Textured Broadband Antireflective Windows & Lenses

Thorlabs' Textured Antireflective (AR) Windows and Lenses have subwavelength nanostructures etched directly into the bulk optic substrate.

Compared to traditional thin-film AR coatings, these textured surfaces offer:

- Lower Reflectance Over a Broad Wavelength Range
- Lower Angular Sensitivity
- Higher Laser-Induced Damage Threshold

With options available for UV, VIS, and NIR applications, our textured AR optics are ideal for applications that require high-power lasers and long-term beam stability.

Enhanced Optical Performance

- <0.25% Average Reflectance per AR Surface
- ≥98% Transmission Over Specified Wavelength Range
- Excellent Broadband Operation
- High Resistance to Laser-Induced Damage

Built for High-Power & Precision Applications

Ultrafast Lasers | Imaging Systems | Spectroscopy | Quantum Optics | Vacuum Systems | Industrial Photonics

Our textured AR windows and lenses are offered in diameters ranging from 1/2" – 1.5" with unmounted and mounted options available.

Textured AR Lenses

Textured AR Windows

Preface

META 2026

This volume constitutes the official proceedings of **META 2026**, the 16th International Conference on Metamaterials, Photonic Crystals and Plasmonics, held on 14–17 July 2026 at Trinity College Dublin, The University of Dublin, Ireland.

Since its first edition in 2008, the META conference series has grown into one of the largest international forums devoted to metamaterials, photonic crystals, plasmonics and nanophotonics. The present volume reflects that breadth: it spans topological and non-Hermitian photonics, quantum metaphotonics, chiral and magnetoelectric phenomena, acoustic and phononic metamaterials, metasurfaces and flat optics, inverse design and machine learning, nanofabrication, biosensing and the industrial exploitation of metasurface devices.

META 2026 gathered authors from **44 countries** across five continents. Following evaluation by the Scientific Advisory Committee and the Technical Program Committee, with the support of the symposium and special-session organisers, **933 contributions** were accepted for presentation and are collected here: 5 plenary lectures, 27 keynote lectures, 1 tutorial, 731 invited and contributed oral presentations and 169 poster presentations, organised in 6 symposia, 24 special sessions, 15 general-session topics and a pre-conference workshop.

Every contribution in this volume was reviewed for originality, technical soundness and relevance to the conference scope, and is published in the form provided by its authors. The peer-review and publication policy is detailed on the following page.

We warmly thank the members of all committees and the session organisers for the quality of the scientific selection, Trinity College Dublin for hosting the conference in an exceptional setting, our sponsors and partner institutions, and above all the authors and participants who make META what it is. We hope this volume will serve as a lasting record of the conference and a useful reference for the community.

Dublin, July 2026 — *The Editors*

Ortwin Hess — Trinity College Dublin, Ireland
Said Zouhdi — Paris-Saclay University, France

Peer Review & Publication Policy

META 2026

Peer Review

All contributions submitted to META 2026 were evaluated by members of the Scientific Advisory Committee and of the Technical Program Committee, with the support of the symposium and special-session organisers. Submissions were assessed on the basis of extended abstracts or full papers; acceptance was notified together with the presentation category (plenary, keynote, invited, oral or poster).

Selection Criteria

Reviewers were asked to assess each submission against the following criteria:

- originality and novelty of the work;
- technical soundness and scientific rigour;
- relevance to the scope of the conference;
- clarity of the presentation.

Publication Ethics

Authors certify that their contribution is original, that it does not infringe any third-party rights, and that all sources are duly acknowledged. Each paper is published as supplied by its authors, who bear full responsibility for its content. At least one author of each contribution registered for and presented the work at the conference.

Indexing & Archiving

The META proceedings are published under **ISSN 2429-1390** and are **indexed in SCOPUS**. The present volume is archived and available at metaconferences.org/proceedings.

SUGGESTED CITATION OF THIS VOLUME

DUBLIN, IRELAND • 14–17 JULY 2026

Welcome to META 2026

Dear Colleagues and Friends,

It is our distinct honour and pleasure to welcome you to **META 2026**, the 16th International Conference on Metamaterials, Photonic Crystals and Plasmonics, hosted this year by **Trinity College Dublin** in the historic city of Dublin, Ireland, from 14 to 17 July 2026.

