spectrum and 2) The generative network, which trains on the design parameters of the metamaterials alone. The latent vector of such generative networks represents a learned parameterization of the design. In this work, we use the Wasserstein generative adversarial neural network (WGAN) as the generator network to re-parameterize the image-based geometries into a regularized latent space. The WGAN network consists of two parts. The first part is the generator, which takes the latent variables as the input and the design as the output. The second part is the discriminator, which generates fake designs and

predicts whether the geometry is fake or true. Here, the discriminator output will be trained with a Wasserstein distance loss function as it offers a stable and more robust convergence. Finally, the geometry for a desired spectrum when GST is in the amorphous phase can be obtained by using gradient descent – neural adjoint method. The use of the WGAN as the generator ensures that during the gradient-based optimization method, the design predicted remains in the forward model's interpolation region, thus avoiding the risk of converging toward a non-physical solution.

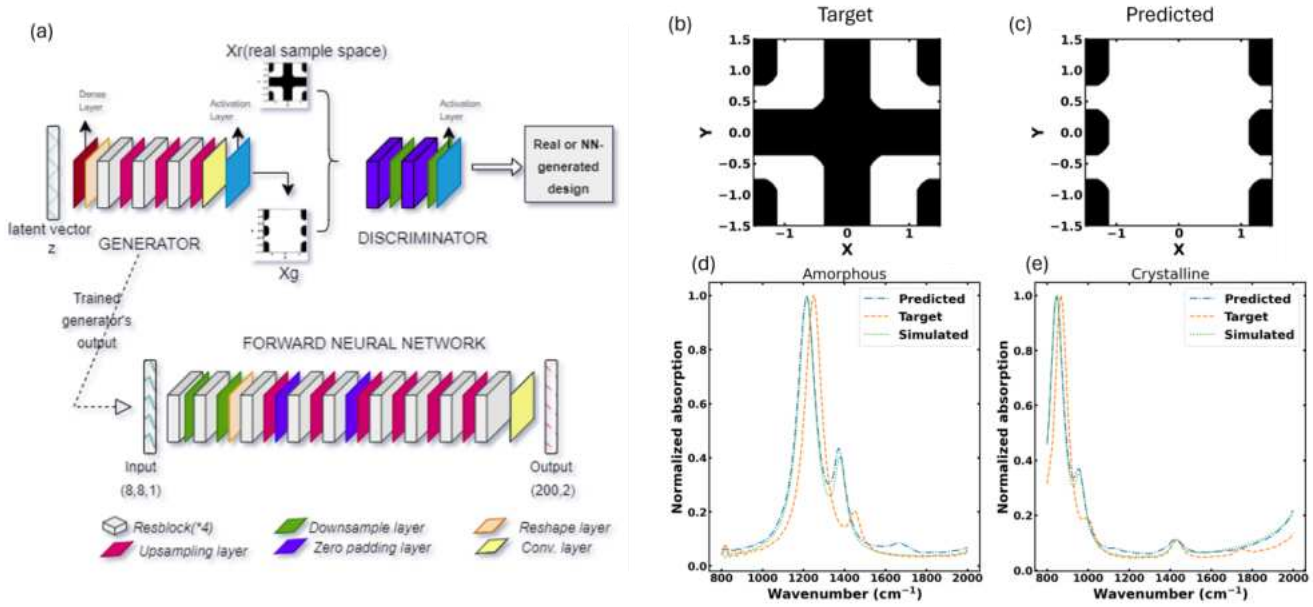

Figure 1: a) Schematic representation of the Inverse neural network. Comparison between (b) target and (c) predicted design by the INN. The predicted, target and the FDTD simulated absorption spectrum when GST is in d) Amorphous and e) crystalline phase.

The design and the corresponding spectrum predicted by the proposed INN are shown in Figure 2. It is seen that a given target spectrum produces a design which is different from the target design. Furthermore, it is noted that the spectrum predicted by the INN matches well with the FDTD-simulated spectrum in both phases of GST. Thus, the above results show that the proposed INN can predict the geometry for any desired absorption spectrum in the MIR region. Furthermore, the use of GST in the structure allows for the tunability of the absorption spectrum thus, we can achieve a dynamically tunable absorber in a wide MIR spectral region.

Abstract. In this work we propose a new methodology to inverse design for the development of high-efficient wafer-scale wavefront engineering structures using direct experimental fabrications without a need of costly first-principle simulations. We illustrate the efficiency of this approach by training the model to accurately predict flat-optics transmission and reflection responses, resulting in a nearly ten-fold reduction in the validation root-mean-square error compared to the model trained with first-principle simulations.

Summary. Experimental Machine Learning (EML) is a recent development of Machine Learning (ML) that leverages scientific experimentation to design, train, and evaluate ML models [1], [2]. This approach gathers substantial interest as it provides a universal platform to train ML models as close to experimental outcomes, delivering human-level predictions in real-time. Experimental ML generates comprehensive training datasets for adaptive ML systems that dynamically adjust to changing environments and automatically update. These adaptive models combine traditional ML with dynamic optimization algorithms, such as Reinforcement Learning (RL) and population methods, which allows agents to learn from their interactions with the environment and improve their performance over time.

Experimental ML impacts major disciplines such as chemistry [3] and robotics [4]. In chemistry, experimental ML accelerates the discovery of new materials, drugs, and catalysts, keeping track of and optimizing their performance dynamically as the reaction progresses. In robotics, EML trains intelligent systems to perform complex tasks by learning from their interactions with the environment. It allows these systems to adapt to changing conditions, such as the appearance of new objects in their environment or changes in the terrain.

Nanophotonics leverages ML for the inverse design of photonic circuitry supporting broad functionalities depending on many constraints, including working bandwidth, fabrication tolerances, and complete vectorial control on the output material response [5]–[8]. These approaches focus on ML software models, including neural networks[7], [9], decision trees, Gaussian processes[10] and Bayesian inference [11]. ML models leverage approximate solvers trained on pre-defined structures datasets to predict spatial and spectral material responses, including transmission and reflection.

To deal with constraints imposed by available computing resources, current inverse design models employ periodic boundary conditions, devising smaller unit cell structures replicating on larger areas [12]. While this approach reported advances in the implementation of devices that do not possess sharp differences among neighboring units, it does not scale up unit cell design beyond hundreds of micron squares. Enhancing these performances is a significant opportunity to leverage advances in experimental nanophotonics circuitry, which permit aperiodic nanostructuring with nanoscale control over single wafers. Current nanolithography techniques support dense photonic integration with features as small as 20 nm, corresponding in one-millimeter square to over 2 billions light processing units, surpassing current electronics of one order of magnitude [13]. A large-scale universal aperiodic inverse design platform that leverages the nanophotonics density available could open classes of photonics circuitry with considerable complexity for light control [5], for operations including matrix-vector product [14], spectral encoding [5] and privacy-preserving imaging [15].

This study addresses the challenge of large-scale aperiodic inverse design in nanophotonics by developing a photonics platform for experimental machine learning. We composed a 10 million distinct experimental photonic structures dataset, producing the largest publicly available dataset for flat-optics design that outperforms the closest competition by a factor of 20 [7]. It is worth noting that acquiring a similar dataset with first-principle simulations would require an estimated 200 million core hours at a rate of 20 core hours per structure. However, by producing the dataset experimentally, we obtained the required data in just 4 electron beam lithography sessions, with a speed of 1 million samples per 12 hours. We estimate an upper bound of 7.2 ms per single structure for the total rate of both sample production and characterization, which is 15000 times faster than parallel 3-dimensional FDTD simulations obtained with 512 cores of KAUST's Shaheen supercomputer. The characterization is done by using a tunable filter to illuminate a portion of the chip with the geometries with a single wavelength and, through a monochrome camera, acquire the response of more than 100 thousand different geometries in a single frame.

Since we obtained the dataset experimentally, it inherently accounted for any differences in responses between simulated and actual structures caused by variations in refractive index, nonlinear optical effects, or fabrication biases. Using this dataset, we train the model to accurately predict flat-optics transmission and reflection responses, resulting in a nearly ten-fold reduction in the validation root-mean-square error compared to the model trained with first-principle simulations, from 0.012 to 0.0018 root-mean-square error (RMSE).

In addition, we allocate a subset of 4 million samples from the dataset to the design of aperiodic structures. With this subset, we develop a fast and efficient inverse design framework called i-ALFRED, which is capable of designing aperiodic structures on a point-to-point basis while taking into account the information about their closest neighbors. We illustrate the framework's performance by designing a 3x3 mm aperiodic structure with pre-defined random responses, achieving an experimental RMSE of 0.0032.

Artificial intelligence optical hardware empowers real-time ultra-sensitive detection of dopamine at 10^{-11} mol/L

Ning Li[1], **Qizhou Wang**[1], **Zhao He**[1], **Arturo Burguete-Lopez**[1], **Fei Xiang**[1], **Andrea Fratalocchi**[1]

1. PRIMALIGHT, King Abdullah University of Science and Technology (KAUST), Thuwal 23955-6900, Saudi Arabia

Abstract We discuss integrated platform for ultrasensitive detection comprising artificial intelligence hardware embedded in a monochrome camera. By utilizing the interference media, it reports detection ranges from 10^{-11} mol/L to 10^{-4} mol/L, which improves one to two orders of magnitude of the current state-of-the-art sensitivity requiring electrochemical workstations or mass spectrometers.

Ultra-sensitive detection plays great roles in the field of explosive detection [1], food safety [2], and disease diagnostic [3]. In medical applications, ultrasensitive trace detection of dopamine is critical for the early diagnosis of Alzheimer [4], Parkinson [5], and schizophrenia [6]. The current state-of-the-art for ultrasensitive detection of dopamine relies on expensive equipment, including electrochemical workstation [7], and mass spectrometry [8]. Since 2015, the state-of-the-art the detection limit is 0.5×10^{-10} mol/L when measuring dopamine with phosphate-buffered saline (PBS) as solvent [9].

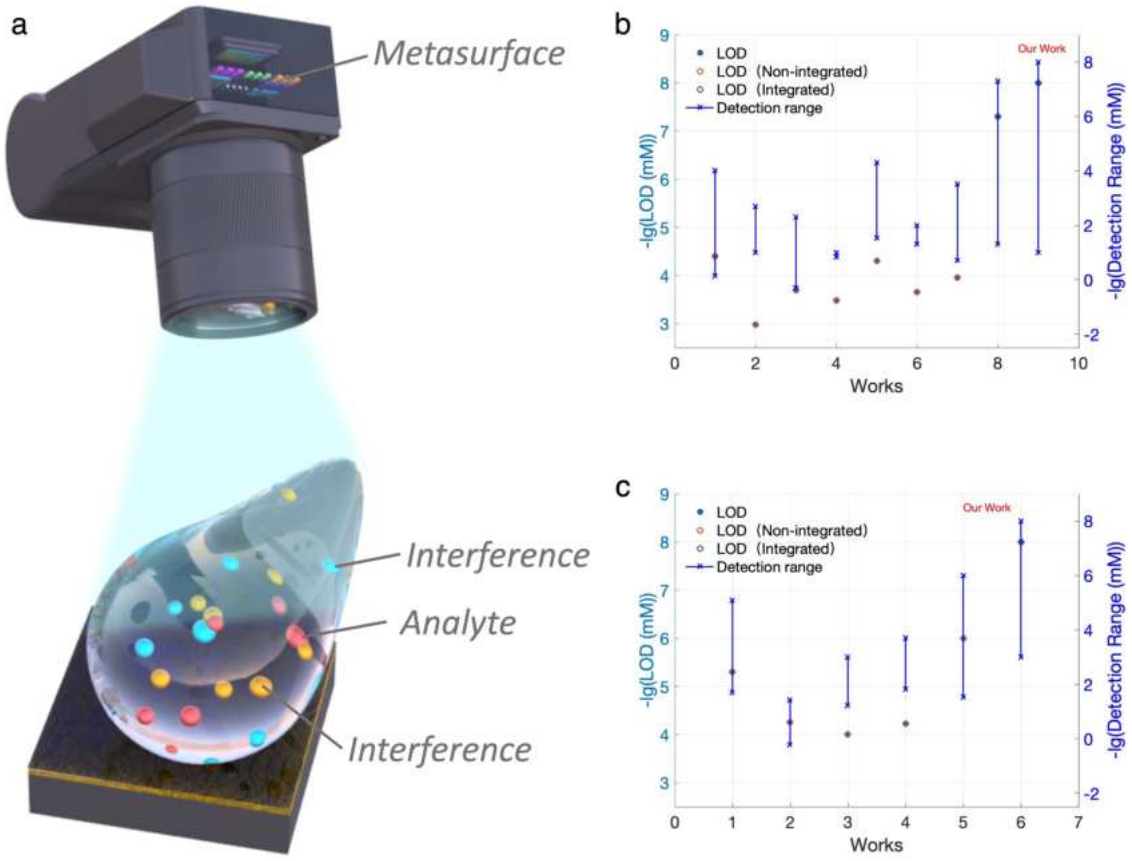

Fig. 1 (a) Integrated platform schematics for ultrasensitive detection. (b-c) State-of-the-art limits of detection and detection range for dopamine are interfered with by (b) PBS solution and (c) uric acid and ascorbic acid.

In this work, we implement an universal platform for ultrasensitive detection employing artificial intelligence (AI) optical hardware, which integrates with a sensor device of a consumer camera. The core of this hardware is inverse-designed metasurface encoders [10–12] (Fig. 1a), trained to provide hardware features extraction to predict the analyte concentration in real-time. In the example of dopamine, this technology reports detection limits as low as 10^{-11} mol/L either with PBS or uric acid and ascorbic acid as interference (Fig. 1b and c). This universal detection platform generalizes to other analytes, providing an inexpensive, scalable platform for rapid, informed detection of diseases at the point of care.

Space-time metasurfaces for photonics

[1*] [1] [1]

[1]Imperial College London, United Kingdom
[*]corresponding author: svezzoli@imperial.ac.uk

Abstract: Metamaterials control light by acting on its momentum, yet they are static devices and bounded by energy conservation. Here we discuss spatial and temporal diffraction in a film of Indium Tin Oxide, as a first step towards a space-time metasurface for photonic applications.

Metamaterials have revolutionised the way we control light waves. By engineering light scattering on sub-wavelength scales, one can design exotic new materials and applications, like invisibility cloaks and negative refraction. Yet, static metamaterials only act on the momentum of light and thus are still bounded by Lorentz reciprocity and energy conservation. A dynamical metasurface, whose optical response can be arbitrarily modulated at the speed of light through a time-varying complex refractive index n(t), would offer access to the manipulation of the frequency spectrum and a whole new range of functionalities. Yet, despite the abundance of theoretical proposals [1], experimental realisations remain elusive, due to the challenge of finding a material platform that can support large and ultrafast modulations without incurring damage.

Here I will discuss our first steps towards optically driven metasurfaces for photonics, based on Indium Tin Oxide, an epsilon-near-zero material with strong nonlinearities and ultrafast time response [2]. I will report on our recent demonstration of double-slit time diffraction from a deeply sub-wavelength and resonant film of Indium Tin Oxide in the near-infrared [3], the first step towards the creation of more complex time modulations. I will then discuss one possible extension of this experiment to the visible range, which employs the non-perturbative modulation of second harmonic generation at the time-varying interface. Finally, I will present our most recent results, aimed at coupling space and time modulations in a time-varying medium: the observation of slits that diffract light both in time and space. These results represent the basic building blocks for the generation of complex spatiotemporal modulations and one of the first evidences of synthetic motion at optical frequencies.

Fabrication of visible metalenses by thermal oxidation of silicon nanopillars

T. Okatani[1*], R. Ando[1], N. Inomata[1] and Y. Kanamori[1†]

[1]Department of Robotics, Graduate School of Engineering, Tohoku University, Japan
[*]taiyu.okatani.a3@tohoku.ac.jp, [†]ykanamori@tohoku.ac.jp

Abstract: We propose a fabrication method of visible metalens composed of SiO_2 formed by thermal oxidation of Si nanopillars. A prototype transmissive metalens was fabricated by performing electron beam lithography, deep reactive ion etching, and wet thermal oxidation on a 2 μm thick monocrystalline Si layer on a quartz glass substrate.

Metalens is an extremely thin lens realized by controlling the effective refractive index distribution using a subwavelength structure [1]. Various materials have been proposed for subwavelength structures, but in the case of visible metalenses, the highest transmittance can be expected by using SiO_2, which is often used for the substrate. We previously reported that reflective metalenses could be realized by forming Si nanopillars on a silicon-on-insulator substrate and thermally oxidizing them into SiO_2 nanopillars [2]. This method allows the formation of SiO_2 nanopillars with a higher aspect ratio than those fabricated by directly etching SiO_2 [3]. However, since the reflective metalens has limitations in its use in actual applications, a transmissive metalens is also required.

In this study, we prototyped a transmissive metalens using approximately 2 μm thick Si layer transferred onto a quartz glass substrate. The substrate was made of SiO_2, and the Si nanopillars also eventually transformed to SiO_2 nanopillars. Therefore, it was expected that a highly transparent metalens made entirely of SiO_2 would be realized. Figure 1(a) and 1(b) shows microscopic images of the metalens surface before and after thermal oxidation, respectively, observed using transmitted illumination. The brightness of the image increases due to thermal oxidation, suggesting that the transformation from Si to SiO_2 increases transmittance. Figure 1(c) is an image obtained by shifting the observation position 70 μm above the metalens surface, which is the designed focal length. It was confirmed that the transmitted light was focused by the prototyped metalens. Details of the fabrication results and transmittance evaluation will be discussed in the presentation.

Water sensors using soft films with metamaterials

C. Y. Huang* and Harry Miyosi Silalahi

Department of Applied Physics, Tunghai University, Taichung 40704, Taiwan
*corresponding author: chiayihuang@thu.edu.tw

Abstract: Metamaterials are artificial materials that comprise split ring resonators, and have strong resonance with incident electromagnetic waves [1–4]. The resonance frequency and transmittance of a metamaterial are determined by the refractive index of the medium that surrounds the metamaterial and its geometrical dimensions. Therefore, metamaterials have been used to develop invisible cloaks [1], signal filters [2], image processors [3] and biosensors [4]. This study involves the creation of a metamaterial sandwiched between two soft films using techniques such as photolithography, sputtering, lift-off process, and imprinting. When exposed to water, the soft films cause cracks in the split ring resonators of the metamaterial due to swelling. These cracks disrupt the electromagnetic resonance, leading to an increase in the transmittance of the metamaterial at its resonance frequency. This heightened transmittance serves as an indicator of the presence of water in the soft films, suggesting potential applications for the metamaterial in humidity sensors and water harvesters.

Polarization-Insensitive Ultra-Broadband Terahertz Metamaterials for 6G Applications

Bhagwat Singh Chouhan, Partha Pratim Barman, and Bhumidhar Barman and Gagan Kumar

Department of Physics, Indian Institute of Technology Guwahati, Assam, India, 781039
bhagwatsingh@iitg.ac.in

Abstract: Our study presents a novel metamaterial design that enables ultra-wideband terahertz transmission while being insensitive to polarization. This is achieved by stacking a cross-shaped resonator on top of a square ring resonator separated by an optimized polyimide spacer. Our results indicate that stacking the resonators provides wideband terahertz transmission.

Introduction: Exploring the electromagnetic spectrum, the terahertz (THz) domain, spanning 0.1 to 10 THz, lies between the microwave and infrared regions and is largely untapped. This "terahertz gap" offers the potential for revolutionizing high-speed wireless communication, promising data transfer rates up to 1 Tbps. To harness this potential, the development of broadband THz devices like wave plates, switches, and filters is crucial for advancing THz photonics and communication systems [1]. Metamaterials (MMs), with their sub-wavelength structures, stand out for their ability to manipulate THz waves beyond conventional material capabilities. Despite progress, broadening the bandwidth of metamaterials, such as through planar metamaterial, remains challenging. In addressing this, we introduce a two-layer multi-stacked metamaterial configuration that comprises a cross-shaped resonator on the top of square ring structure spacing with a loss-free polyimide. We conduct rigorous simulations to investigate the broadband transmission response, focusing on the thickness of the spacer and positioning of resonators and the near-field coupling between them. Additionally, we employ a transmission line model to elucidate the broadband resonance mechanism of our proposed metamaterial. The finding of broadband enhancement can be useful in the THz photonics and next-generation wireless communications [2].

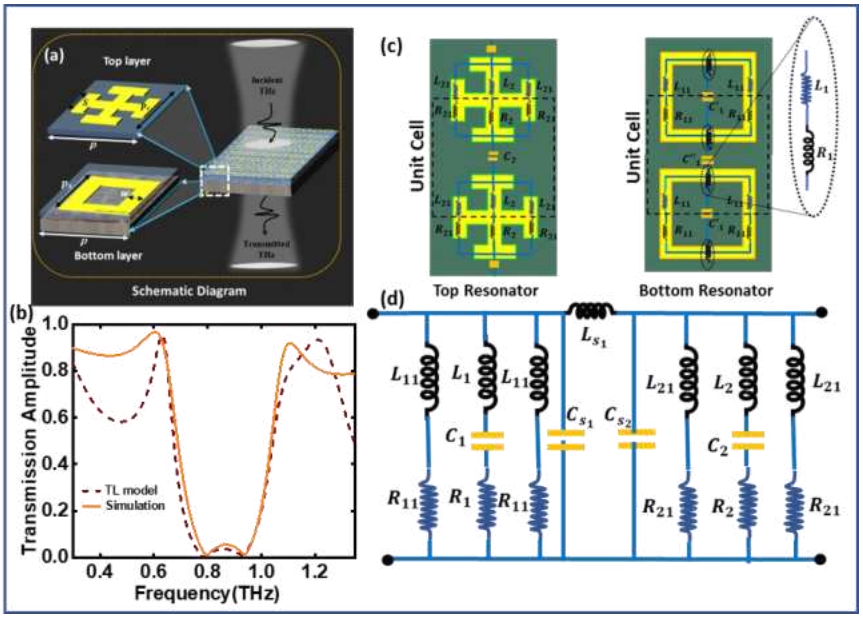

Figure 1: (a) Represents the unit cell of the metamaterial with different resonators. (b) Represents the transmission amplitude calculated from CST and TL line model. (c) Circuital representation of the unit cells. (d) Represents the coupled circuital model of the multistacked MM.

Ultra-broadband transmission of designed MM: The proposed metamaterial configuration, designed using CST software, features a multi-stacked structure with a cross-shaped resonator placed on top of a square ring resonator, separated by a *50 μm* thick loss-free polyimide film. The square ring resonator, with a periodicity of *P=100* µm, lengths of P_c*=63 μm*, and a width of *w=7 μm*, is designed on a *30 μm* thick silicon substrate with *0.2 μm* thick aluminum resonators to prevent THz wave penetration. The cross resonator, with a length of P_s*=81 μm* and *S=20 μm,* is then placed on the ring resonator with the polyimide spacer. The permittivity of quartz and polyimide is chosen to be 4.4 and 3.5, respectively. Simulations utilized a frequency domain solver with tetrahedral meshing and a normally incident plane wave, accommodating both TE and TM polarizations (see Figure 1(a)).

Table 1: Circuit parameters for calculating the electromagnetic response of the TL models.

Parameter	Value	Parameter	Value	Parameter	Value	Parameter	Value	Parameter	Value
$R_1(\Omega)$	05.0	$R_2(\Omega)$	1	C_{S1} (fF)	1.70	$R_{11}(\Omega)$	6.54	L_{21}(pH)	182
L_1(pH)	39.4	L_2(pH)	56.52	C_{S2} (fF)	1.19	$R_{21}(\Omega)$	1.46	-	-
C_1(fF)	0.74	C_2(fF)	0.71	L_{S1} (pH)	41.36	L_{11}(pH)	140	-	-

Analyzing the transmission response of the metamaterial's resonators and their combined effect, we observed a substantial enhancement in transmission bandwidth. The square ring resonator alone showed a bandwidth (FWHM) of 0.22 THz, which enhanced to 0.35 THz upon integrating a cross resonator, marking a bandwidth increase of over 150% in the multilayered setup compared to a single layer. The design's orthogonal symmetry ensures uniform transmission for both TE and TM polarizations, enhancing its applicability. The broadband transmission is due to the superposition of individual resonances (positioned closely), with their convergence boosting the overall bandwidth, demonstrating the synergistic benefit of the multi-stacked approach.

To elucidate the broadband resonance mechanism of our multilayered metamaterial, we formulated a circuital model with coupled resonators [3]. This model employs a series combination of inductance (L), capacitance (C), and resistance (R) to mirror the CST simulation's transmission response, showcased in Figure 1(c) and (d). Table 1 outlines the parameters for L, C, and R. The transmission line (TL) circuit models for this dual-layered structure perfectly matches well validating the model's effectiveness in capturing interactions between the stacked resonators.

Conclusions: We designed polarization-insensitive broadband modulators using stacking of resonators. A FWHM of 350 GHz has been achieved for the multistacked MM, enhancing the bandwidth by over 150% compared to a single resonator. The transmission line model was employed to explain the coupling between the stacked resonators. The designed broadband metamaterial can be used as broad stopband filters and for functional broadband THz device applications.

Bismuth-based color generation devices : from traditional optical cavities to gap-surface plasmon metastructures

F. Chacon-Sanchez, C. Ruiz de Galarreta, and R. Serna

Instituto de Óptica (IO-CSIC), Spain
*corresponding author: fernando.chacon@csic.es

Abstract: We report the successful use of bismuth nanostructures for generating vivid structural colors through two distinct routes: traditional Fabry-Perot cavities and gap-surface plasmon **metasurfaces**. By exhaustively comparing computational and experimental results from each approach, we assess their suitability for both micro- and macro-coloring sustainable **devices** and its tunability potential.

In this work we explore the potential of a non-conventional plasmonic material (bismuth) for metastructures on the visible (VIS) spectrum, while providing a comparative study for the use of metastructures for structural coloring. [1] The choice of material is based on the excellent plasmonic response demonstrated by Bi-based nanostructures in the ultraviolet and visible [4], as well as the similarity of its dielectric constant with aluminum [fig. 1(a)], widely use on VIS. In addition, Bi exhibits a relatively low melting temperature (~270 ºC), with its solid-to-liquid phase transition being accompanied by significant changes in its optical response. This behaviour, as studied in previous works [6-7], creates the opportunity for optical switching of Bi-nanocomposite films by hot-plate annealing (phase light switching) or under ns-laser irradiation (ultrafast response), with future potential applications on reconfigurable plasmonic metastructures.

In addition, we study from a computational and experimental point of view two different approaches for Bi-based structural coloring: a traditional Fabry-Perot cavity (FPC) and a gap-surface plasmon metastructure (GSP), with apparently similar structures, as seen in Fig.1, but with different physical working mechanisms underneath. Using different computational methods (Transfer Matrix Method for FPC and Finite Element Differences for GSP) we have simulated and optimized both structures,

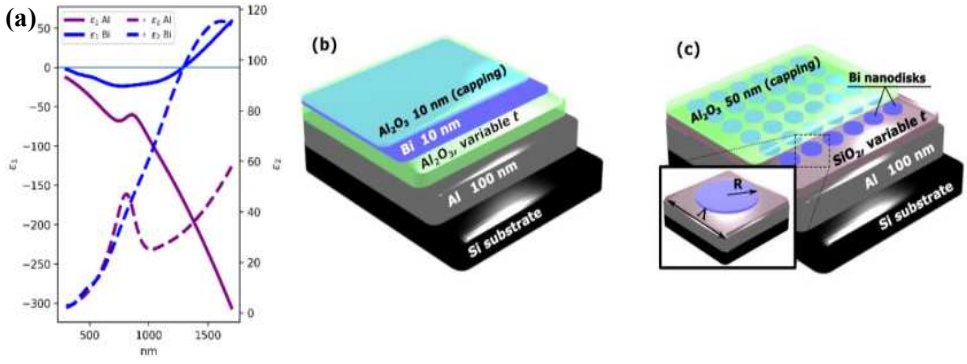

Figure 1. (a) Complex dielectric constant of Bi, compared to Al. (b) General structure of F-P cavity. (c) General structure and variables of gap plasmon metastructures

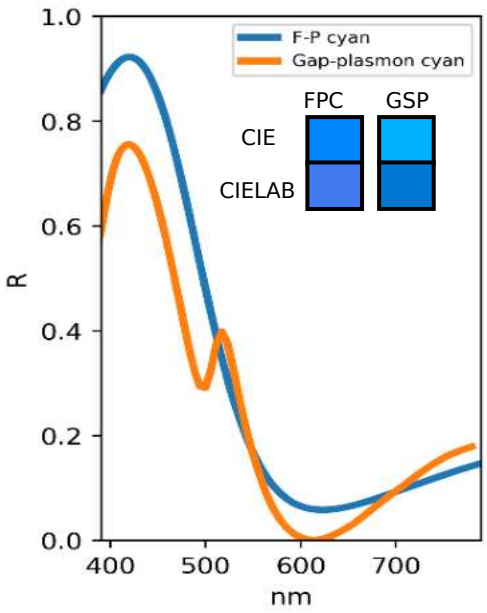

Figure 2. Simulated reflectivity for FPC and GSP tuned for cyan color generation

obtaining crisp, intense colors (Figure 2) for both structures, adding to that the exploration of their angular robustness. We have employed pulsed laser deposition (PLD) for the fabrication of the FPC and PLD and e-beam lithography for the GSP. For the experimental characterization we have performed angular-resolved measurements of their reflectivity and ellipsometry to show their angular robustness. We will discuss the pros and cons of each different type of structure for structural color generation in micro- and macro-structures, the need of a CMY colorbase to obtain a full color palette, and the tunability potential of each structure taking into account Bi's solid-liquid phase change to activate the device.

Abstract: We present a hardware-accelerated hyperspectral video camera that employs a metasurface for real-time spectral analysis. The metasurface implements artificial intelligence algorithms, enabling video-rate assessment of object properties inaccessible to traditional cameras. We show experimental results on the system's performance on spectrally enhanced segmentation and fruit ripeness level sensing.

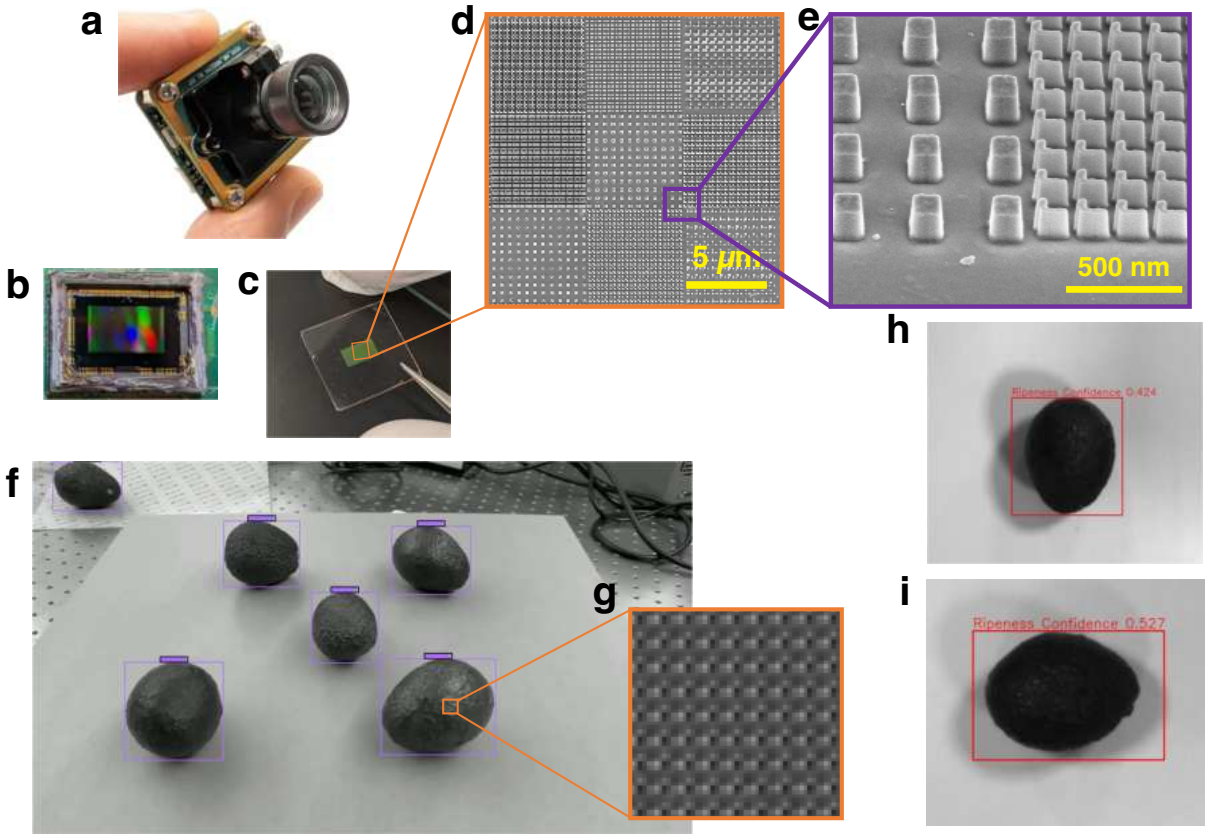

Figure 1: **Metasurface-based AI hyperspectral video camera and demonstration of fruit quality control**. **a** Hyperspectral video camera composed of a modified imaging sensor (**b**) on which a metasurface (**c**) is placed. **d**, **e** Scanning electron microscope images of the nanoresonators comprising the metasurface. **f** Still frame from video footage of a set of avocados on a rotating stage. The panel shows bounding boxes generated in real time around each fruit. **g** closeup of the pixels of the still frame showing the encoding of spectral information by the metasurface. **g,h** Predictions on ripeness using the spectral information of the fruits.

Hyperspectral imaging has emerged as a powerful remote sensing technique spanning diverse disciplines such as astronomy, medicine, environmental monitoring, agricultural science, and archaeology [1]–[4]. This method captures images across hundreds of frequency bands within and beyond the visible light spectrum, assigning a unique spectrum to every pixel, and

facilitating material identification and characterization based on their spectral signatures [5].

Despite notable technological development, state-of-the-art devices face challenges such as low spatial resolution (typically below one megapixel), prolonged acquisition times (up to several minutes per frame), and high cost (ranging from tens to hundreds of thousands of dollars) [6]. Metasurfaces present a promising avenue to address these issues, with the proven realization of components such as frequency filters, spectrometers, and lenses in a highly integrated form factor [7]–[9].

In this work, we introduce a hyperspectral video camera that effectively mitigates the aforementioned challenges. We manufacture the device by integrating metasurface technology with an off-the-shelf camera, resulting in a compact apparatus capable of capturing hyperspectral video at a spatial resolution of over two megapixels and a speed of 120 frames per second. The metasurface is designed to optically execute artificial intelligence operations, encoding the scene's spectral information into a format readable by a conventional camera [10].

Figure 1a displays a photo of the hyperspectral video camera. We enhance the commercial camera sensor (fig. 1b) by adding a suitably engineered transmissive metasurface (fig. 1c) on top. The metasurface comprises nine repeating patterns, illustrated in fig. 1d. The closeup presented in fig. 1e shows that each pattern has distinct nanoresonator structures designed for specific spectral responses. Figure 1f shows a still frame from a video sequence depicting a set of avocados on a moving stage. The bounding boxes around the fruits are generated in real-time, based on spatial and spectral information of the scene. Figure 1g depicts a pixel-level closeup of the frame, illustrating the metasurface's sub-pixel pattern encoding of spectral information. In Figure 1h-i spectral information from the sub-pixel pattern is fed to a neural network classifier, which performs real-time estimation of the fruit's ripeness.

Acknowledgements: Parallel simulations are performed on KAUST's Shaheen supercomputer. Metasurface fabrication is conducted in the KAUST Core Labs nanofabrication cleanroom.

Abstract: We fabricate a device that configures the tunable air gap Fabry–Pérot filter with a static gradient thickness filter to estimate air gap dimension in tunable filter. The chip-level microelectromechanical integration of gradient thickness filter can serve the purpose of device miniaturization while performing air gap sensing in visible wavelength range.

1. Introduction

Microelectromechanical systems (MEMS)-based Fabry–Pérot filters (FPFs) have paved the way to realize miniature, lightweight, and cost-effective spectrometers against their bench-top counterparts [1]. Achieving a wide range of tunability with MEMS-based tunable FPF by controlling the air gap dimension subjected to various actuation mechanisms can enable several novel applications through miniaturization and scalability. However, the conventional tunable FPFs with existing technology[2, 3] have limitations in detecting the exact air gap dimension which ultimately affects the target spectral information in applications such as hyperspectral imaging, for example. In this study, we propose an epoch-making concept MEMS device that combines the tunable air gap FPF with a static gradient thickness filter to enable the accurate estimation of the cavity gap dimension in the tunable FPF.

2. Device concept and fabrication

The concept of the proposed device is depicted in Fig. 1. When a broadband light is incident on the double filter region from the top, then a selective spectral component is transmitted through the air gap FPF which further is transmitted through a selective spatial position of the static gradient thickness filter. Knowing the gradient thickness filter position through which light is transmitted from the CMOS pixel output can provide an accurate estimation of the air gap dimension in the air gap FPF. The fabrication of top mirror involves photolithography patterning and Ag sputtering to form a concavity (Fig. 2) for reducing the area of contact with the bottom mirror to minimize the effect of non-parallelism of mirrors on the transmission of FPF. The fabrication of bottom mirror involves Ag sputtering followed by shadow mask SiO_2 sputtering and Ag sputtering to create a static gradient thickness filter and then, Ag sputtering on the opposite side (Fig. 3).

3. Results and Discussion

The top and bottom mirrors are assembled by a PZT using glue as shown in Fig. 4. The transmittance of the tunable air gap FPF is measured by a microscope spectrometer by applying voltage (V_{app}) to the PZT. Figure 5 shows the transmission spectrum undergoes a spectral shift from 552.9 nm to 587.8 nm ($\Delta\lambda$ = 34.9 nm) when V_{app} increases from 0.0 V to 5.0 V. The measured transmission spectra of the double filter region at different spatial positions are shown in Fig. 6. At V_{app} = 0.0 V, the peak occurs at 549.6 nm with maximum transmittance at X = 0.0 mm (black curve in Fig. 6(a)) whereas that occurs at 580.6 nm with maximum value at X = 0.2 mm (red curve in Fig. 6(b)) for V_{app} = 5.0 V. This means the spatially-resolved spectral position of the transmitted light from the double filter region under different V_{app} values (almost) match the spectral position of transmitted light in tunable air gap FPF.

4. Conclusions

In conclusion, we fabricate a device that combines the tunable air gap FPF with a static gradient thickness filter

on the same platform. The fabricated device provides an easy way for accurate estimation of the air gap dimension in the tunable air gap FPF even in the visible wavelength range. The concept technology satisfies the requirement of device miniaturization for many applications and hence, possesses advantages over the conventional way of air gap sensing by capacitive displacement measurement.

Metamaterial range extended and field localized Parity-Time symmetrical wireless power transfer system.

Abdulrahman Alsaadi[1,2], Inki Kim[1,2*]

[1]Department of Biophysics, Institute of Quantum Biophysics, Sungkyunkwan University, Suwon, Republic of Korea

Abstract: Conventional wireless power systems are limited in range, efficiency, and robustness. Our system provides, extended-range power transfer using the physics of parity-time symmetry and metamaterials, increasing transfer efficiency stability against distance fluctuations with the ability to localize the power from a larger transmitter to smaller size receiver.

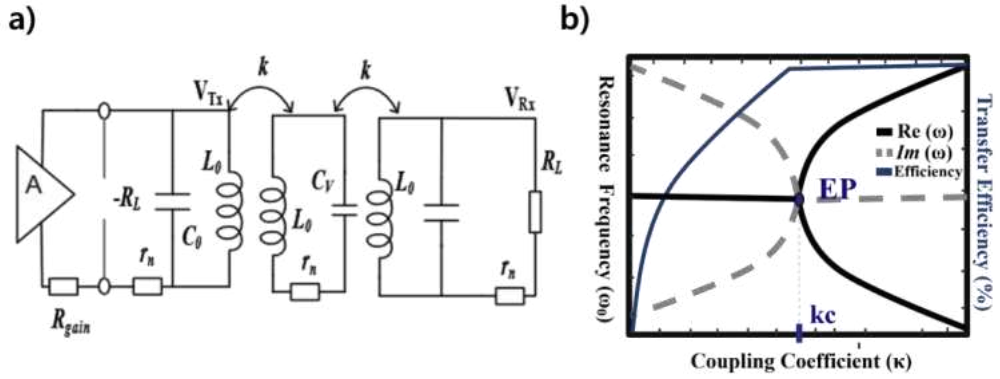

FIG.1 a) PT-WPT circuit schematic b) Resonance frequency and power transfer efficiency against coupling coefficient.

The demand for wireless power transfer (WPT) in medical implants has increased due to its potential to eliminate frequent battery replacements, improving patient well-being and safety. However, conventional wireless power transfer systems have limitations in range efficiency of transmission and Transmitter (Tx) to receiver (Rx) size ratio. This work proposes a stable and extended range wireless power transfer system utilizing parity-time symmetry (PT-symmetry) and electromagnetic metamaterials (MTM) to address these limitations. Previously, Parity-time symmetry was introduced from Quantum physics as a solution to WPT systems instability towards fluctuation in operating frequency and coupling coefficients [1]. PT-symmetry can be implemented in WPT systems by introducing a gain element into the circuit equivalent to the loss element. As shown in Fig.1(a), it is denoted as (-R), which is equivalent to load resistance (RL) [2].

$$\frac{d}{dt}\begin{bmatrix}a_1\\a_2\\a_3\end{bmatrix}=\begin{bmatrix}j\omega_0+g & -j\kappa & 0\\ -j\kappa & j\omega_0 & -j\kappa\\ 0 & -j\kappa & j\omega_0-\gamma\end{bmatrix}\begin{bmatrix}a_1\\a_2\\a_3\end{bmatrix} \quad (1)$$

$$\omega=\omega_0\pm\sqrt{\kappa-\gamma} \quad (2)$$

By utilizing coupled-mode theory for characterizing WPT systems, the operating frequency (ω) can be obtained by solving for the eigenvalues of equation (1). Here ω_0 is the resonance frequency of MTM ($\omega_0=1/\sqrt{(L_0C_0)}$), κ is the coupling rate (ω_0 K/2), g and γ are the gain loss rates, respectively. As shown in equation (2), the system obtains two real fundamental modes if $\kappa\geq\gamma$ which makes it robust against fluctuations in coupling coefficient. Transmission efficiency remains unaffected by the coupling coefficient, as depicted in Fig. 1(b). The inclusion of an electromagnetic metamaterial slab enables the system to transfer power effectively from a larger Transmitter (Tx) to smaller receiver (Rx). Our metamaterial (MTM) is made of

Megahertz spiral resonators that each act as a unit cell, when arranged periodically the structure will behave as a metamaterial with the unique negative refractive index and by making a defect in the structure by tuning one of the unit cells to operate at a lower resonance frequency will make the structure to act as meta lens with hotspot that confines the field into one spot [3]. Electromagnetic wave simulations show that the metamaterial effectively confines the magnetic field (h-field), as shown in Fig. 2(b), surpassing the capabilities of the PT system without Metasurface Fig. 2(a).

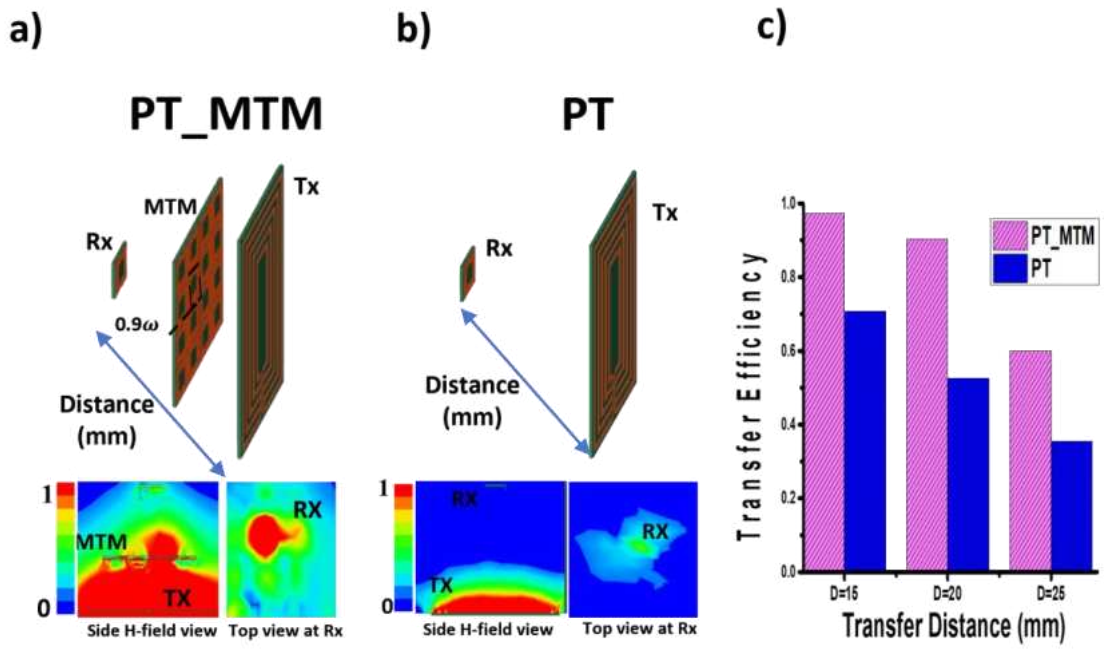

FIG.2 a) and b) shows the H_ Field distribution for PT-WPT system without Metasurface and with PT_MTM respectively. c) Shows the measured transfer efficiency of both configurations at various transfer distances.

Experimental results in FIG. 2 (c) show that the efficiency has increased significantly in the presence of MTM compared to no MTM providing a potential for improving the functionality of wireless power transfer systems to applications where the receiver is not moving continuously and smaller in size than the transmitter such as in medical implants.

Technology of auxetic-structured substrate for skin attachable conformal sensor

Jae-Hwan Lee[1], Tae-Gyong Kim[1], Jun-Sang Lee[2], and Seung-Kyun Kang[1*]

[1]Seoul National University, Republic of Korea

Abstract: This study introduces a novel method to design a substrate with customizable Poisson's ratio using hybrid re-entrant structures and finite element analysis for evaluation and analysis of the strain-dependent Poisson's ratio of substrates. The substrate matches skin's Poisson's ratio across different strains, enabling tailored sensor substrates for various skin areas.

The mismatch in the Poisson's ratios between skin and the substrates of wearable patch sensors leads to mismatched stress, impacting sensor performance and user comfort. Previous solutions have not fully addressed the strain-dependent variability of the skin's Poisson's ratio. This study proposes a solution through the design of a substrate with a tunable Poisson's ratio, capable of matching the skin's properties across a range of strains.

The study employed finite element analysis to evaluate the strain-dependent Poisson's ratio of substrates incorporating a single design of re-entrant structures. By adjusting the design parameters of these structures, the research aimed to tune the substrate's Poisson's ratio to match that of human skin. The hybridization approach of re-entrant structures was explored to achieve a uniform Poisson's ratio across varying strains.

The experimental results are pivotal in validating the effectiveness of re-entrant structure hybridization in controlling the Poisson's ratio of substrates. Through comprehensive finite element analysis (FEA), this study meticulously evaluated the Poisson's ratio of substrates integrated with re-entrant structures under varying strain conditions. The results significantly highlight the capability of these structures to fine-tune the substrate's Poisson's ratio across a broad strain spectrum, showcasing a remarkable alignment with the strain-dependent properties of human skin.

Finite Element Analysis Validation: Initial experiments involved validating the FEA method against traditional tensile testing techniques. By measuring the Poisson's ratio of re-entrant structure-enhanced substrates under controlled conditions, the study confirmed the high accuracy of FEA predictions, underscoring its reliability in simulating biomechanical interactions between the substrate and skin.

Strain-dependent Poisson's Ratio Control: The core achievement of the research was the successful demonstration of strain-dependent control over the substrate's Poisson's ratio. The study illustrated how varying the design parameters of the re-entrant structures—such as their angle, size, and distribution—enabled precise tuning of the substrate's mechanical properties. This adaptability ensured a seamless match with the skin's Poisson's ratio over a wide range of strains, effectively eliminating mismatch stress.

Hybridization of Re-entrant Structures: A novel hybridization strategy involving different re-entrant structure designs was employed to achieve uniform Poisson's ratio control across the entire strain spectrum. This approach led to the development of a substrate that dynamically adjusts its Poisson's ratio in response to changes in applied strain, mirroring the skin's natural biomechanical behavior. The experimental data vividly demonstrate the hybridized substrate's capability to maintain optimal biomechanical compatibility with the skin, ensuring

enhanced performance and comfort of wearable sensors.

Practical Implications and Applications: The practical application of these findings was underscored by the fabrication of a prototype substrate that successfully matched the Poisson's ratio of human skin across various strains. This breakthrough paves the way for the next generation of wearable sensors that can provide high-fidelity data while minimizing discomfort and potential skin irritation, thereby significantly improving user compliance and the overall effectiveness of wearable health monitoring devices.

The research successfully designed and fabricated a substrate with a controlled Poisson's ratio, matching that of the skin across all strains, through the hybridization of re-entrant structures. This achievement opens pathways for developing customized patch sensors capable of adhering to any part of the body without the issue of mismatched stress, enhancing both sensor functionality and wearer comfort.

Flexible Metasurface as an Efficient Resonator for 7T MRI

Santosh K Maurya[1], Eiska Tegareh[2], and Rita Schmidt[1*]

[1]Department of Brain Sciences, Weizmann Institute of Science, Israel,
[2]Life Sciences Core facilities, Weizmann Institute of Science
[*]corresponding author: rita.schmidt@weizmann.ac.il

Abstract: We proposed a flexible and cost-effective metasurface design based on maze-like geometry of concentric split ring resonators (SRRs) for ultra-high field 7T human MRI. This design not only lowered the resonant frequency but also increased the RF field efficiency by x1.5-2 folds. This have been demonstrated both numerically and experimentally.

The ability of the metamaterial structures to offer unique properties and new solutions opened new avenues in a wide range of applications. In recent years, metamaterial designs have also been explored in the field of MRI to increase SNR and efficiency of the RF coils[1-6]. Previously explored structures were based on either high dielectric substrate or structure with many lumped elements. Both approaches not only increase the complexity of the design but also may result in reduced efficiency. The constraints in MRI include a tight coil-patient setup, the requirement for deep penetration of the magnetic field outside the structure and potential power deposition in the body. The most relevant resonant mode of interest for MRI is the lowest transverse-electric (TE) mode since it provides H-field components that are perpendicular to the main static magnetic field and have large penetration depth. In this study, we aimed to design a flexible and compact metasurface that provides high efficiency for MRI applications.

Instead of using a split-ring as a small sub-unit, here the structure was constructed from a set of concentric split-rings (each having two gaps) with alternating split-rings rotated by 90° - generating a maze-like configuration. This design offers two key advantages – i) a configuration based on set of concentric split-rings (in this case six) provides more homogenous RF magnetic field and increases the RF field efficiency (defined as $B_1/\sqrt{SAR}$ in MRI), ii) a configuration based on alternatingly rotated by 90° split-rings compared to aligned set lowered significantly the resonant frequency of the resonant modes. The designed configuration provided a resonant structure tuned at 298 MHz for 7T human MRI without a need for lumped elements. Fig.1 show the advantages of the design.

To characterize and examine the proposed structure EM simulations, including eigen mode solver and time domain, were done followed by measurements in 7T MRI. All the simulations were carried out using CST Microwave Studio, Darmstadt, Germany. A rectangular sucrose phantom with relative permittivity of 53 and conductivity of 0.3S/m was used to mimic brain tissue properties. Simulations with virtual human model "Duke" were performed in a setup for brain imaging with the metasurface structure bended adjacent to the head. B_1 field map was measured in a setup that included a small surface loop, an added metasurface and a sucrose-based phantom.

In time-domain simulations, a comparison of the simulated B_1 distributions between a setup driven by a surface-coil and one with a proposed here metasurface (of the same dimensions) was performed. The maximal increase in RF field with the metasurface was 1.9-fold higher compared to the surface coil with the same size. An experimental result showed an increase of ~1.7 in B_1 (see Fig.2).

In this study, we demonstrated a new metasurface geometry that provided an efficient resonator at 298 MHz for 7T MRI. This design didn't require high dielectric or lumped elements, which offered a simple implementation, a flexible setup and a high efficiency resonator.

Fabrication of delay lines using spoof-surface-plasmon-polariton waveguides coupled with split-ring resonators for microwave integrated circuits

M.V Nguyen, N. Kikuchi, T. Kodama, T. Okatani, N. Inomata, and Y. Kanamori*

Tohoku University, Japan
*Corresponding authors: ykanamori@tohoku.ac.jp

Abstract. We proposed and fabricated three delay lines based on spoof-surface-plasmon-polariton (sSPP) waveguides and split-ring resonators (SRR) with different gap sizes varied at sub-micrometer which results in a phase difference up to 50 degrees and the notch-band central frequency shift of 0.085 GHz for application in phase shifters and modulators.

Introduction

The 5G communication systems require sub-millimeter waves integrated on-chip with microwave-integrated circuit applications in phase shifter and phase/amplitude modulation. Conventional technologies based on radio Frequency (RF) – printed circuits board (PCB) could not be engineered at the sub-micrometer scale, which is not suitable for microwave-integrated circuits [1,2]. Furthermore, to change the time delay, conventional technology takes advantage of the physical length of the transmission line which leads to a large insertion loss [3]. In this work, the propagation constant of the microwaves is engineered to tune the transmission phase.

Design and Fabrication

Three delay lines were designed and fabricated. Each device is constituted by an sSPP waveguide and eight SRRs, which can be divided into five sections: a delay section (I); two transition sections (II), and two co-planar waveguide (CPW) sections (III) as shown in Fig. 1(a). In the delay section, four periodic corrugated rectangular metallic structures, the so-called stubs, are coupled with eight metallic SRRs on both sides; two nearby stubs are connected by a central line as illustrated in Fig. 1(b). Dimensions of the SRRs are depicted in Fig. 1(c). The CPW sections are designed for the input and output of microwaves, which are compatible with an impedance of 50 Ohm for connection with the measurement circuit. Sections (II) are designed for high-efficiency coupling of the microwaves from CPW to the delay line. The designed dimensions of the SRRs are as follows: t = 1.1 μm; w = 500 μm; w_1 = 2.5 mm. g is varied between the three devices for the capacitance difference resulting in phase difference and S_{21} parameter difference at the resonance of the SRRs in the interaction with the incident microwaves.