Since its inception, the META series has grown into one of the world's foremost forums on metamaterials, nanophotonics and the physics of light–matter interaction, uniting a global community of physicists, engineers and material scientists. This year's conference brings together **over 900 researchers from 45 countries**, spanning academia and industry, featuring **five plenary lectures**, **twenty-seven keynote presentations**, **six thematic symposia**, **twenty-four special sessions** and hundreds of contributed talks and posters spanning the most exciting frontiers of the field.

Beyond the science, we warmly invite you to experience the culture, history and renowned hospitality of Dublin — a UNESCO City of Literature and home to one of Europe's oldest universities. We are confident that META 2026 will be a memorable occasion for scientific exchange, new collaborations and lasting friendships.

We gratefully thank our sponsors, partners, committee members and authors, whose dedication makes this conference possible. We wish you a stimulating and enjoyable conference.

"Where light meets matter, new science begins."

The META Conference Series

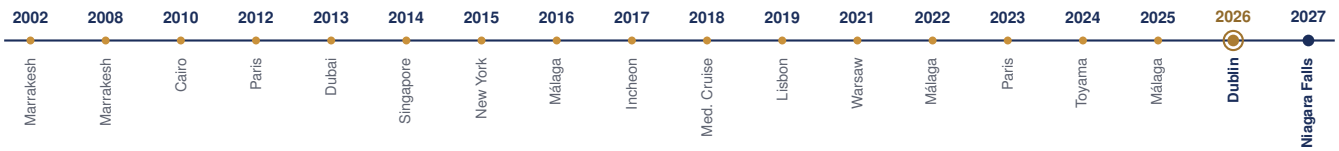
The META Conference traces its origins to the landmark **Bianisotropics 2002** meeting held in Marrakesh, Morocco, one of the earliest international conferences dedicated to advanced electromagnetic materials. As the field of metamaterials rapidly emerged during the early 2000s, the conference naturally evolved into **META**, reflecting the birth of a new scientific discipline.

The inaugural meeting, in 2002, welcomed **Prof. Victor G. Veselago**, whose pioneering theory of negative-index media laid the foundations of modern electromagnetic metamaterials. The same year, the conference founders edited *Advances in Electromagnetics of Complex Media and Metamaterials* (Springer, NATO Science Series), widely recognised as the first international scientific book to feature the term “Metamaterials” in its title.

Today, META is one of the world’s leading conference series in metamaterials, plasmonics, photonic crystals and nanophotonics. Over sixteen editions, it has welcomed more than **10,000 researchers from over 50 countries**, providing an interdisciplinary forum where physics, materials science, optics, engineering and emerging quantum technologies converge. META is recognised for bringing together pioneers of the field with early-career researchers in an environment that fosters scientific excellence, innovation and international collaboration. Its peer-reviewed proceedings are published in **open access** at metaconferences.org/proceedings.

THE META JOURNEY

From the origins of metamaterials to a global conference series



2002 Bianisotropics (origin) · 2008 first META · 2026 host · 2027 next edition

Next edition — META 2027 • Niagara Falls, Canada · 13–16 July 2027

Did you know?

- Prof. Victor Veselago attended the inaugural conference in 2002.
- The term “Metamaterials” appeared in one of the earliest dedicated international books, edited by the conference founders.
- META has been organised across Europe, Asia, Africa and North America.

Sponsors & Partners

The organisations whose generous support makes META 2026 possible — in photonics, optics and scientific publishing.

Sponsors & Partners

META 2026

We gratefully acknowledge the following organisations whose generous support contributes to the success of META 2026.

SILVER SPONSORS

Technology & Research Partners

AIP Publishing

Publisher of APL Quantum — publishing.aip.org

AIP Publishing advances the physical sciences by connecting researchers through high-quality journals and innovative publishing services. As publisher of *APL Quantum*, it supports excellence in photonics, quantum science and emerging technologies.