The structural design and optimization were performed using numerical calculations based on a commercial finite element solver. The devices were micromachined by ion beam milling etching and wet etching of the Cr/Au thin film on a silicon substrate deposited with a 10 μm SiO_2 film on top. The three delay lines were bonded with two SMA connectors (RS PRO SMA board end launch connector) by lead-free solder paste (Sn42Bi58 micro-beads) for optical characterization with a vector network analyzer system (E8363C, Agilent Technologies, Ltd.).

Results and Discussion

The sub-micrometer scale difference in the gap size of the SRRs creates a large phase and transmission contrast between the three delay lines. The optical characterization of the three delay lines varies with different gap sizes of the fabricated SRRs of 2.5, 3, and 4.5 μm are shown in Figs. 1(d) and 1(e). As g increases from 2.5 to 4.5 μm, a large phase difference ($\Delta\varphi$) was achieved at the notch-band between devices with different values of g as shown

in Fig. 1(d): $\Delta\varphi$ = 58.9° with g = 2.5 µm versus g = 3.0 µm (the yellow dotted line), $\Delta\varphi$ = 82.2° with and g = 3.0 µm versus g = 4.5 µm (the blue dotted line); the notch-band central frequency blue shifts as shown in Fig. 1(e): f_1 = 7.031 Ghz, f_2 = 7.073 and f_3 =7.158 GHz, respectively. The frequency difference is 0.042 GHz with g = 2.5 µm versus g = 3 µm, and *0.085* GHz with g = 3.0 µm versus g = 4.5 µm, respectively. The experimental results (the solid lines) are confirmed by numerical calculation (the dotted lines) as presented in Fig. 1(e). Active microwave modulation could be a promising application for delay lines integrating high-speed capacitive switches.

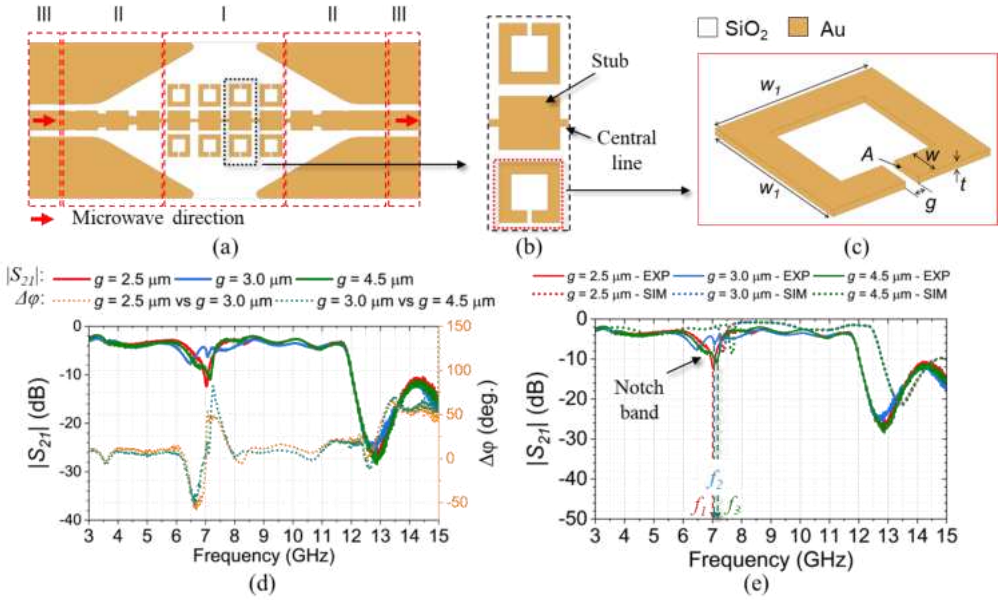

Figure 1. (a) A schematic structure of the delay lines: delay section (I); transition section (II), and CPW section (III). (b) One unit cell of the delay section. (c) Dimensions of SRR. t: the thickness of metal, g: gap, w: width, A: cross-section area, and w_1: width of SRR. (d) The measured $|S_{21}|$ magnitude with g of 2.5, 3, and 4.5 µm and phase difference ($\Delta\varphi$) between devices with g = 2.5 µm versus g = 3 µm; and g = 3 µm versus g = 4.5 µm. (e) Comparison between the measured and simulated $|S_{21}|$ magnitude of the three delay lines with g of 2.5 µm, 3 µm, and 4.5 µm. f_1, f_2, and f_3 are the notch band center frequencies of the notch band, respectively.

Abstract: This paper presents a numerical investigation of dielectric metasurfaces tailored for sensing applications. The structures will be used in the development of biosensors that detect changes in the environment's refractive index. The proposed metasurface is a transmission mode array of amorphous silicon disks patterned on a fused silica substrate.

Optical biosensors are well-suited for detecting analytes in a variety of media, including air, water, blood, and food, due to their high sensitivity, compact size, and affordability [1]. An efficient method for detecting the desired analyte using an optical sensor is by analyzing the refractive index (RI) changes of the surrounding medium [2]. RI detection offers real-time, label-free, and non-invasive optical remote readouts, making it a promising solution for the development biosensors. To increase the sensitivity and quality factor of a biosensor, the design must consider the incident wavelength, near-field enhancement, resonant bandwidth, and the quality of the resonances. Various diseases can be detected using RI sensors, including blood components, biological molecules, DNA, cancerous cells, viruses, and bacteria. Also, protein and glucose concentrations in human urine can be detected using these biosensors [3, 4].

This study will explore the potential of metasurfaces for RI-based biosensing applications in visible and near infrared domains. Metasurfaces can control light propagation and emission at the nanoscale, making them suitable for biosensing applications [5] and are the most efficient option for achieving a miniaturized device [6]. They consist of periodic arrays of resonators, also known as meta-atoms, which come in a variety of shapes and sizes. Meta-atoms can sustain resonances that concentrate electromagnetic fields in small volumes by exciting localized surface plasmons, well below the diffraction limit [7]. Metasurfaces have been used to create flat and lightweight optical components, including gratings, lenses, beam shapers, color filters, and absorbers [8].

This paper presents the initial numerical investigations of metasurface structures designed to achieve high sensitivity to changes in the refractive index of the surrounding medium. The aim is to develop highly selective biosensors based on plasmonic and/or dielectric metasurfaces for the detection of specific harmful pathogens. These sensors can operate in either transmission or reflection mode. We designed and numerically analyzed a dielectric metasurface working in transmission mode composed of amorphous silicon disks patterned on a fused silica substrate. In order to investigate the behavior of the resonant structures to the RI changes we varied the diameters (from 400 to 700 nm), height (from 100 to 300 nm) and period (from 700 nm to 1μm) of the disks. The refractive index of the environment was varied between 1 and 1.35 with a 0.5 step. To assess whether the suggested structures can enhance sensitivity to RI changes, we performed a numerical analysis of the proposed metasurface using the 3D finite-difference time-domain (FDTD) method (with OptiFDTD software). We applied periodic boundary conditions to an elemental unit cell to obtain a periodic metasurface. Perfectly matched layers (PML) conditions were used to minimize reflections that may occur when incident radiation touches the boundary on the propagation direction (Z). The incident light was modelled as a Gaussian wave centered at a

wavelength of 800 nm. The investigation covered a wavelength spectrum ranging from 600 nm to 1200 nm. Figure 1 shows the schematic diagram of the proposed dielectric metasurface when the environment refractive index is 1.

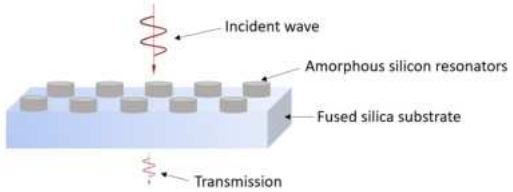

Fig 1 Schematic diagram of the proposed dielectric metasurface place in air

To determine whether this type of dielectric metasurface offers the possibility of developing RI-based biosensors, we calculated the wavelength sensitivity by $S_\lambda\,(\mathrm{nm/RIU}) = \Delta\lambda_{peak} / \Delta n_a$, where $\Delta\lambda_{peak}$ is the shift of the resonance wavelength peak, and Δn_a is the variation of the environment's refractive index. The results from this initial study show a wavelength sensitivity of 160 $\mathrm{nmRIU^{-1}}$ for a metasurface with a periodicity of 900 nm, resonators diameter of 500 nm and 200 nm height. Although the S_λ is small, the results obtained with this dielectric metasurface are comparable to those achieved with more complex structures that are sensitive to light polarization and require expensive and complicated technological processes.

The numerical analysis results, despite the relatively low values for S_λ, demonstrate that the design is a suitable candidate for developing low-cost sensors based on refractive index variation. Our next step is to optimize the design for much bigger wavelength sensitivity. Also, we will fabricate the proposed structures, functionalize the surfaces for pathogen binding, and investigate the sensor performances regarding pathogen detection.

Abstract: We present two metasurfaces capable of full-Stokes polarization analysis in the visible spectrum. One includes a highly sensitive Shack-Hartmann detector for wavefront sensing, while the other incorporates a holographic approach for enhanced human readability and interpretability. Both metasurfaces include polarization-multiplexing for increased efficiency.

Polarization analysis is an important tool in many areas of science and industry, from advanced imaging [1,2] and communication technologies [3,4] to chiral spectroscopy and optical defects mapping. Metasurfaces allow for spatial resolution of the polarization distribution without the need for a complex optical setup involving several branches or rotating components [5,6,7]. While polarization analysis alone is a powerful instrument, combining it with other functionalities provides an even deeper range of applications. For instance, integrating a Shack-Hartmann sensor into the metasurface can allow for simultaneous measurement of polarization state and local wavefront tilt. Determining these two quantities simultaneously, as opposed to with two separate instruments, enables real-time observation of wavefront deformation when, for example, assembling or anchoring a system of lenses. The described metasurface is pictured in Figure 1A, showing the three zones, each responsible for separating and focusing two orthogonal polarization states of different polarization bases into discrete focal points through polarization multiplexing. The total of six focal points responsible for polarization analysis lie in a hexagonal grid, with the orthogonal states at opposite sides of the hexagon. In our design, an extra, polarization-insensitive zone, focusing all light into a central focal point, was added to aid a computer algorithm in computing the local wavefront tilt via the focal point shift from a reference position. Since, at any point, any of the polarization-sensitive focal points can have zero intensity if the corresponding polarization state is not present in the analyzed light, the central polarization-insensitive focal point ensures the robustness of the automated computation. To facilitate a precise measurement of the wavefront tilt, the geometry of the metasurface has been adjusted by greatly increasing the focal length of all the focusing zones. However, there is a tradeoff between the wavefront tilt resolution and spatial sampling resolution. Since the numerical aperture of the lenses is also greatly decreased when increasing the focal distance, the focal points would overlap if the size of the metasurface zones was not also increased. The final parameters of our device are a focal length of 5 mm and a sampling period of 300 μm. The metasurface is composed of TiO_2 high-aspect-ratio nanostructures fabricated using a proven combination of electron beam lithography and atomic layer deposition. Optical characterization measurements, plotted in Figure 1C and Figure 1D, show great polarization analysis and wavefront tilt detection capabilities. Even though the targeted range of wavefront tilt angles was 0-2°, the linearity of the focal point shift is preserved even for angles larger than 15°.

The second presented metasurface focuses on a visual representation of the polarization state for improved human readability. This was achieved by replacing the polarization-multiplexed lenses in the previously described metasurface with polarization-multiplexed holograms, as shown in Figure 1B. The implementation of holograms

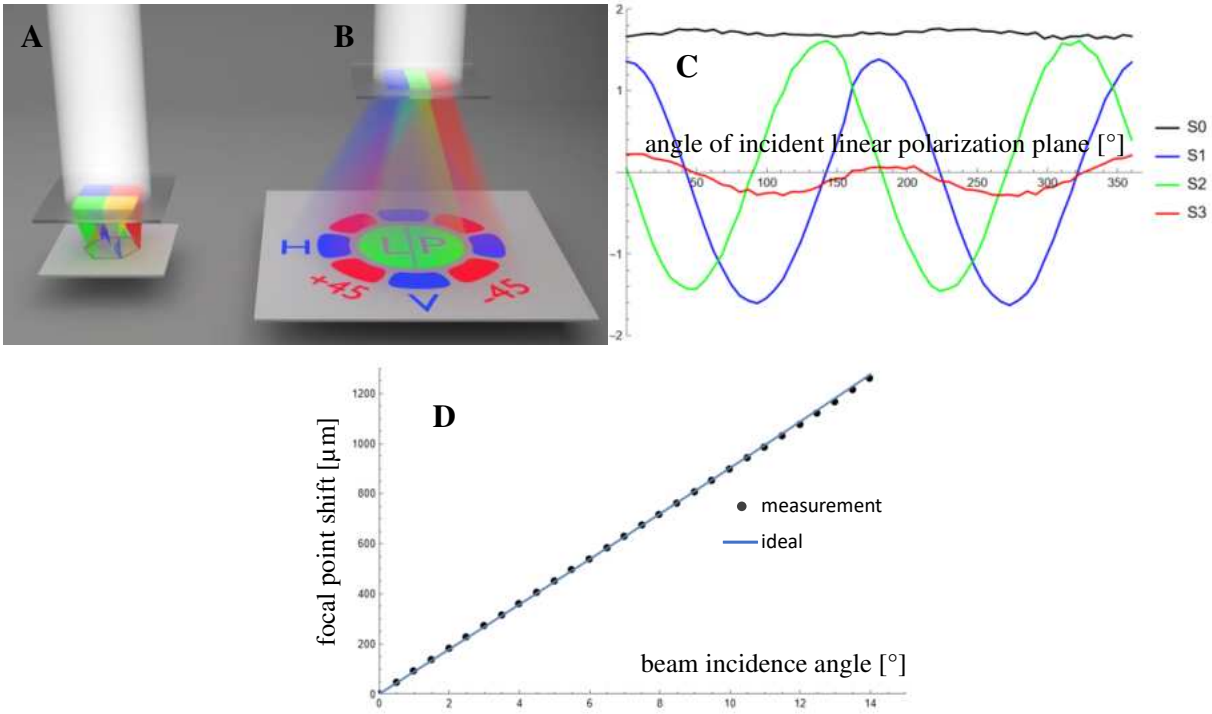

Figure 1: Design of metasurfaces and select optical measurements. (A) Metasurface polarization analyzer with Shack-Hartmann detector, (B) holographic polarization analyzer, (C) full-Stokes polarization measurement for different analyzed polarization states and (D) plot of focal point shift as a function of incoming beam angle.

opens up a great potential for various design options. For example, the focal spots of respective polarizations can now be arbitrarily shaped, allowing for easier comparison of intensities. Moreover, the polarization spots can be equipped with holographic labels designating the given polarization state, greatly improving the interpretability of the polarization measurement to humans. Finally, thanks to a small period of metasurface holograms, their field of view is very large, and the projected polarization-dependent image is easily observable by the eyes. Such a device can then become a handy tool in the assembly of optical setups, where it can be quickly used to assess a polarization state at any given point of an optical setup on optical benches.

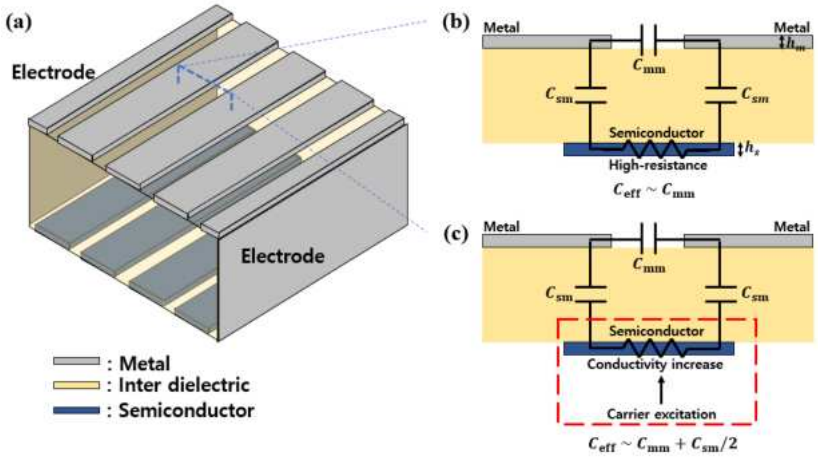
Abstract: In this study, we propose a novel metamaterial configuration utilizing semiconductor conductivity to achieve notable tunability in relative permittivity. Theoretical analysis and simulations confirm the efficacy of this approach. Experimental measurement employing GaAs, including capacitance analysis under LED illumination, reveals this metamaterial's tunability.

Precisely managing the electromagnetic fields is crucial in diverse fields like laser techniques and plasma chambers. Traditional methods of manipulating adjacent materials to control electromagnetic fields had limitations of precise and local adjustment, prompting a shift to metamaterials for more accurate and localized field control. While prior research has left progress in electromagnetic modulation [(1)], obstacles persist, notably in achieving substantial changes and simplifying tuning mechanisms.

Here, we introduce a novel metamaterial concept leveraging the tunable conductivity of semiconductors. The proposed design's functionality is validated through theoretical analysis and electrostatic simulations. Furthermore, experimental validation employing capacitance measurement with a GaAs-based sample confirms this metamaterial's tunable behavior.



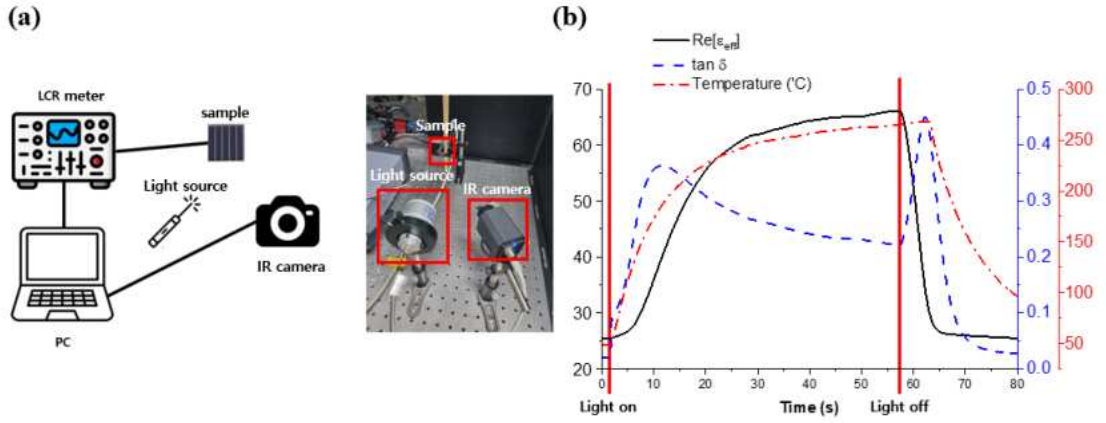


Figure 1. Proposed metamaterial design and working principle analysis from quasi-electrostatic circuit model in the unit cell structure. (a) Schematic of the structure, (b) circuit model and effective capacitance with high-resistance semiconductor and (c) low-resistance semiconductor.

Fig. 1(a) depicts the schematic representation of our metamaterial design, comprising periodic semiconductor

and metal strip-shaped patches arranged in layers, with two layers staggered by half a period. Given the sub-wavelength dimensions of the metamaterial, its operation was elucidated within the quasi-electrostatic regime. Thus, based on the electric circuit analysis, the effective capacitance of one unit cell is determined through the internal capacitor components with a variable resistor that represents the conductivity-variable semiconductor. As demonstrated in Fig. 1(b), when the semiconductor conductivity is low, total capacitance is solely determined by internal capacitance from two metal plates. However, if the semiconductor conductivity becomes sufficiently large, total capacitance increases as an amount of internal capacitance between metal and semiconductor. Detailed value of enhancement can be calculated by using analytical formula derived from quasi-electrostatic assumption:

$$\varepsilon_{\mathrm{eff}} = \frac{a(a-g_{\mathrm{m}}-g_{\mathrm{s}})}{2h_{\mathrm{d}}h_{\mathrm{total}}}\varepsilon_{\mathrm{d}} \tag{1}$$

[Fig.2] (a) experimental setup and (b) measured effective relative permittivity of GaAs-based fabricated sample.

Fig. 2 illustrates the experimental configuration and outcomes of the fabricated GaAs-based metamaterial. The setup utilizes an LED light source to induce conductivity changes in the GaAs semiconductor, and sample temperature is monitored via an IR camera. As depicted in Fig. 2(b), the fabricated metamaterial exhibits a remarkable 2.6 times increase in effective permittivity, closely aligning with the theoretical predictions shown in Fig. 1(b). This newly developed metamaterial holds promise for localized and precise electromagnetic field control.

Real-time terahertz modulation with gold-MoS_2 metasurface

Jianhong Zhang[1], Fangfang Ren[1*], Jiandong Ye[1], Xiaoli Ji[1], and Hai Lu[1]

[1] the School of Electronic Science and Engineering, Nanjing University, Nanjing, China
[*]corresponding author: ffren@nju.edu.cn

Abstract: The authors introduce a method for precise control of terahertz (THz) radiation using a gold split-ring metasurface and MoS_2 layers. Through optical pumping, a high-quality THz signal transmission with 81% modulation depth can be achieved at 0.61 THz, promising advancements in sensing, switching, and filtering for THz applications.

The use of terahertz (THz) radiation, ranging from 0.1 to 10 THz, has gained attention for applications like space exploration, wireless communication, and security checks. Traditional THz devices using natural materials struggle with high modulation depth due to limited interaction with THz signals. Metamaterials, with properties like negative refractive index and perfect lensing, offer potential solutions. This study focuses on metasurface devices with narrowband resonances for advanced THz modulation, aiming for electromagnetically induced transparency-like (EIT-like) resonances with higher quality factors (Q).

The authors demonstrate the modulation of resonance peak intensity by incorporating MoS_2 layers into an asymmetric split-ring metasurface, creating an EIT-like resonance as THz signals traverse the engineered structure. Optical pumps with varying pump fluences are applied to enable real-time manipulation of the EIT-like resonance intensity by adjusting the conductivity in the MoS_2 layers.

The simulation setups using CST studio are employed to analyze the transmission spectra of the proposed hybrid asymmetric split-ring (HASR) metasurface structure. The results demonstrate the emergence of EIT-like resonance profiles under specific structural configurations, particularly when an asymmetric configuration is achieved. To clarify the underlying physical mechanism behind the EIT-like resonance observed in the HASR metasurface structure, the authors conducted calculations to analyze the distribution of surface currents at the transmission resonance peaks or dips, revealing a dipole or quadrupole nature. By systematically varying the structural parameters, the authors delve into the influence of these parameters on the excitation of EIT-like resonances and identifies optimal values for achieving high Q factors and maximizing the modulation depth.

The modulation of the transmission property is investigated under optical excitation with varying pump fluences from 0 to 20.4 $\mu J/cm^2$. In the absence of photoexcitation, an EIT peak emerges amidst two resonance dips, featuring a transmission amplitude of 0.84 at 0.61 THz. As the pump fluence of the pump beam gradually escalates to 20.4 μJ/cm (corresponding to MoS_2 conductivity = 4020 S/m), the EIT transmission decreases in magnitude and undergoes a strong modulation. Consequently, the transmission spectra accomplish a distinctive on-to-off modulation at 0.61 THz characterized by an impressive modulation depth of 81%.

In this modulation process, the recovery time of excited carriers in MoS_2 is approximately in picosecond (ps) range, estimated according to the carrier lifetime of MoS_2.

In summary, the research showcases the potential of metasurface devices for advanced THz modulation through the manipulation of EIT-like resonances. By optimizing structural parameters and conductivity levels within MoS_2 layers, significant modulation depths and precise control over THz signals can be achieved. These findings pave the way for the development of high-speed communication systems and other applications reliant

on THz technology.

Realizing an acoustic T-shaped superscatterer with inverse design

Di Wang[1], Zhongming Gu[1] and Jie Zhu[1]

[1] Institute of Acoustics, School of Physics Science and Engineering, Tongji University, Shanghai 200092, People's Republic of China

Abstract: We present an inverse design approach aimed at realizing efficient and straightforward structures capable of achieving superscattering of ultrasound in water. Through a combination of numerical simulations and experimental investigations, we demonstrate the effectiveness of the proposed super scatterer in significantly enhancing ultrasound backscattering when compared to a rigid cylinder.

Summary

In this work, we propose an effective approach for designing an acoustic super scatterer adorned with T-shaped structures to significantly enhance the sound scattering performance in water. The T-shaped structures are strategically employed to enrich resonant modes and surpass the single-channel limit [1,2]. In order to optimize the structural parameters of the decorations and achieve maximum scattering cross section, we employ the genetic algorithm for global optimization. As a result, the super scatterer exhibits a considerably larger ultrasound shadow region [Fig. 1(b)] in comparison to a cylindrical scatterer with the same diameter [Fig. 1(a)].

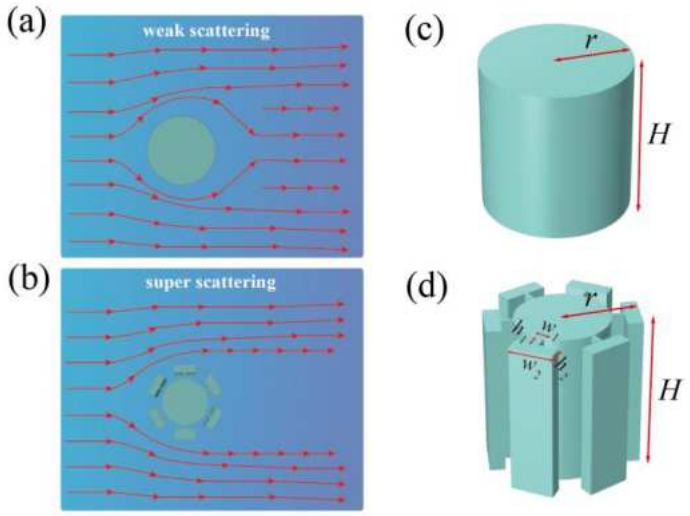

Figure.1 Conceptual schematic of the superscattering effect. (a) and (b) The power flow distribution with the plane ultrasound wave incident from the left. (c) and (d) Models of the cylindrical scatterer and super scatterer.

The T-shaped structures are periodically decorated around the super scatterer, as depicted in Fig. 1(d), which possess four adjustable variables: the length h_1, h_2 and the width w_1, w_2, as well as keep the same radius r with the rigid cylinder in Fig. 1(c). The genetic algorithm is combined with the finite element method to optimize the appropriate geometric parameters, which are all considered as degrees of freedom in the optimization process. It aims to identify the best fit values for the target variables. Subsequently, simulations and calculations are conducted to assess the efficacy

of the proposed methodology. The results obtained through these analyses unequivocally demonstrate that the scattering phenomenon induced by the super scatterer significantly exceeds that of the cylinder scatterer at the target frequency as shown in Figs. 2(a) and (b).

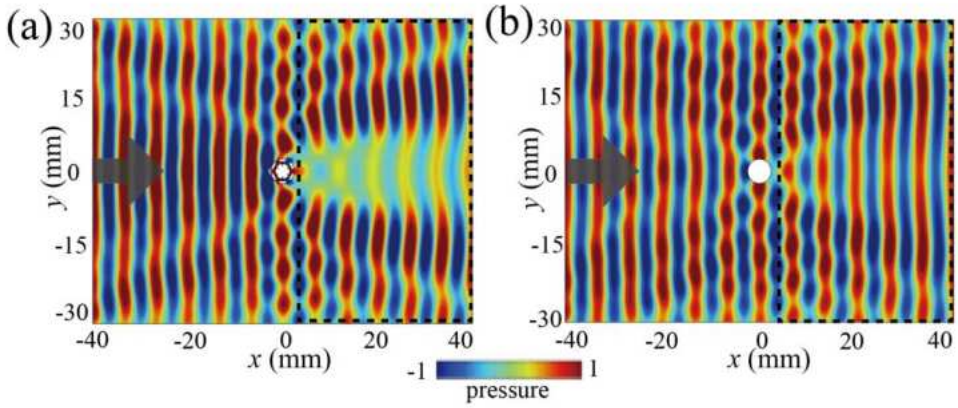

Figure. 2 Numerical simulations of acoustic fields. (a) and (b) Simulated acoustic fields for the super scatterer and cylindrical scatterer, respectively.

Furthermore, we conduct the experimental verifications to validate the superscattering phenomenon. The stainless-steel samples are fabricated using 3D metal printing technology. Besides, all experiments are performed in a dedicated scanning tank and measurements are obtained using an automated scanning system. Notably, the experimental results obtained in water exhibit agreement with the corresponding simulations. The measured data provide compelling evidence of the strong backscattering exhibited by the superscatterer unit. Importantly, it should be emphasized that the working frequency can be arbitrarily tuned by adjusting the structural parameters.

In conclusion, this study successfully achieves ultrasound superscattering in water through the incorporation of T-shaped decorations, which introduces additional resonance modes. By employing an inverse design approach that includes the genetic algorithm and finite element method, we are able to optimize the acoustic super scatterer while considering the complex fluid-structure interaction without relying on complex analytic calculations. The simulation results and experimental measurements exhibit well agreement, validating our proposed model and its superscattering capabilities. The implications of this work extend to various fields where enhanced scattering is demanded, including applications such as acoustic radiation force and medical ultrasound imaging.

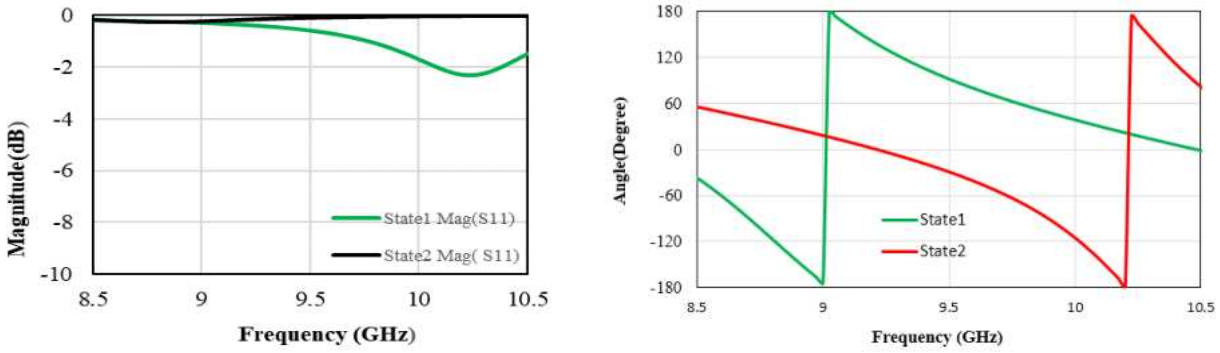
Abstract: In this work, a novel type of reconfigurable intelligent surface (RIS) has been proposed. We have designated these RIS types as '3D RIS.' One advantage that these types of RIS have over traditional RIS is their ability to steer the beam in full space.



Recent research [1-2] suggests that RIS will be the technology of choice for wireless communications applications. The literature describes various types of RIS, including transmissive and reflective [4-5] types, as well as combinations of both reflective and transmissive types, etc. RIS can be categorized into different groups based on various criteria [3]. In this work, we initially designed a 1-bit reflective type of RIS, as illustrated in Figure 1. Figure 1(a) shows a side view of the unit cell, while Figure 1(b) depicts the top view, and Figure 1(c) shows its bottom view.

(a) (b) (c)

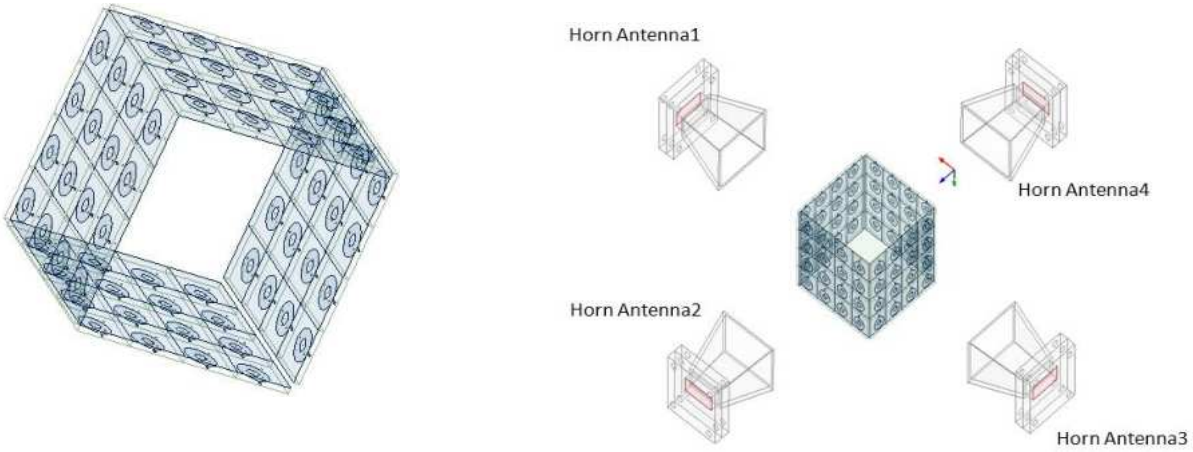


Figure 1: (a) Side view of unit cell (b) top view of the unit cell (c) bottom view of the unit cell

The performance of the unit cell is shown in Figure 2. Figure 2(a) illustrates the magnitude of S_{11} for two different states, indicating magnitudes of -0.31 dB and -0.24 dB observed at 9 GHz. Figure 2(b) displays the

(a) (b)

Figure 2: (a) Magnitude of S_{11} for State1 and State2 (b) Phase of S_{11} for State1 and State2

(a) (b)

Figure 3: (a) Proposed 3D RIS (b) Four horn antenna with proposed 3D RIS

phase of the reflection coefficients at 9 GHz. It is noted here that the unit cell was optimized at 9 GHz for this design. After evaluating the performance of the unit cell, a 3D RIS structure, as shown in Figure 3(a), was proposed. Four planes of the 4×4-unit cell were combined, as depicted in Figure 3(a), to form the 3D RIS structure. To assess the performance of the 3D RIS, four X-band horn antennas, illustrated in Figure 3(b), were designed and positioned in front of the 3D RIS. While similar theoretical concepts have been proposed in the literature, to the best of the authors' knowledge, hardware implementations for this specific type of 3D RIS have not yet been documented. The advantages of this 3D RIS type include its capability to accept incoming signals from various directions and steer the beam as desired. It is noteworthy that in our proposed design, two additional planes can be added, enabling the reflected beam to be steered in all possible directions.

Abstract: A thin, flexible metamaterial-based transmission-type absorber is designed and fabricated on a custom-engineered substrate prepared using silver nanoparticles decorated MWCNT embedded in an epoxy resin polymer. This absorber gives a maximum absorption of 97% at 11.6 GHz with a bandwidth of 0.75 GHz. Fabrication, simulation, and experimental details are presented.

Microwave absorbers are very useful for the defense industry, anechoic chambers, consumer electronics, bolometers etc. Conventional absorbers are generally bulky and do not have frequency frequency-selective nature. In this aspect, metamaterial structures help fabricate thin absorbers for selected frequency ranges. These MMAs are generally designed and fabricated with FR4 as substrates that are not flexible and require more than one resonating element to enhance the bandwidth. Moreover, one cannot modify the property of the substrates to have more loss to improve the bandwidth of absorption. To find the solution for both these problems, one has to fabricate custom-engineered substrates that would have optimum dielectric and magnetic properties for reducing the footprint, introducing flexibility, and enhancing the bandwidth with a simple single-resonating element [1]. To achieve these requirements, one should use polymer nanocomposites that give flexibility in manipulating the properties. It is well known that the properties of the insulating polymers can be tailor-made using different morphologies like spherical particles, 1-D nanotubes, and sheets. Among various electrically conducting fillers, silver nanoparticles, carbon nanotubes, and graphene sheets play a vital role in manipulating the dielectric properties of the composite at microwave frequencies [2].

In this paper, we report the preparation of silver nanoparticles decorated acid-functionalized multiwalled carbon nanotubes embedded in an epoxy resin polymer as a substrate to fabricate a flexible, good bandwidth, and miniaturized metamaterial absorber having a simple resonating structure. The conducting fillers (Ag-MWCNT) were synthesized through chemical methods and reinforced with epoxy (by varying the wt%) through step-wise curing at 90°C for 18 hrs to get polymer nanocomposites of 1.45 mm thickness. The XRD and IR measurements confirmed the presence of Ag-MWCNT and epoxy polymers. The decorations of Ag on MWCNT were confirmed using SEM and HRTEM images. The sample was cut into a sheet of 22 mm × 11 mm such that it fits into the WR-90 waveguide to measure the dielectric permittivity at the X-band (8 to 12 GHz) frequency range. The real part of the relative dielectric permittivity (ε_r') of the substrate varies between 6 and 7 and the loss tangent ($tan\delta$) was around 0.15-0.18. Using this dispersion data, a full wave simulation software CST Microwave Studio® was used to design a simple metamaterial structure on both sides of the sample. Figure 1 shows the front and back sides of the MM structure. The simulated structure had an absorption of over 90% between 10.85 and 12.04 GHz with a

maximum absorption of 97.6% at 11.4 GHz. The structure was fabricated on the polymer substrate and the experiment was performed by keeping the sample in the WR-90 waveguide to obtain the scattering parameters. The obtained absorption indicates a maximum value of 97.3% at 11.26 GHz. Figure 2 provides the comparison between the simulated and fabricated MMA devices showing an excellent match. With a sub-wavelength thickness of only 1.45 mm (0.048λ), this metamaterial absorber is a promising candidate for developing frequency selective, transmission type thin flexible absorber.

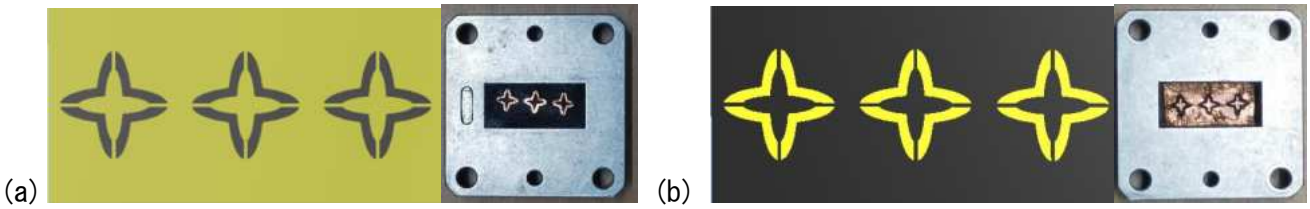

Figure 1. a) Top and (b) bottom views of the proposed metamaterial absorber along with their photographs.

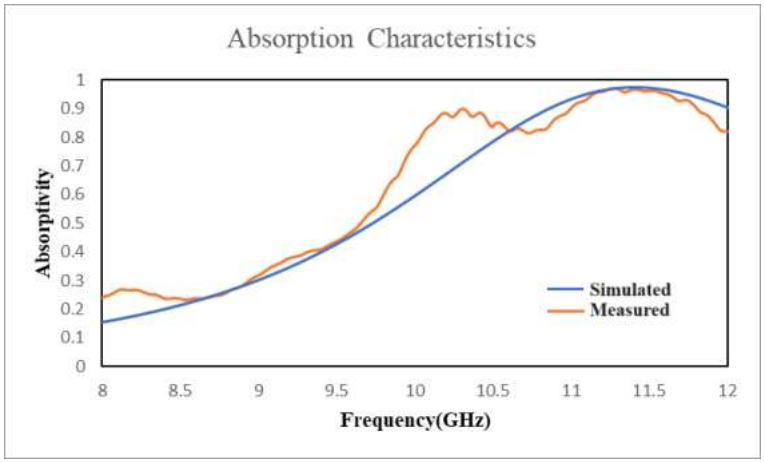

Figure 2: The simulated and experimentally measured absorption data for the developed MMA.

***Abstract*—Here, we introduce dynamic dielectrics medium driven by transmissive tunable metasurfaces. Through the variations of structure or incorporating varactor diode, the metasurfaces exhibits the equivalent electromagnetic features similar to true medium based on the effective medium theory. We validate the viability of dynamic dielectrics and arbitrary permittivity medium.**

I. Introduction

Recent advancements in computational inverse-design approaches have begun to reshape the landscape of structures available in domains of photonics such as nanophotonics and metasurfaces [1], [2]. The methods used to perform structural optimization involve machine learning model, heuristic method (genetic method) or gradient-based approaches (topology optimization) [3], [4]. In the process, the distribution of dielectric medium is gradually optimized to perform ideal optical response. Yet, once the design is complete, the function of the device is fixed, lacking the broad applicability of diverse targets and cannot fulfill the grow demand of real-time and multi-functions for intelligent photonic devices.

In this contribution, we introduce a design strategy that render the transmissive metasurfaces serves as an alternative of dielectric medium in optimization and operation, and give the ability of real-time manipulation of the permittivity based on the equivalent medium theory. The basic thrust of the tunable metasurfaces design stems from the prior knowledge that the incorporated varactor diode or variation of surface structure dimension changes the S parameters of metasurfaces, thus allowing the metasurfaces to serve as a medium whose permittivity depends on the imposed bias voltages. This fine control can achieve arbitrary continuous dielectric constant values, thus reducing the strict requirements for multiphase dielectric medium distribution and improving the convergence speed of optimization. Treating the meta-atom as a tunable dielectric unit, a reconfigurable dynamic focus and the design flowchart are demonstrated. Such on-site regulation features exhibit a promising potential of intelligent photonics devices with multiple functionalities, meanwhile improving the applicability and robustness.

II. Theory And Methodology

According to the effective medium theory, tunable metasurfaces can be equivalent to the corresponding medium with relative permittivity ε and permeability μ [5], [6]. Assuming that a plane wave impinges vertically onto the metasurface slab with thickness d, to retrieve the constitutive parameters, we characterize it as a homogeneous material when d is far less than the incident wavelength λ_0. The S parameters can be formulated as,

$$S_{11} = \frac{R_{01}(1 - e^{i2nk_0d})}{1 - R_{01}^2 e^{i2nk_0d}} \tag{1}$$

$$S_{21} = \frac{(1 - R_{01}^2)e^{i2nk_0d}}{1 - R_{01}^2 e^{i2nk_0d}} \tag{2}$$

where $R_{01} = \frac{z-1}{z+1}$, z is the impedance, and n is the refractive index. Inverting Eq. 1 and Eq. 2, z and n can be derived as,

$$z = \pm\sqrt{\frac{(1 + S_{11})^2 - S_{21}^2}{(1 - S_{21})^2 - S_{11}^2}} \tag{3}$$

$$n = \frac{1}{k_0 d}\{[\ln(e^{ink_0d})]'' + 2m\pi] - i[\ln e^{ink_0d}]'\} \tag{4}$$

Here m is an integer related to the branch index of n'. n' can be obtained by a Taylor expansion approach. Here, ε and μ, as frequency-dependent complex functions, can be extracted as $\varepsilon = n/z$ and $\mu = nz$.

III. Validation

A. Arbitrary permittivity dielectric medium

To be specific, assuming a plane wave impinges onto the metasurfaces vertically where the wave vector is along the negative z-axis. The top layer is rectangular metal patch with the width W. The bottom layer is dielectric substrate with the relative permittivity ε_r = 3.5 (Fig. 1) and the length L = 6 mm. Because the E-field vector is along the y-axis and H-field vector is along the x-axis, the ε_y and μ_x need to be considered as the permittivity and permeability of the effective medium. We set W ranging from 1 mm to 2 mm with the step size of 0.2 mm and the measured permittivity is from 2.83 to 4.45. The retrieved real part of permeability is around 0.995 to 0.998.

And the imaginary part of ε_y and u_x is very close to 0. Thus, the property of the metasurface can be treated as a varying dielectric medium. With the L continuously changing, the effective permittivity of metasurface apparently continuously changes.

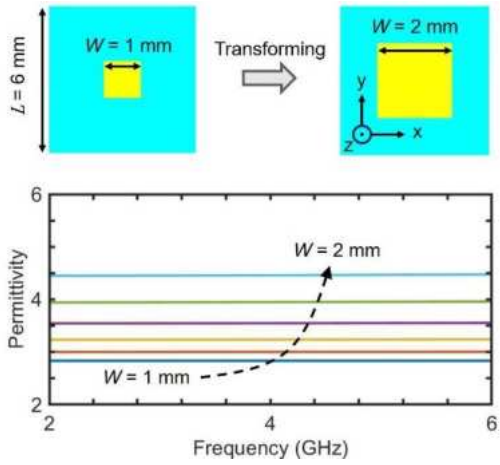

Fig. 1. The front view of metasurface and the retrieved permittivity curves for different metal patches' widths.

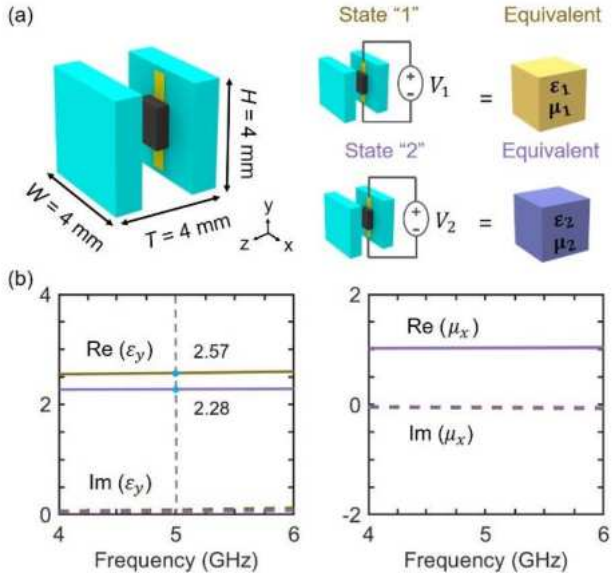

Fig. 2. a, The geometry of tunable metasurface and the corresponding equivalent dielectric under different bias voltages. b, the permittivity and permeability of metasurface when the capacitance of diodes are 0.06 pF and 0.6 pF in 4 – 6 GHz.

B. Dynamic medium based on varactor diodes

The metasurface integrated with varactor diodes can also serve as the dynamic dielectric medium. Tuning the bias voltage on the varactor diodes will change the S parameters of metasurfaces (S_{11} and S_{21}), thus, based on the theory in section 2, it also affects the equivalent constitutive parameters. As a demonstration, the geometry of the designed transmissive metasurface is shown in Fig. 2(a). The meta-atom has three layers; the top and bottom layers (blue blocks) are 1 mm thick F4B substrate with the relative permittivity of 2.55 and the loss tangent of 0.001, and the middle layer is air. The length of cube meta-atom is 4 mm (W, T, H). Two metallic arm-like resonators are etched upon the bottom layer, between which a varactor diode is welded (Aeroflex MGV 125-08). The arm's width b is 0.6 mm and the length h is 1 mm. Without loss of generality, we pick up two states of diode's capacitance (0.6 pF and 0.06 pF) as example, which means that each meta-atom can freely toggle between the two states. Fig. 2(b) shows the retrieved parameters. The retrieved ε_y are 2.28 and 2.57 when the meta-atom works at state "1" and state "2" respectively. For u_x, its real part approaches 1. Both the imaginary part of ε_y and u_x is close to 0.

C. Conclusions

In summary, equivalent dynamic dielectric medium constructed by transmissive metasurfaces have been demonstrated in this work. Based on the effective medium theory, we utilize the change of dimension of metasurface structure to realize the variation of permittivity continuously. Moreover, through biased voltage controlling, the metasurfaces loaded with varactor diodes can be treated as on-site tunable dielectrics. The diodes can respond in microsecond, providing a promising approach to real-time material optimization. Our strategy also can be extended to other multi-functional optical devices with wide band, large scale, and high efficiency, paving the way for the next generation of intelligent photonics devices.

An active Fabry–Pérot interferometer operated at terahertz frequencies based on pitch-variable subwavelength gratings

Y. Huang[1], Y. X. Liu[1], T. Okatani[1], N. Inomata[1], and Y. Kanamori[1*]

[1]Department of Robotics, Tohoku University, Japan

Abstract: We constructed, for the first time, an active Fabry–Pérot interferometer (FPI) operated in the terahertz range by properly integrating a pitch-variable subwavelength-grating (PV-SWG) into an FP cavity. The period of PV-SWG can be varied to change the effective refractive index and shift the optical resonant frequency of the FPI.

1. INTRODUCTION

The waveband of 0.318–0.333 Terahertz (THz) is potential to develop high-speed (~Tb/s) wireless communications[1]. The Fabry–Pérot interferometer (FPI) is a candidate to spectrally filter the waves in this band. Conventional active FPIs tune the resonant frequency by moving the mirror[2] or filling the cavity with the liquid crystal[3], which lead to a lower quality factor (Q-factor) and peak transmittance. In this work, we constructed an active FPI based on subwavelength gratings (SWGs) that exhibits controllable effective refractive indices[4]. The proposed FPI achieves a high Q-factor and peak transmittance.

2. DESIGN

The proposed FPI is schematically shown in Fig. 1. The FPI consists of a pair of Si mirrors separated by an air cavity and an individually adjustable PV-SWG (Fig. 1(a)). As the PV-SWG horizontally deforms, the lattice period p varies and contributes to a change in the effective refractive index n_{SWG} (Fig. 1(b)); the resonance of the FPI then shifts correspondingly (Fig. 1(c)). The geometry of the FPI was designed to obtain an optimal transmittance by performing parameter-sweep calculations using the rigorous coupled-wave analysis method via DiffractMOD. A p of 100 μm, a of 85 μm, t of 200 μm, and d of 1620 μm were determined.

3. EXPERIMENTS

The PV-SWG was fabricated with standard surface micromachining technologies (Fig. 2). The cleaned Si wafer underwent photolithography patterning and ICP-RIE etching followed by resist removal to form the PV-SWG, and then was inserted into a pair of Si mirrors on a holder with a fixed anchor and a movable handle (Fig. 3). The optical performances were measured via a THz time-domain spectrometer (THz-TDS). A sharp peak was found at 0.303 THz in the transmittance spectrum of the FPI with an initial p of 100 μm, the measured Q-factor was 34, and the peak transmittance was 0.87 (Fig. 4). By stretching the movable handle, the pitch of the PV-SWG was varied from the initial p of 100 μm to 150 μm, as a result, the n_{SWG} of the PV-SWG decreased from 2.08 to 1.50, and the measured optical resonant frequency (f_{or}) increased from 0.303 THz to 0.320 THz (Fig. 5).

4. CONCLUSIONS

In conclusion, an active FPI based on effective refractive index control of a PV-SWG was numerically and experimentally proposed. A tunable transmittance peak of a maximum of 0.87 and a Q-factor of 34 for waves around 0.303 THz in frequency was achieved by the PV-SWG-based FPI. The proposed FPI contributes to the development of THz communications.

300-GHz-band transmission-type beamforming metasurface for an outdoor-to-indoor signal coverage extension for future wireless networks

A. Pander*, H. Kagami, D. Kitayama, and H. Takahashi

[1]NTT Device Technology Labs., NTT Corporation, 3-1 Morinosato-Wakamiya, Atsugi, Kanagawa, 243-0198, Japan

Abstract: 300-GHz-band transmission-type metasurface beamformers were designed, fabricated, and evaluated. Beamforming angles in the range of 18° to 38° with a transmission loss of about 4 dB were achieved. Flexibility, good transparency, and broadband operation of the fabricated self-standing devices make them perfect candidates for future outdoor-to-indoor signal coverage extension applications.

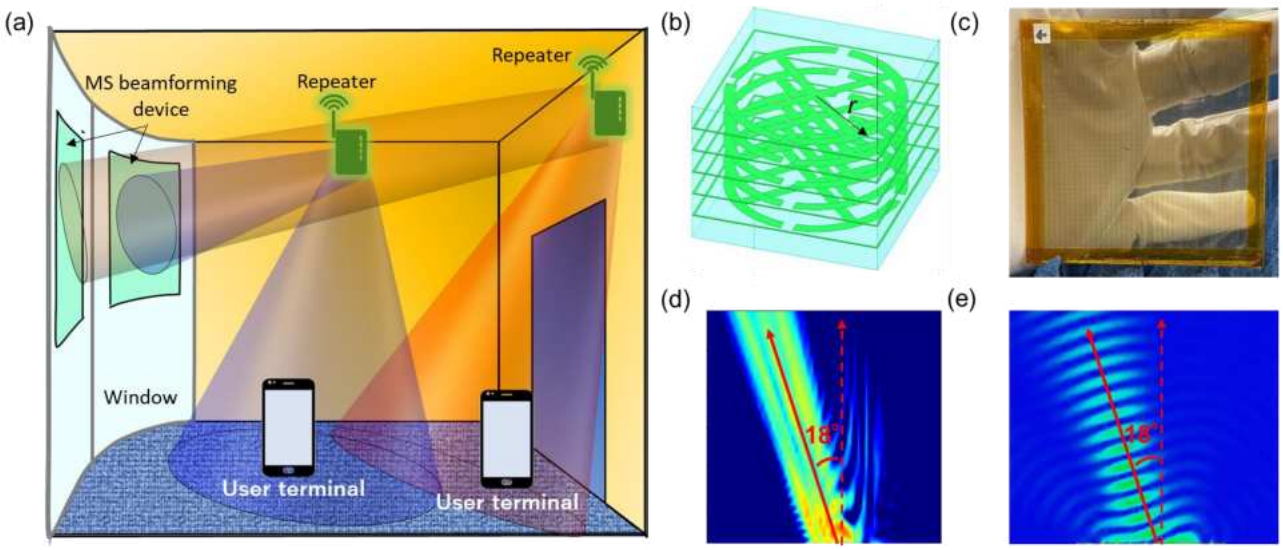

Fig. 1. (a) Schematic representation of the application of passive beamforming metasurfaces in the outdoor-to-indoor signal coverage extension at 300-GHz-band. (b) Schematic of a multilayer metamaterial cell with continuous 2π phase designability. (c) Image of fabricated self-standing beamforming device. (d) The experimental and (e) simulation results of 18° angle beamforming at 300-GHz-band.

In recent years, to meet the constantly increasing demand for larger bandwidth and higher data rates in wireless communication, millimeter-wave frequencies from 30 GHz to 500 GHz became a major development direction to realize high data transmission and high-capacity networks that can support simultaneous users. Despite the promising properties of the high-frequency waves, large space path losses, atmospheric attenuation in gases and rainfall, and non-line-of-sight (NLOS) propagation became the main challenges to overcome [1, 2]. To solve these issues highly-directive millimeter-wave antennas that can configure their radiation pattern to avoid obstacles are required. For this reason, the development of various beamforming techniques, including metamaterial-based designs at millimeter-wave bands, is carried out.

One of the major development directions for passive metasurface (MS) devices at 300-GHz-band wireless communication is the extension of signal coverage. By placing metasurface on various flat and curved surfaces,

such as windows, (Fig.1(a)) is possible to steer the incident beam in the desired direction, for example from the outdoor to the indoor and the other way around [3, 4]. Generally, 300-GHz-band beam steering is difficult to obtain with single-layer binary metasurfaces due to limited phase control and low design efficiency; thus, multilayer metamaterial structures with continuous 2π phase designability are necessary.

In this study, we present a multilayer cell design composed of five layers that can control the transmission phase in over 2π range throughout the change of the radius, *r*, of the structure, as shown in Fig. 1(b). Based on the designed cells, transmission-type devices with different predesigned beamforming angles were fabricated and evaluated. The devices were fabricated using an in-house developed process. An epoxy film was laminated onto the precleaned glass substrates, and the fabrication of metallic patterns was carried out using the conventional photolithography method and electron beam evaporation. The lamination process was repeated five times to form a multilayer structure. As the last step, the device was separated from the bare substrate. An example of a fabricated device is shown in Fig 1(c).

With the successful fabrication of transmission-type metasurfaces, the basic characteristics of the beamforming devices were evaluated. The set of beamforming metasurfaces showed the beam steering angles between 18° and 38° at 300-GHz-band (Fig. 1(d)). The obtained results were in good agreement with the results obtained in the simulation (Fig. 1(e)). The frequency dependency of the fabricated samples was also investigated in the frequency range between 285 and 315 GHz. Only a minor change in the beamforming angle was observed at higher frequencies above 310 GHz. Furthermore, since the devices were stripped from the carrier substrate, the transmission loss was easily evaluated and was within the range of 4-5 dB.

In addition to the evaluated beamforming characteristics, investigated devices exhibited good flexibility and optical transparency of about 60% which makes them very good candidates for low-profile devices that are mounted on buildings, vehicles, and so on.

To the extent of our knowledge, this is the world-first transmission-type metasurface device that combines good flexibility, optical transparency and self-standing design with very good beamforming characteristics, such as low loss, high beam steering angles, good transmission efficiency and broadband operation at 300-GHz-band. The presented device can be successfully applied in the outdoor-to-indoor signal coverage extension in future 6G wireless networks.

Abstract: Van der Waals materials are at the core of modern optoelectronics and nanophotonics. However, relatively litlle research attention is devoted to their giant optical anisotropy. Here, we demonstrate that the use of giant anisotropy leads to the next-generation integrated circuits and optical elements.

Materials with high optical anisotropy are of great importance in technology and science [1]. Recently, one of the largest birefringence in the visible and near-infrared intervals up to 0.8 was reported in quasi-one-dimensional crystal BaTiS3 [2]. However, anisotropic nanophotonics requires optical anisotropy of about 1.5 to fully exploit advantages of anisotropic properties [3, 4]. Inspired by this challenge, we focused on two-dimensional materials and their bulk counterpart – van der Waals (vdW) materials. Our findings showed that their fundamental difference between interlayer strong covalent bonding and interlayer weak van der Waals interaction leads to unprecedented high birefringence with values exceeding 1.5 in the infrared and 3.0 in the visible spectral intervals (for example, see optical constants of MoS2 in Figure 1). Thus, our studies enable a new field of vdW anisotropic nanophotonics.

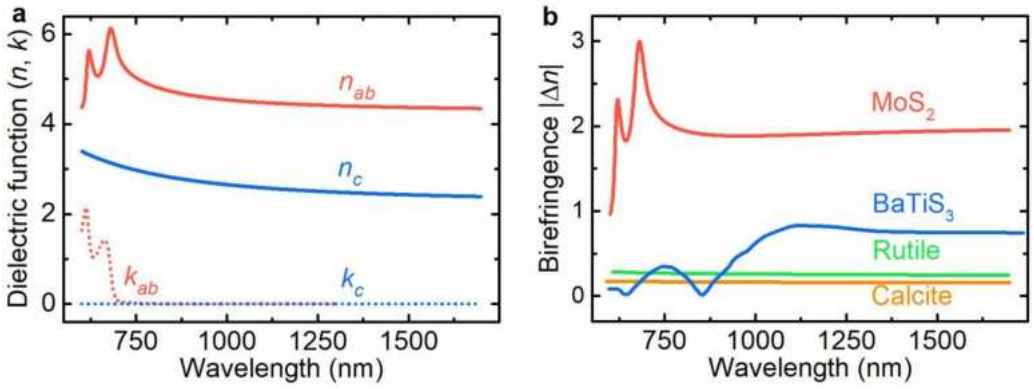

Figure 1: a. Optical constants of MoS2. b. Birefringence of MoS2 in comparison with other anisotropic materials.

In detal, we managed to achieve unmatched lateral dimensions for van der Waals-based waveguides with only several tens of nanometers footprint. In other words, it gives a unique opportunity to place around 10000 waveguides on an mm-scale photonic chip. These characteristics make us a step closer to electronic integrated circuits. Hence, vdW-based photonic integrated circuits can become a decisive platform for an electronic-to-photonic replacement to increase computer data processing. The idea behind the use of vdW materials has four advantages. First, vdW materials have larger optical bandgap in comparison with conventional high refractive index materials (TiO_2, GaP, Si, Ge, and many others) and, therefore, smaller operation wavelength without dissipative losses. Secondly, vdW materials have one of the largest refractive indices among known materials. Thirdly, the record-breaking optical anisotropy of vdW gives an additional degree of freedom for the design optimization of integrated photonic elements. Finally, vdW materials have dangling bonds-free surfaces and atomically sharp edges after the lithography process, which results in minimum scattering losses in photonic waveguides and high intensity nonlinear properties in addition to superior linear response. From a broader perspective, we would like to note that these vdW features are also beneficial for countless optical devices (resonators, dielectric mirrors, waveplates, and many others) beyond on-chip integration.

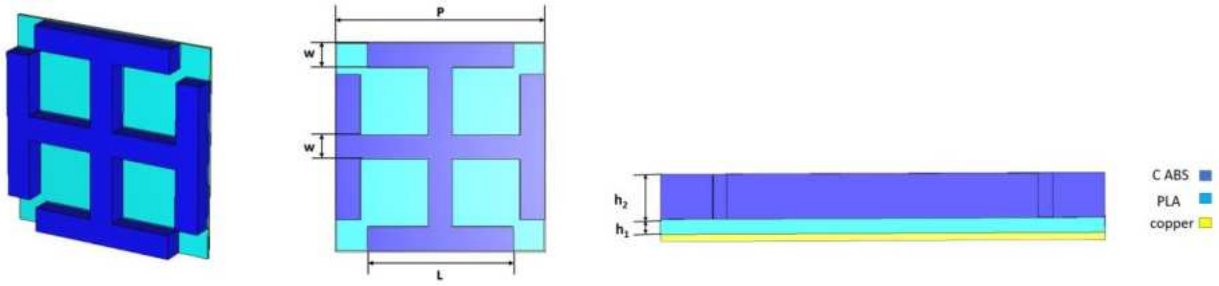
A Broadband Metamaterial-Based Electromagnetic Absorber with the Capability of being Fabricated by 3-D Printers

M. Javadi[1], L. Yousefi[1,2*]

[1] School of Electrical and Computer Engineering, College of Engineering University of Tehran, Tehran, Iran



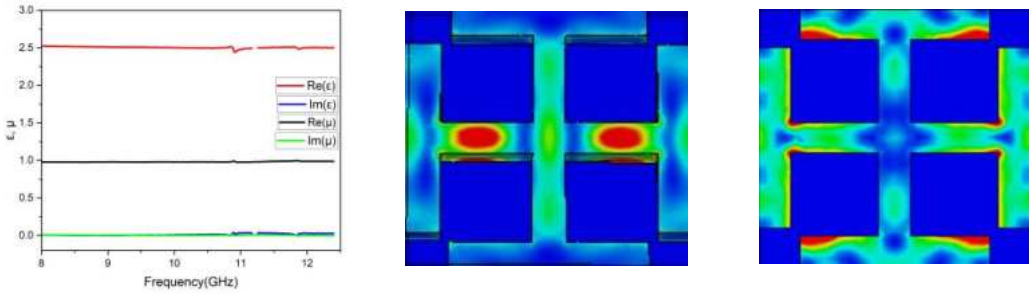
[2] School of Engineering and Informatics, University of Sussex, Falmer, UK, BN1 9RH,

*corresponding Author: l.yousefi@sussex.ac.uk

Abstract: In this paper, a broadband metamaterial-based electromagnetic absorber is proposed which can be fabricated by 3-D printing techniques. The proposed structure provides an absorption of more than 90% in the whole frequency band of 8-12 GHz, for all incident angles in the range of 0 to 30 degrees, and for both TE and TM polarizations.

Electromagnetic (EM) wave absorbers can efficiently absorb the incident waves at their operating frequencies. With the rapid development of Electromagnetic technology, EM wave absorbers have found a variety of practical applications, in sensors [1], imaging systems [2], stealth technology [3], and energy harvesting [4]. Metamaterial-based absorbers are much thinner and lighter than the traditional bulky EM absorbers. However, their absorption bandwidth is inherently narrow due to the resonance nature of metamaterials [5], [6]. Here, a broadband metamaterial-based absorber is proposed that can be fabricated using PLA (Polylactic acid) and conductive ABS (Acrylonitrile Butadiene Styrene), common filaments used in 3-D printing technology. To make the absorber broadband, we have designed the metamaterial to resonate at different frequencies and by using conductive ABS which is a lossy material, we have combined these resonances together resulting in a broadband response for the designed absorber.

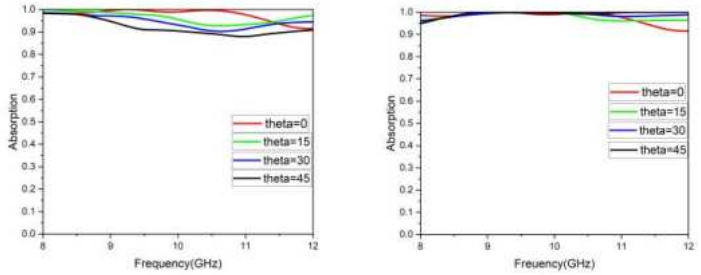
The proposed unit cell is shown in Fig. 1. As shown in this figure, the absorber unit cell consists of a PLA substrate, cross-shaped metamaterials made from conductive ABS, and a thin copper layer. The metamaterial shape and dimensions are optimized to achieve a broadband response.



(a) (b) (c)

Fig. 1. Schematic of the unit cell of the proposed metamaterial-based absorber a) perspective view b) top view c) side view. The dimensions are as P=60 mm, L=42 mm, w=7 mm, h1=0.8mm, h2=5mm.

To illustrate the performance of the proposed structure, here, we perform full wave numerical simulation using CST software. The structure is excited using an incident electromagnetic plane wave, and the copper layer is modeled with the conductivity of 5.96×10^7 S/m. For the electromagnetic properties of the conductive ABS, we have used the data reported in [3]. For the PLA layer, we have measured its electromagnetic properties using the waveguide method [7] and the measured data is shown in Fig. 2a. Figures 2b, c show the field distribution inside the cell at two different resonance



frequencies. As shown in this figure, at different resonance frequencies, field is concentrated in different parts of the metamaterial resulting in a broadband response.

Figure 3 illustrates the absorption of the proposed structure, for different incident angles. As shown in this figure, the absorption exceeds 90% across the whole frequency band of 8-12 GHz , for incident angles in the range of 0 to 30 degrees, and for both TE and TM polarizations of the incident wave, illustrating a polarization-independent broadband response.

[*]corresponding author: atasolam@phys.uoa.gr

Abstract: We present an effective medium approach for the study of metamaterials made of cylindrical scatterers/meta-atoms based on the Coherent Potential Approximation. We demonstrate the power of this approach and a rich metamaterial behaviour, including frequency regions of engineerable negative permittivity, negative permeability, negative refractive index and hyperbolic response.

The emergence of dielectric metamaterials, supporting resonances and thus interesting metamaterial effects beyond the quasitatic regime (where the wavelength inside the scatterer/meta-atom is comparable to the meta-atom size), made extremely valuable the development of effective medium approaches able to accurately describe the metamaterial response in such frequency regimes, i.e. to go beyond the well-established Maxwell-Garnett effective medium approach. Such approaches are more valuable in the case of meta-atoms made of a polaritonic material, where the dielectric function experiences strong positive and strong negative values. To be able to accurately describe the wave propagation in polaritonic systems of *spherical* scatterers (as well as of high-index dielectric scatterers) different extension of the Maxwell-Garnett approaches have been developed [1]. No such approach though is available (to our knowledge) for systems of cylindrical scatterers.

Here we present an effective medium approach able to accurately describe the wave propagation in metamaterials made of cylindrical scatterers well-beyond the quasi-static regime. Our approach is based on the well-known in the Solid State Physics community Coherent Potential Approximation (CPA) method. In the case of metamaterials made of simple cylinders it was first derived by Yu et. al. [2]. In our work we further developed the approach of Yu et. al., and we extend it the case of coated- and multi-coated cylinders with a potential to incorporate a metasurface at each interface. The cylinders material can be either dielectric, or metals, or polaritonic material or any other resonant isotropic material. The covering metasurfaces can have both magnetic and electric surface impedance, representing for example graphene sheets, patterned or unpatented.

Application of our approach in different realistic cylinder-based systems has revealed in almost all cases an interesting and rich metamaterial response [3,4]. The main idea of the CPA approach for the determination of the homogeneous effective medium parameters describing an inhomogeneous system/metamaterial is the vanishing of the average scattering between the actual system/metamaterial and the effective medium under determination as described in Fig. 1. In Fig. 2 we demonstrate the application of our CPA-based approach for a metamaterial made of SiC cylinders in air. Specifically, we show the effective permittivity and permeability for the two possible incident wave polarizations. Observing the resonant response of the effective parameters, one can identify frequency regions of negative permeability, of combined negative permittivity and permeability resulting to negative refractive index, as well as of hyperbolic response (resulting from mixed positive and

negative permittivity or permeability values).

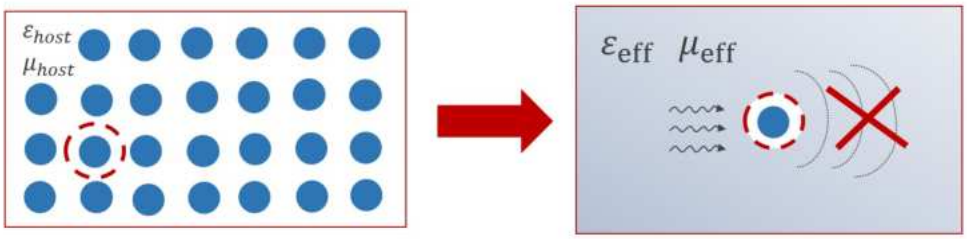

Fig. 1. The application of CPA effective medium approach for the homogenization of a system (left panel) comprising of simple cylinders (blue color) in a host material (white color). The effective medium (uniaxial in this case) is determined by the requirement of vanishing of the average scattering between it (the effective medium) and the actual medium.

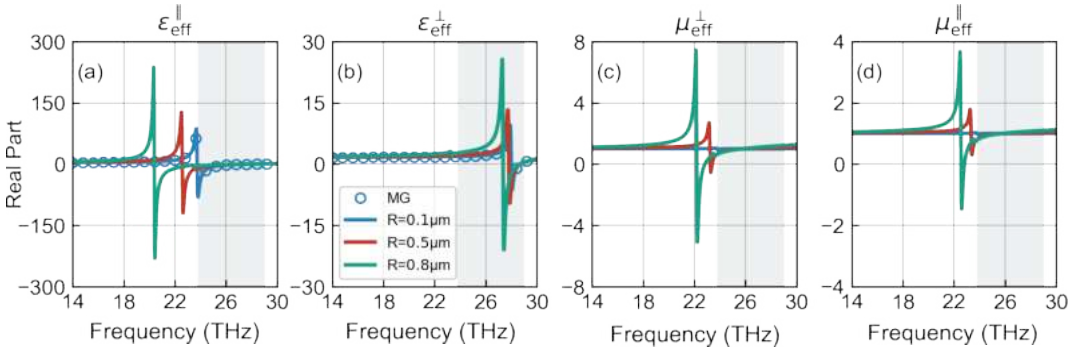

Fig. 2. Real part of the effective permittivity ($\varepsilon_{\mathrm{eff}}$) and permeability ($\mu_{\mathrm{eff}}$) for a system of SiC cylinders in air, in filling ratio 30%. The gray region indicates the frequency regime where the SiC (bulk) permittivity is negative. The superscripts in $\varepsilon_{\mathrm{eff}}$ and μ_{eff} indicate the polarization of the corresponding field in respect to the cylinders axes. The different curves show results for different cylinder radius (R) and the circles present (for comparison) the corresponding results given by the well-established Maxwell-Garnett approach.

We developed an effective medium approach for the description of metamaterials made of cylindrical scatterers. The scatterers can be simple cylinders, coated or multicoated cylinders, and can have a metasurface at each interface. Moreover, almost any material is allowed as constituent of the cylindrical scatters (including resonant materials). Application of the method for systems/metamaterials made of polaritonic cylinders in a host revealed a rich metamaterial response in such systems, including engineerable negative permittivity, negative permeability values, negative refractive index and hyperbolic response.

Enhancing Bandwidth in GHz Metamaterials through Superposed Lorentzian Resonances

Y. Hyeong[1], H. Park[1], and J. Shin[1*]

[1]Korea Institute of Science and Technology, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: In this study, we propose a GHz-metamaterial with an extended μ bandwidth. Initially, we theoretically investigate the trade-off relationship between magnetic permeability and bandwidth. Based on these results, we introduce a magnetic metamaterial comprising superposed Lorentzian resonances at adjacent frequencies.

Magnetic permeability is one of the fundamental properties that determine the electromagnetic response of a material. However, unlike its counterpart, electric permittivity, magnetic permeability has a fundamental limit on bandwidth. This limitation in the case of a system that can be expressed with a single resonance has been well described analytically by Kabiri et al. [1]. However, the calculations only apply to systems consisting of a single magnetic resonance. In order to extend the problem, the magnetic permeability model for multiple resonance systems is introduced:

$$\mu_{\text{eff}} = 1 + \sum_{i=1}^{m} \frac{a_i \omega^2}{\omega_i^2 - \omega^2 - i\omega\Gamma_i} \tag{1}$$

where a_i is the i[th] resonance amplitude, ω_i is the i[th] resonance frequency, and Γ_i is the i[th] damping frequency, respectively.

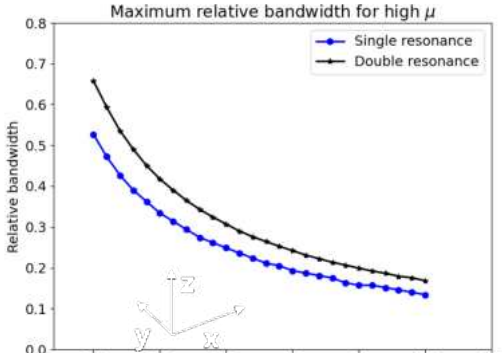

Figure 1 Maximum relative permeability of double resonance system

Based on this model, we investigated the trade-off relation of magnetic permeability and the continuous high permeability bandwidth of a double Lorentzian system using a Brute force method. Figure 1 shows the maximally achievable continuous high-permeability bandwidth depending on the cut-off criteria in single and double Lorentzian resonance systems. For example, the maximally achievable relative bandwidth of $\mu \geq 2$ of single and double Lorentzian resonance systems are 0.343 and 0.4179, respectively. From this result, it is shown that superposing multiple magnetic resonances at adjacent frequencies can extend the high-permeability bandwidth of permeability.

Figure 3 (a) Unit cell of multi-Lorentzian metamaterial (b) Schematic drawing of the multi-Lorentzian metamaterial array

Here, we propose a GHz metamaterial comprising superposed Lorentzian resonances. The metamaterial consists of 2 conductive loops with different loop areas and linewidths as shown in the unit cell in Figure 2 (a). Due to this asymmetry, the magnetic resonances occurring in the structure have slightly different resonance and damping frequencies, thus, resulting in superposition of Lorentzian resonances with similar frequencies. The schematic drawing of the metamaterial array is shown in Figure 2 (b). The structure is periodic in the xy-plane, and 1mm thick (1 layer) in z direction.

Figure 2 Effective permeability extracted from optimized metamaterial structure

We calculated the reflectance and transmittance of the structure using Finite-Difference Time-Domain simulations, and retrieved the effective permeability using the method illustrated by Chen et al. [2]. The optimized result in Figure 3 shows $\mu \geq 2$ bandwidth in $9.55 - 11.9$ GHz, which is 21.9% in relative bandwidth.

The Bandgap Characteristics of Wave Dispersion in Monocoupled Metamaterial

A.Bhatt[1*], and A.Banerjee[2]

[1] Department of Civil Engineering, Indian Institute of Technology Delhi, India
[*]corresponding author: Abhigna.Sandipkumar.Bhatt@civil.iitd.ac.in

Abstract: Previously, wider bandgap and band merging in metamaterial with simultaneous negative mass and stiffness were noted [1,2]. This article identifies double attenuation peaks in such metamaterial, attributed to
resonance coupling of longitudinal and transverse resonators, ensuring significant spatial attenuation throughout the band.

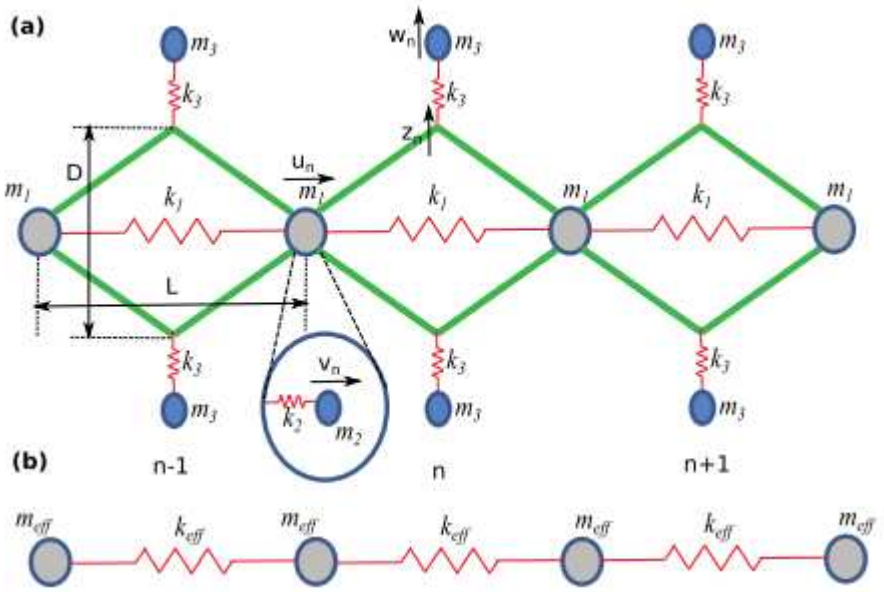

Fig.1 (a) Concurrent negative metamaterial model, (b) Phononic crystals chain

In this research, the focus is on examining the attenuation characteristics, effective mass, and stiffness of acoustic metamaterial that exhibits both negative mass and stiffness simultaneously [3]. By delving into these properties, the study aims to understand how sound waves are affected within this unique material structure. Furthermore, the study investigates the rate at which attenuation occurs across space, which is determined by considering the imaginary component of the propagation constant. This analysis provides insight into how effectively the metamaterial can dampen waves across different spatial dimensions. A crucial aspect explored in the research is the coupling phenomenon between resonators within the metamaterial structure [4]. When the natural frequencies of these resonators are close to each other, they interact and influence each other's behavior. This interaction leads to a distinctive double peak phenomenon within a single attenuation band. This double peak phenomenon is significant because it enhances the material's ability to attenuate sound waves across a wide frequency range. It ensures that the attenuation rate remains substantial throughout the entire bandgap, contributing to the effectiveness of the metamaterial in controlling and manipulating wave propagation.

Wave Dispersion Equation,

$$\xi = \cos^{-1}\left(1 - \frac{\omega^2 M_{eff}}{2 K_{eff}}\right) \tag{1}$$

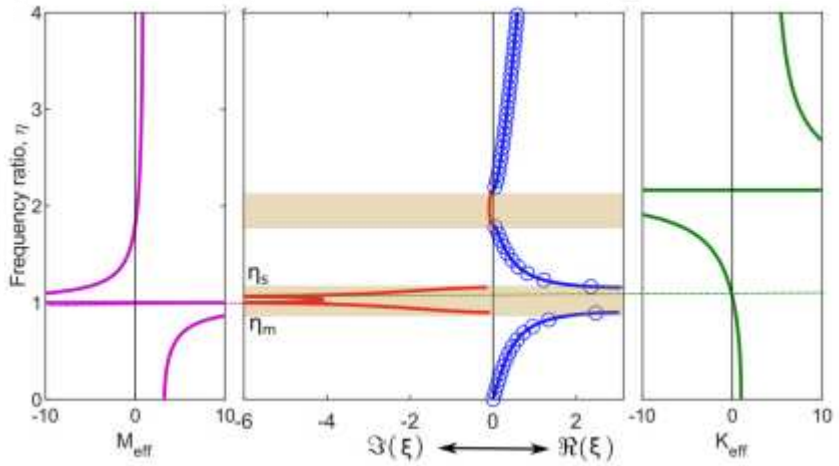

Fig.2 Graphs illustrating Effective Mass, Dispersion Curves, and Effective Stiffness are presented. The dashed purple line represents the peak in attenuation, while the dashed green line indicates the peak within the attenuation band.

This results in coupling between the two resonators, leading to a double peak within a single band. As a consequence, a high level of attenuation is noticeable across the majority of the attenuation band, unlike in other bands. Hence, a substantial decrease in wave amplitude is anticipated in the spatial domain.

Abstract: An innovative design is proposed for a dissipative triatomic elastic metamaterial to obtain asymmetric wave transmission to realize asymmetric wave transmission in two low-frequency bands. These frequency bands can be analytically and experimentally predicted to realize two paths of wave propagation and wave attenuation along two different directions of transmission.

Based on the transmission equations of the inner and end unit cells derivations, the transmission equations of the entire system for both opposite directions, T^L and T^R, can be calculated respectively as:

$$\left.\begin{aligned} T^L &= \left|\frac{\hat{v}_Q}{\hat{v}_0}\right| = \left|\prod_{\eta=1}^{Q} T_\eta^L\right| \\ T^R &= \left|\frac{\hat{z}_Q}{\hat{z}_0}\right| = \left|\prod_{\eta=1}^{Q} T_\eta^R\right| \end{aligned}\right\} \tag{1}$$

The critical size of hybrid metal-dielectric nanoslits guide mode resonance optical filters by the spatial Fourier transform analysis

R. He[1*], C. Chen[2], Y. X. Zheng[2], L. Y. Chen[2], and J. P. Guo[3*]

Abstract: In this work, we analyze the performance of hybrid metal-dielectric nanoslits guide mode resonance optical filters using finite-difference time-domain simulations and spatial Fourier transform analysis. We propose the empirical values of the critical sizes in both lateral dimensions for maintaining the filter performance.

Surface plasmon resonance optical filter, all-dielectric guide mode resonance optical filter, and hybrid guide mode resonance optical filter are three subwavelength nanosurface optical filters. The periodic surface nanostructures function as a light wave coupler to couple the free-space optical wave into the guided mode. Previous works have reported that the finite sizes in both lateral dimensions affect the spectral linewidth and transmittance of the filter[1-2].

In this work, we simulate the performance of hybrid metal-dielectric nanoslits guide mode resonance optical filters using finite-difference time-domain numerical simulations and spatial Fourier transform analysis. Figure 1(a) shows the structure of hybrid metal-dielectric nanoslits guide mode resonance optical filters. The hybrid GMR filter consists of a thin gold nanoslit grating, a low refractive index magnesium fluoride (MgF_2) layer, a high refractive index silicon layer, and an MgF_2 substrate. A finite-difference time-domain (FDTD) software (Lumerical Solutions, Inc.) is used to calculate the transmittance spectra.

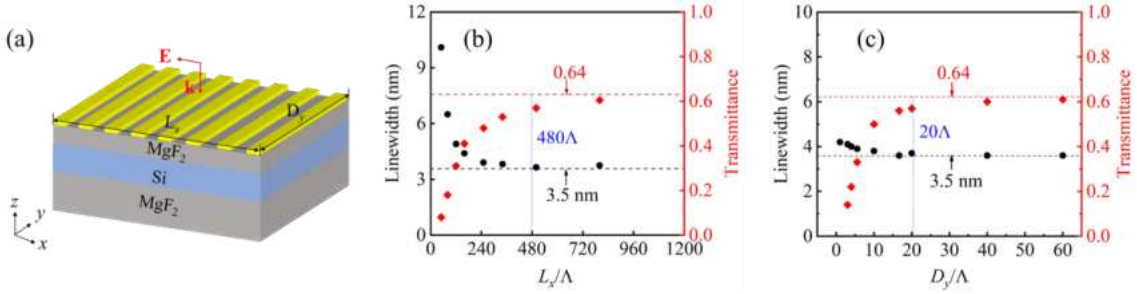

Fig. 1. (a) The structure of the hybrid metal-dielectric nanoslits grating guided-mode resonance metasurface optical filter with a finite size. (b)-(c) The spectral linewidth and transmittance versus the filter sizes in the x and y directions.

Figure. 1(b) shows the transmittance peak linewidth and transmittance versus the filter size L_x. The black dots show that, when the filter size is less than 250Λ, the peak linewidth increases from 3.5 nm corresponding to the peak linewidth of the infinite filter structure. The red diamonds show that the peak transmittance drops dramatically when L_x is less than 480Λ. So, in the x direction, the critical size is 480Λ and the value of 480 is close to the quality factor of the infinite-size filter. Fig. 1(c) plotted the spectral linewidth and the peak transmittance versus the finite size D_y. It is seen that the critical size in the y direction is 20Λ which is much less than the minimum size in the x direction.

Next, the Fourier transform is used to explain the critical size of the hybrid metasurface optical filter in the two lateral directions. When the filter sizes (L_x and D_y) are less than the critical sizes, the device consists equivalently of an aperture window and an infinite-size hybrid optical filter, as shown in Fig. 2(a). After the 1D

aperture window, the diffracted waves with different amplitudes and propagation directions, indicated by θ or α, immediately pass through the infinite-size filter. The transmittance of the finite-size filter is,

$$T(\lambda)=\frac{\iint\left|\iint_{\infty}F(k_x,k_y)\cdot t(k_x,k_y,\lambda)\exp\left[-\mathrm{j}(k_x\cdot x+k_y\cdot y)\right]\mathrm{d}k_x\mathrm{d}k_y\right|^2\mathrm{d}x\mathrm{d}y}{\iint\left|\iint_{\infty}F(k_x,k_y)\exp\left[-\mathrm{j}(k_x\cdot x+k_y\cdot y)\right]\mathrm{d}k_x\mathrm{d}k_y\right|^2\mathrm{d}x\mathrm{d}y}, \qquad (1)$$

where F(k_x, k_y) is the Fourier transform of the aperture function. t (k_x, k_y, λ) is the transmission coefficient of the infinite size filter. According to the spatial Fourier transform of the 1D aperture window function, there exists a critical size to make the most energy focus on the diffracted waves of the incident angle less than the critical angle. Only the diffracted wave of the incident angle less than the critical angle of the infinite-size filter contributes to the transmittance of the filter.

Fig. 2 (b) shows the transmittance versus incident angle (θ and α) of the infinite-size filter in the x-y plane (red) and y-z plane(black). It is seen that the critical angles in the x and y directions of the infinite-size filter are 0.66° and 10°. Figs. 2 (c)-(d) show the calculated transmittance versus filter size L_x or D_y by using the FDTD simulation and Fourier transform analysis. The transmittance curves obtained by the Fourier transform analysis agree well with the transmittance curves calculated by the FDTD numerical simulations. Compared with the minimum size for maintaining the performance of the infinite filter in the x-direction, the size in the y-direction is much less. The different minimum sizes in two lateral directions are due to the difference in critical angles.

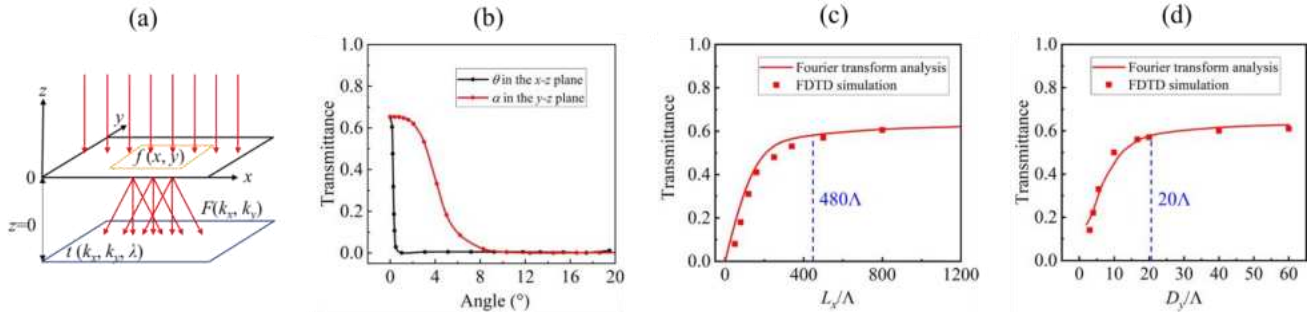

Fig. 2 (a) A schematic of finite size hybrid nanoslits grating GMR optical filter. (b)The transmittance versus incident angle of the infinite-size filter in the x-y plane (red) and y-z plane(black). (c)-(d) The calculated transmittance versus filter size L_x and D_y.

In this work, we show that, in the nanoslits periodic array direction, the critical dimension size for maintaining the performance of the hybrid GMR optical filter is the product of the period and the quality factor of the infinite-size filter. In the grating strip direction, the minimum size is 20 times the slit period which is much less than that of the other direction because of the slow change of the transmittance of the infinite-size device on the angle of incidence in the grating strip direction

Abstract: We propose the first nonreciprocal magnetoelectric metamaterials with resonant responses at visible and mid-infrared frequencies and without the requirement of external magnetic bias. The designed metamaterial consists of randomly oriented nanocylinder meta-atoms comprising a ferromagnet in a single-domain magnetic state and a high-permittivity dielectric operating near the magnetic Mie-type resonance.

The nonreciprocal magnetoelectric (NME) effect refers to bianisotropic phenomena within which a magnetic field leads to the induction of electric polarization, while reciprocally, an electric field results in the production of magnetization [1]. This effect that happens in materials with both broken parity symmetry and reciprocity is negligible in conventional materials, however, it is expected to have a pioneering impact on applied physics, such as magnetless isolators [2]. As the NME effect can be enhanced using the metamaterial paradigm, several attempts have been made based on the metamaterials technique to achieve a remarkable NME effect (surpassing that in some natural materials), however, most of them were restricted to the microwave spectrum rather than the optical spectrum. In addition, the execution of a three-dimensional isotropic NME metamaterial based on the prior proposals at microwave frequencies and more recent advancements at optical frequencies is unattainable with current technology. Here, we propose the first isotropic optical NME metamaterial that operates without the requirement for an external magnetic field, utilizing common materials and nanofabrication methods [3].

In the proposed isotropic NME metamaterial, a bottom-up approach is employed for the design and analysis of an NME meta-atom and subsequently, the electromagnetic response analysis of a bulk metamaterial consisting of randomly oriented meta-atoms in a host medium, which is considered to be air for simplicity. The meta-atom design features a nanocylinder consisting of two components as shown in Fig. 1(a): a ferromagnet or ferrimagnet (ferrite) in a single-domain magnetic state, paired with a high-permittivity semiconductor or dielectric that functions near the magnetic Mie-type resonance. The ferromagnetic Weyl semimetal $EuCd_2As_2$ and amorphous silicon are considered for the upper and bottom parts, respectively. The Weyl semimetal has an anomalously strong magneto-optical response within the mid to far-infrared frequency range. To prevent the requirement of an external magnetic field, the ferromagnetic component of the nanocylinder is selected to maintain a single magnetic domain, which results in its spontaneous magnetization. In addition, the high-permittivity semiconductor nanocylinder considerably increases the NME effect of the meta-atom because its operation is at the magnetic Mie-type resonance. The single-domain state of the ferromagnetic component restricts its dimensions. The dimensions of the meta-atom are mentioned in the caption of Fig. 1(a).

Figure 1(a) presents a qualitative illustration of the NME effect in a meta-atom when it is stimulated by a

standing wave characterized by a *y*-polarized electric field, with the node of the magnetic field located at the center of the meta-atom. To clarify, only the moments that contribute to the NME effect are depicted here. As demonstrated in Fig. 1(a), the *y*-polarized optical electric field generates a *y*-aligned optical magnetic moment within the meta-atom that is the essence of the optical NME effect. As an alternative, an incident optical magnetic field would induce an electric dipole moment.

(a) (b) (c) (d)

Fig. 1. (a) NME meta-atom comprises Weyl (upper) and amorphous silicon (lower) parts. The dimensions of the meta-atom are h_{Si} = 26 nm, h_{Weyl} = 530 nm, and D_{Weyl} = 530 nm. The field map illustrates the distribution of the magnetic field within the meta-atom when it is in resonance (λ = 5 μm). (b) The isotropic mid-infrared NME metamaterial where yellow arrows indicate the directions of the local spontaneous magnetizations ($\mathbf{M}_s$) within the single-domain ferromagnetic nanocylinders. (c, d) Effective permittivity and Tellegen parameters of the metamaterial (effective permeability of metamaterial is approximately one in this spectrum) [3].

The constitutive relations of isotropic NME metamaterial where the designed meta-atoms are distributed and oriented randomly read

$$\mathbf{D} = \varepsilon_0 \varepsilon_{\text{eff}} \mathbf{E} + \chi_{\text{eff}} / c \, \mathbf{H}, \qquad \mathbf{B} = \mu_0 \mu_{\text{eff}} \mathbf{H} + \chi_{\text{eff}} / c \, \mathbf{E}. \tag{1}$$

Here, c stands for the speed of light, and ε_{eff}, μ_{eff}, and χ_{eff} are the effective permittivity, permeability, and NME parameters. As meta-atoms are arranged randomly, only isotropic effects such as the NME effect can remain. The effective parameters of the metamaterial (Fig. 1(c, d)) show that the NME parameter χ_{eff} at 5.2 μm reaches the value of 0.36 where the volume fraction of metamaterial is N_V = 0.12. This value exceeds four orders of magnitude compared to known natural material at optical frequencies. At the same wavelength, the magnitude of effective permittivity is comparable to the NME parameter (Fig. 1(c)).

In this work, we theoretically proposed the first realistic attempt to attain bias-free optical metamaterial with a nonreciprocal magnetoelectric response. We developed the mentioned procedure to design an NME metamaterial based on conventional materials, such as cobalt and silicon. In the cobalt-based metamaterial, the magnitude of the NME effect surpasses that of natural materials at room temperature by a minimum of two orders of magnitude [3].

First-principles prediction of nonlinear optical response in silicon nanostructures

Gosuke Matsuura[1], Shunsuke Yamda[2], and Mitsuharu Uemoto[1]

[1] Graduate School of Engineering, Kobe University, Japan.

[2] National Institutes for Quantum Science and Technology (QST), Japan.

Abstract: We use multiscale method combining electromagnetics and quantum mechanical simulations to make first-principles predictions of harmonic generation by semiconductor nanostructures. The enhancement of harmonic generation in silicon nanocylinder array is investigated, and its dependency on geometric parameters is analyzed; e.g. the optimum radius representing resonant condition R=25nm is found.

The optical response of nanoscale artificial structures gets attention. In particular, nano-optical devices utilizing nonlinear optical effects under intense laser pulses are expected to enable highly efficient optical wavelength conversion and waveform shaping. Second harmonic generations (SHGs) and high harmonic generations (HHGs) by semiconductor nanoparticles and meta-surfaces have been experimentally confirmed. Simulation of optical response by electromagnetic field analysis is widely used for device analysis and design in fields such as nano-optics. However, conventional electromagnetic field analysis has weaknesses, including difficulty in nonlinear responses in strong light fields and the need for empirical parameters such as dielectric constant. To overcome such weakness, we develop the multiscale method, which combines finite-difference time-domain (FDTD) electromagnetic calculations and first-principles electron dynamics calculations [1-2]. In quantum mechanical calculations, the time-dependent density functional theory (TDDFT) has been used for analyzing laser-matter interactions ("Maxwell+TDDFT") [3]. However, it requires a lot of computational cost. We also develop the semiconductor Bloch equation (SBE)-based multiscale calculation ("Maxwell+SBE"). The governing equation of the electron dynamics is expressed as:

$$\mathrm{i}\frac{\partial}{\partial t}\rho_{ij}^{(\mathbf{k})}(t) = \frac{1}{c}\mathbf{A}(t)\cdot\left[\sum_{l}\mathbf{p}_{il}^{(\mathbf{k})}(t)\,\rho_{lj}^{(\mathbf{k})}(t) - \sum_{l}\rho_{il}^{(\mathbf{k})}(t)\,\mathbf{p}_{lj}^{(\mathbf{k})}(t)\right], \tag{1}$$

where ρ is the density matrix, **p** is the transition dipole moment, and **A** is the vector potential. We couple with Maxwell's wave equation involving the current density J in this electron system and calculate the time evolution.

$$\nabla\times\nabla\times\mathbf{A}(\mathbf{r},t) + \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\mathbf{A}(\mathbf{r},t) = \frac{4\pi}{c}\mathbf{J}(\mathbf{r},t). \tag{2}$$

Incidentally, the coefficients in our SBE [Eq. (1)], such as dipole moment **p**, are calculated from the ground state's wavefunctions, also used as the initial state of TDDFT calculations; our SBE results qualitatively agree with those of TDDFT [see Fig.(a)]. Owing to SBE's less computational cost than TDDFT, the Maxwell+SBE is capable of large scale device models.

In this study, we utilize the Maxwell+SBE method to simulate light excitation and scattering properties in a silicon nanocylinder array under the high-intensity laser pulses. An enhancement of electric field due to Mie resonance caused by the cylinder and light focusing by lensing effect [see Fig. (b)]. This behavior significantly differs that observed from the previously studied nanofilm structure [3]. The power spectrum analysis of the electric field indicated the presence of higher-order harmonic components [see Fig. (c)]. We analyze the effect of varying the size and spacing of the nanocylinder on the intensity of the electric field. The results show that there is a dependence on the size of the cylinders, with a maximum around 25 nm in radius, coinciding with Mie resonance condition [see Fig.(d)]. We also calculate the frequency-resolved electric field profile of propagating light and investigate the characteristics of profiles representing each harmonic order [see Fig. (e)]. We will consider not only cylinders, but also geometries with cylinders attached to a base that approximates a practical meta-surface.

In conclusion, we utilize multiscale Maxwell+TDDFT and Maxwell+SBE methods to simulate the harmonic generation from silicon nanostructures. Our results provide insights into the design and optimization of nonlinear optical devices utilizing nanostructures and meta-surfaces.

Abstract: We demonstrate a nonlinear metasurface that combines electrical and optical switching in a single device. Broadband mid-infrared to visible light conversion is attained in a metasurface that couples mid-infrared radiation to electrically tunable hybrid graphene-gold plasmons. All-optical switching measurements suggest that the device can be operated at Terahertz rates.

Nonlinear metasurfaces are versatile multifunctional photonic elements that allow for simultaneous generation and manipulation of light in subwavelength scales[1]. Such minute control of optical nonlinearities has enabled novel applications such as nonlinear holography[2], beam shaping[3,] and the generation of quantum-correlated photon pairs in nanoresonators[4]. Active tuning of nonlinear metasurfaces may greatly expand their viability for integration with photonic devices. However, the metasurfaces' building blocks, usually dielectric or metallic nanostructures, have limited dynamic tuning, and an external voltage barely affects their plasmonic or dielectric resonances.

Here we demonstrate a multifunctional nonlinear metasurface that combines electrical and optical switching in a single device. Figures 1(a) and (b) illustrate the electro-optical tunable metadevice and the optical scheme to convert mid-infrared pulses into visible light. The metasurface consists of an array of gold nanorods on top of graphene – a material with exceptional nonlinear optical properties for its thinness[5]. The device is arranged in a back-gated field-effect transistor configuration, and an SEM image of a section of the metasurface is shown in Fig. 1(c). In this metasurface, mid-infrared radiation couples to hybrid graphene-gold plasmons[6], which can be switched on and off by the back-gate voltage, as shown in the transmittance spectrum in Fig. 1(d). A pulsed mid-infrared beam is converted into visible light using a gating femtosecond (150 fs) near-infrared pulse centered at λ = 800 nm. Through interaction with the third-order nonlinearity of graphene, a four-wave mixing (FWM) signal is generated at the frequency $\omega_{FWM} = 2\omega_{MIR} + \omega_{800nm}$, where ω_{MIR} is the frequency of the mid-infrared beam. The energy diagram of this interaction is shown in Fig. 1(b).

Figure 1(e) shows the spectra of the measured FWM signal for different mid-infrared input frequencies. The FWM signal falls in the visible, between 570 and 710 nm, for the range of mid-infrared input frequencies between 4 and 10.5 μm accessible to our experimental system. In Fig. 1(f) we show the "switching ratio" of the four-wave mixing signal, which is defined as the ratio of the nonlinear signal at high doping (0.45 eV) to the signal at low doping (0.15 eV) for both the metasurface (the rods on graphene) and bare graphene. Bare graphene attains a switching ratio of nearly 3x for 9 μm mid-infrared input and around 2x for most of the input range. The metasurface, however, has a higher switching ratio than bare graphene over the entire range, reaching a maximum switching ratio of approximately 8x. Notably, the metasurface switching ratio increases sharply as the wavelength is increased toward the graphene plasmon resonance centered at 7.5 μm.

To characterize the optical switching dynamics of the device, we conducted a cross-correlation experiment, as shown in Fig. 1(g), where we changed the delay between the mid-infrared beam and the 800 nm gate pulse. The cross-correlation experiment for the metasurface at 7.5 μm was taken for two voltage states: 40 V - near the charge

neutral point -, and -10 V. The temporal dynamics of the metasurface is sensitive to the voltage, showing a tunable FWHM (between 180 and 210 fs) and a 44 fs shift in the maximum FWM signal. At 40V, near the charge neutrality point, the gold nanorod resonance dominates. At -10 V, however, the mid-infrared pulse couples to graphene plasmons, changing the dynamics of the FWM process. The signal remains for longer delays between the beams since the sample contains near-fields even after the mid-infrared beam has passed.

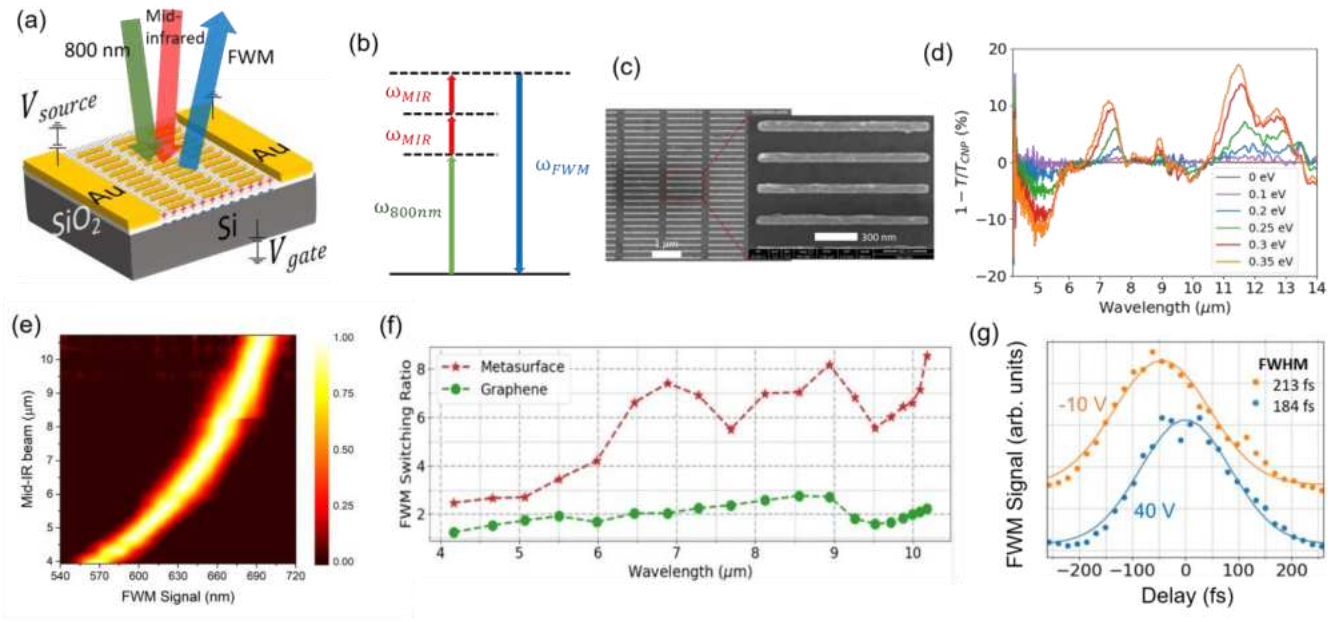

Figure 1. Electro-optical tuning in a nonlinear metasurface. (a) Illustration of the device and the pulse scheme. (b) Energy level diagram for the FWM process. (c) SEM image of the device. (d) Differential transmission spectra of the metasurface as a function of the Fermi level of graphene. (e) FWM signal of the metasurface for several mid-infrared input frequencies. (f) Switching ratio of the FWM signal. (g) Optical switching dynamics of the metasurface.

We demonstrated a novel scheme for simultaneous electrical and optical switching in metasurfaces. Our work represents a significant step for developing electro-optical metasurfaces that convert light from contrasting regions of the electromagnetic spectrum, with potential applications in optical information processing and quantum transduction.

Metasurfaces and flat optics

Tunable filter based on the Brewster effect in metafilms: From all-pass filter to narrowband perfect absorber

Tomohiro Hoshino[1] **and Yasuhiro Tamayama**[1*]

[1] Department of Electrical, Electronics and Information Engineering, Nagaoka University of Technology, Japan

Abstract: We show that the ratio of the non-radiative loss to the radiative loss of a broadband reflectionless single-layer metamaterial designed so that the Brewster effect occurs can be controlled by varying the arrangement of the constituent meta-atoms without changing the structure of the meta-atoms.

Control of the complex transmission (reflection) spectrum is one of the most important topics in applications of electromagnetic waves. To realize an arbitrary complex transmittance (reflectance) in a single-layer metamaterial, the reflectance (transmittance) needs to be zero. As a broadband reflectionless single-layer metamaterial, we developed Brewster metafilms in our previous study.[1] The Brewster metafilm is realized by two-dimensionally arranging the meta-atoms so that the oscillation direction of the induced electric dipole $\boldsymbol{p}$ in the meta-atoms coincides with the propagation direction of the reflected wave as shown in Fig. 1(a). The complex transmittance of the Brewster metafilm is written as

$$t = \frac{-\mathrm{i}(f - f_0) - \gamma_\mathrm{r} + \gamma_\mathrm{nr}}{-\mathrm{i}(f - f_0) + \gamma_\mathrm{r} + \gamma_\mathrm{nr}}, \qquad (1)$$

where f is the incident frequency, f_0 is the resonance frequency of the Brewster metafilm, and γ_r (γ_nr) is the radiative (non-radiative) loss of the Brewster metafilm. It is found from this equation that the Brewster metafilm behaves as an all-pass filter for $\gamma_\mathrm{nr}/\gamma_\mathrm{r} = 0$ and a narrowband perfect absorber for $\gamma_\mathrm{nr}/\gamma_\mathrm{r} = 1$.[2] In this study, we show that $\gamma_\mathrm{nr}/\gamma_\mathrm{r}$ can be controlled by varying θ in Fig. 1(a) without changing the structure of the meta-atoms.

First, we describe the theory for controlling $\gamma_\mathrm{nr}/\gamma_\mathrm{r}$ without changing the structure of the constituent meta-atoms. The non-radiative loss is determined by materials that compose the meta-atoms. In contrast, the radiative loss is determined by the relationship between the incident electromagnetic fields and the arrangement of the meta-atoms as well as by the structure of the meta-atoms.[3] When the electromagnetic wave propagates along the direction for which the radiation pattern of the meta-atom is large, the electromagnetic wave strongly interact with the meta-atom, which implies the large radiative loss. Therefore, when the meta-atoms are arranged as shown in Fig. 1(a), the radiative loss becomes maximum for θ=45˚ and vanishes for θ=0. If the non-radiative loss is independent of θ, $\gamma_\mathrm{nr}/\gamma_\mathrm{r}$ may be controlled by varying θ without changing the structure of the meta-atoms.

To verify the above theory, we design a Brewster metafilm composed of meta-atoms made of only aluminum. In this case, the non-radiative loss is caused by the Joule loss in aluminum. Figure 1(b) schematically shows the structure of the Brewster metafilm. The unit structure is composed of an electric inductor-capacitor (ELC) resonator combined with two vertical lines, which are used

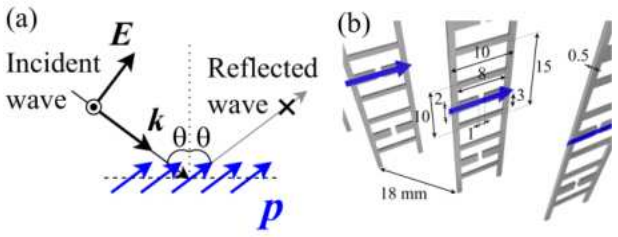

Figure 1: (a) Relationship between the electromagnetic fields and the induced electric dipole in the meta-atoms for realizing the Brewster effect in a single-layer metamaterial. (b) Geometry of the designed Brewster metafilm.

solely for fixing ELC resonators without substrates and do not respond to the incident electric field.

Figure 2 shows the measured and simulated transmission spectra of the Brewster metafilm for several values of θ. As θ decreases, the absolute value of the complex transmittance at the resonance frequency first decreases and then increases. For θ=9˚, the transmittance at the resonance frequency almost vanishes. The variation range of the transmission phase is 2π (smaller than π) when θ is larger (smaller) than 9˚. The theoretical fit of the experimental data to Eq. (1) is also shown in Fig. 2. The fitted curves agree with the experimental data.

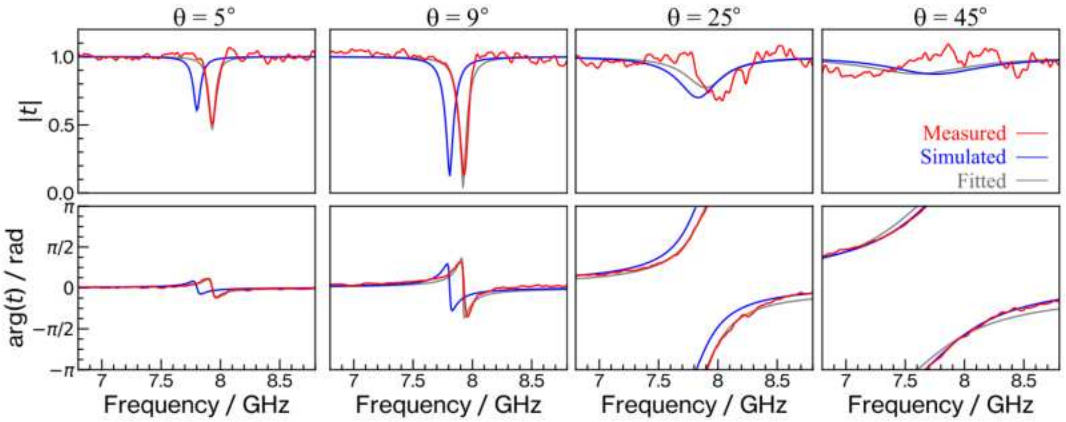

Figure 2: Frequency dependences of the absolute value and the argument of the complex transmittance for several values of θ.

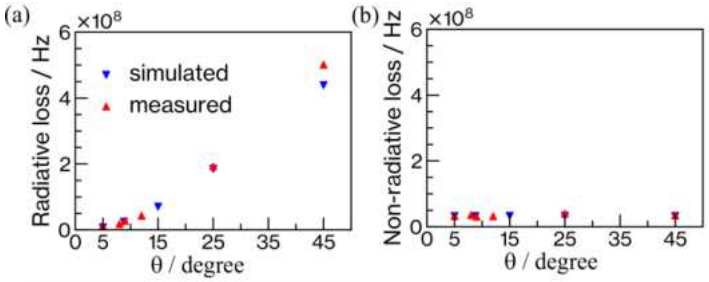

Figure 3: Dependences of (a) the radiative and (b) non-radiative losses on θ.

The radiative and non-radiative losses determined by the fitting are shown in Fig. 3. The radiative loss decreases with decreasing θ, while the non-radiative loss does not show significant dependence on θ. The value of γ_{nr}/γ_r is much smaller than unity for θ=45˚ and becomes unity for about θ=9˚.

In conclusion, we demonstrated the control of γ_{nr}/γ_r in the Brewster metafilm by varying the arrangement of the constituent meta-atoms without changing the structure of the meta-atoms. Because the reflectance of the Brewster metafilms vanishes irrespective of the frequency, the total complex transmittance of the stacked Brewster metafilms agrees with the product of the complex transmittances of the constituent Brewster metafilms. Therefore, the frequency dependence of the complex transmittance may be easily designed in a broad frequency region by stacking the Brewster metafilms with various resonance frequencies, non-radiative losses, and θ.

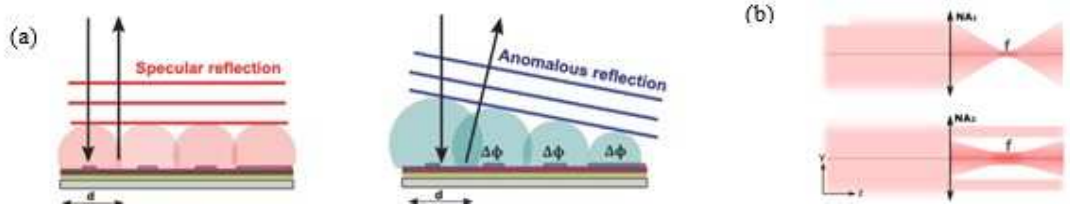
Abstract: Chalcogenide phase-change materials can enable active control of metasurfaces, but the effects of high-power sources on such devices is not yet well-studied. Here, we develop a model for the optical response of metasurfaces subjected to high-power lasers and apply it to previous designs for a beam steerer and a lens.

Metasurfaces allow precise control of optical wavefronts, and have found applications in perfect absorbers, beam steerers, holograms, polarisers, lenses and more [1,2]. Their possible applications are further expanded if they can be actively controlled. Among possible active control mechanisms, one of the most promising is the incorporation of chalcogenide phase-change materials (PCMs) into the metasurface design.

PCMs have two solid phases, amorphous and crystalline, with substantially different optical and electrical properties. Each phase is stable at room temperature, yet can be converted to the other with a suitable thermal stimulus [1]. This allows the optical response of a metasurface to be switched between at least two states, with the further possibility of harnessing intermediate, partially crystallized states for further increased functionality. However, the device will be heated by the light it manipulates, and if the source is high-power, this creates the risk of unwanted switching of the PCM, which could adversely impact on the desired optical response of the device. In this work, we explore the response of PCM metasurfaces to such high-power stimuli, considering in particular, (i) an active beam steerer that switches between anomalous and specular reflection, introduced in reference [2], and (ii) an active lens that controls numerical aperture introduced in reference [1]. These are illustrated schematically in figure 1.



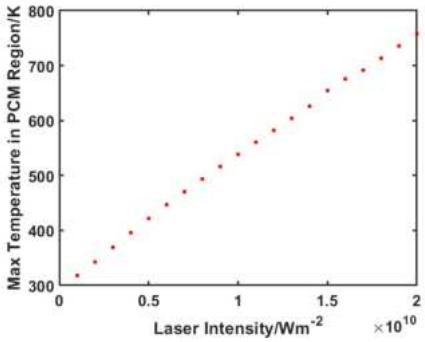


Figure 1. (a) Schematic representation of operation of PCM metasurface beam steerer (adapted with permission from [2]). (b) Schematic representation of operation of NA control lens (adapted with permission from [1]).

We simulate the evolution of the temperature distribution in these metasurfaces under different laser intensities with the commercial finite element analysis package COMSOL Multiphysics. The relationship of maximum temperature to laser intensity for the beam steering metasurface is shown in Figure 2(a). We next combine the thermal model with a Gillespie Cellular Automata (GCA) crystallisation model, based on the work of reference [3], which divides the PCM region into cells to determine stochastically, based on crystal growth and nucleation rate equations, if each cell should experience crystal nucleation, growth or dissociation in each time step. Exemplar growth and nucleation rates, here for the PCM composition $Ge_2Sb_2Se_4Te_1$ (GSST for short) are plotted in figure 2(b), accompanied by simulated crystal distributions for heating at different temperatures.

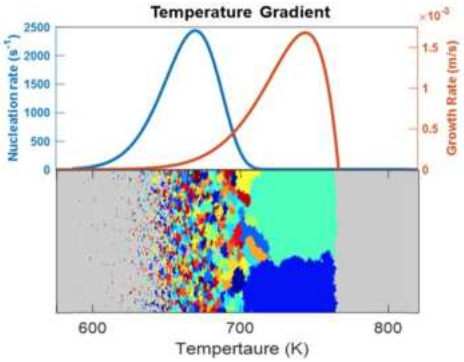
(b)



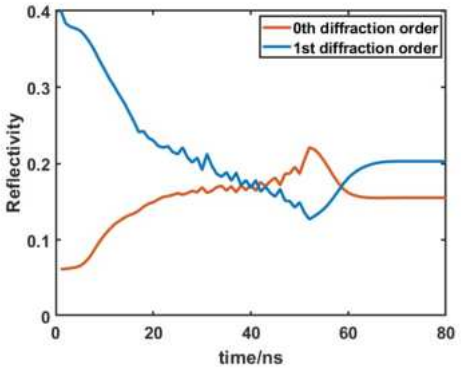


Figure 2. (a) Maximum temperature of PCM layer in the beam steering metasurface of [2] as a function of laser intensity. (b) Nucleation and growth rates for GSST, along with depiction of crystallization at different temperatures. Each colour is a different crystal grain.

Applying our approach to the beam steering metasurface, we find no significant change in optical performance for intensities up to 10^{10} Wm^{-2}, but at higher intensities unwanted crystallization occurs and degrades device performance, as shown in Figure 3(a). We then apply our approach to the active meta-lens. It is computationally demanding to represent the whole lens in one model, so we first explore the responses of individual meta-atoms. High absorption in the crystalline state makes this state the limiting factor. Unwanted amorphisation sets in at around 3×10^{9} Wm^{-2}; the resulting change in optical phase over time is illustrated in figure 3(b).

(a)

(b)

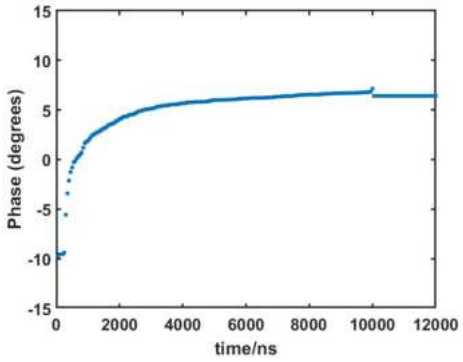

Figure 3. Time evolution of (a) the reflectivity into different diffraction orders when the beam steering metasurface from [2] is subject to a 50 ns pulse of peak intensity 5×10^{10} Wm^{-2}, and (b) the optical phase of crystalline lens unit cell from [1] subject to a 10 μs pulse of peak intensity 3×10^{9} Wm^{-2}.

In summary, we have developed a combined thermal and GCA crystallization model for the response of PCM metasurfaces to high-power laser illumination. Our work highlights the importance of studying the power-handling capabilities of PCM based metasurfaces for high-intensity laser applications.

Abstract-

Metalens is a two-dimensional wave manipulator that enables modulating properties of the light with remarkable versatility. In this work, we investigate centimeter-scale cylindrical metalens which operates at a wavelength of 1064 nm with a focal length of 20 mm.

Conventional optical components such as lenses, beam splitters, and prisms play a crucial role in the functionality of telescopes, microscopes, cameras, and displays. However, intricate manufacturing processes and material constraints restrict implementing finely surface curvature and achieving optimized quality, leading to bulky and complex optical system and aberrations. A metasurface, a two-dimensional (2D) wave manipulator capable of modulating the amplitude, phase, and polarization of waves via tailor-made arrangements of meta-atoms. It has been successfully demonstrated in the role of conventional optical components such as focusing, clocking, absorbing, and steering [1-3].

In this work, we demonstrate centimeter-scale cylindrical metalens. We design and fabricate a size of $14\times17\ mm^2$ metalens which has a focal length of $200\ mm$ and operates at $1064\ \mu m$. It has a thickness of $500\ \mu m$, which is much thinner than the conventional refractive lens. We characterize the metalens with an experimental setup and it shows focusing performance comparable to conventional counterparts. We believe that our work paves the way for practical metalens applications.

Diverse reconfigurability in far- and mid-infrared few-layer metasurfaces capable of polarization manipulation: case of phase-change materials

A. E. Serebryannikov[1,*] and A. Lakhtakia[2]

[1]ISQI, Faculty of Physics, Adam Mickiewicz University, 61-614 Poznan, Poland

Abstract: Numerical studies on few-layer metasurfaces have clarified how functionality and its possible switching depend on the way in which tunable components are incorporated in the meta-atoms. Two thermally tunable materials, VO_2 and InSb, were used in the few-layer metasurfaces with and without resonant components that are capable of polarization manipulation and related asymmetric transmission.

The use of electrically, magnetically, and thermally tunable materials opens diverse avenues for designing reconfigurable and programmable metasurfaces. Metasurfaces containing thermally tunable phase-change materials (PCM) are widely studied, since their electromagnetic properties change at environmentally feasible conditions. The shapes, volume, properties, and locations of components made of tunable materials determine achievable functionalities and reconfigurablity scenarios which can be controlled by just one parameter—the temperature (T). We compared few-layer metasurfaces comprising either subwavelength resonators or grids, or both, which are fully or partially made of a PCM existing in the metallic (M) phase at higher T and the insulator (I) phase at lower T. The purpose was to compare the functional capability in two cases, i.e., when (i) a PCM fully replaces metals, and (ii) a PCM is used as a material for one layer, while a metal is used in the others, assuming that asymmetric transmission (AT) is obtainable for one of the phases. Functionality switching scenarios typically differ for the cases (i) and (ii). Fig. 1 presents normal-incidence transmission-coefficient magnitude (in terms of S-parameters) vs. frequency for three few-layer metasurfaces comprising split rings [1], calculated using VO_2 parameters from Ref. 2.

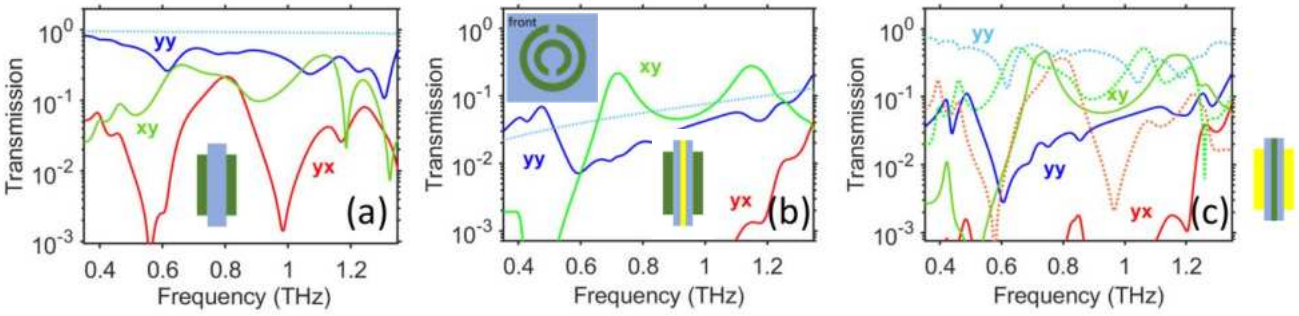

Figure 1. Simulated co-polarized (*xx* and *yy*) and cross-polarized (*yx* and *xy*) transmission-coefficient magnitude for normal incidence on the front (left) face of (a) coupled layers (oriented at 0 deg and 90 deg in the front and back layers) of double split rings made of VO_2; (b) same as (a) but with a Cu-hole layer in the middle; (c) complementary to (b), i.e., with double split rings made of Cu and a VO_2-hole layer. Solid lines – M-phase of VO_2. Dotted (lighter) lines – I-phase of VO_2. Distance between front and back layers is 19.7 μm, period along the *x* and *y* axes is 210 μm, thickness of VO_2 components is 8.75 μm; and interlayer spacer's relative permittivity is 2.1. One of the cross-polarized components must be at least moderately larger than the other cross-polarized and the co-polarized components to achieve AT.

Moderately strong cross-polarized transmittances can appear in the M-phase of VO_2 even in metal-free structure, see Fig. 1(a). However, co-polarized transmission remains strong so that efficient AT cannot be obtained. In the I-phase of VO_2, this regime is changed for co-polarized transmission (passing). Placing a layer of holes in a Cu sheet in the middle results in the weakening of the co-polarized transmittance and of one of the two cross-polarized transmittances, so that AT is possible for M-phase, but the efficiency is not high enough; see Fig. 1(b). Reflection is dominant for I-phase in this case. That is why the resonant and tunable structural components should be *separated*, as in Fig. 1(c). High-contrast AT is achieved in M-phase (at 0.75 and 1.18 THz). In I-phase, it is switchable for the spectral regimes with both co- and cross-polarized transmittances being strong or moderate. Selectivity occurs so that the spectral regimes with strong effect of the phase change do not coincide for *yx* and *xy* transmittances. Moderate-contrast AT is achieved also in I-phase (at 1.06 THz) and replaced by weak transmission in M-phase. Use of only non-resonant components may yield better performance [3].

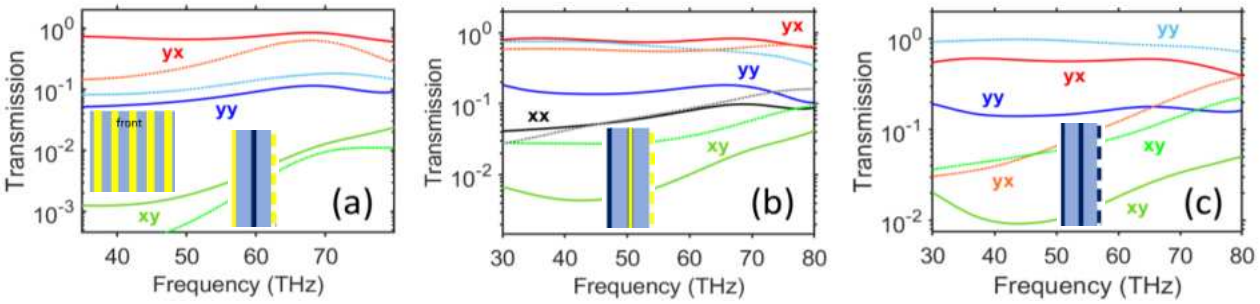

Figure 2. Simulated co- (*xx* and *yy*) and cross-polarized (*yx* and *xy*) transmission-coefficient magnitude (normal incidence) on the front face of three-layer metasurface (oriented at 0 deg, 45 deg, and 90 deg) with strip grids: (a) middle layer is made of VO_2, the other two of Cu; (b) front layer is made of VO_2, the other two of Cu; (c) all layers are made of VO_2. Solid lines – M-phase, dotted lines – I-phase. Distance between front and back layers is 1.75 μm; period in the front/back layers is 1.05 μm and 1.856 μm in the middle layer; thickness of VO_2 components is 87.5 nm; and spacer's relative permittivity is 2.1.

Wideband AT is achieved in M-phase for the only-grid structure in Fig. 2(a). It is switched for dominant reflection, say, at 35-45 THz in I-phase. At 67 THz, the phase change leads rather to variations of contrast and efficiency of AT. Wideband AT is achieved at 30-70 THz in M-phase, also in Fig. 2(b). In I-phase, it is switched for the regime with both *yx* and *yy* transmittances significant but the *xy* transmittance very weak. Generally, the *yy* transmittance is more sensitive to the phase change than the *yx* transmittance. Interestingly, the *yx* transmittance is not sensitive to the phase change at 77 THz. Switching between the moderately efficient AT and co-polarized passing is achieved in Fig. 2(c), at least for 30-60 THz. For I-phase, the cross-polarized transmittance increases with frequency. The structures in Fig. 2 can be *rescaled* for rather arbitrary lower-frequency ranges, including that in Fig. 1. To compare, we examined the same configurations when VO_2 is substituted with InSb and rescaling is applied by decreasing all sizes by factor of 2.5 for Fig. 1 and increasing it by factor of 22 for Fig. 2, so that the aforementioned switching scenarios can be obtained at 1-2.5 THz.

Polarization- and direction-multiplexed vector holography based on asymmetric transmission of bi-layer metasurfaces and its application

Joonkyo Jung[1], Hyeonhee Kim[1], and Jonghwa Shin[1,*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon 34141, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: We investigate the potential of bi-layer metasurfaces for achieving full control of asymmetric transmission in optical systems. We demonstrate that the polarization- and direction-multiplexed vector holography can be achieved using bi-layer metasurfaces. With this approach, we also suggest a novel optical encryption algorithm.

An optical system can exhibit distinctive transmission responses depending on the direction of light illumination, i.e., the front- and back-side illuminations, also known as asymmetric transmission. The asymmetric transmission has been actively studied because of its wide applicability to a variety of scientific and engineering fields such as optical communications, imaging or optical encryption. Metasurfaces, arrays of nanostructures with subwavelength scales, have revolutionized the study of asymmetric transmission based on their high degrees of freedom in manipulating light. However, most existing literature have been confined to partial control of asymmetric transmission; only the cross-polarized transmission has been used for achieving asymmetric transmission and, as a result, control of polarization has been ignored. In this study, we demonstrate the polarization- and direction-multiplexed vector holography based on bi-layer metasurfaces, fully utilizing the vector nature of light.

To achieve full control of asymmetric transmission, both co- and cross-polarized transmissions, relative to two orthogonal polarizations as a basis, should be manipulated at will. Recently, we have demonstrated that bi-layer dielectric metasurfaces can generate arbitrary Jones matrices [1]. Based on this extended controllability, we showed that arbitrary control of co- and cross-polarized transmission is achievable. In general, the reciprocity hinders from achieving direction-multiplexed vector holography. To circumvent this problem, we used the spatial partitioning strategy where arbitrary polarization- and direction-multiplexed vector functionalities can be inscribed in a half of transmission space. With this strategy, we experimentally demonstrated the polarization- and direction-multiplexed vector holography and its application to optical encryption as in Figure 1.

In summary, we have proposed that bi-layer metasurfaces can achieve full control of asymmetric transmission. As a proof of concept, we have demonstrated the polarization- and direction-multiplexed vector holography and its application to optical encryption. We believe this extension of achievable functionalities can directly translate to the extension of applications.

Abstract: Research has demonstrated active control of beam deflection, yet it relies on multiple deflectors or complex integration with intricate circuitry. In this work, we introduce a metasurface to adjust the deflection angle by simply altering the position of incident light. This breakthrough holds promise for applications in LiDAR and AR/VR.

As the development of LiDAR and AR/VR technology progresses, the requirements for smaller and more compatible optoelectronic devices have dramatically increased in demand. Metasurfaces are one of the solutions because they possess unprecedented capabilities to manipulate the properties of light at subwavelength scales. Studies have demonstrated dynamical control the direction of deflection light by combining active materials and meticulously designed circuit[1]. However, this design principle needs careful consideration of the interaction between active material and metasurfaces, which presents a significant challenge in achieving the desired design.

In this work, we introduce a novel metasurface characterized by simple design that facilitates multiple deflection angles within a single chip. Our approach begins with the application of the generalized Snell's law[2], assuming the incident light to be normal to the device, which leads to the optical response described by Eq. (1). We subsequently allow the deflection angle to linearly vary along the *x*-direction from 2° to 30°, originating from the origin and extending to *x* equal to the size of the metasurface (*L*), as presented in Eq. (2). By combining Eqs. (1) and (2), we can obtain the required phase profile of the metasurface, as shown in Eq. (3). Notably, Eq. (3) reveals that the deflection angle can be modulated by adjusting the incident light position along the *x*-direction. Here, n_t and θ_t represent the refractive index and deflected angle, respectively. k_0 is the wavenumber. $\theta(x)$ denotes the deflected angle at *x* position across the metasurface.

To ensure a polarization-independent response in our proposed amorphous silicon (a-Si) based metasurface, we opted for a square shape with a variable width (*w*) ranging from 50 nm to 350 nm, while keeping a constant height (*h*) and period (*p*) at 480 nm and 400 nm, respectively, during simulation process (refer to Fig. 1a). The transmittance and phase responses at a wavelength of 940 nm are illustrated in Figs. 1a and 1b. Subsequently, after obtaining the meta-atoms data library, we commence metasurface design using proposed methodology, and the optimized phase distribution profile is represented in Fig. 1c.

$$n_t \sin(\theta_t) = -\frac{1}{k_0}\frac{\partial \Phi(x)}{\partial x} \tag{1}$$

$$\theta(x) = \frac{(\theta(L)-\theta(0))}{L}x + \theta(0) \tag{2}$$

$$\Phi(x) = -k_0 * \frac{L}{(\theta(L)-\theta(0))}\cos\left(\frac{(\theta(L)-\theta(0))}{L}x + \theta(0)\right) \tag{3}$$

To validate the concept, we confirmed in simulations that the direction of deflected light can indeed be modulated by changing the position of incident light. Figure 2a illustrates the operational mechanism of the proposed metasurface. The device has a total size of 1 mm by 1 mm, and the left side of the metasurface is defined as the origin of the *x*-axis.

We have chosen to input light at x equal to 0.1 mm, 0.5 mm, and 0.9 mm, which results in deflection angles of 4.8°, 16°, and 27.2° respectively.

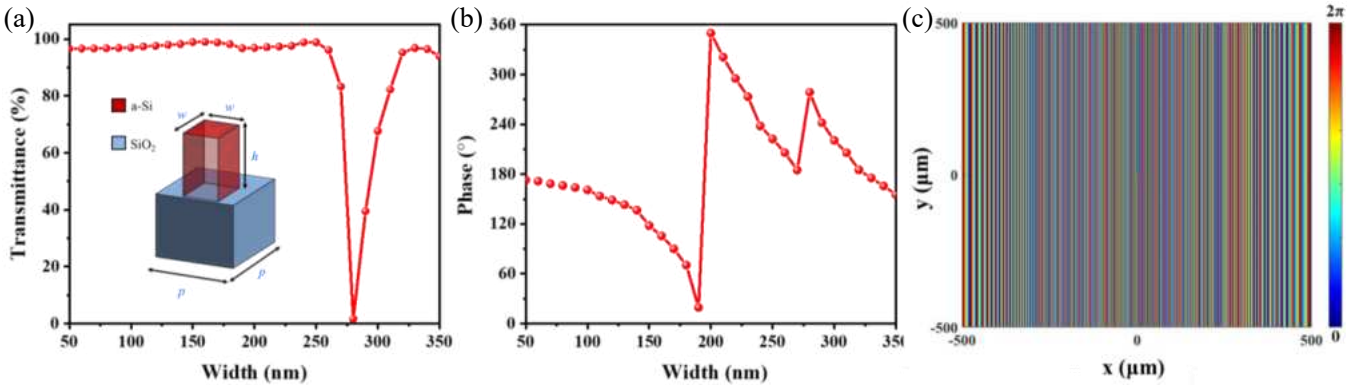

Fig. 1 (a, b) Simulated transmittance and phase spectra versus width of nanostructure at a wavelength of 940 nm. The inset illustrates the unit structure, where the height h and period p are set at 480 nm and 400 nm. (c) Calculated phase distribution of the proposed metasurface. The deflected angle varies along the x-direction from 2° to 30°

Subsequently, we have set the distance of observation 1 mm apart from the device, and the resulting far-field patterns are shown in Figs. 2b, 2c, and 2d. The positions of the patterns in the far-field are in great agreement with predictions from theory. This demonstration suggests that we can achieve any deflection angle within the range of 2° to 30°, depending solely on the position of the incident light.

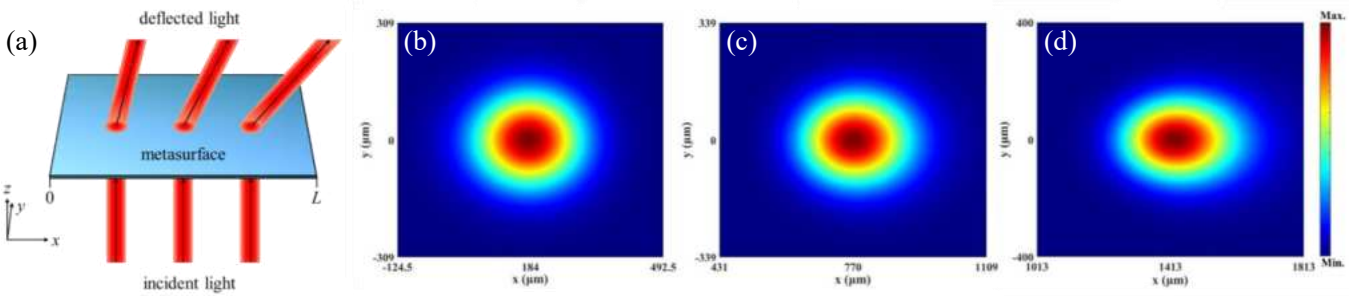

Fig 2. (a) Operational mechanism of the proposed metasurface. (b, c, d) Simulated far-field intensity distribution of light incoming at x = 100 μm, 500 μm, 900 μm. The output beam angle corresponds to 4.8°, 16°, and 27.2°.

In conclusion, our numerical simulations have successfully demonstrated the capability of achieving beam steering within a single metasurface. Based on the design principle, the realized metasurface is able to steering the incoming light along one specific direction without complex design processes. Notably, the deflection angle is not limited to 30°, and can be adjusted as needed. The proposed metasurface holds exciting opportunities for applications in LiDAR, AR/VR systems.

Abstract: In this work, we demonstrate a telecentric-based metalens operating at a wavelength of 940 nm, providing a high-quality focal spot at viewing angles from 0° to 60°. Due to the maximum aspect ratio of the meta-atom being only 4, this metalens is relatively easy to be fabricated.

Near-infrared light at 940 nm is commonly used in facial recognition systems for mobile phones, employing diffractive optical elements [1] and corresponding lenses. The trend toward thinner mobile devices underscores the potential for metalenses, with their thin and lightweight characteristics [2-5], to replace traditional lenses in such systems. Here, we present a telecentric-based metalens designed for operation at 940 nm. With a maximum aspect ratio of only 4 for the meta-atom, this metalens is relatively easy to fabricate. Furthermore, it provides a high-quality focal spot over viewing angles ranging from 0° to 60°.

As shown in the inset of Figure 1(a), the fundamental unit of the metalens is an amorphous silicon (a-Si) nano-cylinder on a silica substrate. The nano-cylinder maintains fixed basic dimensions (thickness: 600 nm and period: 400 nm), while its diameter (D) is varied to analyze corresponding optical properties. Figure 1(a) illustrates the phase shift and transmittance of the nano-cylinder with various D values. These simulations were conducted using the Rigorous Coupled-Wave Analysis method under normal illumination with a wavelength of 940 nm. The refractive index of the a-Si film is 659nm at 940 nm measured by using Spectro ellipsometer. The results indicate that the phase shift reaches 2π as D varies from 150 to 300 nm. Additionally, the majority of the nano-cylinder transmittances up to 0.8, indicating improved performance of the metalens. Notably, the maximum aspect ratio of the nano-cylinder is only 4, making the circular pattern relatively easy for production [6]. Therefore, this metalens is beneficial for mass production. To achieve high-quality images at various viewing angles, this metalens is designed within a telecentric system. Figure 1(b) illustrates the ray tracing diagrams of the metalens' imaging system, including an aperture and the metalens. It is evident that the metalens provides excellent focusing quality at viewing angles ranging from 0 to 60°. Fabrication of the metalens involves E-beam lithography, followed by inductively coupled plasma reactive ion etching (ICP-RIE) processing. Figure 1(c) displays scanning electron microscope (SEM) images of the fabricated metalens. With a diameter of 3 mm, the optical microscope image is shown in the inset of Figure 1(c).

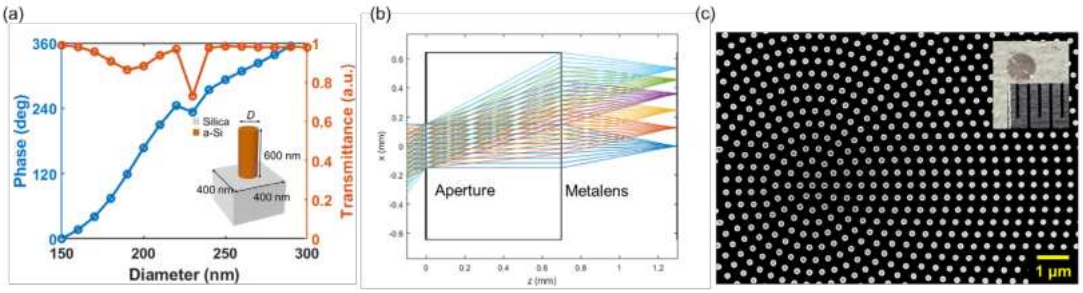

Figure 1. (a) Geometric diagram and optical property of an a-Si nano-cylinder. (b) Ray tracing diagrams of the metalens' imaging system under incident light with various angle from 0° to 60°. (c) SEM images of the fabricated metalens.

Figure 2(a) presents the simulated focus point of the metalens under normal illumination, serving as a reference. A clear theoretical focal spot is evident, along with a weak aperture around the focus point, representing the first-order sidelobe of the Airy disc. For measurement, as shown in Figure 2(b), the measured focus point is comparable to the simulation result. Notably, the first-order sidelobe is too weak to be detected by the sensor, hence it is not observed in the measured focus point. Figure 2(c) displays the modulation transfer function (MTF) curves obtained from the corresponding simulation and measured focus points in Figure 2(a) and 2(b). The measured MTF curve is comparable to the simulation curve. Even when the incident angle is 45°, the metalens still provides a high-quality focal point without obvious deformation, as demonstrated in Figure 2(d) and 2(e). Finally, Figure 2(f) illustrates that the simulation and measurement MTF curves are comparable. It is worth noting that the measurement focus point does not exhibit the first-order sidelobe of the Airy disc. Therefore, the measurement MTF has higher resolution in the spatial low-frequency region.

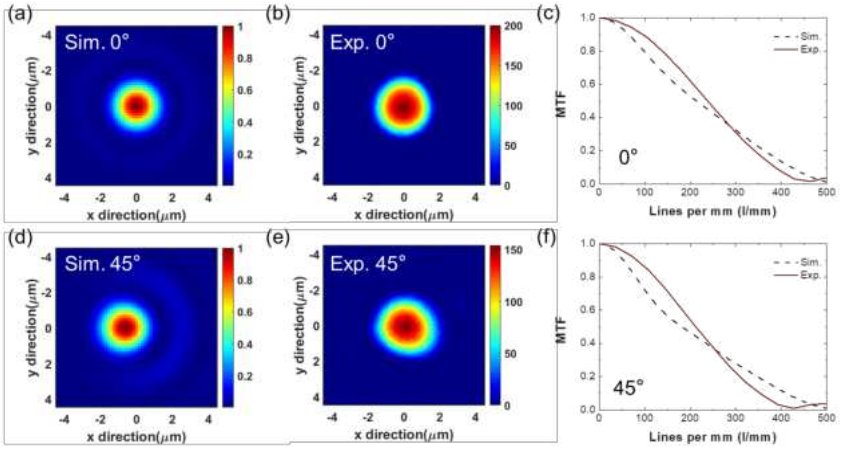

Figure 2. The (a) simulated and (b) measurement focus point under normal illumination. (c) MTF curves corresponding simulation and measured focus points in Figure 2(a) and 2(b). The (d) simulated and (e) measurement focus point when the incident light angle is 45°. (c) MTF curves corresponding simulation and measured focus points in Figure 2(d) and 2(e).

Abstract: Two-dimensional Transition Metal Dichalcogenide semiconductors (2D-TMDs) show potential for optoelectronics and photon-to-energy conversion. Moreover, by combining different TMDs layers into van der Waals heterostructures, their optoelectronic response can be engineered further. This work introduces large-area flat optics light harvesting and growth methods to maximize their potential.

Two-dimensional Transition Metal Dichalcogenides semiconductors (2D-TMDs) have recently collected a strong scientific and technological interest over a broad community due to their peculiar optoelectronic response within a broadband spectrum, and to their tunable bandgap that enables promising optoelectronic and photonic functionalities. Additionally, the superior optical absorption coefficients in the Visible spectrum, enhanced by about two orders of magnitude with respect to conventional bulk semiconductors, qualify TMDs as optimal candidates for photodetection and photoconversion applications[1,2]. However, to fully leverage their potential in extreme thickness regimes, effective photon harvesting strategies and large-area growth techniques are essential.

Here, we present an homogeneous growth of large area 2D-TMDs films by means of a physical deposition process based on Ion Beam Sputtering, followed by high temperature recrystallization in a sulfur enriched atmosphere[3]. Furthermore, through periodic modulation of TMDs layers (MoS_2) on a large area nanostructured template, we efficiently steer light parallel to the 2D material, exploiting photonic anomalies in the flat-optics regime[1,4] As a case study, we demonstrate that flat-optics light harvesting in periodically corrugated MoS_2 layers employed as photocatalysts boosts photodissociation of Methylene Blue (MB), a polluting dye molecule commonly used in the textile industry[5]. Additionally, the atomically smooth surfaces and fully saturated in-plane chemical bonds of 2D-TMDs offer an opportunity to engineer the optoelectronic response further by combining different TMDs layers to form van der Waals heterostructures[6].

The fabrication process has been subsequently optimized for the sequential synthesis of vertically stacked large area MoS_2-WS_2 van der Waals heterostructures, which can be supported on a large area graphene layer, which acts as a transparent conductive window. This vertical stacking ensures a type-II staggered band alignment which in turn allows to split excitons across the junction, thus increasing the lifetime of the photogenerated carriers compared to the individual TMD components. Charge separation can be exploited for energy conversion and photocatalytic applications, reflected in the superior photodissociation rate of molecular dye probes in solution near the heterostructure sample, and in the photovoltage and photocurrent measured upon illumination of the large area device.

These results demonstrate that TMDs van der Waals heterostructures represent optimal building blocks for the fabrication of self-powered photodetectors, exploiting charge separation of photogenerated carriers at the 2D interface without any external bias.

Abstract: This research integrates a liquid crystal cell with a holographic metasurface for dynamic polarization control, utilizing the Gerchberg-Saxton algorithm and Jones matrix. Devices based on this technology can operate in arbitrary polarization, thereby enhancing the flexibility of optical systems.

Metasurface-based holography is gaining attention in the field of metasurface research due to its flexibility and high precision. In particular, polarization control using metasurfaces can be applied in various areas such as information storage, imaging, and communications. However, existing technologies have primarily focused on fixed polarization states, and there were limitations in changing polarization states in real-time.

We aim to overcome these limitations by combining a liquid crystal cell (LC cell) with a holographic metasurface, presenting a new method that can electrically control any polarization state [1,2]. Such structures can convert linear polarization to circular polarization or vice versa. Meanwhile, the LC cell contains a liquid crystal material that changes its properties in response to electrical signals, allowing for real-time optical property adjustments of the metasurface. The design of this device involves the following process:

Typically, the Gerchberg-Saxton (GS) algorithm is used when designing holography. The GS algorithm plays a pivotal role in the structural design optimization of holography, going through a repetitive optimization process to minimize the difference between the intended and actual optical outputs. For the production of metasurface-based holography, we applied the Jones matrix mathematical model to this GS algorithm [3]. The adoption of the Jones matrix allows for the mathematical representation of arbitrary polarization states and the prediction and control of light behavior. In this process, the optical field and pattern of the metasurface that are necessary to generate the desired optical output are determined, making it possible to predict the metasurface's response to specific polarization conditions. The GS algorithm's repetitive optimization process is carried out to update the optical field data of the metasurface in a direction that makes the desired optical output and the actual optical output nearly identical.

The structure of the metasurface determined through this design and optimization process then moves on to the integration stage with the liquid crystal cell (LC cell). Through the electrical control of the LC cell, the optical properties of the metasurface can be adjusted in real-time. This provides the metasurface with the flexibility to manipulate light in any polarization state. Through this process, metasurface-based holography can realize various optical functions, including polarization control.

In conclusion, the design of LC cell-based metasurface holography involves optimization through the Jones matrix-based GS algorithm, followed by integration with the LC cell. This continuous process lays the

foundation for precisely controlling the optical properties of the metasurface and providing flexibility for a wide range of applications. The development of this technology can contribute to various fields such as high-resolution holographic displays, high-performance optical filters, and real-time information processing. It also enables applications in security, data storage, and optical encryption. Moreover, the ability to electrically control any polarization state significantly enhances the flexibility of optical systems, enabling new forms of optical interfaces and interaction methods.

Photocurrent Enhancement induced by Fabry-Pérot quasi-Bound States in the Continuum in Silicon Nanodisk Hexagonal Array beyond 1400 nm in Wavelength

K. Moriasa[1], H. Hasebe[1], H. Sugimoto[1] M. Fujii[1*]

[1]Electrical and Electronic Engineering, Kobe university
[*]fujii@eedept.kobe-u.ac.jp

Abstract: A nanodisk array of polycrystalline silicon with the toroidal dipole resonances in the sub-bandgap region is produced on a metal mirror via a spacer. The structure possesses the Fabry-Pérot bound states in the continuum, and strongly enhances the photocurrent in the eye-safe wavelength.

1. Introduction

Near infrared light in the wavelength longer than 1400 nm is called "eye safe" due to its relatively low hazards to retinas. Eye safe lasers have been used as a light source for LiDARs in atmospheric physics, autonomous driving, etc. However, since the sensitivity of conventional silicon (Si)-based photodetectors is limited to ~1100 nm, several novel photodetection mechanisms have been proposed to extend the detection range[1]. An example is utilizing internal photoemission at the Schottky interface between Si and noble metal nanoantennas. Another approach uses an optical resonator to enhance defect-mediated absorption of polycrystalline Si in the sub-band gap region. In previous work, we demonstrated that sub-radiant toroidal dipole (TD) resonances in a hexagonal array of Si nanodisks can effectively enhance the light absorption in the low extinction coefficient range, and thus can be used for the photocurrent enhancement in the eye safe wavelength range[2].

In this work, we propose a new structure that can achieve perfect absorption in the low extinction coefficient range. The structure is schematically shown in Figure 1(a). A metal mirror is formed below a hexagonal array of Si nanodisks via a silica spacer. The key concept to achieve the perfect absorption is as follows. At a proper spacer thickness, radiation from the nanodisk array is fully suppressed due to the interference with the mirror image in the metal mirror. This state is the Fabry-Pérot bound states in the continuum (FP-BICs). By slightly detuning the interference condition, i.e., by changing the TD radiation phase from the image dipole one via spacer thickness, the nanodisk array comes to partially couple with light. When the radiation loss of the system matches with the material loss, i.e., the critical coupling condition, incident light is perfectly absorbed[3]. In this work, we first discuss the validity of the concept by numerical simulation, and then demonstrate that this approach is useful for photocurrent enhancement of polycrystalline Si in the sub-band gap range.

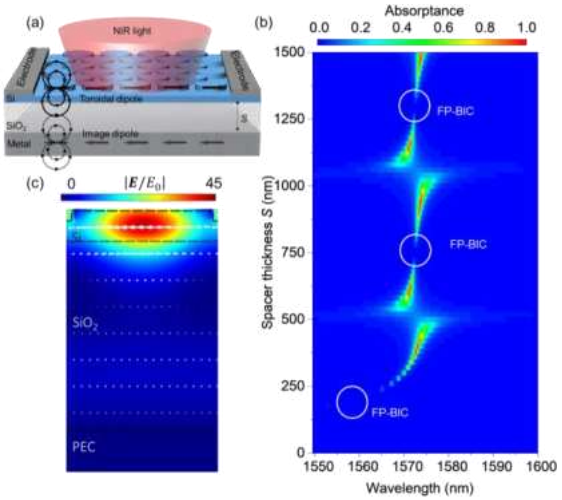

Figure 1. (a) Schematic of Si nanodisk hexagonal array on mirror structure. Interference between a toroidal dipole in a nanodisk and its image creates FP-BIC. (b) Calculated absorption spectra of the structure shown in (a) as a function of spacer thickness (*S*). (c) Electric field map in the cross section in (a) at 1573.7 nm (*S* = 940 nm).

2. Results and discussion

Figure 1(b) shows the calculated absorption spectra of the structure shown in Figure 1(a) as a function of the silica spacer thickness (*S*). A hexagonal array of polycrystalline Si nanodisks with the diameter and the height of

700 and 50 nm, respectively, is formed on a 100 nm thick polycrystalline Si film. The period is 750 nm. The nanodisk array has the TD resonance around 1570 nm. Below the nanodisk array, a silica spacer and a perfect electric conductor mirror are formed. The silica spacer thickness is changed from 0 to 1500 nm. The absorption peak due to TD resonance is periodically modified by the spacer thickness. The absorption disappears at S = 200, 760, and 1280 nm. This is the FP-BIC. Detuning the spacer thickness from the BIC condition turns the FP-BIC into quasi-BIC. At the spacer thicknesses satisfying the critical coupling condition (S = 400, 620, 940, 1160, and 1480 nm), the absorptance becomes nearly unity. Figure 1(c) shows the cross sectional electric field distribution for S = 940 nm. The incident power is strongly confined in the Si nanodisk array.

We fabricate the nanodisk array on mirror structure by using a nanosphere lithography[2]. Figure 2 shows the measured reflectance and photocurrent spectra. The spacer thickness is changed from 980 to 1120 nm. The reflectance dip around 1450 nm is due to the TD resonance. We can see that the reflectance dip and the photocurrent peak are strongly modified by the spacer thickness. When S = 1120 nm, the reflectance peak almost disappears. This is the appearance of FP-BICs. With decreasing the spacer thickness, i.e., by detuning the BIC condition, the reflectance dip becomes deeper. This is accompanied by the increase of the photocurrent at the TD resonance. Therefore, the FP-quasi-BIC enhances photocurrent of the Si nanodisk array in the sub-bandgap wavelength range.

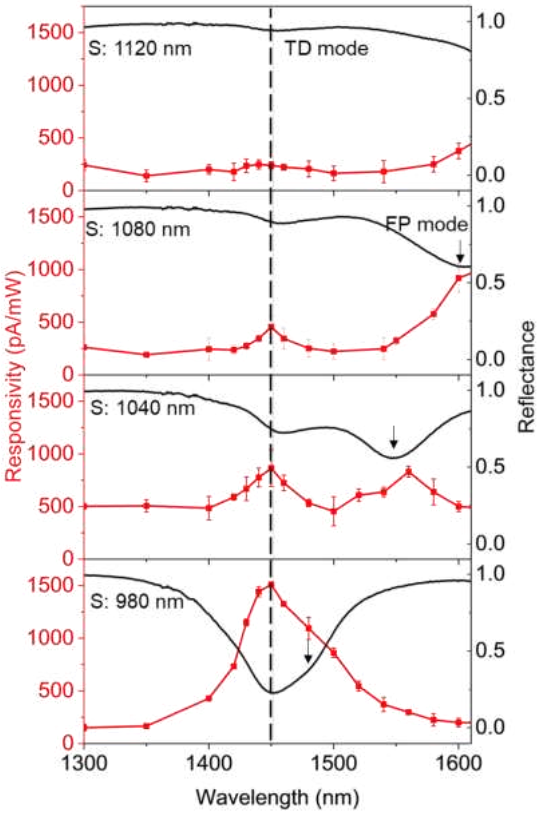

Figure 2. Reflectance (black) and responsivity (red curves) spectra of Si nanodisk array on mirror with different spacer thickness from 980 to 1120 nm. Black arrows and broken line indicate the FP and TD mode wavelength, respectively.

3. Conclusion

We numerically and experimentally investigate absorption property of a Si nanodisk array on a metal mirror structure. Numerical simulations show that the proposed structure possesses FP-BIC in the NIR range and perfect absorption can be achieved at proper spacer thicknesses. In experiments, the reflectance dips at TD resonance are strongly modified by the spacer thickness, and the photocurrent is strongly enhanced in the sub-band gap range. This result indicates that the combination of a TD mode and FP-BIC provides a novel platform for Si-based NIR photodetectors.

Abstract: We demonstrate that ion-beam irradiation of chiral dielectric metasurface can enhance optical chirality by carefully tailoring the material absorption. We approach the critical coupling regime associated with maximum circular dichroism by irradiating chiral silicon dimers with energetic Ne^+ ions. This provides potential of tweaking metasurface properties post fabrication using ion-beams.

Chiral dielectric metasurfaces can exhibit strong circular dichroism (CD) while preserving typical properties associated with metasurfaces, such as a flat profile and resonant response [1] based on the excitation of a collective chiral mode in the supercell consisting of four dimers [2]. Importantly, due to the inherent connection between dissipation and CD, chiral dielectrics need to operate in the weak dissipation regime to reach large values of CD. For any given chiral metasurface design, optimal performance in terms of CD is reached for critical coupling, which can be achieved by carefully adjusting the dissipation in the system [3]. Here, we make use of ion-beam irradiation to tune the optical properties of tailored photonic metasurface post fabrication. Specifically, we study periodic three-dimensional dielectric bilayer metasurface with four-fold (C4) rotational symmetry consisting of chiral dimers of silicon nanocuboids embedded in a silica matrix [2]. Figure 1 shows a sketch of the metasurface geometry. We gradually increase the dissipative loss in the chiral silicon metasurfaces via ion-beam induced structural damage. The metasurface was irradiated by Ne^+ ions at energies of 200 keV with carefully adjusted ion fluences ranging from 10^{13} to 10^{15} ions/cm^2 in six irradiation steps. After each step, the polarization-resolved transmission spectra of the metasurface for normal incidence were recorded for the left (LCP) and right-circularly (RCP) polarized light in near-infra-red (NIR) regime. As a reference, we also recorded the spectra for the pristine sample before irradiation. The CD spectra were evaluated based on the relative difference between LCP and RCP transmission and plotted as a function of ion fluence in Fig. 2(a). Fig 2(b) presents the maxima of the CD spectra for different ion fluence. At lower fluences, the results show a substantial increase of the CD signal due to the radiation-induced damage in the nanostructures. We observe a maximum optical chirality with CD of ~0.85 for an ion fluence of 10^{14} ions/cm^2, clearly exceeding that of 0.70 for the pristine metasurface. This indicates that ion-beam irradiation brings the system closer to the critical coupling condition as compared to the pristine fabricated structure. With even higher ion fluences, the overall CD is reduced, which is consistent with an increase of losses beyond the critical coupling condition. As another feature, we also observe a redshift of the CD maxima with increasing ion fluence in Fig. 2(a).

Next, to analyze the effect of ion-beam irradiation on the optical parameters of the silicon, we perform numerical calculations of the transmission spectra for a variation of the silicon's complex refractive index and compare the results with experimental spectra. Good overall agreement is obtained assuming a gradual increase of the

imaginary part of the silicon refractive index with increasing ion fluence. The simulated transmission for optimized geometrical parameters of the metasurface is depicted in Fig. 2(c) alongside corresponding measurement results for a fluence of 10^{14} ion/cm^2. Here, the imaginary part of the silicon refractive index is raised by a factor of 3.8 compared to the pristine material. Furthermore, the observed shift of the CD maxima could be reproduced in the numerical spectra by an increase of the real part of the refractive index, indicating the expected material densification effect due to ion irradiation [4,5].

In summary, we successfully demonstrated a new approach to enhance CD in chiral dielectric metasurface using ion-beam irradiation. Importantly, our approach allows for flexible loss manipulation in the material by controlling the ion fluence. More generally, our results underline the critical importance of carefully tailored dissipation losses for maximizing CD in a given chiral metasurface and establish ion-beam irradiation as a new powerful tool for tweaking metasurface properties post fabrication.

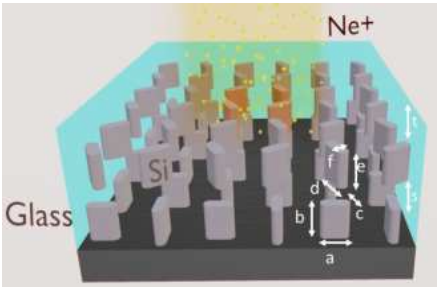

Fig 1 (a) Schematic of the investigated chiral metasurface, here a × b × c = 379 × 391 × 149 nm^3, d × e × f = 423 × 326 × 179 nm^3 and s = 299 nm.

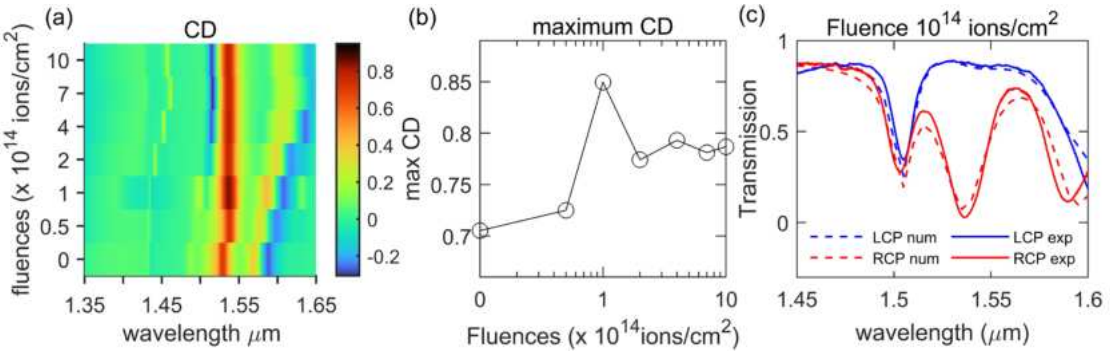

Fig 2 (a) CD spectra with respect to the varying Ne$^+$ ion fluence: 5×10^{13}, 10^{14}, 2×10^{14}, 4×10^{14}, 7×10^{14}, and 10^{15} ions/cm^2. (b) Maxima in CD signals for different fluences. Abstract: Local and non-local phase-change optical metasurface designs for reconfigurable edge-detection/bright-field imaging are explored. Reconfigurability is achieved via switching phase-change material between crystal and amorphous states. Applications include fast pre-processing for image analysis, optical microscopy and more.

Analog optical computing has seen an increase in attention in recent years due to potential advantages it holds over its digital counterpart, including intrinsic parallelism, low-loss transmission and ultra-high bandwidth [1]. Fast and energy efficient optical computing systems have been demonstrated, for example implementing neural networks [2] and matrix-vector multiplication [3]. Such demonstrations include both free-space and integrated photonic configurations: here we work with free-space arrangements to perform the specific task of edge detection. Edge detection is a key part of image processing and previous metasurface designs have been presented to tackle this (e.g. [4]). Here we introduce the added element of reconfigurability, specifically an ability to switch between edge detection and bright-field imaging modes. This tuneability is achieved through the integration of chalcogenide phase-change materials (PCMs) within the designs. PCMs exhibit vastly different optical properties (n and k) between their amorphous and crystalline states and can be actively switched between states via the use of a thermal stimulus [5]. These differences are exploited in our designs for reconfigurable metasurfaces in the visible through to the mid-infrared wavelength regimes. We demonstrate, in simulation, both simple 1D edge-detection and more complex 2D polarization insensitive operation, whilst also comparing designs based on so-called 'local' metasurfaces operating in the Fourier plane with 'non-local' metasurfaces operating directly in the spatial domain.

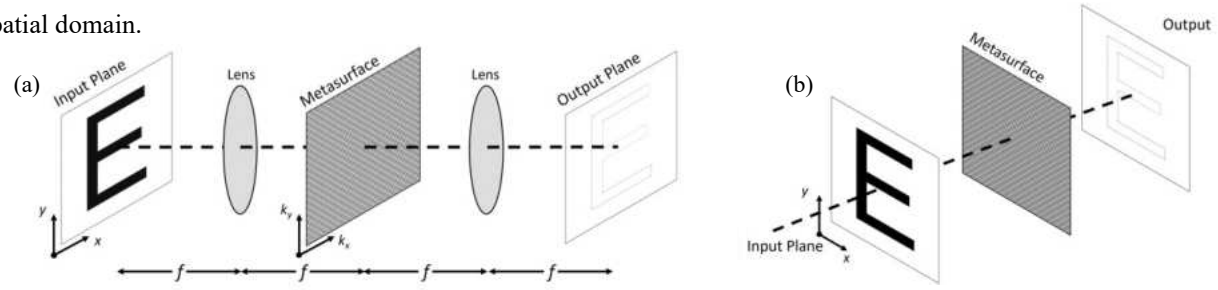

Figure. 1: Schematics of (a) a 4f system designed for edge-detection via the use of a 'local' PCM metasurface placed in the Fourier plane and (b) a system that utilizes a non-local PCM metasurface for edge-detection directly in the spatial domain. The PCM metasurfaces can be reconfigured to switch to and from their amorphous and crystalline states which in turn switches the metasurfaces from an edge-detection mode to a bright-field imaging mode.

Figure 1a demonstrates the concept of edge detection using a metasurface placed in the Fourier plane of a 4f system of the type used in conventional spatial filtering. Here, the 'meta-atoms' vary in size as a function of position on the metasurface. Figure 1b shows a schematic of a system for edge-detection using a non-local metasurface, in which the meta-

atoms are identical across the whole metasurface (in turn simplifying fabrication). Edge-detection functionality can be implemented using optical systems with transfer functions that mimic differentiation, typically second-order differentiation [4]. Hence, the transfer function we aim for is parabolic in transmission amplitude (and constant in optical phase), with the transfer function for bright-field simply being a flat (high) transmission amplitude and again constant optical phase.

In Figure 2a we demonstrate an example of the transmission amplitude and phase response of a $Ge_2Sb_2Te_5$ (GST) local metasurface designed for the mid-infrared regime (specifically at λ=4.5 μm). The radii of the meta-atoms vary in size as a function of position to deliver the desired parabolic transmission amplitude profile, with the response being dominated by localized resonances. The parabolic response shown is for the GST meta-atoms in their amorphous state, the crystalline state shows a flat transmission profile, hence switching to a bright-field imaging mode.

We also created a design for edge-detection via a non-local PCM metasurface, the metasurface meta-atoms are identical such that the whole metasurface can be designed to have a collective parabolic transmission amplitude response as a function of the angle of incident light. Figure 2b shows exemplar results: here we utilize the PCM material Sb_2Se_3 in the near-infrared (λ=1550 nm). The metasurface consists of a hexagonal array of holes in a thin Sb_2Se_3 layer. Edge-detection (up to angles of ±30 °) is obtained with the Sb_2Se_3 layer in its crystalline state, with the amorphous state resulting in bright-field imaging. Usage of a hexagonal array gives access to 2D relatively polarization insensitive edge-detection (particularly at low angles), previously shown for non-reconfigurable Si metasurfaces [6]. The simulated outputs of an example input image into such a non-local metasurface is shown in Figure 2b, displaying its edge-detection and bright-field modes.

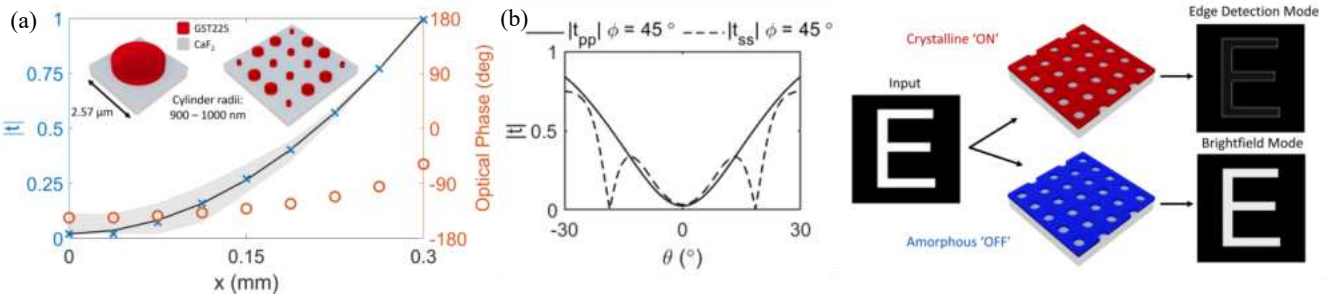

Figure. 2: (a) Optical transmission amplitude and phase response of a local PCM (GST) metasurface designed for edge-detection in the mid-infrared, when the GST is in its amorphous state. Switching the GST to its crystalline state results in bright-field imaging. The grey shaded region around transmission amplitude curve displays upper and lower bounds assuming a fabrication tolerance of 3 nm for meta-atom radii. (b) The transmission amplitude of a non-local Sb_2Se_3 metasurface designed to have a 2D polarization insensitive parabolic response as a function of the elevation and azimuth angle of incident light. This example shows both the s and p polarization responses at an azimuthal angle of 45 °. On the right we show the simulated output of such a metasurface in edge-detection and bright-field imaging modes respectively.

Inverse design of microwave absorber based on adjoint topological optimization

Hyeonjin Park[1], **Jonghwa Shin**[1*]

[1]Korea Advanced Institute of Science and Technology, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: Optimization of metal-backed multi-layered slab structure were considered for X-band absorption. The permittivity of each slab was assumed to possess a single Lorentzian resonance. The permittivity value was optimized with a topological adjoint algorithm and achieved an ultra-thin microwave close to the theoretical limit near 89%

It is well known that the minimum thickness of absorber structure cannot be smaller than a certain value confined as integration of reflection coefficient as a function of wavelength as shown below [1] and it is non-trivial to get a structure which approaching the theoretical limit.

$$\left|\int_0^\infty \ln|\rho(\lambda)|d\lambda\right| \leq 2\pi^2 \sum_i \mu_{s,i} d_i \tag{1}$$

In this research, to get a clue about a microwave absorber structure with ultra-thin thickness which approaching the causal limit, we considered topologically freeform multilayered slab structure with N layers where permittivity of each layer considered as single Lorentzian resonance with 4 parameters where $\epsilon_{i,0}, \omega_{i,p}, \omega_{i,o}, \gamma_i$ denotes for contribution of higher frequency resonances, plasma frequency, resonance frequency, and damping frequency, respectively for each i^{th} layer.

$$\epsilon_i(\omega) = \epsilon_{i,0} + \frac{\omega_{i,p}^2}{\omega_{i,0}^2 - \omega^2 - i\omega\gamma_i} \tag{2}$$

Based on this configuration, we conducted inverse design of microwave absorber with 4N in total design parameters based on topological adjoint optimization [2]. In the optimization, the cost function was set as reflectance $f = |E_r|^2$ and the process iterated to the maximum reflectance in X-band frequency range (8–12 GHz) lower than 10 dB.

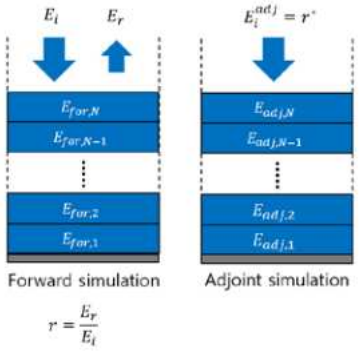

Figure 1. Schematic simulations for adjoint optimization

Figure 1 shows the schematic of adjoint optmization process. In the forward simulation, incident field with unit amplitude exerted on the N layered structure and calculate reflected field and field inside each Lorentzian layer. In the adjoint simulation, nothing but incident field amplitude is now the complex conjugate of reflected

field, and calculate fields inside each layer as a result. The gradient of cost function with respect to each parameter can be defined as this when $\epsilon_{i,j}$ indicates j^{th} parameter of i^{th} layer slab.

$$\frac{\delta f}{\delta \epsilon_{i,j}} = \frac{\delta f}{\delta \epsilon_i}\frac{\delta \epsilon_i}{\delta \epsilon_{i,j}} = 2Re\left[E_{adj} \cdot E_{for} \cdot \frac{\delta \epsilon_i}{\delta \epsilon_{i,j}}\right] \quad (3)$$

Figure 2 shows the target response of optimization and the resultant optimized response of structures with different thicknesses with 20 layers. Right side of figure 2 shows that the total thickness 1 mm thickness is enough to attain 10 dB reflectance in X-band range, and the required permittivity distribution as a function of frequency and layer position in Figure 3 with its real and imaginary values.

The minimum thickness derived with equation (1) for the target response was calculated as 0.89 mm, so with the topological adjoint approach, it was possible to get an absorber structure with 89% performance of the theoretical limit.

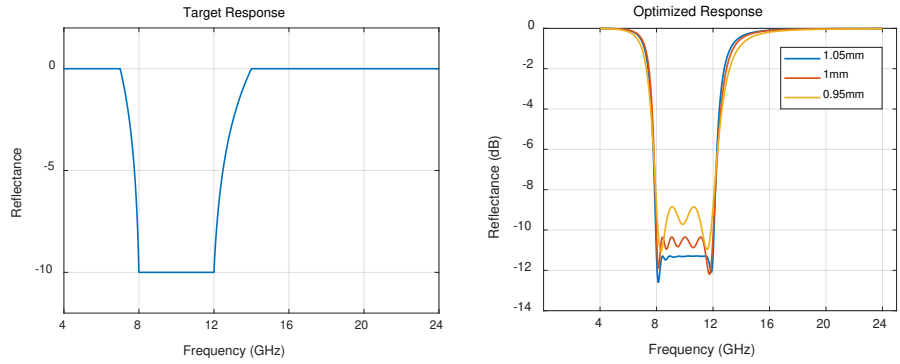

Figure 2. (Left) Target response, (Right) Optimized response of multilayer structure with 20 layers in different total thickness

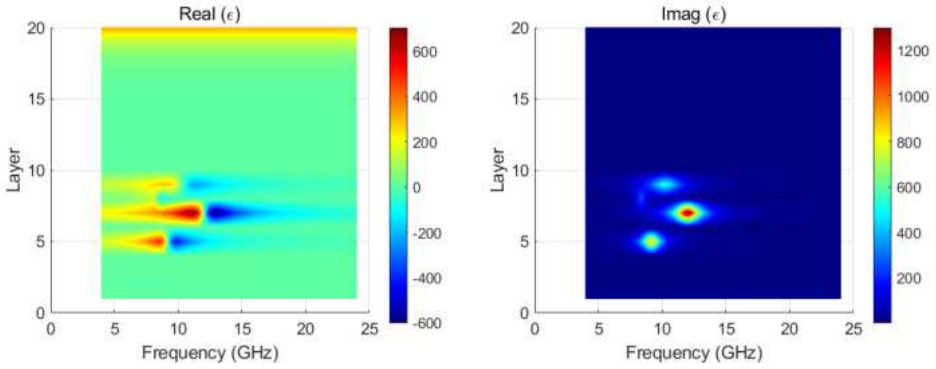

Figure 3 Required permittivity distribution of 1 mm thickness structure case

Performing accurate optical FDTD simulations of large meta-diffusors (~mm) with subwavelength meshing is challenging. A common technique [1-2] involves subdividing the domain and stitching the simulation results, but the resulting error has been rarely studied. We propose a novel approach to emulate this stitching simulation strategy error on meta-diffusors.

Keywords: Meta-diffusor, Metasurface, Boundary-domain-decomposition, stitching, distortion, Optical simulation, Electromagnetics, FDTD, Maxwell Solver.

I- INTRODUCTION

To make possible optical simulations of large meta-surfaces, a commonly used technique consists in boundary domain decomposition [1-2], or stitching, that divides the structure into smaller subdomains with fixed boundary conditions for simulation. This enables efficient optical simulations of large-scale devices but can induce error over the whole optical domain. In this paper, we examined the impact of such error in the Near Fields (NF) and the Far Fields (FF) of a propagating light beam through a metasurface. A metasurface [3] is an engineered material designed to exhibit unique optical properties with subwavelength patterns, formed by scatterers called meta-atoms (MA). Here, the considered metasurfaces have MA grids with regular spacing of size of 256*256.

A systematic study has been conducted using a series of large meta-diffusor designs obtained using a Phase Retrieval (PR) algorithm [4] on a series of random targets (see Figure 1). The targeted phase is mapped using a scalar-to-meta-atom relation, linking a meta-atom parameter to the locally induced phase shift.

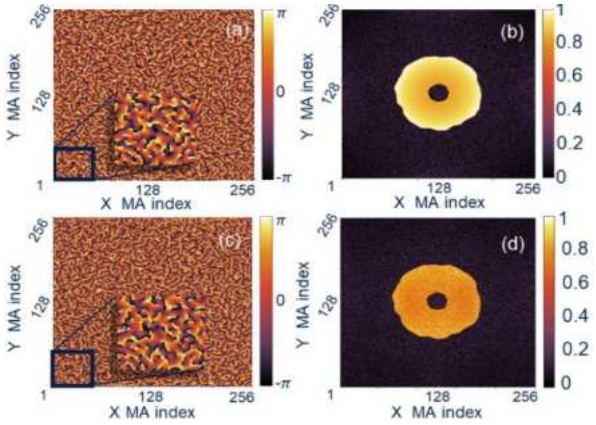

Figure 1 – Metasurface samples from PR. The phase and Far Field moduli (max normalized to unity) respectively in (a,b) come from the PR results and (c,d) from the simulation of the same design.

The designs are simulated with Finite Difference Time Difference (FDTD) and compared to the PR results (Figure 1). The same designs are simulated with and without applying a domain-decomposition (see Figure 2).

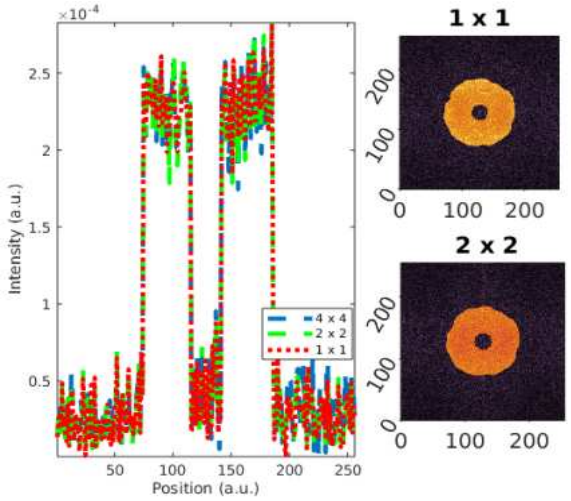

Figure 2 – FF middle cut of the full domain simulation (1 x 1) superposed with stitched example in 2 x 2 and 4 x 4 crops. 2D results (1x1, 2x2) are displayed on the right side.

Despite this seemingly negligeable error in FF (see Figure 2), we develop an error model in NF, and then expand upon this model, in order to approach this error in FF.

The error masks (EM), defined as the difference between the full-domain FDTD NF simulation and the stitched one $|NF - NF_{stitched}|$, are shown in Figure 3, for two sub-domain decomposition sizes (128*128 and 64*64) on non-overlapping regions. The error introduced by this domain-decomposition is clearly visible on both sides of the stitching lines and is roughly of the same amplitude as the maximum of the full NF simulation. Its impact on the FF is obtained using the Fourier Transform of the previous error masks (exact equivalent), with ~0.1 the scale of full NF simulation. In Figure 3, are displayed very clear Dirac combs in FF of the EM. To account for these, we need a model emulating the error induced by the phase and moduli parts.

II- ERROR MODEL FOR STITCHING

In order to perform a systematic study of the impact of stitching errors on the optical zeroth-order (mode in FF) of meta-diffusors, we modeled the error mask using a statistical-based approach. Figure 4 shows the horizontal cutlines of Figure 3-(a) and 3-(b) plots (horizontal crop boundary being removed, thus no perpendicular line overlap), highlighting NF amplitude error profile. The phase difference is also extracted from the same NFs of 6 designs (with 256*256 MA) with their stitched counterparts.

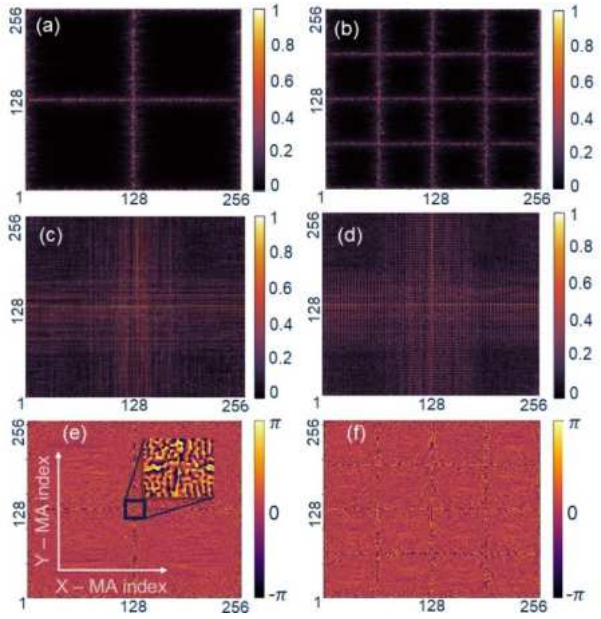

Figure 3– NF moduli of EM for stitching examples cropped in 2x2 (a) and 4x4 (b), (c, d) the respective FF moduli, (e, f) the NF phase.

This error exhibits a maximum at the domain-boundary regions and extends on both sides. We found out that a pseudo-Lorentzian function provides a reasonable fit of the EM (Figure 4 in red) for crop size of 128*128 and 64*64. We verified that this function fits the EM even for smaller crops.

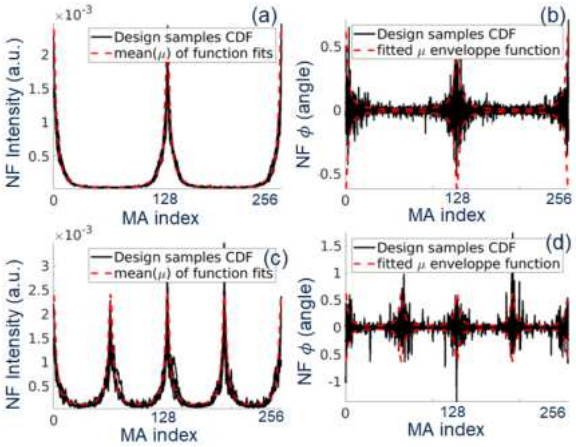

Figure 4– Superposition of 6 different designs EM moduli and phase difference. Also shown are quasi-Lorentzian fit: 2x2 for moduli (a), phase difference (b), 4x4 for moduli (c), phase difference (d).

This fitted model is a sum of pseudo-Lorentzian function: $\mathcal{L}(x,\mu,\gamma) = A/\left(\frac{(x-\mu)^2}{\gamma} + B\gamma\right)$ (1), with μ the center, A a normalization constant and $B{\sim}1/4$ an empirical parameter. For a system size of 256*256 MA, $\gamma{\sim}24.5$ is related to the width of the pseudo-lorentzian, i.e. the typical length of the error range on both sides of the stitching.

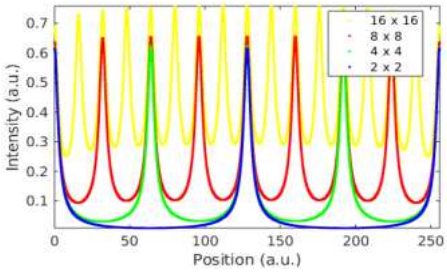

*Figure 5: Prediction of NF EM moduli in 128*128 (2 x 2), 64*64 (4 x 4), 32*32 (8 x 8 crops), and 16*16 crop sizes.*

Figure 5 shows the model predictions for crops as small as 16 x 16 subdomains (i.e. each composed by 16*16 MA). As the crop numbers rise, the minimum error also increases.

To further explain the impact of the stitching error (w.r.t. I), we implemented a stochastic NF error function δ accounting for the white noise or fluctuations in NF error and phase error, using ζ, a gaussian random signal convolved with a pseudo-Gaussian function (accounting for a correlation between MA): $U\left(x, \sigma = \frac{N}{\nu}\right) = \frac{1}{2\sigma} e^{-\frac{|x|}{\sigma}}$ (2), [5] with σ the correlation range, N the size of the system in MA scale and ν the crop factor. ζ maps with various ν are shown in Figure 6. This random fluctuation ζ is combined with the fitted model θ shown in Figure 4, as a filter mask, to produce δ the stochastic error model. We use two embedding models for δ: $\{ U + \delta$ (3), a constant model, $U + \delta U(1-U)$ (4), a quadratic model$\}$. This stochastic approach results are shown in Figure 7 and a clear impact of the random phase and amplitude fluctuation model is pointed out at low ν (sets ζ smoothing range, see Figure 6). This shows that a white noise induced in Near field related to the EM and the phase difference, has also a negligible effect on the Far Field (see Figure 7).

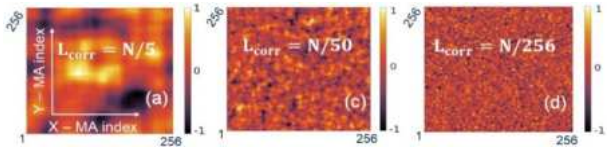

Figure 6 – ζ maps for various correlation $\sigma = N/\nu$ with $N = 256$.

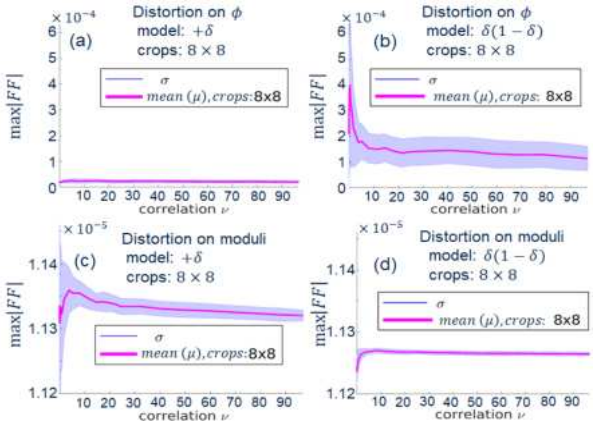

Figure 7– Probability plot of FF maxima with emulated stitched NFs, with distortion on phase, on 128x128 meta-atoms.

Indeed, in Figure 7 we highlight the effect of various distortions on FF zero-order, and the impact of correlation frequency ν, notably the maxima close to the MA scale in (b), or close to the crops number in (c) and (d).With this modelling approach, it is possible to conduct a rigorous analysis and emulate the Z0th error occurring from stitching method in FDTD simulations.

III- CONCLUSION

We propose a statistical error model enabling the predictions of the impact of simulation stitching errors on the optical properties of large metasurfaces. More systematic studies and models will be shown at the conference, in particular the correlation length that is crucial to understand the impact of the stitching error on the optical performances of meta-diffusors.

Abstract: Metasurfaces provide control of light properties, including enhancement of nonlinear effects, with potential applications through active manipulation of radiation parameters via external refractive index perturbations. In this study, the metasurface we propose is feasible for fabrication and demonstrates an increase in quality factor following photo-excitation from optical pump pulses and dynamically enhanced third harmonic generation.

Dielectric resonant metasurfaces offer significant control over the polarization, phase, amplitude, and frequency of radiation. However, the pursuit of active devices capable of dynamically modulating light parameters remains a focus of current research. Laser pulses represent a particularly compelling external influence, capable of inducing free carrier generation in materials and consequent changes in refractive index (Δn). Leveraging this phenomenon, ultrafast all-optical switching and frequency conversion can be realized through techniques such as pump-probe spectroscopy.

Recent studies have demonstrated the potential for substantial transmission modulation and frequency conversion in various metasurfaces. For instance, experiments utilizing amorphous silicon (a-Si) nanodisks have shown transmission modulation up to 0.5%[1], while metasurfaces composed of germanium (Ge) nanoparticles exhibit frequency conversion and blue shifts of significant magnitude[2].

One avenue towards achieving high-quality resonances lies in breaking the symmetry of metasurface unit cells, leading to the emergence of bound states of the continuum. Such resonances not only amplify optical effects but also enhance magneto-optical ones. Notably, metasurfaces featuring nanodisks with deliberately shifted holes exhibit enhanced magneto-optical effects under external magnetic fields[3].

The concept of Q-boosting metasurfaces has garnered attention for its potential to surpass traditional time-bandwidth limits, enabling efficient interaction between broadband laser pulses and narrowband resonators[4, 5]. By prolonging the interaction time within the resonator system, the quality factor (Q-factor) can be substantially enhanced. In [4], the unit cell design includes two pillars made of different semiconductor materials, e.g., silicon (Si) and Ge. To dynamically control the asymmetry between the pillars, two materials with different bandgaps are chosen, allowing one to excite free carriers in one of the pillars while leaving the other unchanged. With appropriate metasurface dimensions, reducing the refractive index will lower the effective light path in Ge and make the mode more symmetric, lowering the radiative losses and boosting the Q-factor. Along with a blue shift of the resonance, it can be seen a significant Q-factor boost for realistic values of Δn_{Ge} of up to -0.08 experimentally demonstrated earlier[6].

Despite promising theoretical groundwork, the previously proposed structures are extremely challenging under the fabrication point of view [4]. To address these challenges and facilitate experimental exploration, we present a novel approach to studying analogous effects experimentally.

The unit cells of the simulated metasurface are composed by stacked Si and Ge cuboids separated by a silica (SiO2) gap (Fig. 1a). Since in the spectral region of interest Ge has a refractive index of 4.1, such a structure has a resonance at a wavelength of 2285nm with a Q-factor of 550 (Fig 1b). In this case, according to the multipole decomposition, the electric dipole resonance dominates in the particles. Under the influence of laser radiation at a wavelength above the Ge bandgap and below the Si absorption region, for example 1200nm, the refractive index of Ge decreases to 4.02. The resonance of the metasurface undergoes spectral shifts up to 30nm, accompanied by an almost fourfold increase in the Q-factor. In this case, the electric field is relocated from Si to Ge. Now the value of the electrical dipole component in Ge increases by 8 times, while in Si it decreases by 1.5.

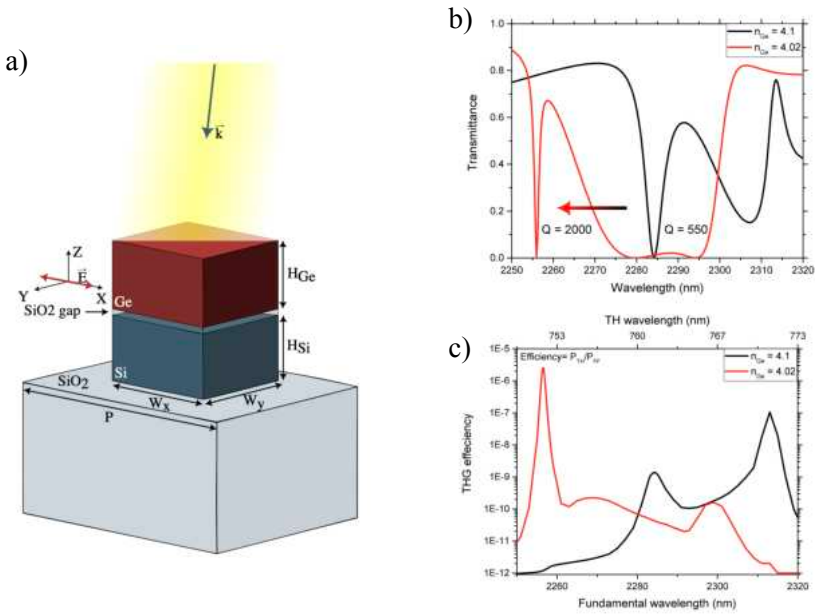

Fig 1: a) Schematic image of simulated metasurface. b) Transmission spectra for static case (black) and new high-Q state (red). c) Third harmonic spectra for unperturbated (black) and perturbed system (red).

Furthermore, we demonstrate nonlinear responses through simulations of third harmonic generation (Fig 1c). The efficiency of third harmonic generation experiences a profound enhancement, surpassing three orders of magnitude, indicative of the metasurface's capacity for nonlinear modulation.

In conclusion, our study underscores the potential of Q-boosting metasurfaces in enabling dynamic control over light-matter interactions, offering insights into both theoretical principles and experimental feasibility in nonlinear optics research.

Abstract: For more than 30 years, optical vortices (OVs) have been an active research topic with numerous applications. The emergence of metasurfaces has opened up new avenues for the generation of OVs. We propose here a study of optical vortices generated with metasurfaces using a wavefront sensor based on quadriwave lateral shearing interferometer (QLSI).

Ovs show a great interest in the research community during the last years with many applications like optical tweezers[1,2], astrometry[3], supper-diffraction-limit imaging[4] and, quantum states control [5,6]. OVs are mainly characterized by their topological charges (TC), which are normally integers, representing the number of 2π wraps of the phase of optical field around its optical axis (fig1.b). Generation and manipulation of OVs with large TC can be tricky leading to a drop in efficiency for targeted application.

On other hand, metasurfaces offer a way to control wavefront at a subwavelength scale and allows naturally to the generation of OVs (fig1.a). To characterize the phase of metasurfaces, a common way is to use wavefront sensor like QLSI[7]. However, this method is based on the measurement of the spatial derivative of the phase and direct integration of this derivative does not show the presence of OVs on the wavefront. This can be interpreted as the ambiguity of integrate a non-continuous 2D function where the phase singularity at the center of the OV plays the role of the discontinuity.

In this work, we propose a study on the metrology of OVs generated using metasurfaces (MS). The use of metasurfaces allows the generation of several OVs on the same beam with even non-integer TCs. However, taking into account the fabrication errors of the metasurface building blocks, the resulting TC as well as the efficiency can be different from the expected ones. Thus, an accurate and rapid metrology technique is necessary to check the quality of the samples and can significantly help for to optimize the metasurfaces. Here, we use quadriwave lateral shearing interferometery combined with several phase retrieval methods to properly identify and quantify such wavefronts (fig1.c). We used two types of MS (Effective Refractive Index and Pancharatnam-Berry) in this study and compare their performances.

Reciprocal Lens: Imaging Based on Lateral Ray Shifting via Non-Local Metasurfaces

Jingguang Chen[1], Wenzhe Liu[1,2*], Lei Shi[1], Jian Zi[1*], and C. T. Chan[2*]

[1]Fudan University, Shanghai, China

Abstract: We report an imaging mechanism via lateral ray shifting from non-local metasurfaces without spatially-varying features and a geometric center, producing upright real images. Experimentally, a C_{6v}-symmetric periodic metasurface at 28.5 GHz demonstrates this "reciprocal lens" behavior following $u+v=\tilde{f}$. Stacking multiple layers additively increases the focal length $\tilde{f}$.

Conventional lenses bend light rays to produce images of an object, which is achieved by space-variant structures, inevitably introducing a geometric center to the lens. These lenses have some fundamental limitations: the rays emitted from an object always get "inverted" when producing a real image, so single lenses cannot produce upright real images. Moreover, precise alignment is needed to produce high-quality images.

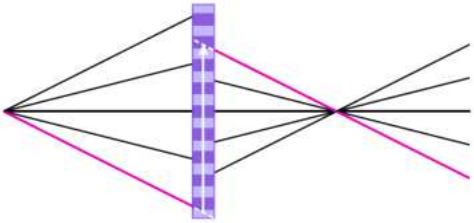

Fig. 1. Imaging based on lateral ray shifting.

We employ a different imaging mechanism based on lateral ray shifting provided by non-local metasurfaces. If a ray emitted from an object with incident angle θ is shifted by a distance proportional to θ in the paraxial limit, an upright real image is formed [Fig .1], following a distinct lens formula

$$u+v=\tilde{f}, \tag{1}$$

Where $\tilde{f}$ is the effective focal length, u and v are the object and image distances, respectively. As this lens formula is of a reciprocal form of the well-known Gaussian lens formula $1/u+1/v=1/f$, we call these ray-shifting imaging element as "reciprocal lenses". A reciprocal lens has a momentum-phase phase modulation that has a positive quadratic dependence on the in-plane wavevector (i.e., incident angle) [1], which is similar to metasurfaces known as "space squeezers" or "space plates" but with a negative squeezing distance [2,3].

We designed and fabricated a C_{6v}-symmetric reciprocal lens [Fig. 2(a)] operating at 28.5 GHz, where the momentum-space phase modulation best fits the quadratic dependence required for the lateral ray displacements [Fig. 2(b)]. Using a metallic mask with an "F"-shaped slot as the object [Fig. 2(c)], we observed an upright, real image with sharp boundaries at 7.5 cm away from the object [Fig. 2(e)], confirming the imaging behavior.

Furthermore, stacking two identical metasurfaces doubled the phase modulation [Fig. 2 (d)], resulting in a focal length of approximately 15-16 cm and producing a high-quality image at this distance [Fig. 2 (f)].

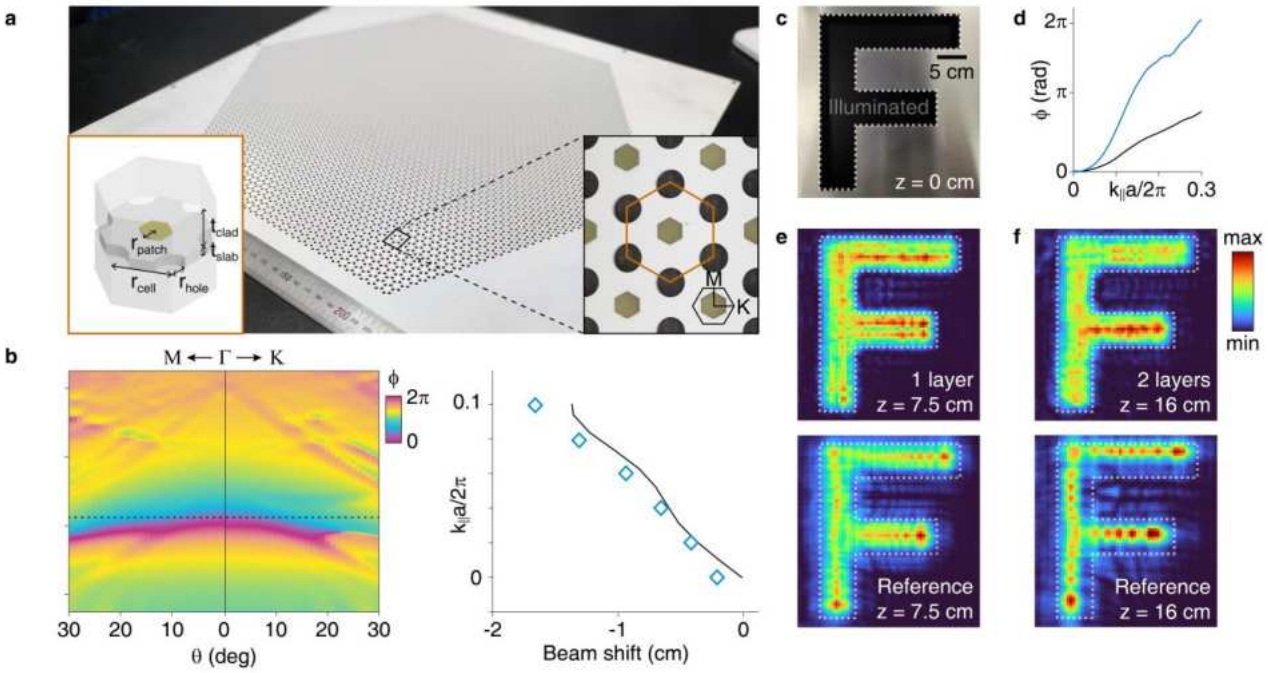

Fig. 2. (a) **Photo of the core layer of the designed reciprocal lens** comprising a honeycomb array of circular holes etched on a PCB. A hexagonal metallic patch is printed at the center of each honeycomb unit cell. The structured PCB acts as a photonic crystal slab and is clad by two background layers. Left inset: schematics of the unit cell. Right inset: zoomed-in photo of the structure. (b) **Angle-resolved transmissive phase-change spectra of the structure (with circularly co-polarized input and output) and the measured beam shifts for different incident angles.** The shifts of the beam centroids for different incident angles (blue diamonds) follow the displacements calculated from the momentum-space phase gradients (black curve). (c) **The "z = 0 cm" photo showing the object**, which is a metallic plate with an "F"-shaped slot cut into it. (d) **Measured transmissive phase distributions** for the one-layered (black curve) and two-layered (blue curve) reciprocal lenses. (e) **The image produced by one layer of reciprocal lens** and its reference. (f) **The image produced by two layers of reciprocal lens** and its reference.

Abstract: Array of micro-metalenses have been proposed to be integrated with pixels matrices of imaging systems to improve the modulation transfer function of imaging systems. Here, we investigate the theoretical limits of the metasurface approach for such applications and identify suitable operating domains.

In the context of the development of more performant imaging systems, arrays of refractive microlenses have been integrated to matrix of pixels in order to improve the spatial resolution and increase signal-to-noise ratio [1]. The role of these microlenses is to focalize at the center of each pixel to decrease the optical and electronic cross-talks between pixels. For practical integration, the size of each of these microlenses is about the size of a single pixel, thus a few microns. Consequently, precisely fabricating refractive microlens is a challenging task[2] compare to the flexibility and semiconductor compatible technology offered by the metasurface approach. However, with a size of few microns only, diffraction by the metasurface itself cannot be neglected and thus the metasurface enters a hybrid diffractive regime affecting its overall performances, and leading to "focal shift" [3].

Here, we theoretically investigated the fundamental limits of micro-metalenses by considering the finite size of the metasurface. To conduct our theoretical study, we based our approach to the Stratton-Chu integral[4] that we adapted to model a metasurface with finite size. We identified two fundamental limits which define the region of operation of metalenses: (i) an upper limit defined by the size of the metasurface itself, and (ii) a lower limit defined by the pitch of the metasurface. The first limit is a hard limit which cannot be overcome. The aperture defines a region of space in which we can achieve control of the phase. Outside of this region, the diffraction by the aperture itself alters the wavefront control. Therefore, to achieve full control of the wavefront, smaller metalens require higher numerical aperture (NA). However, it leads to the emergence of the second limit. High numerical aperture yields to abrupt phase variation which have to be discretized by the meta-atoms. This becomes critical when the size of the metasurface is only few times the wavelength, and thus we dispose of only limited number of meta-atoms to control the wavefront. However, this is a soft limit, meaning it could potentially be alleviate depending on the fabrication processes and physical mechanism used to induce the phase shift.

Consequently, in the domain defined by the upper and lower limits, we can identify two regimes of metalens operation, (i) a regime with full control of the wavefront, characterized by a metalens with high numerical aperture, (ii) a diffractive regime, in which the diffraction of the metalens itself hinder the metasurface optical properties.

In order to test and validate our theory, we fabricated arrays of $10\mu m$ diameter metalenses. The meta-atoms are made of $1\mu m$ height GaN pillars on sapphire substrate and operates at $617nm$ wavelength. Each metalens is designed with different numerical apertures which span the different regime of operation we identified.

Our study highlights the limits of applications of small metasurfaces and clarifies the physical mechanism at works. Moreover, by clearly defining the boundaries of the metasurface approach, our work identifies a path to follow to benefit wavefront control properties of metasurfaces at small scale.

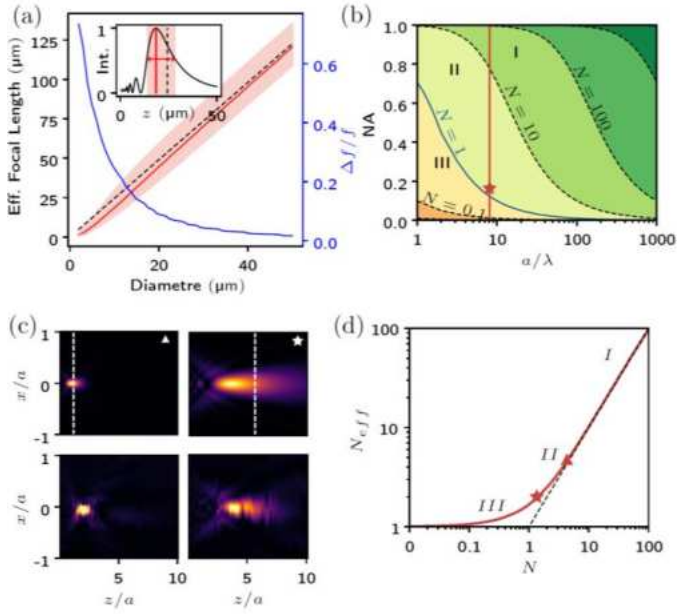

Figure 1: (a) In red, variation of the effective distance focal (maximum of amplitude) in function of the diameter of the metalenses with fix numerical aperture NA = 0.2. In blue (right y-axis), variation of the focal shift with regards to the designed focal length. (b) Mapping of the Fresnel number $N = a^2/\lambda f$, in function of the numerical aperture and the size of the aperture (in wavelength). The green color shows N > 1 and the yellow colors N<1. (c) Comparison between numerical simulations and measurements for GaN metalenses of $2a = 10\mu m$ at $\lambda = 617nm$, with focal length $f = 10\mu m$ and $f = 30\mu m$, represented by the with dashed line. (d) Evolution of the effective Fresnel number in function of the Fresnel number. Red line corresponds to the simulations and the symbols refer to (c).

Abstract: We proposed an achromatic metalens with a 90° large field of view and a diameter of 5.75 mm for a wavelength range of 8 to 12 μm. This metalens is fabricated by an i-line stepper, which has mass-production advantages and is low-cost. Additionally, it captures great-quality images.

In optical imaging systems, chromatic aberration-free metalenses with large dimensions and a wide field-of-view (FOV) are sought after for delivering high-quality images. However, controlling the group delay of meta-atoms while eliminating chromatic aberration imposes limitations on the maximum diameter [1] of a metalens. Designing a chromatic aberration-free metalens with a substantial diameter presents a significant challenge [2]. In our study, we addressed this challenge by developing a large-area, chromatic aberration-free metalens with a wide FOV for mid-infrared (MIR) wavelength applications.

Figure 1 illustrates the ray tracing diagram, which includes an aperture that limits the range of the marginal ray, forming a telecentric system consisting of an aperture, metalens, and sensor. Typically, a cover layer is used to protect the sensor. Therefore, in this setup, we placed a silicon-based cover layer in front of the sensor. In our design, this metalens provides great focusing quality at viewing angles ranging from 0 to 45°.

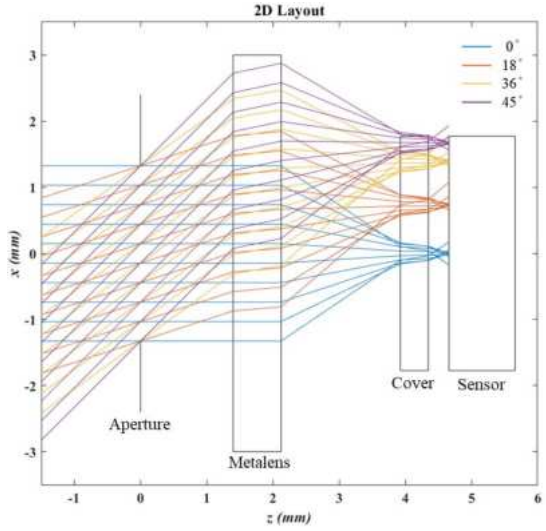

Figure 1. Schematic ray trace of the propose optical system, using an aperture to limit the range of the marginal ray and form a telecentric system.

This metalens features a silicon-based donut-shaped nanorod as its basic building block, situated on a silicon substrate. We utilized the Finite-Difference Time-Domain (FDTD) method to calculate the propagation phase and group delay for the donut-shaped nanorod with various dimensions. Fabrication of the metalens involved i-line stepper lithography, followed by deep reactive ion etching (Deep-RIE) processing [3]. All manufacturing processes comply with the specifications of regular semiconductor factories, enabling mass production of this

metalens. The SEM image in Figure 2(a) presents a tilt view at 45°. The donut-shaped nanorod reaches a height of 11 μm after the Deep-RIE, and the photograph of the 5.75 mm diameter metalens is shown in Figure 2(b).

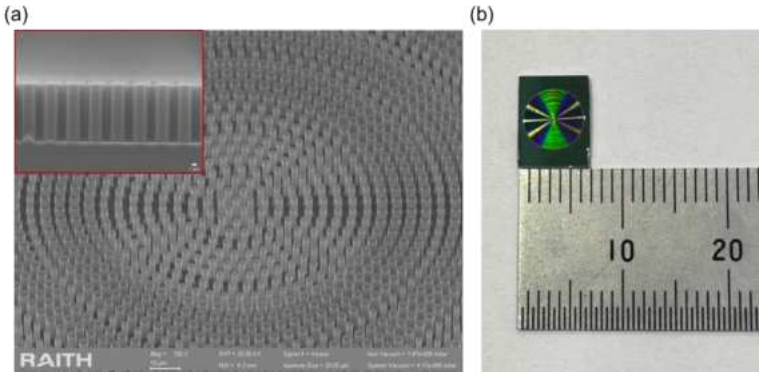

Figure 2(a) The SEM image of proposed MIR metalens, the sub-image show the height of nanorod be approximately 11 μm. (b) The photograph of the 5.75 mm diameter metalens.

In the measurement setup, as depicted in Figure 3(a), a hotplate served as the mid-infrared (MIR) light source, while a chess-type metal frame acted as the object. The proposed metalens was employed to image the object at distance of 9 mm, with the resulting image shown in Figure 3(c). The FOV was measured to be approximately 87°. This metalens demonstrated great image quality, clearly resolving the edges of the metal frame.

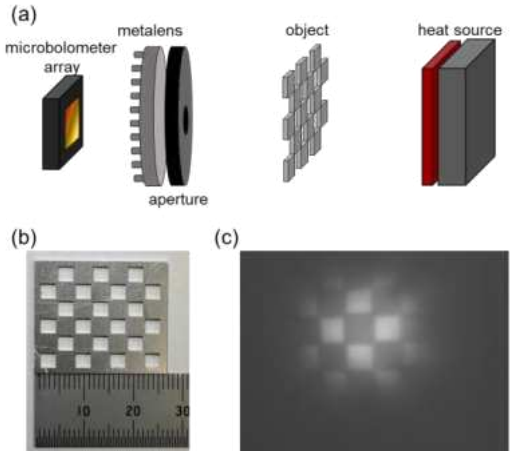

Figure 3 (a)The measurement setup of propose meta-optics system, (b)and the chess-type metal frame acted as the object. (c)The image results of the propose system, the FOV was measured to be approximately 87°.

Abstract: Meta-optics allow the realization of new optical functions that are increasingly complex to realize and characterize locally. We propose an interferometric method to measure both amplitude and phase of an array of meta-elements constituting a metasurface. Tested for MIM (Metal-Isolating-Metal) metasurfaces, this technique can be applied to all metasurfaces.

For more than twenty years, meta-optics have allowed the development of a wide variety of optical functions. Some of them were well known like lenses, wave plates, or prisms. But new or modified functions have also been created such as phase mask coding, color filter, color printing or special holograms. Meta-optics are composed of arrays of dielectric or metallic nano-antennas (or meta-elements).[1, 2] They allow to modify the wavefront of the incident beam and thus to create a particular optical function. By controlling the size, shape, orientation or position of the nano-antennas, it is possible to control the amplitude, phase or polarization of the optical wave.[3–5]

As the optical functions developed become more and more complex, the design step becomes more and more important and must face important modeling problems such as the non-periodization of surfaces, the consideration of non-normal incidences or the multiplicity of different antennas on the same period. On the other hand, the phase of the antennas remain complicated to measure directly, thus the characterization of the metasurfaces is done indirectly through the verification of the designed optical function.[2, 6]

Faced with these two issues, we propose the development of an interferometric technique for the robust metrology of nano-antennas. This technique allows to characterize, experimentally, in amplitude and phase, an array of nano-antennas and thus to build a library of meta-atoms that can then be directly integrated into optical components. It is based on the PISTIL interferometer, a lateral shift interferometer whose use has already been demonstrated in the measurement of coherent laser beams.[7]

PISTIL stands for PISton and TILt. It differs from other lateral shift interferometer such as the Quadri-Wave Lateral Shifting Interferometer (QWLSI)[8] by a mask that split the incident beam and allows to measure the phase shift of two nearby elements. In our configuration, the subsamples are placed on a hexagonal lattice, which allows measuring the phase shift of an element with six of its neighbors directly. As shown in Figure 1, we want to characterize a sample composed of at least two subsamples each inducing a phase shift. At the exit of the sample, the beam is thus locally dephased. It then passes through a mask. We then have several beams each with a different phase shift. All these beams then pass through a diffraction grating that sends the orders -1 and +1 in three directions. These orders will interfere and create an interference pattern, the pistillogram. On this figure, we can observe the 0 orders of each beam, surrounded by interference figures, the petals.

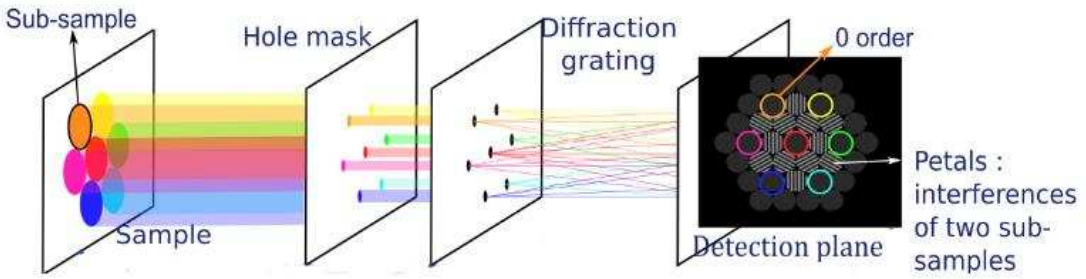

Figure 1: Scheme of PISTIL Interferometer.

Our interferometer can simultaneously measure the phase of nano-structures positioned on the same test sample, and cause them to interfere in pairs. By recovering a global interferogram containing the interference patterns of each sample with its neighbors, and using Fourier processing, we can reconstruct the phase induced by each type of nanostructure at each wavelength. By integrating these results over a wide range of wavelengths, we can then obtain the phase spectrum of each desired structure.

We tested our method on a test sample made up of fifty-two sub-samples containing reflective MIM (Metal-Insulator-Metal) structures in Gold and Zinc Sulfide, for which we varied three geometric parameters (period, length, width) in order to vary phase and amplitude with respect to the wavelength. But this particular case can be generalized to all kinds of nano-antennas, which will allow its user to design its own library of nano-atoms characterized in amplitude and phase.

Meta-lenses for second harmonic generation imaging on the tip of hair-thin optical fiber for advanced endoscopic imaging

R. Fuentes-Dominguez[1*], D. Afuwape[1], F. He[1], R. Cousins[2], and G. S. D. Gordon[1]

Abstract: We present a method for second harmonic generation (SHG) imaging compatible with hair-thin optical fibres with the use of two meta-lenses for 900 and 450 nm wavelength. These are fabricated using conventional e-beam lithography, polymer encapsulated, and transferred one-by-one to the tip of single-mode optical fibres.

Second-harmonic generation (SHG) has emerged as a powerful nonlinear optical contrast mechanism for biological imaging applications, in particular, imaging fibrillar collagen in a diverse range of tissues [1]. SHG is a coherent process where two lower energy photon are converted to exactly twice the incident frequency or half the wavelength. SHG microscopy has several advantages over conventional fluorescence imaging: the contrast arises from the sample itself, so there is no need for a dye or fluorophore, as well as being free from photobleaching (the signal generated is not limited in time) and occurs instantaneously (no limitation on the laser repetition rate) [2]. However, there are some limitations: SHG is a low efficient process without high numerical aperture objectives and high-power femtosecond pulses, which makes it challenging to translate this technology to in-vivo clinical environment. Previous works have combined SHG imaging with optical fibres, but still with the need of an optical objective to focus light on the sample [3].

Here, we present a method for second harmonic generation imaging compatible with hair-thin optical fibres. The meta-lenses are first fabricated by conventional e-beam lithography on a silicon substrate coated with a thin Cr sacrificial layer, then polymer encapsulated via photolithography, peeled away from the substrate through wet etching the Cr layer, and finally bonded onto fibre facets by optical adhesive. As proof-of-principle, we show two different meta-lenses to focus 900 and 450 nm optical wavelength for generation and detection SHG, respectively, using an array of aluminium dots with the shape of a Fresnel zone-plate lens with a focal length of 250 μm. We also show that by using this method, we can fabricate multi-layer stacks, which are increasingly finding use in advanced imaging systems [4].

Optimized design strategy of polychromatic metasurfaces considering their fundamental dispersion limits

A. Patoux[1], N. Kossowski[1], C. Majorel[1], S. Khadir[1] and P. Genevet[2*]

[1] Université Cote d'Azur, CNRS-CRHEA, France
[2] Physics department, Colorado School of Mines, USA

Abstract: In this work we describe a simple way of quantifying the dispersion limits of a dataset, which can be used to optimize the design of polychromatic metasurfaces. As an example, the design, fabrication and characterization of a highly effective achromatic metalens was performed using this approach.

Metasurface elements, based on fixed nanostructures, are inherently limited in terms of dispersion for the design of achromatic components. To design such components, a very large number of different meta-atoms is required, usually leading to the construction of complex meta-atom designs with high geometric tunability [1].

However, recent studies highlighted some fundamental limits of achromatic diffractive lenses or metalenses performances due to the limited effective refractive index range that such components can achieve [2,3].

Such analysis can be pursue further considering any achromatic metasurface or even polychromatic metasurfaces. Taking the example of an achromatic metasurface, its unwrapped phase function at position (x, y) can be defined as $\boldsymbol{\Phi_{uw}(\lambda, x, y)} = \frac{\boldsymbol{\Phi_{uw}(\lambda_0, x, y)}\,\boldsymbol{\lambda_0}}{\boldsymbol{\lambda}}$ [1,4], where $\boldsymbol{\lambda}$ is the operating wavelength, and $\boldsymbol{\lambda_0}$ is a wavelength of reference within the studied bandwidth.

In that case, the phase equation to solve regarding the meta-atoms optical responses is the following:

$$\boldsymbol{\delta\Phi_{s,i}(\lambda) + C(\lambda) = \Phi_{uw}(\lambda, x_i, y_i) = \frac{\Phi_{uw}(\lambda_0, x_i, y_i)\,\lambda_0}{\lambda}} \quad (1)$$

Where $\delta\Phi_{s,i}(\lambda)$ is the phase shift of the structure #i that is required to get an achromatic response at the position (x_i, y_i), and $\boldsymbol{C(\lambda)}$ represent an arbitrary phase piston varying with λ, spatially constant, thus not impacting the optical response.

To graphically represent how to solve this equation, we consider the ensemble of functions $\Phi(\boldsymbol{\lambda}) = \boldsymbol{A} * \boldsymbol{\lambda_0/\lambda + C_0}$, using the couple of parameters $\boldsymbol{(A, \Phi(\lambda_0))}$. In **Fig. 1b**, we show different phase dispersions obtained for a high number of different structures geometries (illustrated in **Fig. 1a**), obtained through FDTD simulations for the [400-700] nm bandwidth (here, $C(\lambda) = 0$). We also show in orange some target phase shifts, associated to an achromatic metalens whose phase profile at $\boldsymbol{\lambda_0}$ = 400nm is shown in **Fig. 1c**.

We note that with such representation, the target phase shifts are in fact completely represented by the linear function $\boldsymbol{A = \Phi_{uw}(\lambda_0, x_i, y_i)}$. This allows to conclude that the dispersion range, represented by $\boldsymbol{A}$, represents in fact the dispersion limit of the dataset. Hence, here, any optical component having an unwrapped phase shift range greater than 30 radians for $\boldsymbol{\lambda_0} = 400$nm cannot be fully reconstructed using this meta-atom library.

Regarding the influence of $C(\boldsymbol{\lambda})$, this latter can, in this configuration, only take the form $C(\boldsymbol{\lambda}) = \boldsymbol{A' * \lambda_0/\lambda + C'_0}$. Tuning $C(\boldsymbol{\lambda})$ then allows to shift all dataset points cloud identically. As this points cloud representing our dataset does not cover fully the 2D space, this degree of freedom is very interesting to optimize the selection of the geometries to get the best efficiency, i.e. to move the blue points cloud to get the best overlapping with the orange target points.

Based on this approach, we studied the more general case of polychromatic metasurfaces, as well as the influence of several parameters regarding the meta-atom geometries. We also designed, fabricated and characterized a 1mm achromatic metalens that stays within the accessible dispersion range allowed by our dataset in the visible. The results showed very good performances with Strehl ratios remaining overall greater than 80%.

Toroidal dipole bound states in the continuum in dielectric metasurfaces

Sheng-Wei Kao, Yi-Chi Kao, and Ruey-Lin Chern*

Institute of Applied Mechanics, National Taiwan University, Taiwan
*corresponding author: chernrl@ntu.edu.tw

Abstract: We propose a design of dielectric metasurfaces for investigating the bound states in the continuum (BICs), which are recognized as toroidal dipoles (TDs) characterized by the electric or magnetic fields bent into a torus. Several electric or magnetic TDs are gathered in the unit cell to form multiple TD BICs.

Bound states in the continuum (BICs) are non-leaky localized resonance modes that coexist with a continuous spectrum of radiating waves [1-4]. Since BICs will not radiate to the far field, they are decoupled from the far-field radiation and possess infinite quality factors with zero spectral linewidths. In the presence of the absorption loss, roughness, or finite size of the structure, an idal BIC is turned into a quasi-BIC with a finite quality factor. In 1929, von Neumann and Wigner discovered that one-dimensional (1D) potential can support localized solutions that correspond to isolated discrete eigenvalues embedded in the continuum of positive energy states [5]. In 1985, Friedrich and Wintgen proposed the concept of BIC as a result of complete destructive interference of two resonances undergoing an avoided crossing. When two resonant states approach each other as a function of certain continuous parameter, the resonance width of one of them vanishes and forms the so-called Friedrich-Wintgen (FW) BIC [6]. In recent years, BICs have been found in quantum, photonic, acoustic and water wave, and mathematical systems, which can be applied in a variety of areas, including integrated photonic circuits, filters, lasers, and biosensors.

Toroidal dipoles (TDs) are high order terms of the electric multipole moments, which arise in an electrodynamic multipole expansion as additional terms compared to the electrostatic multipole expansion [7]. For a static TD, the external field of the TD mode is identically zero and the currents create a magnetic field confined within the torus. The static TD, therefore, do not interact directly with electric and magnetic fields [8]. For a dynamic TD, the electric toroidal dipole (ETD) is usually represented as poloidal electric currents flowing on a torus surface and magnetic dipoles arranged in a head-to-tail configuration, which can be excited as BICs in metamaterials [9-10]. On the other hand, magnetic currents flowing in the surface of a torus generates a magnetic toroidal dipole (MTD) [11-12].

In this study, we propose a design of dielectric metasurface consisting of corner or square patches in the unit cell of a square lattice. Symmetric-protected BICs occur at the Brillouin zone center, which are associated with extremely large quality factors and small linewidths. In particular, the BICs are identified as toroidal dipole modes characterized by the electric or magnetic fields bend into a torus, with the magnetic or electric circling around the surface. Several electric or magnetic TDs are gathered in the unit cell to form the multiple TD modes. Multiple electric TDs and magnetic TDs may be oriented normal or parallel to the metasurface, which appear at the polarization singularities in the momentum space and carry integer topological charges.

Abstract: In this work, we experimentally demonstrate new types of hybrid supercell metasurfaces which exploit different types of supercells and unit cells in the same design, creating a smooth transition between them. We use this new method to control phase and amplitude of light at the same time designing speckle-free holograms.

Metasurfaces consisting of an array of two-dimensional (2D) subwavelength nanostructures, provide unprecedented control over light at the nanoscale. Metasurfaces are typically created using subwavelength unit cells, which are engineered to impart a local phase profile of light as it propagate through. This technique enables the attainment of various functionalities such as focusing, holograms, polarization functions, and beam shaping. By employing hybrid metasurfaces (comprising multiple cells/supercells optimized collectively) it becomes feasible to simultaneously achieve multiple functions [1,2].

In this work, we propose a new type of hybrid supercell metasurfaces based on smooth transitions between unit-cell-based design and supercells for wide angle and large numerical aperture optics [3]. Figure 1A illustrates an example of a metalens designed in this way, where the center is implemented via traditional unit cell metasurfaces and the edges are implemented with different types of supercells. Each type is identified by the order n_x and n_y it uses to diffract light towards the focus. Previous designs of this type (e.g. [4]) use radial supercells which create a periodic discontinuity on the radius, in order to maintain the same pillar size at different distances from the center. With this design it is possible to smoothly map the full surface to continuous unit cells (e.g. see pillars arrangements in Figure 1B).

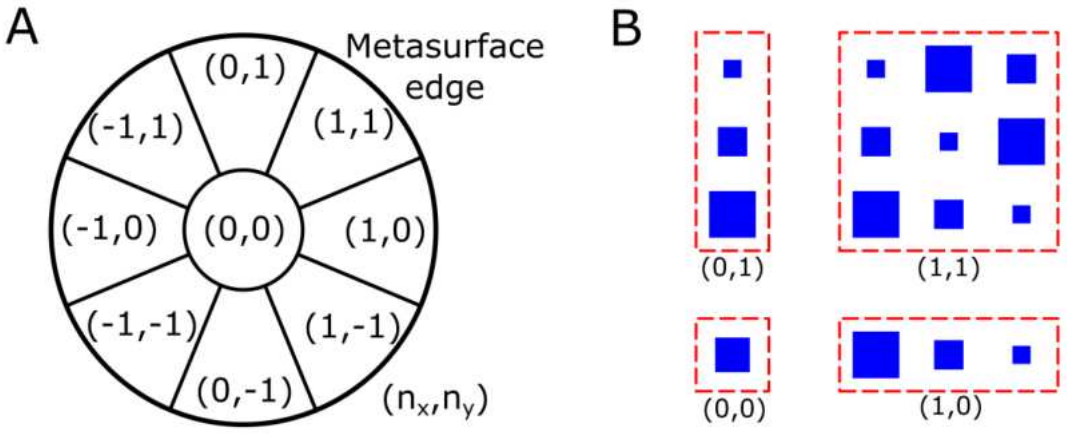

Figure 1. Schematic of the hybrid metasurface. **A**. The design is divided into different regions, each implemented with a different type of unit cell/supercells. **B**. Example of unit cells and supercells.

As a benchmark, we tested experimentally a metasurface composed of (n_x=1, n_y=0) supercells. The selected supercell (Figure 2A) scatters light into the selected order with variable phase and amplitude. Phase is modulated by the position of the pillar (i.e. the detour phase) while amplitude by its length. Thanks to the possibility of modulating both phase and amplitude, we demonstrated a speckle-free hologram design based uniquely on Fresnel diffraction (i.e. without using the Gerchberg-Saxton algorithm or similar methods). Figure 2B shows the designed phase and amplitude. The metasurface operates in reflection, and the pillars (in TiO_2) were fabricated on a silicon substrate coated with aluminum (Figure 2C). A 680 nm laser beam incident at 45° from the normal was used to test the hologram, which was projected normally from the metasurface onto a screen (Figure 2D).

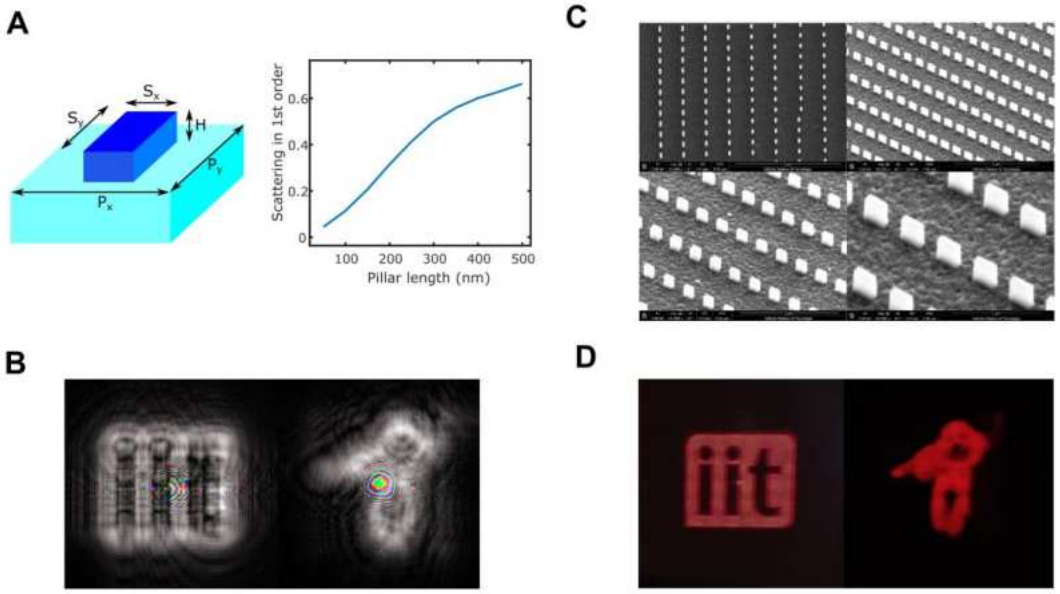

Figure 2. Speckle-free hologram. **A**. Supercell element. P_x = 1000 nm, P_y = 500 nm, H=300 nm, S_x = 100 nm, S_y is variable. The plot represents the simulated scattering amplitude as function of pillar length S_y. **B**. Designed amplitude and phase of the holograms **C**. SEM image of the fabricated metasurface. **D**. Generated hologram projected on a screen.

The presentation will provide additional details on this design, which paves the way to 3D holograms at large viewing angles, which are essential for AR/VR applications.

Abstract: Our study introduces an unconventional metagrating that surpasses the traditional 2π phase constraint within the supercell of a metasurface, enabling precise control over high-order diffraction with adjustable efficiency redistribution. This work shines light on the design of multifunctional diffraction ultrathin optical components, such as metalens and holograms.

Optical metasurfaces, comprising 2D arrays of subwavelength structures, hold promise for advanced functions in nanophotonics.[1] By optimizing phase discretization of nanoscale meta-atoms, these metasurfaces are able to manipulate wavefronts, polarization, intensity, and spectrum.[2-3] Large period metagratings reveal new wavefront manipulation capabilities, often requiring inverse optimization to enhance diffraction efficiency.[4] Traditionally, metasurfaces aim for a full-range 2π phase change to achieve complete wavefront manipulation akin to conventional optics.[5] However, limiting the phase range to 2π is unnecessary in certain metasurface designs. On the other hand, incomplete phase provides an additional degree of freedom for optical wavefront control. In this study, we present incomplete phase metagratings achieved through intuitive supercell design, deviating from the conventional 2π phase change. Leveraging the flexible phase modulation capability in metagratings, efficiencies of diffracted beams are tailored by incorporating meta-atoms with incomplete phase ranges (e.g., π, 3π, 4π). Under normal incidence of light, the designed metagratings predominantly diffract the light into two adjacent diffraction orders, allowing for adjustable splitting ratios of 0th and 1st order ranging from 0.07 to 24.8.

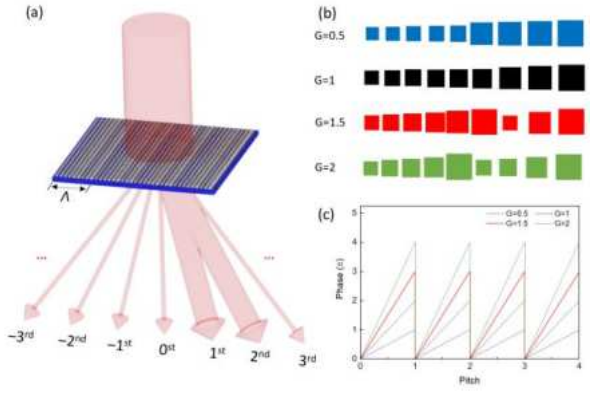

Figure 1. a) Sketch of an incomplete phase metagrating with controlled diffraction efficiency redistribution. b) The design of metagrating unit cells with G factors of 0.5, 1, 1.5 and 2, respectively. The G is the factor of total phase change of each supercell. The pitch of each unit along x- and y-direction is the same (Δ = 270 nm). c) Design phase profile for each metagrating with different G factor.

In contrast to conventional metagratings with fixed 2π phase gradient, incomplete phase metagratings introduce total phase of G*2π per supercell, with G as a scaling factor. As shown in Figure 1 (a) and (b), each grating period contains nine nanobricks. When G = 0.5, nanobrick size gradually increases to cover 0-π phase range per supercell. G = 1 represents conventional metagrating with 2π phase change per supercell, 1st order

being the blazing order. Increasing G from 1.5 to 2 results in non-monotonic nanobrick size increase, yielding wrapped phase of 2πG. Fig. 1c illustrates phase ramp across consecutive unit cells for different G values. The metagratings are fabricated on a quartz substrate, covering a 400×400 μm^2 area. Electron-beam lithography patterns metagratings onto ZEP 520A resist, followed by atomic layer deposition of amorphous TiO_2. Excess TiO_2 atop the resist is removed via controlled reactive ion etching. Remaining resist is stripped, leaving nanobricks.

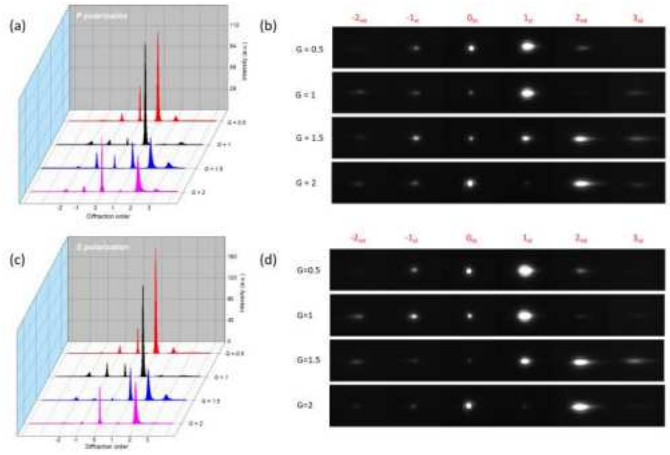

Figure 2. a,b) show the measured diffraction intensity of 0th, ±1st, ±2nd, and +3rd order metagrating with *P* and *S* polarization incidence, respectively; c,d) display the CCD images of diffraction beams of metagratings with G = 0.5, 1, 1.5, 2.

To assess optical performance, a collimated laser source (405 nm central wavelength) is utilized for incidence. A wire-polarizer follows the laser, allowing flexible beam polarization control. Subsequently, the illumination beams is confined to a spot smaller than the area of metagrating. CCD camera (Thorlabs DCC3260M) captures images of diffracted beams, revealing multiple spots with varying brightness, as expected. Corresponding intensity profiles (Fig. 2a, b) are extracted. For G = 1 or 2, the diffraction beam converges into a specified order (1st or 2nd). When G = 0.5 or 1.5, diffraction beam mostly splits into adjacent orders (e.g. 1st and 2nd or 2nd and 3rd). Splitting ratio (I_1/I_0) ranges from 0.07 (G = 2) to 24.8 (G = 1), with polarization independence well demonstrated. Optical images of diffractive spots under *P* and *S* polarized incidences are shown in Fig. 2c, d. Satellite tails appear in high diffraction orders due to oblique incidence on the perpendicular CCD screen. Additionally, introducing oblique incidence angle or wavelength variation adjusts diffraction direction and transmitted beam intensity distribution within a small range due to effective G factor changes.

Our study breaks the 2π phase constraint, designing incomplete phase metagratings for controllable wavefront and intensity reconstruction. Discrete phase distribution offers flexibility to design optical devices with incomplete phases, a feat unattainable with conventional optics. Achieved splitting ratio of I_1/I_0 spans 0.07 to 24.8, with performance unaffected by incidence polarizations.

Selective excitation of diverse subwavelength resonances in meta-surfaces comprising volumetric resonators: a brief discussion

A. E. Serebryannikov[1,*]

[1]ISQI, Faculty of Physics, Adam Mickiewicz University, 61-614 Poznan, Poland

[*]corresponding author: andser@amu.edu.pl

Abstract: The approaches to selective excitation of subwavelength resonances in metasurfaces comprising volumetric resonators made of dielectric and phase-change materials are briefly reviewed. The applicability of particular approaches depend on the spectral and spatial features of the incident electromagnetic wave.

While overlaps or coupling of two or more individual resonances may yield a variety of useful physical effects, like Kerker effect or BIC, rarefying the spectrum of resonant modes is the opposite scenario, which is demanded for applications. To this end, selective excitation of the individual resonances is of practical importance, especially when overlaps or coupling effects should be avoided within wide ranges of variation of geometrical parameters and frequency. In particular, resonators made of a dielectric with moderate or high permittivity are widely used, in which diverse resonances can be obtained at subwavelength scale. One of the purposes here is justification of the systematic approach to the selective excitation, based on the recent literature and original theoretico-numerical results.

The approaches to the selective excitation of subwavelength resonances can be assigned to the two big group: (i) the approaches applicable at the *design level* and (ii) the approaches applicable at the *excitation level*. The former includes but is not restricted to:

- proper perturbation and optimization of the resonator geometry;
- the use of higher (nonzero) diffraction orders;
- absorption engineering.

In turn, the latter may include

- excitation by electromagnetic wave with the synthesized spectrum;
- angular selectivity;
- spatial structuring of the incident wave.

The possible choice of a suitable approach depends on the *illumination type*, whose choice, in turn, depends on the targeted frequency range and functionality. We distinguish between (i) monochromatic and (ii) white light illumination types when the selective excitation is considered. It is assumed that the sequences of rectangular pulses could be used to synthesize a desired spectrum. Consideration has been restricted to non-gradient reflective metasurfaces; it was assumed that the unit cells of those metasurfaces can be used to build the gradient ones. The selectively excited resonances may include both volumetric (Mie) and array resonances.

Among the design-level approaches, variations of *geometrical parameters*, e.g., height-to-radius ratio of micro-/nanocylinders is probably the most commonly used technique that may yield a desired number and properties of subwavelength resonances [1]. Moreover, the designed deviation from the canonical shapes can improve the excitation conditions for some resonances and worsen for the others; for example, see ref. [2]. This approach is demanded for the both illumination types. One more but a less common approach is based on such structural design that the spectral locations of the resonances to be suppressed and those remaining in zero-order

reflection are chosen (due to a specific design of unit cell), respectively, at insignificantly larger or smaller frequencies than the *frequency-domain diffraction threshold*. In other words, it works only at the boundary of the diffraction-free range. In this case, redistribution of the incident-wave energy in favor of other transmission/reflection channels than zero-order reflection takes place. Finally, *absorption engineering* exploits the fact that the given imaginary part of permittivity or tan δ may lead to different excitation conditions for the resonances with lower and higher radiation losses, including the case when resonances are closely spaced in the frequency domain. For instance, adding a portion of lossy impurities may weakly or moderately affect the latter, but strongly affect and even suppress the former.

Among the excitation-level approaches, one should mention, first of all, excitation by the incident wave with the *synthesized spectrum*. The strong side of this approach is that it needs no special arrangement at the design level. The selective excitation of resonances is controlled by a waveform whose frequency spectrum is designed so that its maximums correspond to the spectral locations of the desired resonances, whereas the minimums correspond to the undesired resonances. The weak side is that it may be realizable rather at lower, e.g., microwave frequencies, while the possibility of transferring this approach to infrared and visible frequencies is limited. Next, which resonances are efficiently excited and which are not may depend on *incidence angle*. Indeed, the effect of angle variations is known (e.g., see ref. [3]) but has not yet been adequately exploited in metasurfaces. It is probably the simplest approach to reconfiguration, since it needs neither tunable materials nor specially designed waveforms. This approach may use the spectral shift of the diffraction threshold at variable angle of incidence. The preliminary coupling analysis should include examination of wavevector matching and symmetry consistency. *Structuring waves* is a modern approach, which can be applied to the selective excitation; see ref. [4]. In fact, any non-plane wave front yields some extent of freedom for the selective excitation. The Talbot effect can be considered as (one of) the earliest attempts of spatial structuring. Its potential still invokes exploration.

Special attention will be paid to the comparison of two classes of the *reconfiguration* scenarios [5], i.e., the ones achieved (i) without tunable materials but by changing the selectivity conditions within the aforementioned approaches, or (ii) due to the joint effect of tunable materials and those approaches, either at the excitation level or at the design level, or both. For the case (ii), the emphasis will be put on the scenarios which are not achievable without such a joint effect. Some approaches will be discussed in the context of reconfiguration that may involve passive PT-symmetry [6] as one of the states. As a result of the comparative analysis, routes to systematic management of multiple, functionality-enabling subwavelength resonances can be identified.

Abstract

Metasurface color routers have emerged as a promising solution to address the inefficiencies associated with traditional color filters. Here, we present a metasurface color router, designed using an adjoint-based inverse design approach, with optical efficiencies of 57%, 75%, and 54% for red, green, and blue channels, respectively.

1. Introduction

CMOS image sensors (CIS) are ubiquitous in digital cameras and smartphones, providing the foundation for color imaging. These sensors employ color filters to selectively allow specific wavelength ranges to illuminate designated pixels which are composed of red, green, and blue sub-pixels. However, traditional Bayer color filters, which are invented by Bryce E. Bayer in 1976 [1], suffer from a critical limitation: they operate through light absorptions, resulting in significant light loss.

To overcome this challenge, metasurfaces [2], an innovation in the field of nanophotonics, are proposed because of unique properties to manipulate light properties such as amplitude, phase, and polarization. This metasurface selectively guides light of different wavelengths (RGB colors) to specific spatial locations.

Nevertheless, various solutions of metasurfaces, such as metalens [3], and metasurface color router [4], are proposed, designing the new metasurfaces requires a significant amount of computational resources and time.

In here, we leverage an adjoint-based photonic inverse design (PID) approach, which can reduce the computational resources, and design a metasurface color router with a sub-pixel size of 1 μm x 1 μm.

2. Results

2.1. Optimization process of adjoint-based metasurface color router

The adjoint method allows us to efficiently calculate the gradient at all points in space with only two simulations, forward and adjoint, per iteration. Therefore, we can reduce computational resources and time.

To simulate and optimize this metasurface color router, we employed the open-source PID package ‘lumopt’ [5]. This package is based on adjoint method and leverages the Ansys Lumerical FDTD solver for CIS simulations and Silicon photonics. We extended the existing lumopt code by introducing a novel FoM. The FoM is defined as

$$FoM = |\boldsymbol{E}(x_0)|^2, \quad (1)$$

where x_0 describes the positions in the simulation region. This FoM aims to maximize the absorbed energy within a specified volume, thereby enhancing overall performance. To strike a balance between performance and manufacturability, we employed 2D topology optimization. Our design region spans 2 μm x 2 μm x 2 μm**.** The metasurface materials consist of TiO_2 (n=2.4) and Si_3N_4 (n=1.49). The resulting metasurface color router structure, depicted in Fig. 1, achieves optical efficiencies that surpass conventional color filter systems.

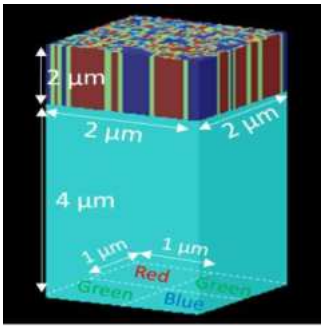

Figure 1: Optimized metasurface color router. Schematic of optimized metasurface color router which is 2 μm x 2 μm x 2 μm in size. The color router is composed of TiO_2 (red) and Si_3N_4 (blue) and has a focal length of 4 μm. The substrate is SiO_2 (cyan)

2.2. FDTD simulation results of the metasurface color router

In Figs 2a-c, we present the electric field distribution on the surface (XY plane) of the color pixels at wavelengths of 650 nm (Red), 550 nm (Green), 450 nm (Blue). The metasurface effectively routes and focuses light to individual sub-pixels while minimizing optical cross talk.

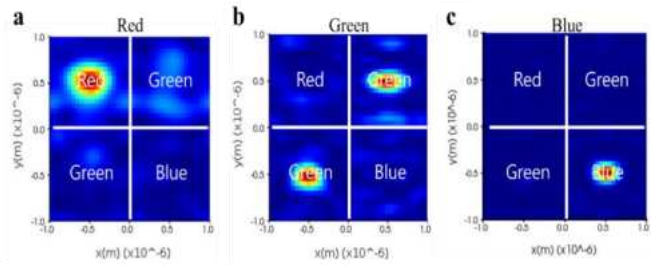

Figure 2 Electric field distribution a-c: The simulated electric field distributions of the transmitted light on the surface of the pixel at 650 nm (Red), 550 nm (Green), and 450 nm (Blue), respectively.

To quantitatively evaluate our metasurface color router, we introduce the concept of optical efficiency (OE) as

$$OE_i = \frac{P_{i-channel}}{P_{inc}}, \quad (2)$$

where i corresponds the color (RGB), $P_{i\text{-channel}}$ denotes the power on the surface of each sub-pixels, and P_{inc} represents the power of the incident light.

Figure 3 illustrates the OE of our optimized metasurface color router across the visible region (400-700 nm). Each color curve corresponds to a specific sub-pixel. Notably, the peak OE values occur at wavelengths of 680 nm (Red), 550 nm (Green), and 540 nm (Blue), with percentages of 57%, 74%, and 54%, respectively. These results significantly outperform the OE of common color filters. Furthermore, the total OE over the visible spectrum reaches an impressive 92%. Our metasurface design demonstrates the potential for enhancing CIS performance while maintaining manufacturability.

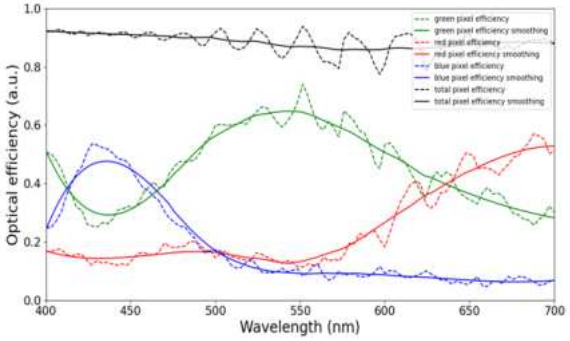

Figure 3 Optical efficiency graph. The optical efficiency of each pixel in the visible region. Each dot line represents the simulated OE results of each pixel. Each solid line is smoothing results of calculated OE.

3. Discussion

We can see the three different colors (RGB), which are primary color, are routed in Bayer pixel (RGGB) by our optimized metasurface color router shown in Fig. 2. Even though there is optical cross talk in the case of red and green, it would be resolved by setting the other FoM to minimize the optical cross talk. In this paper, we used two materials for metasurface color router. It might be a challenge for fabrication. This challenge could be resolved by using only one material such as Si_3N_4. In this case, the only one kind of nanopillars, surrounded with air, compose the metasurface color router.

4. Conclusions

In this work, we designed and optimized the metasurface color router with a high optical efficiency and a commercial pixel size via adjoint-based PID. The total OE is calculated to be 92% over the visible region and it is 57%, 75%, and 54% for red, green, and blue. In comparison with commercial CIS, the OE of our metasurface color router is much higher. We believe that this one will be a new generation of CIS structure and plan next to optimize the color router in different incident angles of light, different polarization of light, and reduce the optical cross talk.

Abstract: We report a highly efficient stimulated Raman conversion of a nanosecond pulsed Ytterbium-doped laser from 1065 nm to the first Stokes at 1161 nm using a hollow-core photonic crystal fiber pressurized with SF_6. Non-trivially, optimization of the input pump angle of linear polarization facilitates a 100% conversion efficiency increase over previous reports.

In previous work [1], An experimental investigation of stimulated Raman scattering (SRS) conversion with hollow-core photonic bandgap fiber (HC-PCF), filled with Tetrafluoromethane CF4 and Sulphur Hexafluoride SF6 gases, was reported. The conversion process of ns-duration pulses as a function of gas, fiber length, input power, and gas pressure was characterized. For SF_6 pumped at wavelengths of 1030 nm and 1065 nm, the first Stokes was observed at 1119 nm and 1161 nm, respectively. Fiber lengths of 5 m, 6 m, and 15 m generated maximum conversion efficiencies of 11.9%, 34.3%, and 55.7%, respectively, with the 1030 nm pump. The highest conversion efficiency for the 1065 nm pump reached 52.2% with a 15 m fiber, though it required double the peak power of the 1030 nm pump. In this study, we optimize the SRS conversion conditions such that the efficiency reaches up to 70% in a 6 m fiber with a 1065 nm pump. This demonstrates twice as much enhancement over the previous report. The increase is mainly due to a non-trivial correlation between the vibrational Raman conversion efficiency and the input pump beam's angle of linear polarization (AoLP). Also, the pump pulse dynamics (i.e., the rise and fall time relative to the pulse duration) were better adjusted for higher conversion efficiency.

The experimental setup is portrayed in Fig. 1a. The pump source is a high peak power Q-switched Ytterbium-doped PCF laser with a pulse duration of ~25 ns, a wavelength of 1065 nm, and a bandwidth of 0.2 nm. The pump beam is attenuated and linearly polarized via two perpendicularly oriented linear polarizers and a half-wave plate placed in between. These are followed by an additional rotatable half-wave plate to control the AoLP of the beam. The beam is focused using a short focal length aspherical lens into the bare end of the HC-PBG fiber, which is open to the air. The opposite end of the HC-PBG fiber is mounted inside a gas cell, pointing at an antireflection-coated window of the cell. The cell is first vacuum-pumped, except for a minor leakage of the open-aired fiber tip, and then pressurized to 12 bar of SF_6. The fiber is gradually filled with the gas to the state of a steady differential pressure distribution throughout the fiber (with a very slow flow of gas out of the fiber). The output beam, comprising both the pump and the converted Stokes signal, is collimated after the cell window and reflected off two dichroic mirrors to separate the first Stokes signal from the pump. The pump and Stokes beams are measured at the transmission of the first and the reflection of the second dichroic mirrors, respectively. The HC fiber is a commercially available NKT Photonics HC-1060-02 designed for single-mode operation in the transmission range. Fig. 1b displays a scanning electron micrograph of the transverse microstructure of the fiber and its measured attenuation at the relevant spectrum.

In Fig. 2a, we visualize the average powers of the pump and Stokes signal measured at the exit of a 6 m long SF6-filled fiber versus the AoLP of the input pump beam. The Stokes signal power shows significant variations of ~±68.5%, whereas the pump exhibits ~±17.5%. It is noted that we experimentally verified that the input AoLP

does not affect the transmitted pump power for peak powers below the SRS threshold. Consequently, the pump's variations in Fig. 2a are mostly due to corresponding stimulated Raman losses. The conversion efficiency, measured ratio of first Stokes to total coupled power, is plotted in Fig. 2b. The efficiency strongly depends on the AoLP with up to ~±70.6% peak variation, minima are clearly π/2 periodic, and the maxima seem similar though less sharp. Vibrational SRS in a perfectly circular symmetric fiber with a seedless configuration is independent of the AoLP of the pump beam. Thus, we hypothesized that the significant variations of the conversion efficiency stem from the polarization sensitivity of the fiber and that the fiber's imperfection is more significant at the Stokes wavelength as it is out of the fiber's bandgap and has a larger mode field diameter and deeper penetration into the microstructured cladding than the pump. Due to the nonlinear nature of SRS and the long interaction length inside the fiber, slight asymmetries that result in discrepancies in the losses and field distributions can yield significant SRS polarization sensitivity. Consequently, with the optimized AoLP of the input pump beam, we reached ~ 70% conversion efficiency in a 6 m SF_6-filled HC-PBG fiber. This is more than double the efficiency reported in [1] with the same fiber length. To the best of our knowledge, it also displays a record conversion efficiency to a single Stokes order in SF_6-filled HC fibers.

Abstract: We present new designs for open optical cavities based on reflecting metasurfaces. Our metasurfaces are a new hybrid of traditional unit cells and supercells. We consider several types of cavities to enhance the Purcell factor of an emitter, including one type that requires only one metasurface to establish a mode.

Metasurfaces are composite structures with two-dimensional arrangements of subwavelength scatterers. By carefully designing the shape, size and position of the scatterers, we can control the propagation of light, its phase, polarization and intensity [1,2,3]. Recently, metasurfaces have been considered to design optical cavities [4-7]. In particular, a wavelength tunable external cavity laser has been demonstrated using a metasurface which can focus light from a laser diode back on itself as feedback [5].

This new approach allows us to design different optical devices with new functionalities based on reflective metasurfaces (using either a metallic or dielectric reflective substrate).

In our contribution, we focus on the potential of metasurfaces for cavity quantum electrodynamics, and we estimate the Purcell factor enhancement for a single photon emitter.

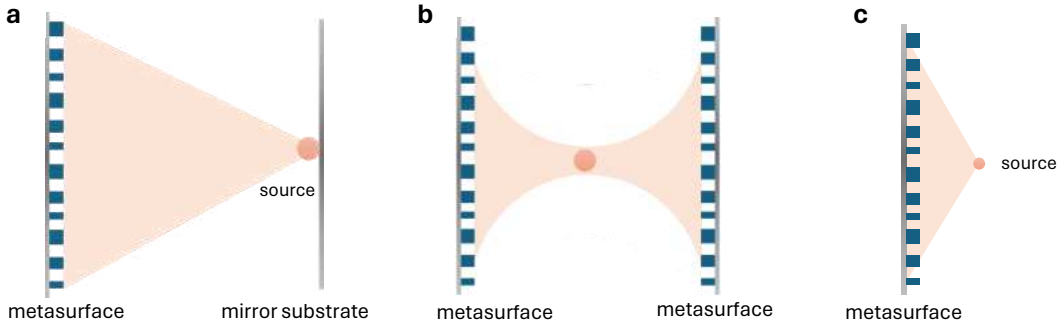

Figure-1: Types of metasurface cavities: (a) metasurface and mirror, (b) two-metasurfaces cavity, (c) evanescent metasurface.

The mathematical framework of implementing an open optical cavity based on one or more reflective metasurfaces and computation of resonant modes was reported in a vision paper [4]. The metasurface cavities considered here are of 3 types (illustrated in Fig. 1): (i) metsurface and mirror, (ii) two reflective metasurfaces, and (iii) a single metasurface which sustains an evanescent field at a significant distance; in all cases, the emitter (source) is coupled inside the field of metasurface. For the first two cases, the metasurfaces are designed to achieve a desired phase profile to retroreflect and focus light emitted by the source back on it. This can be achieved by doubling the wavevector deflection and the phase profile of a traditional metalens:

$$\Phi = 2\varphi(\mathrm{r}) = 2k_0\left(\sqrt{r^2+f^2}-f\right)+\Phi_0$$

The effects that can be achieved are an increase in the Purcell factor, control of polarization and, to some extent, wavelength of emitted light using the chromatic dispersion of the metasurface. We implemented the metasurfaces with hybrid unit cells and supercells design. As an example, in Fig. 2 we show the design of a unit cell (Fig 2a) and a supercell (Fig 2b). Figure 2c also shows the spatial dependence of the Purcell factor of a metasurface designed to target a specific position (circle in the Figure). The Purcell factor is maximized at the design position.

We are using TiO_2 pillars with square cross-sections on a metallic substrate. The simulations have been performed using HFSS and a code developed in our lab.

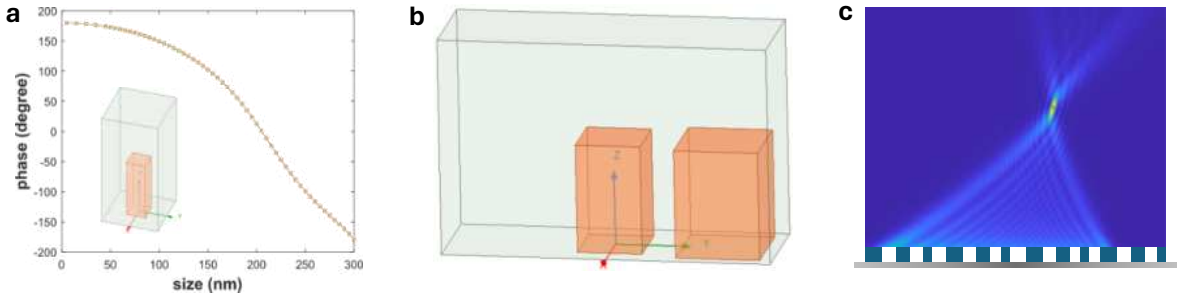

Figure-2: (a) Metasurface phase library: (b) example of designed supercell, (c) plot of the Purcell enhancement for the final design as a function of the position of the emitter.

This idea can also be used to couple different sources and can be applied to photoluminescent materials, quantum dots, nanocrystals, and more.

Abstract: We present a novel reconfigurable device, Nested Ring Coupled Dual Ring Resonators (NCDRR) for high-speed communication. This device enables the generation of a tunable notch spectrum (through port) and comb spectrum (drop port) through the adjustment of coupling coefficients. Additionally, we have investigated various lineshapes inherent in the nested ring resonator (NRR), rendering it versatile for numerous applications in high-speed communication.

Nested Ring Resonator (NRR) structures, renowned for their double Fano resonance, are favoured in filtering and sensing applications. Like Microring resonators (MRR), NRR output is heavily influenced by resonance linewidth and sharpness. NRR's coupled resonance enables diverse lineshapes, facilitating the production of various filtering responses like Notch, Comb, and Bandpass with an additional cavity. Given the significance of filtering applications, amalgamating these two functionalities into a single reconfigurable Photonic Integrated circuit (PIC) offers substantial advantages. Moreover, We have analyzed different material platforms for tuning the device. The tunability and reconfigurability of the device make it a suitable candidate for general-purpose photonic processors.

This study comprehensively analyses a novel programmable optical device configuration based on nested ring architecture coupled with two racetrack ring resonators. The device can effectively generate notch and comb responses tailored to desired frequencies by optimizing device parameters such as resonator lengths and coupling coefficient.

This research is funded by the Prime Minister's Research Fellowship (PMRF) by the Government of India.

Abstract: This study explores generation of Orbital Angular Momenta (OAMs) in sub-wavelength nanowires. We reveal that a hexagonal GaN hollow nanowire exhibits distinctive OAM when Au nanopillars are closely placed, which is due to non-Hermitian perturbation breaking the mirror symmetry. We show a variety of structures optimizing the OAM.

Optical vortices with spiral wavefronts are known to have orbital angular momentum (OAM) and phase singularities near the optical axis. The optical vortices are expected to be used in various fields, such as rotation control of nano-materials and high-capacity information communication. Conventional optical vortex generation methods have involved large device sizes, such as computer holograms and spiral phase plates. Recently, compact optical vortex generation devices are proposed for application to on-chip devices and communication devices, including micro-sized devices using metasurfaces [1] and ring resonators [2]. However, these devices have problems such as few active systems [3] and complex structures. In addition, sub-micron size devices have not yet been realized. We have reported on polarization vortex generation by a hexagonal GaN hollow nanowire laser[4][5] (Fig. 1), but it does not produce OAM. Here, we propose a novel way to generate OAM optical vortex generation device based on hexagonal hollow nanowires.

In this study, we propose a novel structure where Au nanopillars are placed in the vicinity of a hexagonal GaN hollow nanowire, and investigate its eigenmodes of light propagating in the z direction using the finite element method(FEM). We found that when the Au nanopillar is placed in a position that breaks the mirror symmetry of the hexagon, a sufficiently large OAM appears in the eigenmode. The phase rotation direction does not depend on the light propagation direction. First, we optimize the position and size of the Au nanopillar to maximize OAM for infinitely-long nanowires with frequency of 750[THz]. Figure 2(a) shows the electric field profile of the optimized mode having OAM of 3.66. Note that the position of the Au pillar is slightly displaced from the symmetric position. We confirmed that OAM does not appear when we place dielectric nanopillars in a similar manner, which shows that the OAM is generated by non-Hermitian perturbation breaking the mirror symmetry.

Figures 2(b) and 2(d) also show the OAM spectra, which represent the Fourier components of each azimuthal quantum number. Notice that the positive part and negative part of spectrum become asymmetric. This asymmetry generates overall non-zero OAM.

Next, we examine another situation. Here, the Au nanopillar shape is changed to a rectangle and the position and size of the Au nanopillar were optimized under the condition that the pillar always contacts the outer edge of

the hexagonal GaN hollow nanowire. The obtained solution is shown in Fig. 2(c) and has OAM of 4.23.

Note the diameter of hexagonal nanowires is just 0.6λ. Although it has been demonstrated that non-Hermitian perturbation can produce chiral optical properties, our result indicates an interesting possibility of guided modes themselves in the nanowires with sub-wavelength diameters will have orbital angular momentum, the size of this structure can be smaller than conventional OAM devices and different applications can be expected. We will discuss a variety of structures producing OAM by the same method, and discuss the physical mechanism of OAM generation.

Photonic bandgap structures

3D Soft Photonic Crystal Photoswitch between Cubic Lattices

E. Oton[1*], M. Cigl[2], P. Morawiak[1], S. Mironov[2], A. Bubnov[2], W. Piecek[1]

[1]Faculty of New Technologies and Chemistry, Military University of Technology, Warsaw, Poland

Abstract: An all-optical switchable 3D soft photonic crystal was demonstrated. Two photomodulated systems were prepared: a photoswitch changing from cubic lattice BCC to SC, and shutter from BCC to isotropic medium. Both can switch between states by swapping the illumination source and without loss of monocrystallinity of the photonic crystals.

ABSTRACT

Introducing novel functionalities in 3D photonic crystals has become the focus of study for enhanced ground-breaking photonic applications. Blue Phase (BPs) liquid crystals (LC) are currently being intensively investigated for their unusual optical properties and structure. Unlike other liquid crystals, they self-assemble into highly organized 3D structures [1,2] with lattice periods in the hundreds of nm, which is achieved by the self-assembly of the LC molecules into periodic cubic structures, producing bright selective Bragg reflections – they are 3D photonic crystals.

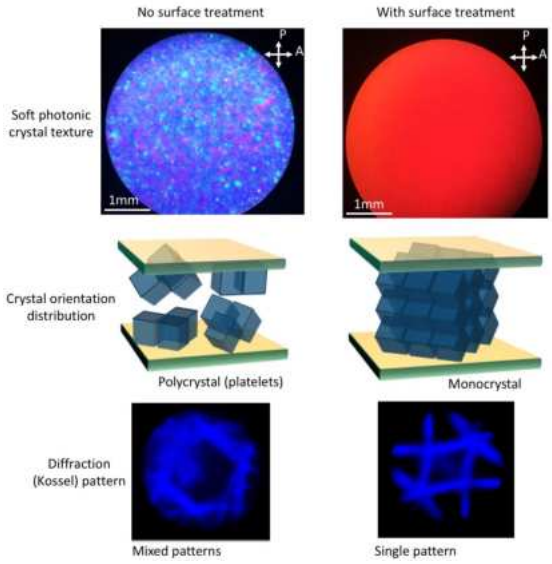

Fig.1 – 3D soft photonic crystal – poly and monocrystalline BPs.

New functionalities can be induced into the BP structures improving their properties [3]. For instance, new properties or improved responses can be designed by adding different kinds of dopants to the crystals structure. A promising research direction involves inducing photoswitching properties in BP crystals solely by light stimuli [4].

However, direct applications for BPs are often limited because crystals notoriously grow as disorganized polycrystals. Polycrystalline (platelet) structure shows a multitude of tiny disorganized 3D photonic crystals that tend to produce scattering thus they show poor optical and electrooptical properties [5]. The efficient control of BP crystal orientation is a problem that must be solved for this advanced material to be used in photonic devices. However, producing large 3D BP monocrystals is a complex problem that becomes even more complicated when involving the control of the lattice orientation.

In our previous work [6], we successfully produced 3D BP photonic crystals (of mm-sized) by designing smart surface anchoring properties and using specific precursor chemical formulations (Fig.1). We proved that large BPs monocrystals can be obtained and specific lattice orientations can be arbitrarily chosen.

This work demonstrates an all-optical switchable 3D photonic crystal obtained by doping monocrystalline BPs with newly synthesized photosensitive derivatives and the same crystal growth tools to produce large monocrystals.

Two systems were produced: a photoswitch between BCC and SC (switch BPI (110) and BPII (100)), and a light shutter, switching between BCC and isotropic state. Both systems can switch stable states back and forth by changing the illumination source only and maintaining the monocrystallinity. Such an all-optical switch provides and accurate control over illumination and material properties. Tailored photoactive dopants work like a molecular switch in the crystal matrix: the cooperative effect of the BP host molecules produces visible macroscopic changes in the crystal structure (Fig.2).

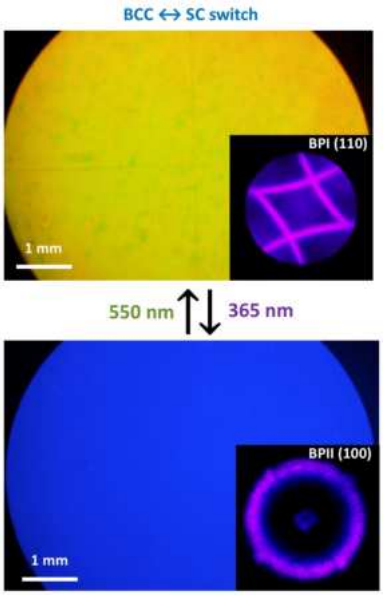

Fig.2 – Photoswitching between BCC and SC.

By illuminating the BP crystals back and forth, the all-optical the BPI ↔ BPII and BPI ↔ ISO switches can be continuously written and erased. The demonstrated effect of reconfigurable BP photonic crystals can be repeatedly recorded and employed in diverse photonics applications like adaptive holographic systems.

These all-optical driven devices demonstrate a rapid and smooth optical transition between two cubic crystal lattices and a cubic crystal lattice and isotropic medium. Newly developed 3D photonic crystal switches promise significant progress in photonic technologies of adaptive optics systems and integrated photonic circuits. Technologies mainly based on all-optical-driven photonic materials show considerable potential for advanced reconfigurable photonic devices such as dynamic optical filters and sensors and optically driven logical elements.

This study offers a valuable insight into driving the use of BPs in practical photonic devices. A deeper understanding of these unique materials will drive the progress of their functionalities for application in innovative photonic technologies.

Abstract: We report a newly observed lasing from a 3D soft-matter-based photonic crystal with topologically protected distribution of emission. Directional lasing with light of circular polarization is emitted from a custom-made microcavity. It was observed and recorded in real and reciprocal space.

ABSTRACT

Structures of liquid crystals with chiral molecules, producing photonic band structures are promising photonic materials for manipulating of light. Liquid crystal (LC) phases incorporating chiral molecules display 1D, 2D and 3D periodic structures leading to the emergence of a photonic bandgaps, eventually with well defined spatial orienatation and distribution. Blue Phase (BPs) liquid crystals are now in the current focus of exciting research due to their ability to self-assemble into 3D photonic crystals. They show a cubic 3D periodic order, unlike other kinds of LCs, with bright selective Bragg reflection and lattice periods in the order of hundreds of nm [1].

Employing BPs in genuine photonic applications is hindered by the typical tendency of photonic crystals to grow as polycrystalline structures which notoriously exhibit high scattering, so their optical properties are usually worse than those of solid-matter ones [2]. Effectively controlling of mesogenic monocrystal growth is still a problem that needs to be solved. Especially, the control of the monodomain lattice orientation is still not well understood.

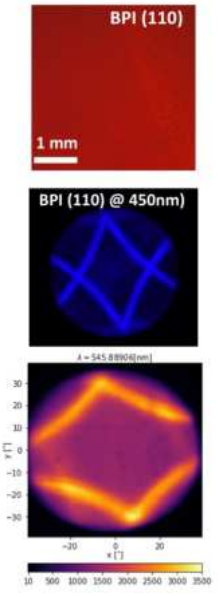

Fig.1 – 3D soft photonic crystal microlaser: texture, diffraction (Kossel) pattern, lasing in reciprocal space.

Through the implementation of specific surface anchoring properties and targeted precursor for chemical formulation of the working mesogen, we successfully grew uniform, millimeters-sized 3D BP photonic crystals. Large monocrystalline BPs (see Kossel patterns) with selected specific crystal lattice orientations were prepared [3]. Custom made large BP photonic crystals were doped with laser dyes and assembled into custom made microcavities. Here we report the successful generation of topologically protected, spatially distributed lasing from such 3D BP photonic crystals. High-intensity, directional topological emission was obtained in the reciprocal space (Fig.1). We show the distinct emission originating from resonant polarization modes that was analyzed, showing strong circular polarizations.

This work shows a significant progress at use of BPs into actual practical photonic applications. Improving the control of these unique materials will surely develop new functionalities to be used in cutting-edge photonic technologies. Notably, the generation of laser light on-demand is an emerging crucial topic in the field of photonic materials.

Dirac bound states in the continuum in honeycomb photonic crystal slabs

Yi-Chi Kao, Sheng-Wei Kao, and Ruey-Lin Chern*

Institute of Applied Mechanics, National Taiwan University, Taiwan
*corresponding author: chernrl@ntu.edu.tw

Abstract: We propose a design of photonic crystal slabs for investigating the bound states in the continuum (BICs), which are identified as the Dirac BICs. By changing the geometric parameters of the unit cell without breaking the C_{6v} symmetry, a pair of Friedrich-Wintgen BICs appear near the Dirac point.

Bound states in the continuum (BICs) are non-leaky localized resonance modes that coexist with a continuous spectrum of radiating waves [1–4]. Since BICs will not radiate to the far field, they are decoupled from the far-field radiation. Ideal BICs may have infinite quality factors and zero spectral linewidths. In the presence of the absorption loss, roughness, or finite size of the structure, an ideal BIC is turned into a quasi-BIC with a finite (yet very large) quality factor and nonzero (yet very small) linewidth.

There are in general two categories of BICs. The first one is symmetry-protected (SP) BICs due to symmetry mismatch between resonance modes and incident waves, which usually appear at the center of Brillouin zone for a periodic lattice with perfect symmetry in structure geometry [5,6]. The second one is accidental BICs originating from wave interference between two or more radiation channels, which usually appear at certain wave vector points on isolated dispersion bands (at or off the Brillouin zone center) when the relevant coupling to the radiation continuum completely vanishes [7], which can further be divided into two types: Fabry-Perot (FP) BICs [8,9] and Friedrich-Wintgen (FW) BICs [10]. The former are constructed by two interacting objects with one resonance, while the latter by two interacting resonances in one object1.

Recently, a new type of BICs in the photonic crystal slabs occur at the Dirac point, where two or four dispersion bands meet at a single point. The so-called Dirac BICs can be realized by the generation or annihilation of one or two pairs of *C* points with a Dirac point, resulting in one or two accidental BICs at the *K* point [11]. A Dirac BIC can also obtained by tuning the geometric parameters such that a Dirac point becomes a quasi-BIC, along with a pair of *C* points [12].

In this study, we propose a design of photonic crystal slab consisting of triangular holes arranged as a hexagonal cluster in the unit cell of a honeycomb lattice. When the system holds the C_{6v} symmetry, a SP BIC with an extremely large quality factor occurs at the double Dirac point, where four dispersion bands meet at a single point. By changing the geometric parameters of the unit cell without breaking the C_{6v} symmetry, a band gap is opened near the Dirac point and a pair of FW BIC appear at the anti-crossing points between two upper and two lower dispersion bands.

Enhancing photodetection and photoluminescence in low dimensional materials with photonic crystals

M. A. Yaqub[1,2,*], H. Gupta[1,2], T. Contino[1,2], M. W. Ashraf[1], M. Tamagnone[1]

[1]*Nano-Photonic Devices, Istituto Italiano di Tecnologia, via Morego 30, 16163 Genova, Italy*

Abstract: We integrate photonic crystals into 2D and vdW materials (in particular GaTe and InSe) aiming to enhance their optical properties such as photoconductivity and photoluminescence. These materials were selected owing to their direct bandgaps. We optimized the design of photonic crystal to maximize the absorption and photoluminescence characteristics.

Keywords: Two-dimensional materials; Photodetectors; Photoluminescence; Photonic crystals

Photodetectors (PDs) are key optoelectronic devices that transform light signals into electrical signals and have received a lot of interest in recent years. The aim is to produce PDs with excellent capabilities including substantial gain, strong detectivity, and significant responsivity with quick response-time and minimal power usage. Due to their remarkable electrical and optoelectronic properties, III-VI group stacked semiconductors, GaSe, GaTe, and InSe, for instance, have just recently gained recognition among 2D materials. In contrast to indirect bandgap multilayer TMDCs like WSe_2 and MoS_2, multilayer InSe and GaTe have direct bandgap values i.e., 1.27 and 1.67 eV, respectively and owing to direct bandwidth they are proved to be promising optoelectronic materials [1, 2].

In this contribution we aim to maximize the efficiency of PDs based on GaTe and InSe using photonic crystal structures. We can achieve that by optimizing the photonic crystal to resonate at the target wavelength. The same approach can be used at the photoluminescence wavelength to maximize it. Ansys HFSS was used to design the structure of GaTe/InSe based photodetectors and for the numerical simulations. We tried different structure (hexagonal and square) photonic crystals, and the results were almost the same for both. The maximum absorption peaks were found at ~500 THz (600 nm) depicting the application of the photodetectors in the visible spectrum, as shown in Figure 1(a) [square photonic crystal not shown]. Some changes were made in design to optimize our structure for the PL characteristics and numerical simulations were carried out for GaTe as shown in Figure 1(b). For GaTe, the dip was observed at ~403 THz (1.67 eV) and for InSe dip was observed at 308 THz (1.27 eV), in consistent with the existing literature [3, 4] (InSe not shown).

We fabricated the devices with electron beam lithography followed by TiO_2 deposition. We developed a new exfoliation method based on UV tape to maximize the yield and to avoid the residues of glue which are commonly found when performing scotch tape exfoliation. The optical pictures of GaTe and InSe flakes

are shown in Figure 2(a) and 2(b), respectively. Figure 2(c) depicts the optimized design to be used in our work to fabricate the photodetector.

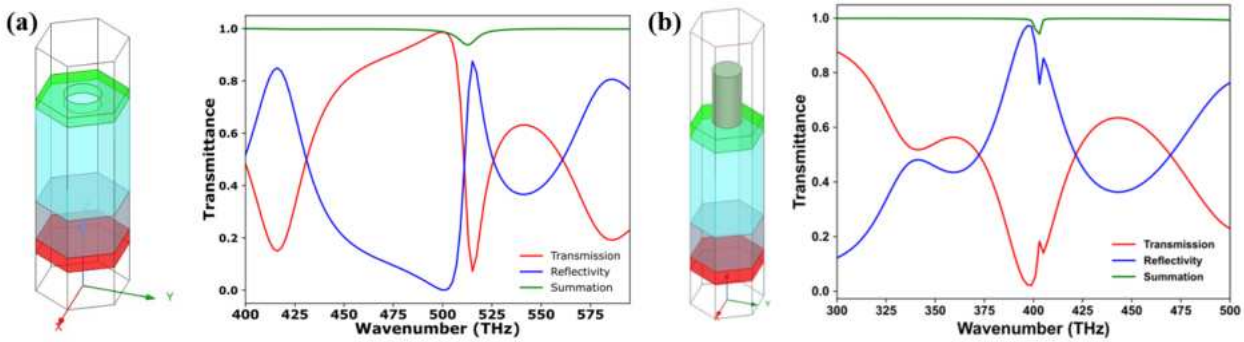

Figure 1 Design and simulation for **(a)** Hexagonal photonic crystal for photodetector for InSe, and **(b)** simulations for PL analysis for GaTe

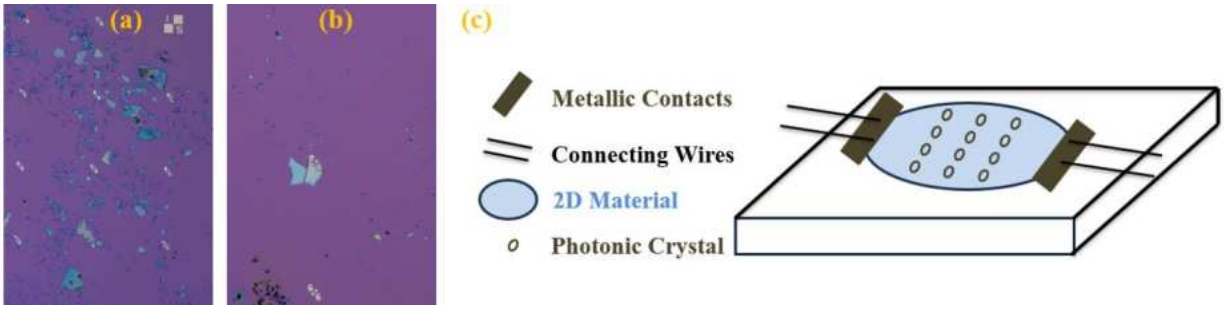

Figure 2 Microscope images of the flakes of **(a)** GaTe, **(b)** InSe, and **(c)** design for our photodetector

We will present more details as well as numerical and experimental results (measurements are currently in progress). In the future we will also explore substrate effects to induce changes in the band structure of the material and to further enhance the performance [5].

High-bandwidth slow-light silicon modulators

[1]Xingjun Wang, and Changhao Han, China
[*]corresponding author: xjwang@pku.edu.cn

Abstract: We realize a modulator with an EO bandwidth of 110 GHz in a length of about 100μm, and enables transmission beyond 224 Gbps PAM-4 per lane.

Silicon modulators are key components in silicon photonics to support the dense integration of electro-optic (EO) functional elements on a compact chip for various applications including high-speed data transmission, signal processing, and photonic computing. Despite numerous advances in promoting the operation speed of silicon modulators, a bandwidth ceiling of 67 GHz emerges in practices and becomes an obstacle to paving silicon photonics toward Tbps level data throughput on a single chip. Here, we theoretically propose and experimentally demonstrate a design strategy for silicon modulators by employing the slow light effect, which shatters the present bandwidth ceiling of silicon modulators and pushes its limit beyond 110 GHz in a small footprint. The proposed silicon modulator is built on a coupled-resonator optical waveguide (CROW) architecture, in which a set of Bragg gratings are appropriately cascaded to give rise to a slow light effect. By comprehensively balancing a series of merits including the group index, photon lifetime, electrical bandwidth, and losses, we found the modulators can benefit from the slow light for better modulation efficiency and compact size while remaining their bandwidth sufficiently high to support ultra-high-speed data transmission. Consequently, we realize a modulator with an EO bandwidth of 110 GHz in a length of about 100μm, and demonstrate a data rate beyond 110 Gbps by applying simple on-off keying modulation for a DSP-free operation. Our work proves that silicon modulators beyond 110 GHz are feasible, thus shedding light on the potentials of silicon photonics in ultra-high-bandwidth applications such as data communication, optical interconnection, and photonic machine learning.

We also have demonstrated the first slow-light-based wavelength-division-multiplexed signal transmitter beyond 1.6 Tbps on SOI platform. By adopting slow-light approach, the bandwidth-efficiency trade-off for pure silicon modulators is reduced greatly, paving the way for beyond 224 Gbps transmission per lane with DNN. Our slow-light modulators with compact footprint and large passband lead to an on-chip data-rate density of greater than 0.8 Tb/s/mm2 is achieved, without any individual resonant wavelength adjusting and temperature control system. This proposed pure-silicon transmitter solution illustrates the great potential of silicon photonics for next-generation optical interconnection in 1.6TE.

Topological valley plasmons in twisted monolayer-double graphene moiré superlattices

Weiwei Luo[1*], Jiang Fan[1], Alexey B. Kuzmenko[2], Wei Cai[1] and Jingjun Xu[1*]

[1]School of Physics, Nankai University, China

Abstract: We combine the two active fields of topological photonics and moiré superlattices, by demonstrating theoretically that moiré superlattices of small-angle twisted monolayer-bilayer graphene provide a natural platform for valley protected plasmons. Particularly, complete plasmonic bandgap appears and unidirectional transport of plasmonic edge states protected from inter-valley scattering is presented.

Graphene plasmons, hybrids of Dirac quasiparticles and photons, exhibit low-loss, strong electromagnetic confinement and electrical tunability. Graphene plasmons provide excellent opportunities for exploring light-matter interactions at the nanoscale, which is promising for applications in integrated photonics and biosensing[1]. By introducing the concept of topology, unidirectional propagation of graphene plasmons protected against disorder and backscattering can be realized[2]. However, the requirements of complex artificial geometries and configurations obstruct the experimental realizations of topological graphene plasmons. On the other hand, by stacking and twisting different layers of Van der Waals materials, two-dimensional (2D) moiré superlattices are emerging as an important avenue for engineering quantum materials with novel properties[3].

In this work, plasmon properties of small-angle twisted monolayer-bilayer graphene (tMBG) is investigated, whose moiré superlattices consist of triangular domains with the Bernal (ABA) and the rhombohedral (ABC) stacking. The ABA and ABC graphene have different electronic bandstructures where the ABA graphene is a semi-metal with a tunable band overlap, while the ABC one is a semiconductor with a gate-tunable band gap and a flat band [4]. Here we demonstrate theoretically that tMBG moiré superlattice provides a natural platform for GPC, where complete plasmonic bandgap occurs. Furthermore, the effects of nontrivial chiral valley topology of the GPC are emphasized. Finally, robust transport of graphene plasmon waves with suppressed inter-valley scattering is shown at the interfaces separating two GPCs with opposite valley Chern numbers. Our study motivates further explorations of novel photonic phenomena in the rich platform of reconstructed moiré superlattices.

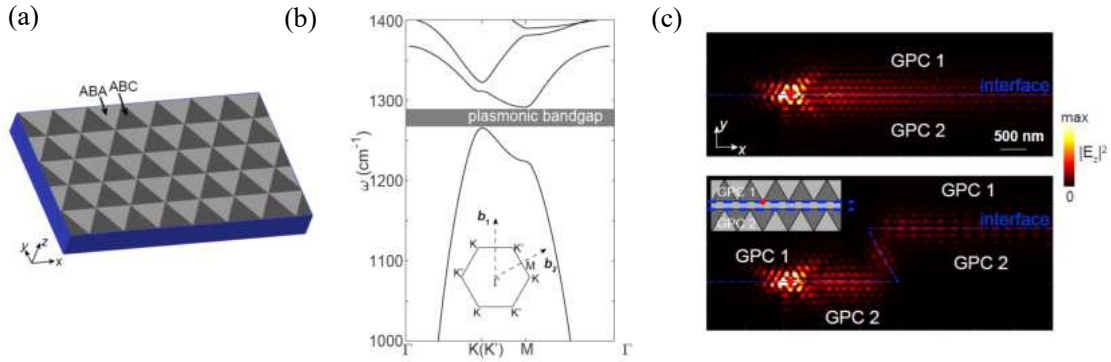

Fig.1 Topological valley plasmons in twisted monolayer-double graphene moiré superlattices. (a) Moiré superlattices of TMBG is consisted of triangular domains of the ABA and ABC stacking graphene. (b) Plasmonic bandgap occurs in the moiré superlattices of TMBG. (c) Backscattering-free propagation of graphene plasmons for the valley topologically protected edge states.

Abstract: This work describes the elaboration of photoelectrodes based on an inverse opal structure made of semiconductor oxides and hexamolybdenum clusters as light harvesters. Nanostructure fabrication is possible thanks to electrophoretic deposition method, a low-cost and scalable process.

Metal cluster (MC) family gathers a wide range of compounds among them $A_2[Mo_6L^i_8L^a_6]$ are based on a central Mo_6 octahedra, supported by eight inner ligands face-capping the octahedra (L^i = halogen, chalcogen) by six apical ligands at the terminal position (L^a = halogen, hydroxyl, water…) and stabilized by two counter cations (A = alkali, ammonium). They present interesting physicochemical properties such as light absorption which make those compounds attractive for catalysis, optoelectronic, or photovoltaic applications.[1] The association of molybdenum clusters and a photonic crystal (PC) structure have been already thought to increase the emission intensity at the passband's energy,[2] or more recently, to enhance the photo-induced current by a slow photon effect.[3]

This work focuses on the design of photoelectrodes built up from periodic design of PCs with inverse opal (IO) structures. Starting from the silica beads synthesis, their arrangement, the infiltration of the pores by semiconducting metal oxide, the etching of the template and the insertion of MC in the freshly obtain cavities. SiO_2 synthesis has been optimized to modify the size of the beads, so that IO's pore size fits light confinement of MCs. Both SiO_2 opal structure and MC insertion are based on electrophoretic deposition (EPD) to reduce the structure fabrication time, to make possible the scaling and more generally, to promote a low-cost process.

Emerging applications

Plasmonic Copper Nanorings for Building Energy Management

X. Baami González[1*], J. D. Tran[2], and D. S. Sutherland[1]

[1] iNANO – Aarhus University, Denmark
[2] Technical University of Denmark, Denmark
[*]: xbaami@inano.au.dk

Abstract: Copper nanorings of a diverse range of sizes (200-800 nm) have been successfully fabricated showing plasmonic behavior. They represent an alternative for future applications such as energy-saving glasses coatings and films to block infrared radiation.

In modern technology and industry, there is a pressing need for energy-saving materials, one of the major examples is advanced materials for windows. Regarding the mentioned application, the major goal is to design new materials capable of blocking infrared (IR) radiation while being optically transparent to visible light [1]. These IR-blocking materials would allow to reduce the transfer of heat radioactivity inside buildings, decreasing the consumption of active cooling systems. This would lead to what we cold smart windows, there are two main types of it: Active smart glass, which necessitates external stimuli for mode switching, and passive smart glass, which alters modes through internal stimuli. In the literature, there can be found several examples of active solutions including low-emissivity materials [2], thermochromic materials [3], and gas-chromic approaches [4]. However, we believe that plasmonic metamaterials represent a feasible alternative and might lead to cost-effective solutions for passive smart windows.

Previously in our group, we have used Sparse Colloidal Lithography (SCL) and Hole Mask Colloidal Lithography (HMCL) to fabricate a diverse number of nanostructures, including gold (Au) nanorings [5-7]. The fabrication method that was described for Au nanorings and crescents in previous publications was not useful when trying to fabricate structures with new metallic materials. To solve this problem, we came up with a solution that combines features of both SCL and HMCL coupled with Physical Vapor Deposition to synthesize new nanorings. This, among others, allowed us to fabricate copper (Cu) structures presenting very similar properties to those made from Au (**Figure 1A**).

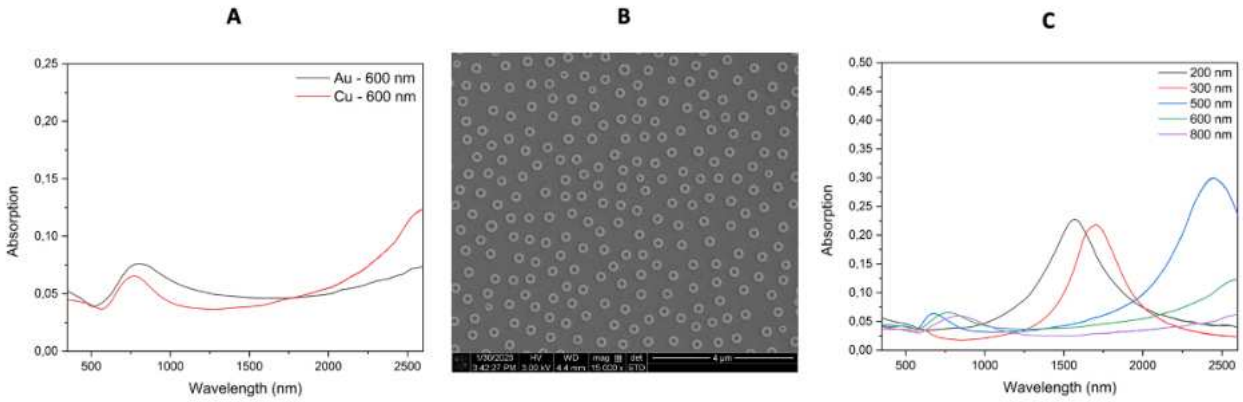

Figure 1: (a) Comparison Au and Cu, **(b)** 300 nm Cu nanorings, **(c)** Absorption results for different sizes Cu nanorings

As presented in **Figure 1B** the Cu nanorings showed a homogeneous structure and distribution. When comparing different ring sizes (**Figure 1C**) there is a clear trend for the displacement of the peak positions. For the low energy peak

as the size of the rings decreases the peak shifts to higher energy, this trend is replicated for the lower intensity high energy peak, but the observed shift is less significant.

Complementary studies have shown that Cu nanorings are stable to oxidation conditions. Consequently, the next efforts within the project are placed on ideally shifting one of the peaks to a region between 750-1150 nm by changing the size of the rings, coupling different sizes, or tunning some of the fabrication parameters.

The resonance peak positions were also shown to be customizable by tuning the size, shape, and material of the nanorings. These results suggest that other parameters such as the temperature or the medium refractive index could be other ways to tune the optical response. Moreover, the results shown by FDTD simulations (**Figure 2**) matched with the experimental ones and allowed us to understand the E-field components, for both, the high- and low-energy resonances. These results suggest that copper, silver, or other metallic materials might be interesting when it comes to applying these nanorings as a new solution for controlling heat dissipation in buildings.

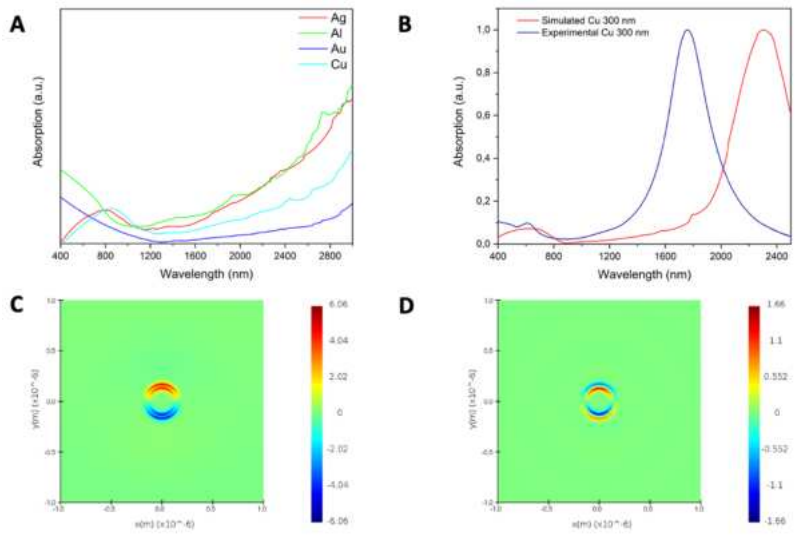

Figure 2: Optical absorption spectra showing; A Simulated 800 nm metallic nanorings, B) Experimental 300 nm Cu nanorings vs Simulated (normalized), C) Z-component of the E-field plot of low energy peak (1977 nm) for a simulated 300 nm Au nanorings, D) Z-component of the E-field plot of high energy peak (594 nm) for a simulated 300 nm Au nanorings.

Abstract: Silver nanowires attract great interest for optoelectronics applications, including highly efficient flexible transparent electrodes. However, knowledge of their reliability remains scarce and lacks systematization. Here, we present a comprehensive reliability study of silver nanowire transparent electrodes and compare them with state-of-the-art indium tin oxide electrodes.

Flexible transparent electrodes enable various emerging devices, such as flexible and bendable organic and quantum dot light emitting diode (OLED & QLED) displays, rollable solar cells, and related photovoltaic (PV) applications [1]. Silver nanowires (AgNW) offer exceptional flexibility, scalability, solution-processability, and additional unique properties, including plasmonic, antibacterial, and more [2]. However, the reliability of AgNW transparent electrodes (TEs) remains scarcely covered in the literature. We propose a comprehensive reliability study on AgNW, indium tin oxide (ITO), and graphene-covered AgNW (AgNW/G) flexible TEs. We conducted temperature-humidity (TH), low-temperature storage (LTS), high-temperature storage (HTS), highly-accelerated stress testing (HAST), and thermal shock testing on TEs studying their electrical and optical degradation over testing periods. Figure 1 shows the preliminary results of TS (left) and TH (right) testing on comparable flexible ITO, AgNW, and AgNW/G TEs on polyethylene terephthalate (PET) substrate.

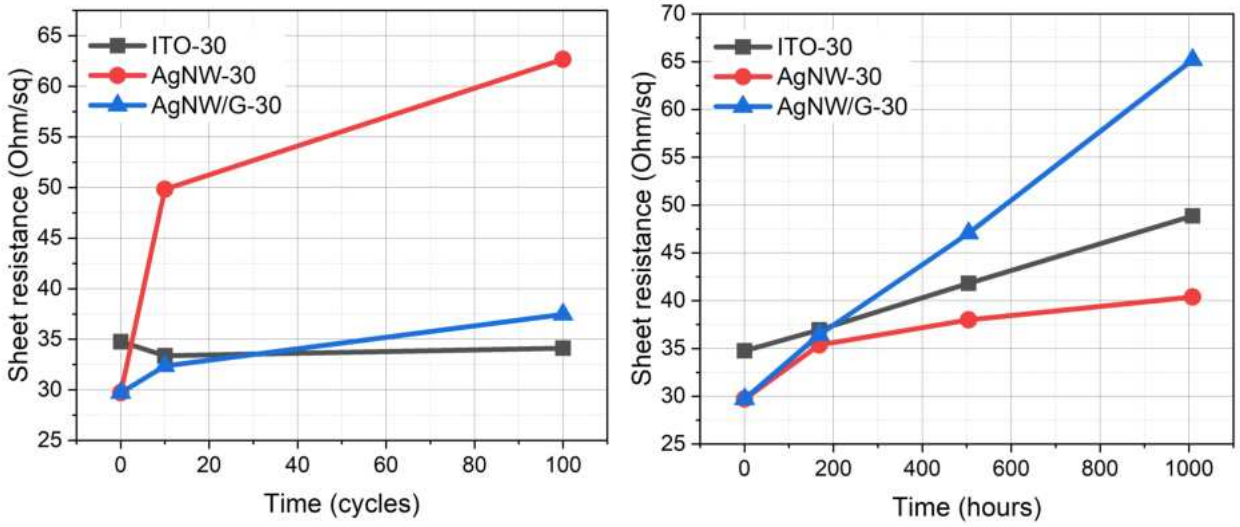

Figure 1 Results of accelerated lifetime testing (ALT) on ITO, AgNW and AgNW/G electrodes with tuned initial sheet resistance of 30 Ohm/s: (left) thermal shock, 0-100 cycles; (right) temperature-humidity testing at 85 °C / 85 R.H.

Initial results indicate advantage of AgNW/G over bare AgNW TEs under TS testing. At the same time, flexible ITO electrode demonstrated advantage at TH testing; while bare AgNW remained more conductive than AgNW/G under same testing.

The work presented in this article is supported by the Centre for Advances in Reliability and Safety (CAiRS) admitted under AIR@InnoHK Research Cluster.

Abstract: Investigating high-refractive-index materials for visible metasurfaces, we propose a direct printing method using polymer with titanium dioxide (TiO_2) nanoparticles. This enables precise control of refractive index (up to 1.9), optimized metasurface design, and high-performance fabrication on flexible substrates. This approach offers promise for efficient, multifunctional metasurface applications.

Visible metasurfaces, composed of periodic nanostructures, have garnered significant interest due to their precise manipulation of electromagnetic waves for applications such as holograms, lenses, and optical sensors [1]. Despite their potential, the practical fabrication of these metasurfaces has been hindered by the expensive and time-consuming nature of high-resolution electron-beam lithography (EBL), the conventional method used for their production. Recent efforts have focused on exploring high-refractive-index materials in the visible spectrum to achieve highly efficient metasurfaces. However, these materials typically exist as thin films, requiring additional processes such as etching and lift-off. In our study, we propose a direct printing process using a polymer infused with high-refractive-index nanoparticles for the efficient fabrication of high-performance metasurfaces [2-4].

By incorporating TiO_2 nanoparticles into the polymer matrix, we can finely tune the effective refractive index of the mixture, reaching up to 1.9 depending on the concentration of TiO_2 nanoparticles, as depicted in Fig. 1a. Subsequently, through rigorous analysis based on effective medium theory, we develop optimized designs for metasurfaces (Fig. 1b). Finally, employing the direct printing process with the polymer yields high-performance metasurfaces on flexible substrates, validated through a comparison of diffraction efficiencies (Fig. 1c). Furthermore, we anticipate that various functional materials, beyond TiO_2, can be integrated into this fabrication approach, paving the way for the practical realization of highly efficient and multifunctional metasurfaces [5,6].

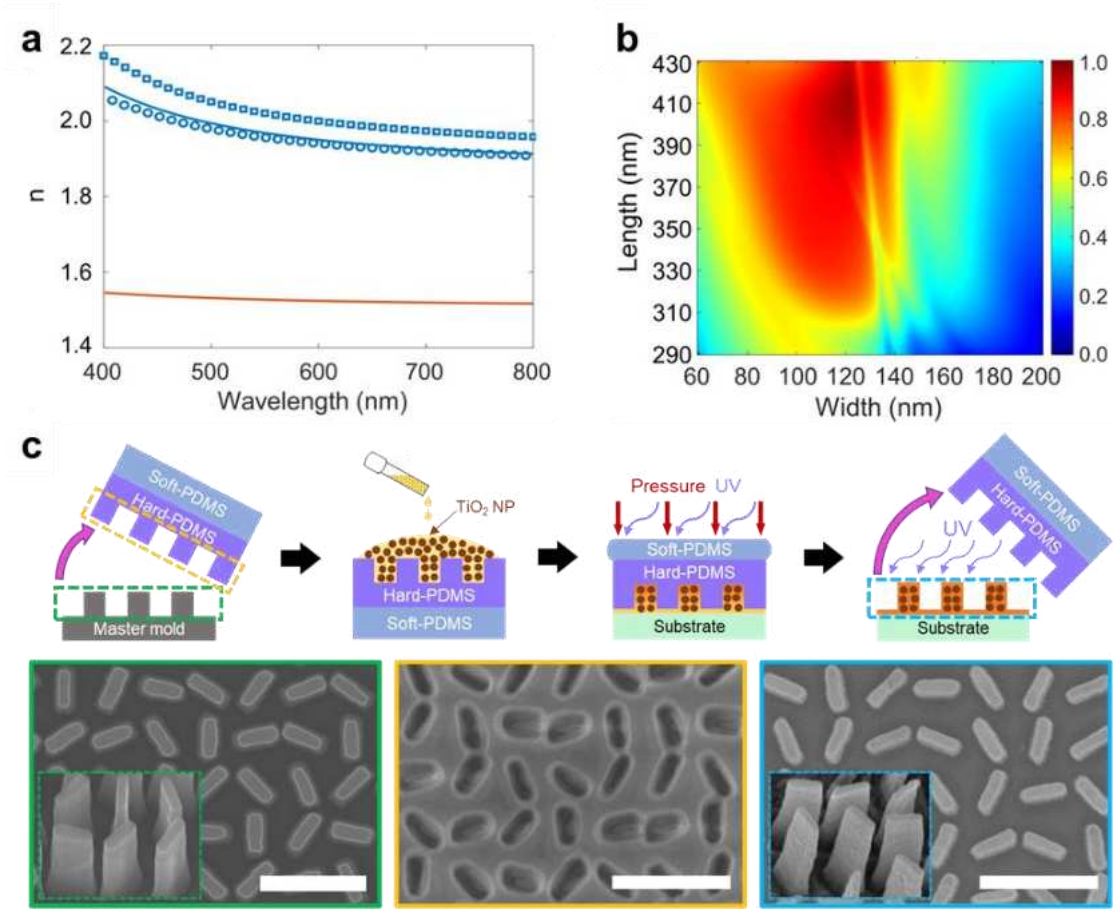

Figure 1. (a) Measured and modeled optical properties of the polymer with TiO_2 nanoparticles and comparison with conventional UV-curable polymer. (b) Rigorous analysis of metaatom dimensions depending on the effective polymer. The height of the metaatom is fixed at 910 nm. (c) the direct printing process of high-refractive-index polymer and SEM images of respective colored surfaces. All scale bars: 1 μm.

Scanning Reflectance Anisotropy Microscopy: mapping of strained amorphous semiconductors and chiral metasurfaces.

F. Haake[1*], H. Galinski[1], and R. Spoleank[1]

[1]Author: Department of Materials ETH Zurich, Switzerland
[*]corresponding author: fabian.haake@mat.ethz.ch

Abstract: We present a broadband scanning reflectance anisotropy microscope as a platform for measuring ellipsometric properties, particularly sensitive to anisotropies such as strain. Leveraging its inherent phase sensitivity, we can distinguish enantiomorphic states of chiral nano resonators. We show non-destructive mechanical characterization of amorphous semiconductors and chiral metasurfaces.

A common failure mode of flexible electronic devices is catastrophic failure or device degradation due to mechanical strain, making accurate strain control a critical aspect in their design and characterization.

Here, we introduce scanning reflectance microscopy (SRAM) as a broadband multi-material platform for mapping ellipsometric properties on the microscale. This multi-material optical platform serves not only to access microscopic strain distributions but also shows high phase sensitivity.

This technique provides a practical approach to mechanical characterization, yielding valuable insights into the mechanical behavior of diverse materials, including metamaterials, amorphous and crystalline semiconductors, and metals. The microscope's capability to generate diffraction-limited strain and phase maps enables a thorough analysis of materials properties without causing damage. [1]

The capabilities of the technique are discussed on the specific example, strained amorphous semiconductors (aSi & aGe). Recent results include the measurement of chiral nano resonators highlighting the phase sensitivity of SRAM.

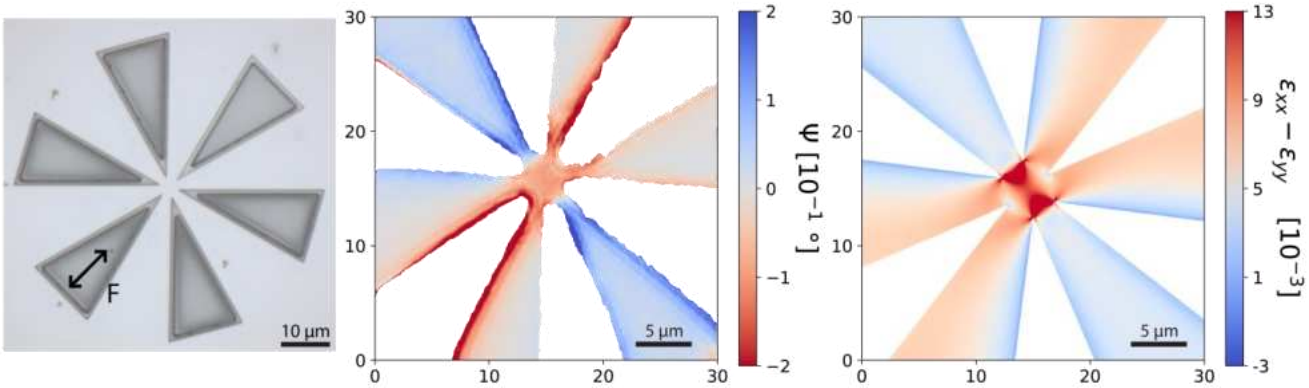

Figure 1: Light microscopy image, SRAM measurement and computed strain distribution ε_{xx}-ε_{yy} and of an uniaxially strained photonic crystal-like structure milled into amorphous silicon.

Figure 1 shows the light microscopy image of a photonic crystal-like structure milled into an amorphous Silicon thin film. The thin film is strained to a total strain of 0.8%. SRAM can resolve the strain distribution of the computed strain state.

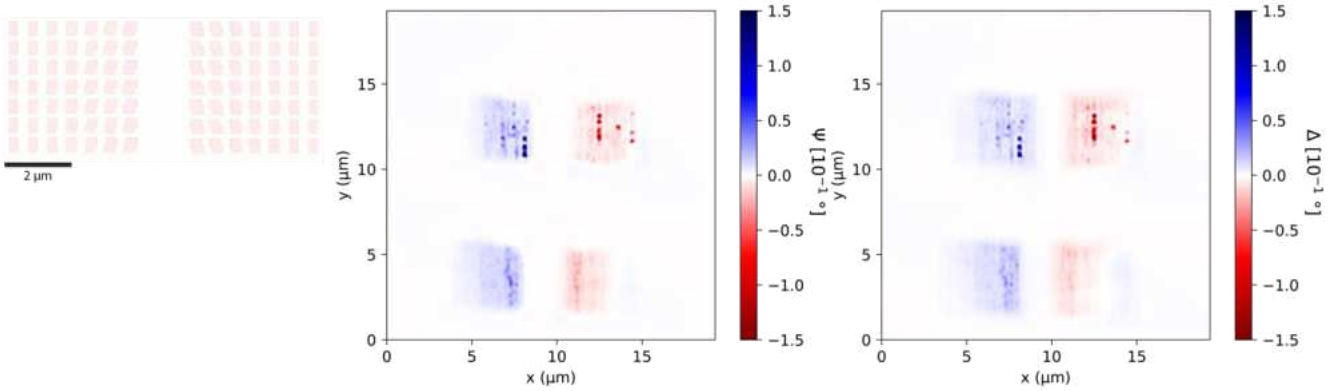

Figure 2: Dimensions of enantiomorphic nano resonators and SRAM maps with ellipsometric amplitude and phase.

Figure 2 shows first results of the amplitude and phase maps of the L/R forms of nano resonator arrays. The arrays are milled with focused ion beam and their chiral feature gets stronger towards the center of the two arrays. The scan is acquired with a probing wavelength of 950 nm.s

Abstract: High-index atomic layer-nanoparticle embedded-resin hybrid metasurfaces are introduced as cost-effective and high-throughput method for high-performance visible metasurfaces. With theoretical 93.7% conversion efficiency at 450 nm, featuring 3 nm titanium dioxide layer, 600 nm height, and 6.6 aspect ratio, these hybrids are poised for commercial adoption, potentially replacing traditional optical components.

Metasurfaces operating in the visible spectrum, composed of subwavelength structures, are gaining attention as viable alternatives to traditional optical components due to their remarkable light modulation capabilities [1]. The conventional electron beam lithography method, traditionally used for their fabrication, is both time-consuming and expensive, impeding the smooth transition of metasurfaces from scientific concepts to practical technology [2]. In response to these challenges, nanoimprint lithography (NIL) has emerged as an efficient and rapid technique for replicating nanostructures from a master mold directly onto a substrate [3]. However, the conventional use of nanoparticle-embedded-resin (nano-PER) is associated with a low refractive index, resulting in a high aspect ratio of nanostructures, thereby posing challenges in fabrication and structural stability. In this study, we introduce a high-index atomic layer-nanoparticle embedded-resin hybrid metasurfaces as a cost-effective and high-throughput method for high-performance visible metasurfaces.

Through the atomic layer coating of titanium dioxide (TiO_2) on the surface of nano-PER, the effective refractive index of the hybrid metasurfaces can be enhanced, with the degree of enhancement depending on the thickness of the TiO2 layer. Using particle swarm optimization method, we determine the optimal parameters for width, length, period, height, and thickness of the TiO2 layer. Ultimately, a mere 3 nm layer of TiO2 allows us to achieve a high theoretical conversion efficiency of 93.7% at a wavelength of 450 nm, coupled with a height of 600 nm and an aspect ratio of 6.6. We hope that these hybrid high-index metasurfaces can be commercially utilized to replace conventional optical components with metasurfaces.

3D Inkjet Printing for the Manufacture of Micron-to-Millimeter-Scale Metamaterial Structures

O. Nelson-Dummett, R. Hague, C. Tuck, and L. Turyanska

University of Nottingham, United Kingdom
*presenting author: oliver.nelson-dummett@nottingham.ac.uk

Abstract: We demonstrate additive manufacturing of complex 3D geometries using inkjet deposition of silver nanoparticles and other materials. We produce 3D lattice structures as well as unsupported overhangs, which can be encapsulated in various materials to enhance the dielectric contrast and create floating elements with a view to create metamaterials.

Inkjet and other drop-on-demand printing is increasingly being adopted for additive manufacturing (AM) of functional materials, including polymers, metals, ceramics, and low-dimensional materials [1]. Being digitally driven and with high geometric degrees of freedom, it has strong potential for the fabrication of metamaterial designs but has mostly been limited to simple 2D designs in the GHz-THz region [2,3]. We developed an Off the Grid strategy for material-jet printing, which allows for higher (sub-droplet) precision of the deposition, and consequently enabled us to create more complex designs with high fidelity [4] (Figure 1a). This strategy was utilized to produce complex 3D architectures. Starting with high solid content inks, we have produced arrays of individual pillars. Inks of silver nanoparticles suspended in a volatile solvent were deposited onto a substrate heated to 70 °C to facilitate fast solvent evaporation. The coffee-ring effect [1] causes the base of the pillar to be flared; the equilibrium diameter of 50 µm is reached after 10-12 drops (Figure 1b-c) with a small depression at the tip (Figure 1d). The pillars were successfully produced in patterned arrays for 2.5D metamaterials, such as photonic cavities (Figure 1e).

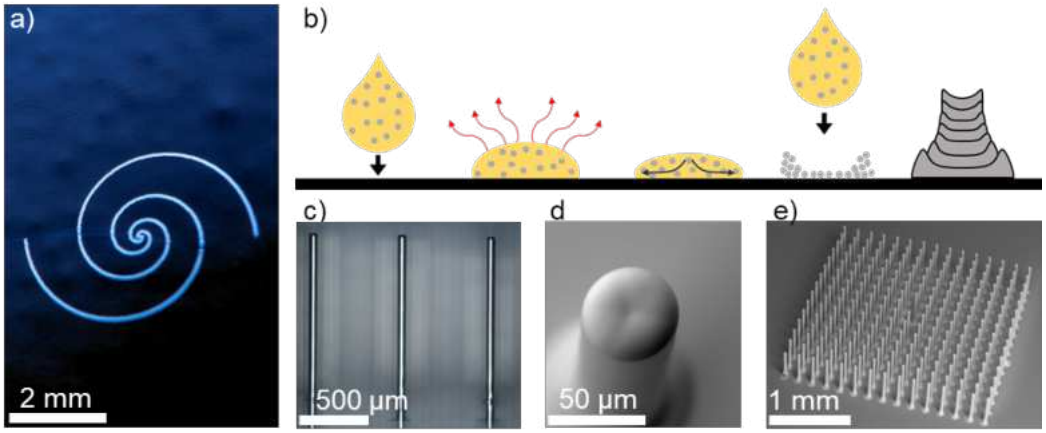

Figure 1. a) Schematic of silver nanoparticle ink (yellow) deposition onto a heated substrate (black) followed by solvent evaporation and drying. Internal flow drives the silver nanoparticles (grey circles) to the edge forming a coffee ring shape, which acts as a template for consecutive droplets. b) A representative optical image of printed pillars with diameter of 50 µm, and SEM images of c) the tip of a pillar with 1500 layers, and d) a 14 x 14 pillar array forming the structure of a photonic cavity metamaterial by leaving out the centermost pillar.

To create overhanging features, we employed the OtG strategy [4], applying a small lateral offset to each layer. Several structures were manufactured, including slanted self-supporting pillars at angles up to 34° from the vertical, as well as tripods and lattices with lateral sizes of 100 mm and heights up to 1.5 mm (Figure 2b-e).

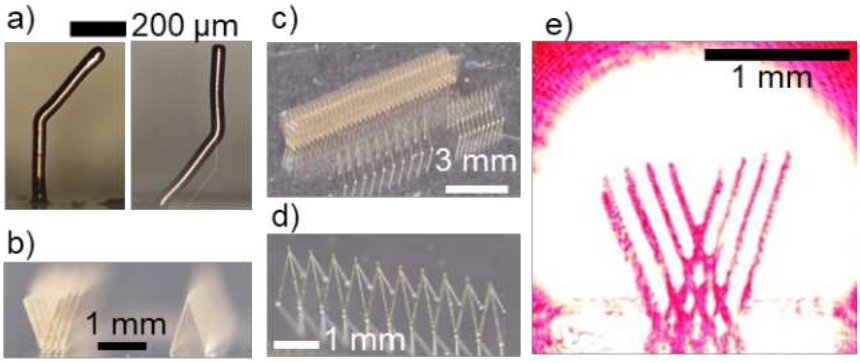

Figure 2. Representative optical images of a) slanted pillars produced using a 1 µm offset per layer, and b-d) various angles of a freestanding lattice and individual tripod structures. The lattice is shown in e) with a laser being shone along its length, demonstrating that the designed gaps in the lattice are continuous throughout.

These pillars, as well as larger silver elements, can be encapsulated in a UV-curable polymer for enhanced dielectric contrast and to support floating elements. When built up in this manner, it unlocks the potential for a range of potential uses, such as anisotropic dielectrics and 3D waveguides.

In conclusion, inkjet printing has the potential to manufacture metamaterials with complex 3D geometry, with accuracy in the micron scale across a range of materials. We demonstrate the ability to print pillar arrays, self-supporting strut-based lattices, and silver embedded in polymer dielectrics for metamaterials such as 2.5D photonic cavities, photonic lattices, and anisotropic dielectrics. The results of this work, opportunities for multi-material inkjet to introduce support materials and higher dielectric contrast materials, could offer promising manufacturing solutions for a wide range of metamaterials.

Abstract: In this work, we show the fabrication process of the aluminum nitride (AlN) nanostructure pattern, an attractive material for optoelectronic device research, such as for photodetectors and light-emitting diodes (LEDs) by utilizing a low-temperature, substrate independent and selective deposition method called sequential Infiltration synthesis (SIS).

Optoelectronic devices, such as photodetectors, solar cells, and light-emitting diodes (LEDs), are essentially energy-conversion devices that convert light to electricity or vice versa. In this field of group III-nitride semiconductors such as Gallium Nitride (GaN), Aluminum Nitride (AlN), and compound nitrides such as AlGaN have been pivotal in technology enrichment, [1-3] especially in the light emitting applications whereas bulk and thin films of these nitride materials are used as the active layer for light emitting and light harvesting purposes.[4, 5] Nanostructures of group III nitride materials are attracting significant attention for their advantages over planar structures currently used in commercial devices. In this work, we develop a fabrication process of AlN nanostructure patterns by utilizing a method called Sequential Infiltration Synthesis (SIS). SIS is a localized vapor deposition process using polymers as guiding patterns to achieve large-scale uniformity of organized nanoscale materials at lower temperatures than the conventional process. Conventionally, nitride deposition is

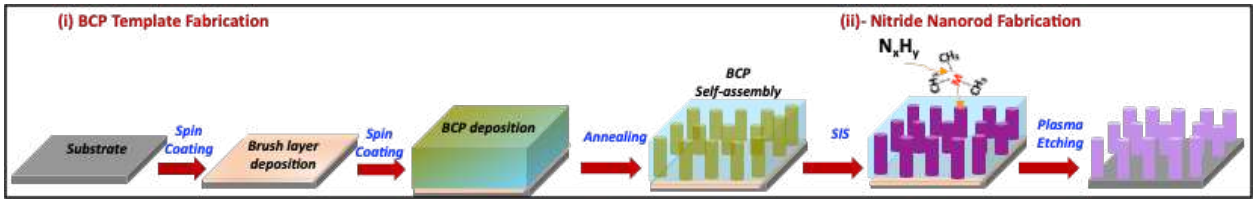

Figure 1: Schematic of the nitride nanopattern growth process using BCP template and SIS method. Step (i) shows a self-assembled vertical cylinder forming BCP nanostructure fabrication process; and step (ii) shows metal nitride nanorod array formation using the template fabricated in step (i), SIS deposition and plasma etching.

performed at high temperature using the established methods such as MBE, MOCVD, and ALD. [6-9] The low-temperature deposition of nitrides is usually challenging because of the unreactivity of the nitride precursors with the starting substrates at temperatures below 500 ºC. SIS has been explored extensively by several research groups and by industry leaders in the last few years including our group for oxide materials. We developed nanopatterns of AlN by SIS technique that can produce scalable, well-ordered, and relatively easy integration of the patterned nanomaterials and investigate their growth mechanism and optical properties. We have characterized the patterns by scanning electron microscope, energy dispersive X-ray spectroscopy (EDS), and Fourier transform infrared (FTIR) spectroscopy. Our approach is expected to produce scalable, well-ordered nanopatterns to be integrated easily into the existing technology.

This material is based upon work supported by the National Science Foundation (NSF), Division of Material Research under Grant No. DMR-2213365.

Post-synthesis band gap halide anion exchange tuning in $CsPbBr_3$ nanocrystals and issues of light-induced phase segregation

Abstract: This study investigates post-synthesis band gap tuning of $CsPbBr_3$ nanocrystals through halide anion exchange (HAE) with CsI. While effective HAE occurs, phase segregation leads to Br-rich core and I-rich shell formations, impacting optical properties. Comprehending these phenomena enhances the development of precise optoelectronic engineering strategies tailored for semiconductor nanocrystals.

The semiconductor industry's reliance on chemical doping for electrical property engineering is paralleled by the effective tuning of optoelectronic properties in LHPs through halide anion exchange (HAE)[1]. Post-synthesis tuning of $CsPbBr_3$ nanocrystals alters their bandgap and optical characteristics, offering replaceable and reversible passive optoelectronic elements, e.g. for photovoltaics[2], high-resolution displays[3], or functional metasurfaces[4]. The photoluminescence response of $CsPbBr_3$ nanocrystals was tuned by employing post-synthesis treatment with CsI in isopropyl alcohol. These nanocrystals were prepared via the hot-injection method and dropcasted onto silicon substrates.

To examine the resulting optical band gap of the HA exchanged $CsPbBr_3$ nanocrystals, scanning electron microscopy (SEM) imaging and photoluminescence (PL) mapping were employed. The overlay of the two images is incorporated in Figure 1a. Here, the nanocrystals are highlighted by white dashed lines, and their PL response is further post-processed. The raw PL spectrum contains two distinguishable peaks, which we assign, in comparison to the literature and our own expertise, to Br-rich (mapped as green) and I-rich (mapped as red) phases. This suggests light-induced segregation of the nanocrystals. However, several sites appear to change their PL response according to the prospect of band gap tuning, as seen in Figure 1d, where several spectra are shown with Br-rich, I-rich, and mixed PL responses. The mixed PL responses exhibit much lower intensities than the rich phases.

To unravel the nature and impact of the phase segregation, time-of-flight secondary ion mass spectrometry (ToF-SIMS) was utilized to image the spatial distribution together with the depth profile of Br and I ions, as seen in Figures 1b and 1c, respectively. Here, the Br ions are detected at the sites of the nanocrystals as expected. However, I ions seem to follow a random pattern across the sample with a preference for occurrence on the edges of the nanocrystals. Moreover, upon examining the depth profile of Br and I ions in Figure 1e and comparing it with the depth PL profile in Figure 1f, we see a strong Br signal present on the surface with I signal rapidly decreasing when reaching certain depth. It is evident that the HAE mainly occurs on the outer shell of the nanocrystal which becomes I-rich. The shell reaches a certain saturation depth and leaves the core of the nanocrystal purely made of the Br-rich phase.

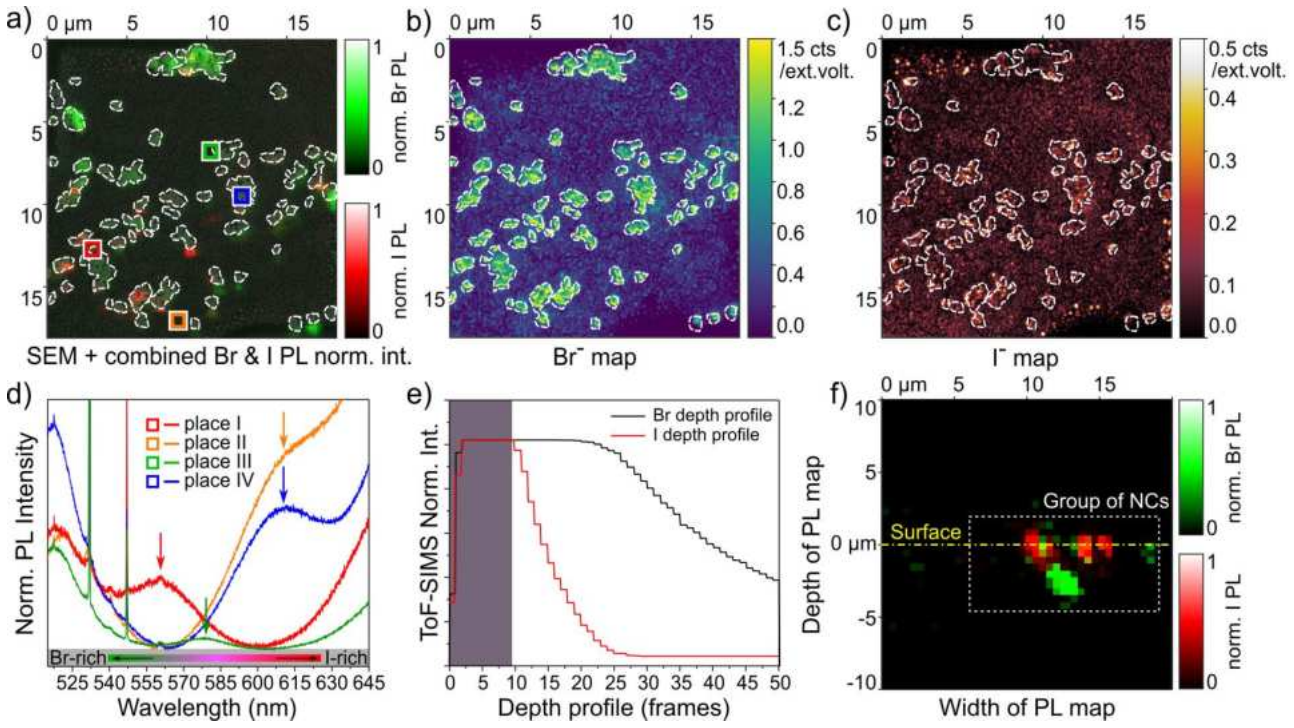

Figure 1 a) SEM and PL map overlay with $CsPbBr_3$ nanocrystals in the white dashed lines regions. b), c) ToF-SIMS chemical maps of Br and I respectively. d) Single spectra obtained from rectangular areas. e) ToF-SIMS depth profile. f) PL depth profile.

To summarize, the correlative optical and chemical imaging of HAE $CsPbBr_3$ nanocrystals revealed that light-induced phase segregation takes place leading to formation of Br-rich and I-rich phases. The band gap tuning of individual HAE $CsPbBr_3$ nanocrystals was found to be existent and prevalent even after light illumination at several sites, however, it was regarded as inefficient and random. Additional sensitive chemical mapping reveals that phase segregation primarily occurs on the outer shell of the $CsPbBr_3$ nanocrystals, saturating at an effective depth. This indicates that, rather than engineering the bandgap and PL response of the $CsPbBr_3$ NCs, non-selective mixing was prevalent due to phase segregation.

Abstract: A metalens containing silicon pillars arranged in a triangular lattice for near-infrared wavelengths is fabricated through a high-precision all-in-one etch to avoid wet chemistry processes during fabrication. Measurements demonstrate the focusing property of the metalens. It can be placed on photonic circuits or components to form a 2.5D integrated system.

Metalenses are promising components for micro- and nano-scale optical systems due to their small footprint, planar geometry, and excellent optical performance, and their possible applications include sensing, imaging, communication, astronomy, quantum photonics, and virtual/augmented reality [1]. Silicon offers unique advantages for metalenses but the accurate mapping of device design to fabricated chip remains a challenge. In our work, we apply a recently developed silicon deep-etching process [2] to obtain high-quality fabrication with precise control over the nanostructure geometries. This process replaces the common fluorocarbon inhibitor in the Bosch deep-etching process with oxygen to eliminate passivation build-up, making it a greener process for the environment while keeping a low-power and low-speed etching with fine control. It is also compatible with metal hard masks, which enables very high resolutions [2,3].

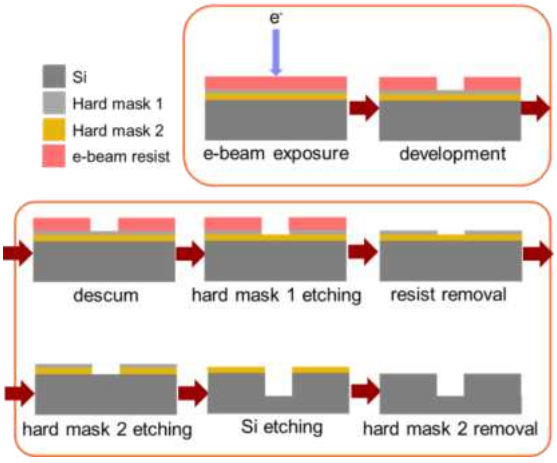

Figure 1. The all-in-one etch fabrication process flow for the silicon metalens.

We consider metalenses consisting of silicon pillars with diameter, D, and height, H, and the pillars are arranged in a triangular lattice. By varying D, an arbitrary phase profile can be realized when the relative phase delay between pillars spans 2π. By exploring the design space for D and H while constraining parameters to realistic values, we find that for a lattice constant of 450 nm and H = 1.5 µm, the required 2π phase span can be achieved for D varying between 140 nm and 356 nm. When using a 110 µm beam waist of collimated Gaussian

input, the designed metalens with a width of 327 µm are simulated to have focal lengths of 884 µm, 806 µm, and 730 µm, respectively, for wavelengths of 1410 nm, 1550 nm, and 1690 nm.

We fabricate our devices using electron-beam lithography (JEOL JBX-9500 FSZ) with proximity effect correction (Beamfox Proximity) and use a metal hard-mask to obtain a high etching selectivity, which is needed for enabling our high-aspect-ratio pillars. Characteristic metalenses fabricated by our method are shown in Fig. 2. We characterize the devices with a collimated light source with a wavelength of 1550 nm and a beam diameter of 2 mm and our experiments confirm the focusing property of the fabricated metalenses. We will present the most recent developments in our labs towards integrating the metalenses with photonic circuits [4,5,6].

Abstract: This research aims to develop a novel optical sensor integrated into a battery system for early detection of lithium-ion electrolyte leakage failures. The sensor utilizes surface enhanced Raman scattering measurements and features a graphene-protected substrate comprising a 2D array of silver nanoparticles with a tailored lattice resonance.

Lithium-ion batteries (LIBs) offer the best balance between energy efficiency and performance for high-density energy storage applications. Nevertheless, damage caused by overcharging and heating during LIB operation can lead to major changes in the electrolyte composition and leaks of chemical products outside of the battery. Detecting and monitoring the leakage of trace amounts of electrolyte with high sensitivity is of great significance to improve the safety of LIBs and the devices they power. Traditional analysis techniques often fail to provide in-depth insights into electrolyte dynamics, particularly during operation. This gap underscores the need for innovative approaches to examine the complex interactions within the microenvironment of the battery.

This research aims to develop a novel optical sensor integrated into a battery system for early detection of LIB electrolyte leakage failures. We developed this sensor by leveraging and adapting the localized surface plasmon resonance as well as surface lattice resonance (SLR) (collective response of an ordered plasmonic system) in 2D silver nanoparticle metasurfaces [1, 2]. Recently, we have demonstrated that it is possible to produce surface-enhanced Raman spectroscopy (SERS) substrates that are targeted for the excitation wavelength or a specific Raman peak by tailoring the SLR wavelength [3]. The achieved record quality factor of the tailored SERS substrates was exploited in the current research to detect the specific organic molecules (derivatives of lithium carbonate, organic small molecules such as formaldehyde) emitted by the LIB electrolyte [4].

The fabrication of SERS substrates tuned to match the excitation wavelength (532 nm) comprise several technological steps. Silver nanoparticles with a diameter of 77 nm ± 4.5 nm were chemically synthesized using the seeded growth method. A 20 mm × 20 mm Si mold was fabricated using electron beam lithography (eLine plus, Raith) and reactive ion etching (Apex SLR ICP, Plasma-Therm). The pattern consisted of a square array of 180 nm diameter, 100 nm tall pillars spaced 330 nm center-to-center. The patterned Si mold was used in soft lithography replication cycles to produce polydimethylsiloxane (PDMS) replicas used for the capillarity-assisted deposition of silver nanoparticles. The deposition was performed using a custom-made setup equipped with a motorized linear precision translator and a temperature control system. Long-term stability of the SERS substrates was enhanced by applying a monolayer of graphene onto the plasmonic lattice. Large area graphene layers were deposited from CH_4 and H_2 gas mixture on a metallic catalyst (Cu foil) using a microwave plasma-enhanced chemical vapor deposition technique (IPLAS Innovative Plasma Systems GmbH). Graphene was released from the copper substrate by wet etching and the floating graphene film was subsequently placed on the surface of deionized water for 24 hours for cleaning. Finally, the graphene film was transferred onto the SERS substrate.

SERS mapping was performed using a Raman microscope InVia (Renishaw) equipped with a thermoelectrically cooled CCD detector. The samples were excited and the spectra were collected using the following combination of laser

wavelength and grating: 532 nm (1800 lines/mm). The 30×30 μm^2 surface area was mapped with a step size of 1.5 μm. Long-term stability studies of the SERS substrates were performed by repeatedly measuring the Raman scattering spectrum of the organic molecule 2-Naphthalenethiol (Sigma-Aldrich) within a 3 months' period. The results have proven excellent stability of the elaborated SERS substrate.

A custom-made container made of aluminum oxide ceramic, sealed within an argon atmosphere, was used in the SERS studies of LIB electrolyte lithium hexafluorophosphate ($LiPF_6$) dissolved in a mixture of ethylene carbonate and ethyl methyl carbonate. With an optical window of sapphire for SERS spectroscopy measurements, this chamber served as a reservoir for the LIB electrolyte. The measurements included direct placement of the electrolyte on the SERS substrate (for calibration needs), or measurements, when a few drops of the electrolyte were placed within the chamber, adjacent to a custom SERS substrate, which is not in direct contact with the liquid electrolyte. Periodic SERS measurements were conducted to monitor the presence and concentration of electrolyte analytes adsorbed on the SERS substrate. Preliminary results have demonstrated the ability of the technique to detect time evolution of the signature peaks of the electrolyte components. We have found that the top layer of the SERS substrate – graphene, having a large surface area, possessing superior molecule adsorption ability, can protect the nanoparticles from oxidation or corrosion and improves the uniformity and stability of the SERS signal.

This study leverages a meticulously engineered SERS substrate within a specially designed microenvironment to analyze the evaporative behavior of LIB electrolytes. We believe that this methodology opens new avenues for real-time monitoring of volatile components in LIB, providing insights into electrolyte stability and decomposition pathways.

Abstract

In this paper we report the fabrication of metasurfaces-based microlenses on 300 mm glass wafer using 193 nm immersion photolithography and their characterization using Quadriwave Lateral Shearing Interferometry (QLSI). Through this wavefront analysis, we can determine the quality of the fabrication and understand how imperfections affect the metasurface performance.

1. Introduction

In the pursuit of high-resolution CMOS sensors, there is a trend toward reducing pixel size. This miniaturization presents an increasing challenge in gathering sufficient light to maintain the sensor's sensitivity. To increase the light concentration, refractive microlenses are used to focus light on the photosensitive part of the pixel. Metasurfaces provide a planar alternative to refractive microlens and are good candidates to be integrated in a CMOS process [1]. A metalens is a structured surface made of high-refractive index and subwavelength nanopillars (poly-Si) embedded in a low refractive index substrate (SiO2). Local phase-shift manipulation is achieved by varying the pillar diameter and the capacity of a metalens to concentrate light relies on its ability to reproduce a focusing phase function. Most of metalenses use a hyperbolic phase profile [2] as it is allowing for spherical aberration free focusing. However, fabrication errors and the finite size of the metalens disturbs the phase profile actually obtained. Fabrication errors can lead to variability on meta-atoms morphology and positions which create a phase-shift offset between target and fabricated devices. To alleviate these problems, intensive metrology is employed to ensure that the fabrication follows the designs specification with tools such as scanning electron microscopy, ellipsometry or transmission electron microscopy. These measurements only provide morphological information on nanopillar such as the diameter, the height or the side wall angle. To accurately assess the influence of variations in nanopillars morphology on the performance of metasurfaces, it is necessary to perform complementary electromagnetics propagation simulations. Another approach could involve the direct measurement of the phase-shift using a wavefront sensor. To this end, we cannot use the metalens on a CMOS matrix as we have only access to integrated irradiance on pixel. Thus, to observe the wavefront we fabricated similar microlens on a transmissive glass substrate (see figure 1). Wavefront sensors directly provide phase images which holds the complete information on metalens light control performance. It can be used to validate the results of simulations and refine the fidelity of the simulated model. In this paper, we present wavefront characterization of small metalenses with different focal lengths in order to evaluate their fabrication quality. In the first part we present characterization results of metalenses and nanopillars arrays. In the second part we will presents how wavefront analysis can be used to study the impact of fabrication imperfections on metasurface performances.

Direct bonding of glass wafer and grinding 7. Silicon wafer grinding.

2. Fabrication and simulation process

The samples were fabricated using 193 nm DUV immersion photolithography on 300 mm glass wafers [3]. It starts on a silicon wafer on which alternating layers of silicon oxide (SiO_2) and silicon nitride (Si_3N_4) are deposited by PECVD (Plasma Enhanced Chemical Vapor Deposition). The thin Si_3N_4 uniform layer acts as an etch stop layer during the fabrication process and does not alter the relative phase-shift difference between meta-atoms of different sizes. Then nanoholes are etched into the substrate before being filled with amorphous silicon which is then annealed to form poly-silicon. At this stage chemical-mechanical polishing (CMP) is employed to planarize the substrate material until the

targeted height is reached. Finally, silicon oxide is added for passivation and anti-reflecting effect. Other process steps are performed after the passivation but they have no significant effects on metasurface phase-shift function. This process allows for the fabrication of metasurfaces with nanopillars with a diameter (referred as Critical Dimension or CD) ranging from 120 nm to 350 nm, for a height of 700 nm.

Prior to fabrication, simulations based on Rigorous Coupled Wave Analysis (RCWA) using the software Reticolo [4] were conducted in order to calculate the transmission and the local phase-shift variation with nanopillars diameter. The simulation is performed under periodic conditions and with plane wave incidence at 0°. These data are gathered in libraries and used to discretize the phase profile of the metalens to be fabricated.

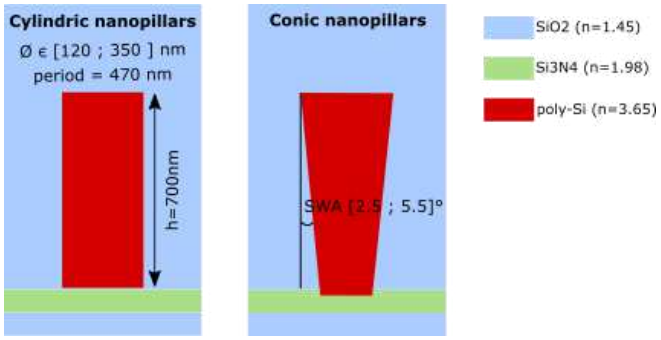

Figure 2: The etching process results in a sidewall angle that produces a top diameter which can be reduced to as low as 80% of the intended diameter. This reduction corresponds to an approximate volume loss of nearly 20%.

To assess the impact of the sidewall angle (see figure 2), the top and bottom critical dimensions of nanopillars with sizes of 120, 218, 290, and 350 nm have been measured using Scanning Electron Microscopy (SEM). The changes in diameter were found to be linearly related to the targeted diameter, thus allowing a linear regression to determine the actual fabricated dimensions for each nanopillar size in the library.

3. Measurement setup

Quadriwave Lateral Shearing Interferometry (QLSI) is a wavefront sensing technology [5]. The system relies on a diffractive grating which may be referred to as a Modified-Hartmann mask to produce an interferogram. The interferogram is made of a dense array of light dots whose displacement can be tracked to retrieve the wavefront gradient information. The measurement setup is precisely described in [6] since it is the same at the exception of the objective and camera used. Two objectives have been used: the Nikon 100X CFI TU Plan Fluor (NA=0.9) and the 10x Nikon CFI planar Fluor (NA = 0.3). The metasurfaces are designed to work at 940 nm and the source is a fiber coupled diode of 10 mW. The camera has a resolution of 1600×1200 which generate a 400×300 pixels phase images. The camera sensor is 11.6×8.7 mm so that the maximal ROI (Region of Interest) that can be defined with $\times 100$ magnification is 116×87 µm with a phase image resolution of 0.290 µm/pixel. In this configuration, the setup is at the diffraction limit which can estimated using Abbe diffraction limit for the microscope at $d = \lambda/2NA = 0.522$ µm.

To construct the phase image, the QLSI measure the phase gradient in the ROI. The interferogram is studied in Fourier space where diffraction spots are identified, cropped and centered before being inverse Fourier transformed. The resulting image contains complex values and the argument of this complex image is proportional to the local wavefront gradient. The resolution is reduced to one-third of its original size due to the cropping steps involved in the gradient retrieval algorithm [5].

4. Wavefront measurement

In this section we discuss the results from the wavefront transmitted through the metasurface analysis. The measurement aimed at three goals: characterizing uniform array of nanopillars referred as a piston, characterizing metalens to retrieve their focal lengths and studying the impact of fabrication.

4.1. Measurement preparation

The nanopillar arrays and metalens are embedded in a silicon oxide ($n = 1.45$) substrate and we must consider the refractive index of the materials to analyze the measured wavefront (see figure 3).

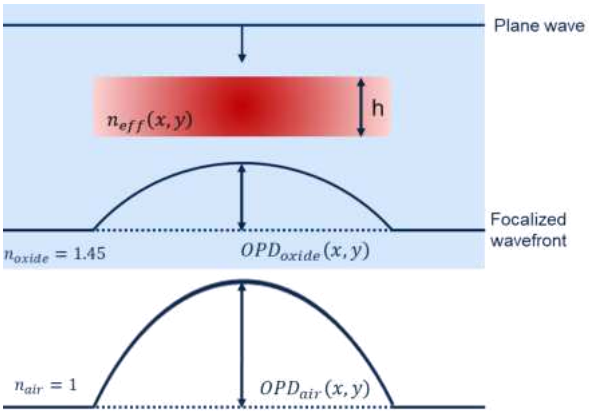

Figure 3: The metasurface we want to characterize is embeded in a silicon oxide substrate. As light propagate through the metasurface the phase accumulated shapes the incident plane wave into a focalized wavefront following a hyperbolic profile.

QLSI is a wavefront sensing technique [5] which returns the Optical Path Difference (OPD) distribution in the object plane. OPD and phase-shift are linked by equation (1):

$$\varphi(x,y) = 2\pi \frac{OPD(x,y)}{\lambda} \qquad (1)$$

where λ is the wavelength of the light in the medium it is observed. The measured OPD originates from the interaction of light with the nanopillars embedded in silicon oxide but

during its propagation it encounter an oxide/air interface which modifies the OPD distribution following equation (2):

$$OPD_{oxide} = \frac{OPD_{air}}{n_{oxyde}} \quad (2)$$

In the scenario examined in this paper, our aim is to validate the phase-shift that has been simulated and measured within the oxide layer. This is to approximate the conditions of a metalens integrated atop a CMOS pixel stack.

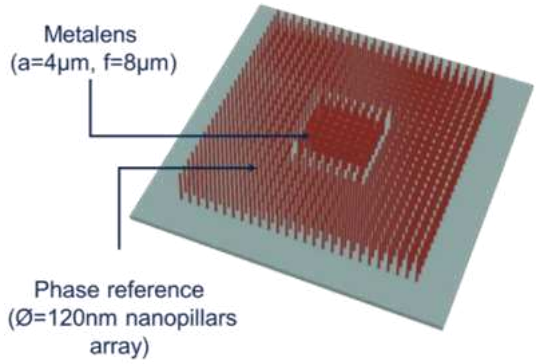

Figure 4: Each design incorporates a surrounding array of nanopillars with a uniform diameter that functions as a phase reference. This reference area is dimensioned to cover at least the same area as the design to be characterized. The sample is arranged in a checkerboard pattern.

QLSI allows to compute a relative phase-shift measurement and therefore requires an area of reference equal to the one that will be characterized. To satisfy this condition, we first designed metasurfaces surrounded by constant phase areas made of a uniform pillar arrays with a diameter of 120 nm (see figure 4). As mentioned in [5] the wavefront gradient retrieved by the QLSI is defined by calculating the argument of a complex number which is defined modulo 2π. In our case we want to characterize a library of nanopillars with phase-shift values ranging from 0 to 2π so local phase step close to π can be found in some places of the samples between reference and the nanopillars arrays.

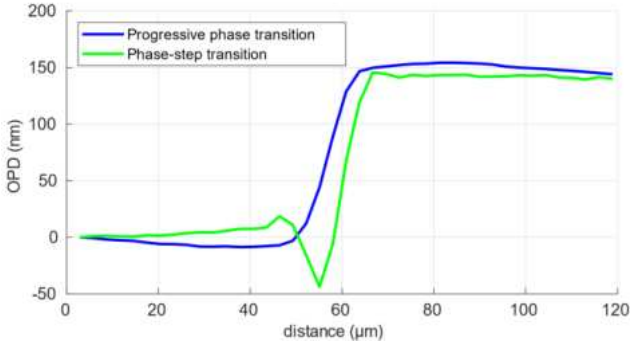

Figure 5: Comparison of the phase variation between the nanopillars arrays of reference and the nanopillars arrays which phase is to be measured. The blue curve describes the phase variation when progressive phase transition is implemented. The green curve describes the same transition with an abrupt separation between the reference and piston.

A phase step of π in the phase image introduces ambiguities during the gradient calculation and should be avoided. Hence, we introduced pillar arrays with increasing diameter, varying from the diameter of reference to the diameter of the array to be measured, in the 20 µm wide region around the target array. By implementing a progressive transition of nanopillars diameter, we create a smooth transition between the arrays of reference and the arrays to be characterized. This design adaptation generates a continuous and linear phase gradient of 3.14 rad/µm, which in turn reduces the risk of errors during the wavefront gradient calculation (see figure 5).

4.2. Nanopillars phase-shift

To validate the phase-shift induced by the nanopillars in periodic conditions, 32 uniforms arrays of nanopillars with diameters ranging from 120 nm to 350 nm (see figure 6) were measured. As previously mentioned, a necessary step for metasurface design is the generation of libraries through simulation. A library may be defined as the variation of the phase-shift with nanopillars diameters at fixed height and period. These simulations are performed considering periodic boundary condition so the phase-shift extracted correspond to the phase-shift of the nanopillars surrounded by morphologically identical nanopillars. This hypothesis is not rigorously verified in a metalens with varying nanopillar diameter. However, as it is customary done with Look-Up Table (LUT) approach, for slow varying phase profile it is still a good approximation.

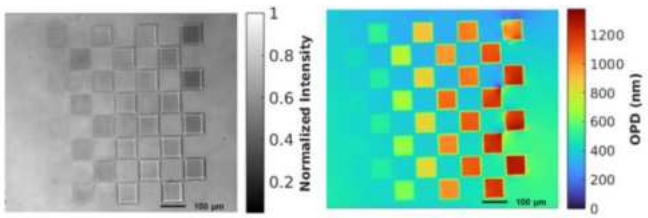

Figure 6: 32 uniforms arrays of nanopillars are disposed on a 800×800 µm square. Each array is 80×80 µm large and is surrounded by 20 µm of phase reference nanopillars. The images have been taken with $\times 10$ magnification inside an ROI of 1.16×0.87 mm. (Left) Intensity Image (Right) Phase Image.

The first objective of our characterization was to validate the library obtained by simulation used for our designs. The comparison between the simulations and the characterization results are displayed on figure 7. The measurements and simulations of cylindric meta-atoms are in good agreement up to 200 nm beyond which the two curves differ significantly. Several factors could explain the discrepancy between the two curves. While the simulations assume perfectly cylindrical nanopillars, the actual pillars exhibit a sidewall angle ranging from 2.5° to 5.5° (see figure 2). Also, significant resonances are observed for larger pillars.

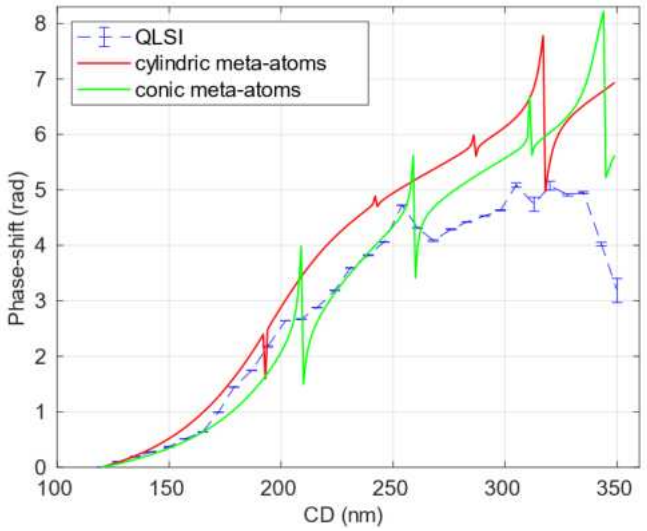

Figure 7: Measured OPD variation with nanopillars diameter (Blue dotted line). The values of OPD are sequentially calculated from the mean OPD of the pixel group located on the targeted area and subtracted from the neighboring nanopillars of reference. The red and green dotted line is extracted from simulation realized with the software Reticolo.

These localized phenomena amplify the impact of fabrication defect, potentially shifting the resonance location and thereby greatly affecting the phase response. In metasurface creation, the phase function is sampled using nanopillars chosen to induce specific phase-shifts. If there is a substantial deviation in the phase-shift, we can expect a degradation of optical performance, including displacement of the focal plane and reduced light concentration. By utilizing SEM data to assess the top and bottom CD, we generate a library of truncated conical nanopillars for comparison with cylindrical nanopillars and measured values.

We note a comparable trend in the phase increment between the experimental data and the conical library up to a 260 nm. Additionally, near the anticipated resonance positions for diameters of 215 nm and 260 nm we measure disturbances in phase variation. Although the two curves do not align perfectly, the discrepancy between the simulated and characterized nanopillars is significantly reduced. This suggests that the meta-atoms sidewall has a non-negligible impact on the phase responses. For pillars with a diameter exceeding 260 nm, there is a higher difference between the experimental data and both simulated libraries. At this stage, the lack of correspondence is presumably due to errors during the acquisition of the phase image despite employing progressive phase transitions. Upon examining the phase image presented in figure 6, it is observed that there is a significant phase gradient at the periphery of the nanopillar arrays with larger diameter. This pronounced gradient disrupts the local comparison between the reference region and the area under investigation, consequently hindering the accurate characterization of this meta-atoms.

4.3. Focal length measurement

The second main objective is to characterize the metalenses to determine focal lengths and analyze their phase profiles. In this study we will specifically examine metalens with an aperture of 8 µm and a focal length of 4 µm and 8 µm. These parameters have been specifically chosen to replicate the metalenses that are being fabricated on CMOS wafers. Smaller metalens have been characterized but the measurement did not have sufficient resolution for a detailed analysis. The metalenses have been designed with a hyperbolic phase [2] profile defined by equation (3):

$$\Phi(x,y) = \frac{2\pi}{\lambda}\left(f - \sqrt{f^2 + r^2}\right) \qquad (3)$$

Where f is the focal length, λ the wavelength in the considered media and r the radial coordinate.

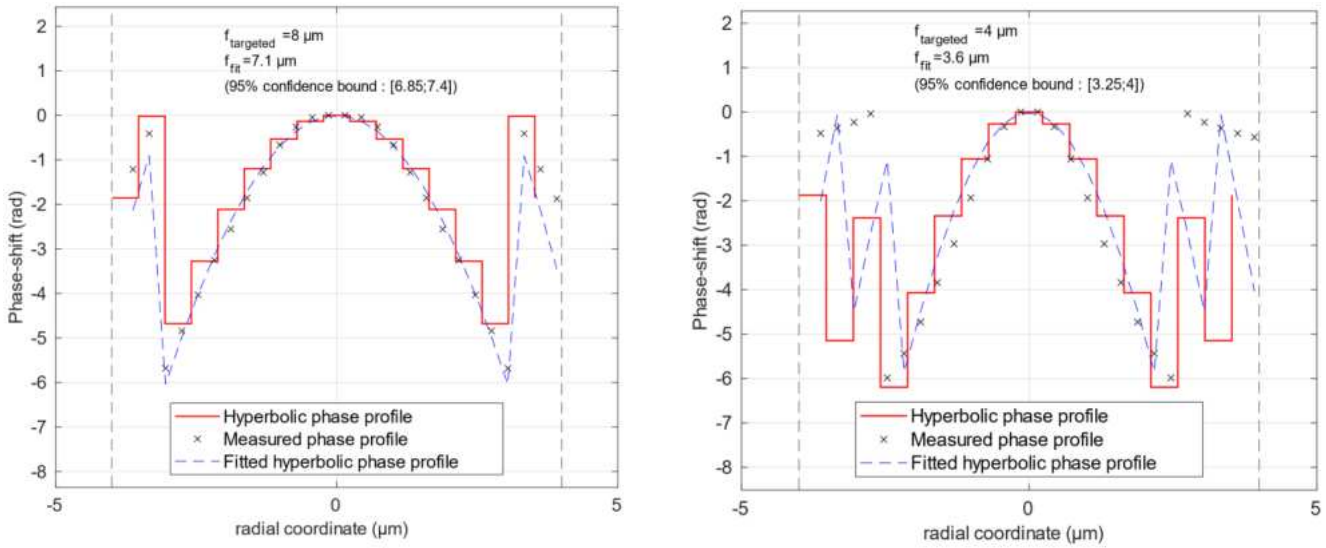

Figure 8: Wrapped measured phase profile (black cross) comparison with the discretized theoric hyperbolic phase profile (red line). The hyperbolic phase profile fitted from experimental point is represented in dashed blue line. The metalens have an 8 µm aperture and 8 and 4 µm focal length. The confidence bound is derived from the variance-covariance matrix of the parameter estimation.

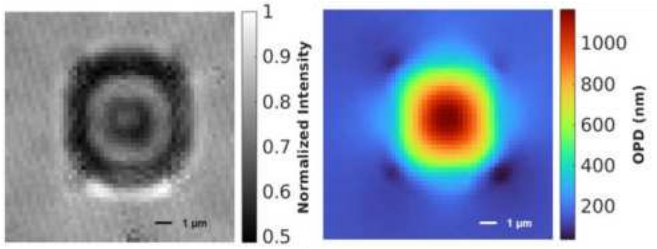

Figure 9: (Left) Intensity image and (Right) phase image of a square metalens with an aperture of 8 µm and focal length of 8 µm.

To retrieve the focal length from the phase profile, we first calculate the radial average of the phase distribution. Then, we fit this data to a hyperbolic phase profile described by equation (3) with f as a fitting parameter. To mitigate the impact of edge effects on the metasurface and limitations in resolution, we fit the function using points only within the first Fresnel zone. The measured phase profile adheres closely to a hyperbolic variation, demonstrating the overall ability to shape the wavefront of the transmitted light. We measure respective focal length of 7.1 µm and 3.6 µm (see figure 8). This slightly lower value may be explained by the shape of the phase profile in the first Fresnel Zones. For the metalens designed with a focal length of 8 µm, the phase-shift appears to decrease more rapidly, resulting in an offset of phase reaching 0.5 radians at (r = 2.5 µm). Such variations in the phase profile can result in a lower fitted focal length and may induce defocus aberrations if not accounted in the pixel stack design. Finally, it is essential to consider uncertainties regarding the position of the object plane when assessing the precision of the methods. In our case, we determined its location based on the sharpness of the intensity image. Increased accuracy in focal length determination maybe achieved adding focusing reticle in the design. Upon examining the metalens, with a targeted focal length of 4 µm, we successfully measured a focal length that aligns with our intended target. Nevertheless, our assessment of the phase profile at the periphery revealed a deviation from the expected phase function. This discrepancy is likely attributable to the fact that peripheral Fresnel zone is sampled by only two nanopillars, which is below the threshold for adequate sampling.

Analyzing the phase function of the metalens through QLSI could enable the measurement of the focal length with sub-micron precision opening up applications related to fabrication quality assessment. Furthermore, the phase profile provides informations on aberrations levels, which could offer additional insights into metalens performance and fabrication quality.

4.4. Discussion of process impact on metalens gradient

The generalized Snell-Descartes equation tells us that light incident on a metasurface is sensitive to phase-shift variation along the direction of interest [7]. For example, the angle of deviation of a plane wave incident on an x-axis gradient follows the equation (4):

$$\sin(\theta_t)\, n_t - \sin(\theta_i)\, n_i = \frac{1}{k_0}\frac{d\phi}{dx} \qquad (4)$$

At the scale of the metasurface, this means we must examine the phase-shift gradient to perceive the change induced by the fabrication process on the wavefront control. We can calculate the gradient of the targeted phase profile from the phase function using the central difference gradient (5):

$$G_x = \frac{d\phi(x,y)}{dx} = \frac{\phi(x+dx,y)-\phi(x-dx,y)}{2dx} \qquad (5.a)$$

$$Gy = \frac{d\phi(x,y)}{dy} = \frac{\phi(x,y+dy)-\phi(x,y-dy)}{2dy} \qquad (5.b)$$

We can then compare the measured gradients along X and Y axis with the gradient extracted from the phase function calculated from equation (3). For instance, we illustrate the comparison between the experimental and theoretical gradients of an 8 µm metalens with an 8 µm focal length.

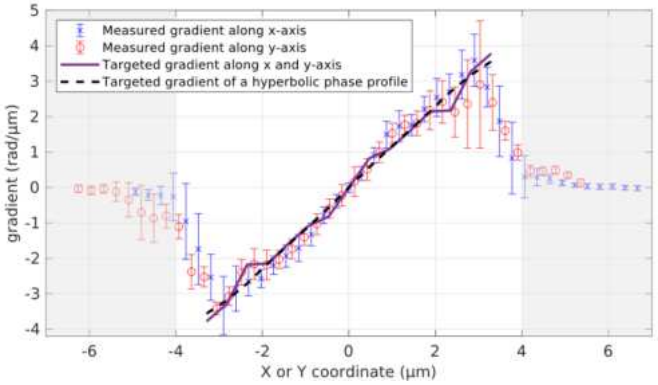

Figure 10: Comparison between measured phase gradient along X and Y axis (blue and red points) with phase gradient expected from conical nanopillars (black dotted line) and phase gradient obtained with cylindrical nanopillars (purple line). The targeted phase gradients are calculated from the theoretical phase distribution following equation (3). The resulting data is presented in the format µ±σ.

The experimental gradient depicted on figure 10, come directly from the gradient measured by the QLSI camera, which is then averaged along the axis normal to the gradient direction. We observe a correspondence between the measured and predicted gradients on both axis of the metalens. We anticipated a minor difference between the phase gradient formed by conical nanopillars and cylindrical nanopillars and we do observe an expected deviation at a distance of 2 µm from the center of the metalens on the y-axis. The validation of the gradient obtained post-fabrication verifies the fidelity of the manufactured structure to generate the intended gradient. We can evaluate the effect of gradient variation on the performance of metalenses obtained from cylindrical and conical libraries. For this aim, we look for the gradient difference between library (6):

$$\Delta G_x = G_{x,cylindric} - G_{x,conic} \qquad (6.a)$$

$$\Delta G_y = G_{y,cylindric} - G_{y,conic} \qquad (6.b)$$

By applying equation (4) and assuming small angle approximations we can compute the difference in the deviation angle between the targeted gradient and the one achieved post-fabrication:

$$\Delta\theta_x = \frac{1}{k_0 n_t}\,\Delta G_x \qquad (7.a)$$

$$\Delta\theta_y = \frac{1}{k_0 n_t}\,\Delta G_Y \qquad (7.b)$$

The difference of deviation angle distribution is represented on figure 11.

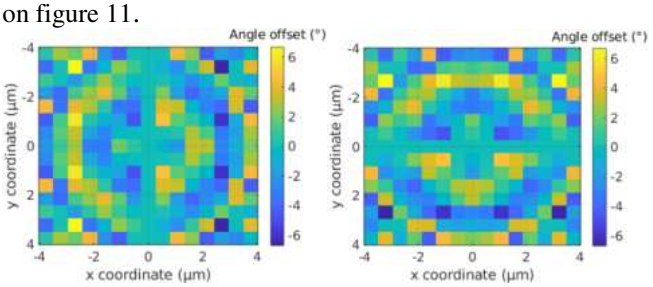

Figure 11: Deviation angle difference distribution between and ideal hyperbolic phase profile and the altered phase profile after fabrication.

The distribution of the deviation angle differences is centered on 0, with values below 2° for 48% on the metalens surface and below 4° on 77% of the metalens surface. At the center of the metalens, the difference in deviation angle is close to 0°, since both cylindric and conic libraries vary theoretically in the same manner for high diameter nanopillars (see figure 7). We have identified two regions where the difference in deviation angle seems to increase. At a radius of 2 µm, a deviation difference of ±4° is attained, which corresponds to an area containing a pillar with a diameter of 260 nm which aligns with a region where a resonance is observed (see figure 11). At the edge of the first Fresnel zone which begins at a radius of 3 µm we observe a deviation difference reaching 6°. In this region, the gradient exhibits more complex behavior due to the inverted distribution of pillar diameters, a consequence of the lens phase profile wrapping. This greater discrepancy may also be attributed to the narrower phase-shift range produced by the library of conical shapes, which does not cover the entire 0 to 2π range. These observations should be considered with caution, given that they are based on comparisons with libraries where each nanopillar is simulated under periodic conditions. There remains uncertainty regarding how these resonances behave within a metalens where such conditions are not strictly met. The resilience of the phase gradient and the contained deviation angle offset could explain the similarities observed in simulation between the two configurations (see figure 12). The simulated focal length is close to 7.3 µm for each configuration and the normalized ensquared energy shows similar concentration capabilities for both designs. The ensquared energy is determined by taking the ratio of the Poynting vector flux through a progressively expanding square aperture up to the limits of the focal plane, to the total Poynting vector flux across the entire focal plane.

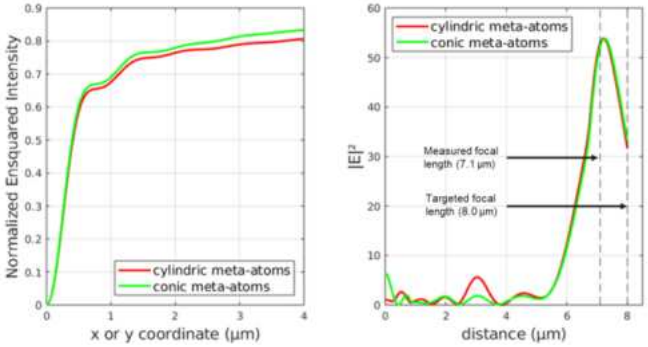

Figure 12: (Left) Normalized Ensquared Energy and (Right) Intensity profile along z-axis comparison between cylindric and conic metalens.

Conclusions

The use of wavefront imaging technology, such as QLSI, enables the analysis of wavefront at a microscopic level, thereby opening new characterization opportunities for micrometer size metasurface. Wavefront sensor allows to validate meta-atoms libraries consistency with simulations, to determine metalens focal length and to assess the impact of fabrication on the original design. In the study presented in this article we acquired valuable experimental data that corroborated our simulations and confirmed our design approach. The sidewall angle created by the process leads to a significant reduction in the volume of the nanopillars, which, in turn, is expected to cause substantial alterations in their performance. The results of the phase characterization confirmed that there was minimal shift in the focal plane and negligible change in focus efficiency. These findings mitigate the importance of process-induced sidewall angle as long as the phase gradient is preserved. This work does not cover the change in transmission resulting from the process modification which could significantly impair the metalens performance. Although characterizing designs with π phase jump poses challenges, QLSI offers a rapid and efficient solution to evaluate metalens performances. The result developed in this paper could be replicated using alternative technique such as ptychography or conventional Shack-Hartmann wavefront sensor, particularly for slow varying phase metasurface. Refinements in the analysis techniques and the experimental apparatus are projected to yield more accurate measurement results. The application of wavefront analyzers for the examination of metasurfaces could be a standard component of most design processes.

Abstract: We present a novel method to fabricate single- and multi-layer diffractive lenses on optical fibres, which is achieved via transfer bonding pre-fabricated patterns onto fiber facets. As proof-of-principle, we bond Fresnel zone plates, diffractive axicons and double-layer Fresnel zone plates onto optical fiber facets shaping output light with versatile depth-of-fields.

Hair-thin fiber endoscopes are creating new paradigms for biological imaging applications with minimal invasiveness and sub-cellular resolution. To properly perform functionalities desired by various imaging applications, fiber endoscopes may require on-tip light-shaping structures to manipulate the light flow. This can be achieved by fabricating 2D planar optics (i.e. diffractive lenses [1]) with sub-wavelength thickness, which can be designed with nano- and micro-scale structures that enable spatial control of amplitude, phase and polarization with subwavelength resolution [2, 3]. The fabrication methods include FIB milling the designed patterns, directly printing nanostructures and transferring pre-fabricated patterns onto fibers [4, 5]. Despite demonstrating effective light control at fiber facets, they are not all compatible with multi-layer stacking of devices or metasurfaces, which limits their applicability in emerging imaging applications that use multilayered structures to enable advanced imaging modalities [6].

We present a novel method to fabricate single- and multi-layer diffractive light shaping structures on optical fibres. It is achieved via transfer bonding pre-fabricated diffractive lenses onto fiber facets, which means the devices are simple to design, fabricate and transfer. The fabrication process uses a conventional top-down method to define nano- and micro-structures on bulk substrates via electron-beam lithography (EBL) and lift-off processes, but is adapted to facilitate repeated transfer to optical fibers for multi-layer fabrication. Specifically, diffractive lenses are encapsulated in optically transparent polymers, detached from the substrate by etching a sacrificial layer, then finally bonded to fibre tips. As proof-of-principle, we demonstrate Fresnel zone plates, diffractive axicons and double-layer Fresnel zone plates bonded onto optical fiber facets focusing light with versatile depth-of-fields.

Abstract: We report on the realization of form birefringent phase retarder structures using 3D laser printing technique. The retarders use anisotropic 3D photonic crystal architecture to achieve the high optical birefringence and phase retardation needed in practical applications. In particular, we report on the realization of Q-plate structures having a half-wave retardation and a spatially-variant orientation of the local optical axis, and capable of converting the spin angular momentum (SAM) to orbital angular momentum (OAM) at visible wavelengths.

Form birefringence enables control over the polarization state of light using optically-isotropic, non-birefringent materials, and is highly sought in photonics. The simplest uniaxially form birefringent structures are one-dimensional (1D) sub-wavelength gratings (SWG)[1]. Although such structures can be realized using semiconductor nanofabrication based on planar lithography, this approach requires advanced cleanroom equipment and is time-consuming. Femtosecond 3D laser printing technique, which allows rapid prototyping of 3D nano- and micro-structures[2], may allow simpler and more accessible realization of form birefringent structures. Unfortunately, earlier efforts to use this technique for the fabrication of functional quarter and half-wave retarder elements were successful only partially[3]. In order to increase the retardance, thickness (height) of the laser-printed gratings had to be increased to the degree at which the gratings became unstable mechanically and collapsed after the fabrication. As a solution, the use of anisotropic 3D photonic crystal (PhC) structures was proposed due to the superior mechanical stability and self-supporting nature of 3D structures[4]. This has enabled fabrication of super-compact form birefringent phase retarders exhibiting quarter- and half-wave retardance at optical wavelengths[4]. Here we report on application of these results for the realization of spatially variant Q-plate devices[5]. Schematic image of a Q-plate structure composed of 1D SWGs is shown in Fig. 1(a). Q-plate composed of anisotropic 3D PhC structures is schematically depicted in Fig. 1(b). In both cases orientation of the optic axis exhibits azimuthal variation while the magnitude of retardance is uniform and equal to half-wave. Opto-mechanical setup used for the fabrication is depicted in Fig. 1(c). As a light source, a femtosecond laser (Carbide, Light Conversion) is used. The laser beam is tightly focused into the bulk of photoresist SZ2080™[6], and position of the focal spot is scanned using a 3D nanopositioning system (Aerotech). Figure 1(d) shows Scanning Electron Microscopy (SEM) image of a fabricated Q-plate structure. Experimental characterization of the Q-plate retardance is shown in Fig. 1(e). Here, retardance of the diagonally-oriented sectors appears to be zero, which is an artifact caused by their orientation and the characterization technique used. Retardance of vertically and horizontally-oriented sectors is shown accurately, and is close to the required half-wavelength level. Figure 1(f) shows several experimental and simulated far-field patterns of a Gaussian beam with a central wavelength of 632 nm transmitted through the Q-plate, The incident beam has a vertical linear polarization, whereas the far-field patterns are shown for linearly-polarized vertical, horizontal, as well as right-circular polarization (RCP) components. A satisfactory qualitative agreement

between the experimental and simulated patterns illustrates the SAM-OAM converter functionality.

In conclusion, 3D laser printing of spatially-uniform and spatially-variant form birefringent 3D structures using a modified 3D PhC architecture were realized using 3D laser printing technique, and experimental evidence of their optical functionality was obtained. These results suggest that these and other similar super-compact photonic devices can be realized using the 3D laser printing technique.

Abstract: Zeiss Crossbeam FIB-SEM solutions for nanofabrication and nanomaterials research for photonics application are presented. The benefits of Zeiss Gemini optic for high-quality imaging and the long-term current stability of the Ion-sculptor focused ion beam (FIB) column for a very long-running nanostructuring process are demonstrated.

Nanophotonic is currently one of the most promising fields of research in modern optical technologies. The development, study, manipulation, and characterization of optically active nanostructures allow the creation of new materials and devices with unique optical properties for applications in nanoelectronics, biomedicine, energy, telecommunications, etc. The development of materials with advanced optical properties and the creation of nanophotonic devices is one of the main tasks of nanophotonics today.

To increase the efficiency of interaction between light and nanostructures, resonant structures or arrays of structures are used, which leads to the fact that the effective size of the interaction becomes larger than the structure itself. Therefore, producing multiple structural elements with nanometer precision with high productivity is a challenge for nanophotonic research [1,2].

For developing of new nanostructured materials and devices for nanophotonic applications the instruments for nanofabrication and control are needed. Electron microscopy is an indispensable method for studying nanophotonic materials and investigating their fundamental physical phenomena, as well as developing architectures and manufacturing nanostructured devices.

ZEISS Crossbeam FIB-SEM microscope provides a solution for nanofabrication with high precision and high spatial resolution, high stability of processing for array structure fabrication, visualization, and analytics to study their structure, chemistry, and physical properties of nanomaterials. It combines the powerful imaging and analytical performance of a field emission scanning electron microscope (FE-SEM) with superior next-generation focused ion beam (FIB) processing capabilities for the use of nanofabrication of nanophotonic materials [3].

This talk presents the advantages of nanofabrication using a ZEISS Crossbeam FIB-SEM microscope for fundamental research in photonic nanomaterials, such as metamaterials, metasurfaces, nanoantennas, quantum materials, nanoplasmonics.

A combination of high-resolution Zeiss Germini optics for imaging and super stable integrated FIB-column for nanofabrication is an ingenious solution that pushes fabrication approaches in nanodevice fabrication, enabling experiments, and demonstrating new nanophotonic concepts.

ZEISS Crossbeam FIB-SEM microscope allows to production of periodic nanostructures in different materials and visualize the structure with high resolution during the process of nanofabrication for control.

Abstract:
We demonstrate a topology optimization-based algorithm to design thin liquid crystal phase-only 2D computer-generated holograms. Our method considers the material properties of liquid crystal, such as elastic energy, by using “gradient limiter” mapping functions. With our method and photopatterning, we can produce high-fidelity and high-contrast liquid crystal-based computer-generated holograms.

We developed a topology optimization-based algorithm which generates phase-only 2D computer-generated holograms based on grayscale or binary target images, named TO-CGH. While there are several similar algorithms, one of the most notable ones is the Gerchberg-Saxton algorithm [1], but with our algorithm, we can enforce design, manufacturing, and material constraints.
Computer-generated holograms (CGHs) are a promising technique to realise direct view 3D holographic displays [2] or holographic displays for virtual (VR) or augmented reality (AR) devices [3], and other applications [4] including data encoding [5], and optical trapping[6]. The CGHs aim to compute a 2D phase or amplitude pattern which when illuminated by a coherent light source is reconstructed into a 2D or 3D image in space.
Topology optimization is a powerful computational inverse design method that has been applied in engineering and scientific research to design and optimize structures with optimal physical or mechanical properties [7]. In the last few years, methods for topology optimization for photonics and optics have emerged enabling the design of improved optical/photonic components and devices [8, 9, 10]. To our best knowledge topology optimization has not yet been used to design a liquid crystal-based optical device.
Optical elements based on liquid crystals (LCs) are widely used for different applications due to their mechanical and electro-optical properties. The average orientation of LC molecules in an enclosed LC material can be tuned via surface anchoring or external stimuli such as electric fields. The emergent optical birefringence is actively exploited in LC-based optical devices [11, 12, 13]. With photoalignment, it is possible to create alignment patterns with very fine features, but the LC will not follow an arbitrarily fine anchoring pattern. The characteristic length scale of the LC is a necessary consideration during the design of LC optical devices.
We use the TO-CGH algorithm, to generate liquid crystal-based computer-generated phase-only holograms, which we manufacture using photoalignment. The algorithm optimizes the values of a 2D phase pattern, based on the value of a cost/objective function which is calculated from the simulated far-field image, using the Fourier transform, and the target far-field image. The algorithm can impose material/design constraints by using "gradient limiter" mapping functions, which are in reality imposed by the elastic energy of the liquid crystal. The algorithm can be modified for different specific applications by using different mapping functions, objective functions or a different optimizer. We compare our algorithm to the standard Gerchberg-Saxton algorithm and discuss the effects of different initial conditions, gradient limiters, target image size, and different target images. Specifically, we apply our algorithm to two binary and four greyscale target images of various sizes and test four different gradient

limiter mappings, with all the numerical simulations supported by experiments. With our TO-CGH algorithm and photoalignment, we can make holograms, which form a far-field image with great accuracy and contrast when reconstructed using a circularly polarized laser. More generally, our liquid crystal-based devices could be used for static augmented reality and indoor lighting applications.

Finite-difference frequency-domain calculations of chiral material composites

Takamichi Terao

*corresponding author, E-mail: terao.takamichi.x0@f.gifu-u.ac.jp

Abstract

The finite-difference frequency-domain method to investigate electromagnetic wave propagation in chiral material composites was presented. Eigenmode analysis of random chiral material multilayers were demonstrated. These approaches will be useful for the analysis of chiral metamaterials and their composites.

1. Introduction

For the analysis of electromagnetic waves, the finite-difference time-domain (FDTD) method is a calculation method that can be applied regardless of the dimension of the system [1]. The transfer matrix method is also known as a numerical method for multilayer materials, but this method is limited to one-dimensional systems. The finite-difference frequency-domain (FDFD) method, on the other hand, has the advantages of much higher frequency resolution than the FDTD method and, in the case of dispersive media, can be applied to materials with arbitrary frequency dispersion properties. However, because of the numerical computations required to treat very large matrices, in many previous studies it has been applied to problems with small systems. In our previous studies, numerical studies have been performed on metamaterial composites, combining numerical methods suitable for large-scale matrix analysis with the FDFD method [2].

Chiral materials have been manufactured in the microwave range, and the analysis of chiral materials is an important topic [3]. The propagation properties of electromagnetic waves in chiral materials are also related to the topic of the creation of chiral metamaterials, and it is of practical interest to develop a numerical simulation method for this. Related to this issue, it is of interest to verify the effectiveness of the FDFD method by applying it to chiral materials, whose constitutive equations are different from those of normal materials. In a previous study [4], the FDFD method was formulated for the input of a wave source and its response in chiral materials. In this case, the problem is formulated as solving a system of equations numerically. In contrast, the FDFD method for eigenmode analysis and the calculation of photonic band structures requires the solution of large-scale eigenvalue problems. In this study, the application of the FDFD method to chiral materials was presented and its effectiveness was demonstrated.

2. Numerical method

The Maxwell equations in frequency domain are given as

$$\nabla \times \vec{E} = -j\omega\vec{B} \quad (1)$$

$$\nabla \times \vec{H} = j\omega\vec{D} \quad (2)$$

where $e^{j\omega t}$ time harmonic convention is assumed. The constitutive equations of chiral media are given by

$$\vec{D} = \varepsilon\vec{E} + \frac{\chi - j\kappa}{c_0}\vec{H} \quad (3)$$

$$\vec{B} = \mu\vec{H} + \frac{\chi + j\kappa}{c_0}\vec{E} \quad (4)$$

where ε is the permittivity of the medium, μ is the permeability of the medium, c_0 is the speed of light in vacuum, χ is the dimensionless magneto-electric parameter and describes the reciprocity of the material, κ is the dimensionless chirality parameter of the material.

As discussed in the previous section, the FDFD method can be applied irrespective of the dimension of the system. Here, the differential equations of the one-dimensional FDFD method are described. The electric and magnatic field vector components are located as shown in Fig.1.

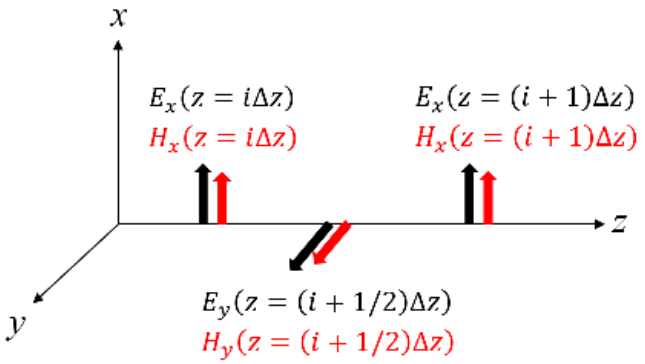

Figure 1: Positions of the field components.

Using these notations, finite-difference expressions for Maxwell's equations are given by

$$\frac{j\mu(z=i\Delta z)}{\alpha(z=i\Delta z)\Delta z}\left[H_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right) - H_y(z=(i-1/2)\Delta z)\right] + \frac{j\xi(z=i\Delta z)}{\alpha(z=i\Delta z)\Delta z}\left[E_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right) - E_y(z=(i-1/2)\Delta z)\right] = \omega E_x(z=i\Delta z) \quad (5)$$

$$-\frac{j\zeta(z=i\Delta z)}{\alpha(z=i\Delta z)\Delta z}\left[H_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)-H_y\left(z=\left(i-\frac{1}{2}\right)\Delta z\right)\right]-\frac{j\varepsilon(z=i\Delta z)}{\alpha(z=i\Delta z)\Delta z}\left[E_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)-E_y(z=(i-1/2)\Delta z)\right]=\omega H_x(z=i\Delta z) \quad (6)$$

$$-\frac{j\mu\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)}{\alpha\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)\Delta z}[H_x(z=(i+1)\Delta z)-H_x(z=i\Delta z)]-\frac{j\xi\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)}{\alpha\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)\Delta z}[E_x(z=(i+1)\Delta z)-E_x(z=i\Delta z)]=\omega E_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right) \quad (7)$$

$$\frac{j\zeta\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)}{\alpha\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)\Delta z}[H_x(z=(i+1)\Delta z)-H_x(z=i\Delta z)]+\frac{j\varepsilon\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)}{\alpha\left(z=\left(i+\frac{1}{2}\right)\Delta z\right)\Delta z}[E_x(z=(i+1)\Delta z)-E_x(z=i\Delta z)]=\omega H_y\left(z=\left(i+\frac{1}{2}\right)\Delta z\right) \quad , \quad (8)$$

where $\alpha(z)$, $\xi(z)$ and $\zeta(z)$ are defined to be

$$\alpha(z)=\varepsilon(z)\mu(z)-\xi(z)\zeta(z)\,, \quad (9)$$

$$\xi(z)=\frac{\xi(z)-j\kappa(z)}{c_0}\,, \quad (10)$$

$$\zeta(z)=\frac{\xi(z)+j\kappa(z)}{c_0}\,, \quad (11)$$

respectively.

3. Chiral multilayer systems

Multilayers composed of metamaterials with negative refractive index and different materials with positive refractive index have been investigated, and characteristic phenomena such as the zero-*n* gap have been reported in the electromagnetic wave propagation. It has also been pointed out that in random metamaterial multilayers, the nature of wave localization exhibits peculiar properties different from those of ordinary random systems [5]. In view of the above, it is interesting to clarify the wave propagation in chiral (metamaterial) composites with random structures. In this study, a multilayer of chiral material, as shown in Fig. 2, is taken up for eigenmode analysis by applying the FDFD method described above.

Calculated results of eigenmodes calculated by the FDFD method described above was shown in Figure 3. The thickness of each layer d and Δz were given by $d = 1.0$ mm and $\Delta z = 0.1$ mm, respectively. The total number of layers and the ratio of chiral material layers were given as $N = 10^3$ and 0.50, respectively. The parameters are given as $\varepsilon_1 = \varepsilon_0$, $\mu_1 = \mu_0$, $\varepsilon_2 = 4.0\varepsilon_0$, $\mu_2 = \mu_0$, $\chi_2 = 0.0$, and $\kappa_2 = 0.3$. The periodic boundary condition was imposed in z-direction. Using the implicitly restarted Arnoldi method, calculations were also performed for the case $N = 1.5 \times 10^5$. In this case, the dimension of the matrix to be diagonalized was 6×10^6, and the typical CPU time for the calculation was 123 seconds with an Intel Xeon Platinum 8360Y 2.4GHz processor.

4. Conclusions

An eigenmode analysis method based on the FDFD method suitable for bi-isotropic and chiral media was proposed. The method is applied to random chiral multilayers and the localization of electromagnetic waves is investigated numerically. This computational method is also applicable to high-dimensional systems and is expected to be a powerful method for the analysis of chiral metamaterial composites.

Applications of a ray-based metalens design tool on freeform metasurfaces

Yijun Ding[1*], Bryan D. Stone[1], and Motoyuki Otake[1]

[1]Synopsys Inc., Pasadena, CA 91101, USA

Abstract: We discuss applications of a ray-based design tool for metalenses. The application examples include (1) reflective metalens on a curved surface for near-eye displays, (2) meta-Alvarez lens, and (3) a metalens for projecting illumination to various angles from an actuated fiber tip in a scanning fiber endoscope.

Summary

In our prior work [1], we developed a ray-based design tool for metalens to reduce the complexity of design workflow. This design tool is especially useful when multiple wavelengths and incident angles need to be considered at the same time or for designing a hybrid imaging system that incorporates both conventional optical elements and metalenses. The ray-based metalens design tool is linked to a meta-atom database that describes the optical properties of the meta-atoms, including transmission and added phase for polarization-insensitive meta-atoms and Jones matrix for polarization-sensitive meta-atoms. These properties are calculated with RCWA or FDTD algorithms using local periodic approximation [2]. Using this link, we can bridge the gap between the length scale of the lenses and that of the meta-atoms, and hence reduce the complexity of the design workflow.

In this paper, we discuss applications of this ray-based design tool. The application examples include (1) reflective metalens on a curved surface for near-eye displays, (2) meta-Alvarez lens, and (3) a metalens for projecting illumination to various angles from an actuated fiber tip in a scanning fiber endoscope.

Metaform elements are formed by combining freeform optic with metasurfaces. They offer greater flexibility for aberration control and form-factor reduction. It may offer solutions to high-resolution optical systems that have volume or weight constraints. In such a system, the metalens is placed on a freeform surface and the meta-atom arrangement on the surface follows a freeform (non-rotational symmetric) function. We followed the example in [3] to design a miniature imager for a near-eye display using a metaform mirror. Note that the metaform mirror tilts the incident beam and corrects the aberrations introduced by the tilt.

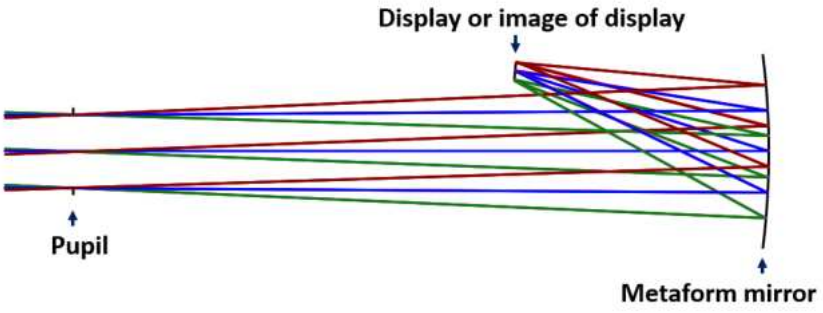

Figure 1: Miniature imager for a near-eye display using a metaform mirror.

The capability of fabricating metalens and MEMS actuation on the same device [4] has generated interests in using meta-Alvarez lens to achieve tunable focus. We started with an Alvarez lens with two cubic metalenses and improved the system performance by adding higher order terms and allowing the two metalenses to be different. Figure 2 shows the modulation transfer function (MTF) plots at the starting point and with the two strategies to improve the system

performance.

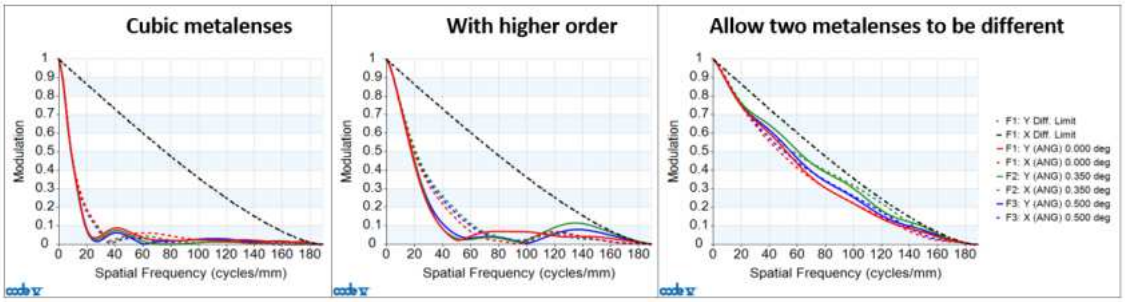

Figure 2: Modulation transfer function (MTF) of meta-Alvarez lens with two identical cubic metalenses (left), two identical metalenses with higher orders (middle), and two freeform metalenses that are allowed to be different (right). MTFs for various focuses are calculated, but not shown here due to space limitations.

Scanning fiber endoscope is one of the smallest forward viewing endoscopes. In a scanning fiber endoscope, the fiber tip can be moved with an actuator in a spiral pattern. The end of the fiber tip is on a spherical surface. A metalens can be used to project light from the fiber tip at a given location to a specific angle to provide illumination. We followed the example of [5] to design such a metalens. The design is shown in Figure 3 (left). The MTF plots in Figure 3 (right) show close to diffraction limited performance for all fields.

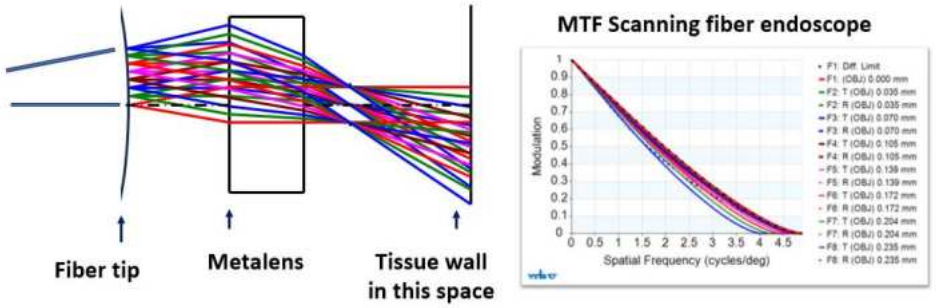

Figure 3: A scanning fiber endoscope illumination system with a metalens as the projector (left). The MTF plots for this system (right).

In conclusion, we find that the design process with the ray-based design tool is simple and intuitive. The design examples have demonstrated that the ray-based design tool offers many flexibilities, including: (1) reflective type metalenses, (2) metalenses on curved surfaces, (3) freeform arrangements (non-rotational symmetric) of the meta-atoms, and (4) designing for an application where the object and/or the image are on curved surfaces.