ZEISS

Optical and Photonics Solutions — zeiss.com

Seeing beyond

ZEISS is a global technology leader in optics and optoelectronics, providing advanced microscopy, imaging and semiconductor manufacturing solutions that enable cutting-edge scientific research.

Phasics

Wavefront Sensing Technologies — phasics.com

Phasics develops innovative wavefront sensing and quantitative phase imaging systems for industrial inspection, biomedical imaging and advanced optical metrology.

MetacMed

Metamaterials for Medical Technologies — metacmed.eu

A European Doctoral Network funded by Horizon Europe, dedicated to metamaterials and medical technologies, fostering interdisciplinary research and international training.

MAGNIFIC

Multifunctional Nanophotonics — euproject-magnific.com

A Horizon Europe Doctoral Network developing next-generation multifunctional nanophotonic materials and devices for future photonic technologies.

SmartIR

Active Light Control across IR, THz & Visible smartir.co.uk

SmartIR develops smart optical devices that actively control, shape and detect light across the infrared, terahertz and visible ranges, combining advanced materials, photonics and intelligent sensing for space, defence and industrial applications.

Frontiers

Open-Access Publisher & Open Science Platform frontiersin.org

Frontiers is one of the world's leading open-access publishers and open science platforms, making millions of peer-reviewed research articles openly available and advancing discovery across research, health and technology.

PARTNERS & SUPPORTERS

Academic & publishing partners

Trinity College Dublin

HOST INSTITUTION

One of Europe's oldest and most prestigious universities.

Université Paris-Saclay

FOUNDING ACADEMIC PARTNER

Ranked among the world's leading research universities.

Fáilte Ireland

SUPPORTER

Ireland's National Tourism Development Authority.

Thorlabs

PHOTONICS INSTRUMENTATION

Global supplier of photonics equipment supporting research worldwide.

META Awards

META recognises outstanding scientific contributions through a series of awards, presented in partnership with leading international journals.

APL Quantum META Award

PRESENTED BY APL QUANTUM · AIP PUBLISHING

Honours a landmark contribution to the physics and applications of metamaterials, nanophotonics and quantum science.

Best Poster Award

PRESENTED BY ADVANCED DEVICES & INSTRUMENTATION

Celebrates the most compelling poster, rewarding clarity, originality and scientific impact among the contributed posters.

Best Talk Award

PRESENTED BY LASER & PHOTONICS REVIEWS · WILEY & NANOPHOTONICS · WILEY

Two outstanding oral presentations are distinguished for the quality of their science and the excellence of their delivery, underlining the breadth of excellence across the technical program.

Award recipients are announced during the conference. We warmly thank our award partners for their generous support.

Plenary Talks

META 2026

PLENARY 5 plenary lectures · 35 minutes each including Q&A

PLENARY LECTURE 1

PLENARY · 35 min

Jeremy J. Baumberg

University of Cambridge, UK

Directs the NanoPhotonics Centre at the University of Cambridge and the Cambridge Nano Doctoral Training Centre. A leading innovator in nanoscale optical materials. **Fellow of the Royal Society**, Optica and the Institute of Physics. Recipient of the IoP Faraday Gold Medal (2017), the Royal Society Rumford Medal (2014) and the IoP Mott Lectureship (2005).

TALK TITLE

Precision Nanogap Metamaterials for Tracking Bioanalytes using SERS and SEIRA

ABSTRACT

I will discuss a range of recent key advances that give robust, repeatable, and recleanable nanogap plasmonic sensors, as well as midIR metamaterials enabling real-time flow electrochemistry.

PLENARY LECTURE 2

PLENARY · 35 min

Alexandra Boltasseva

Purdue University, USA

Ron and Dotty Garvin Tonjes Distinguished Professor of Electrical and Computer Engineering at Purdue University. PhD from the Technical University of Denmark (2004). **Fellow of NAI, MRS, IEEE, Optica and SPIE.** Former Editor-in-Chief of *Optical Materials Express*. Recipient of the **2023 R.W. Wood Prize** (Optica), 2022 Guggenheim Fellowship, MRS Outstanding Young Investigator (2013) and IEEE Photonics Society Young Investigator Award (2013).

TALK TITLE

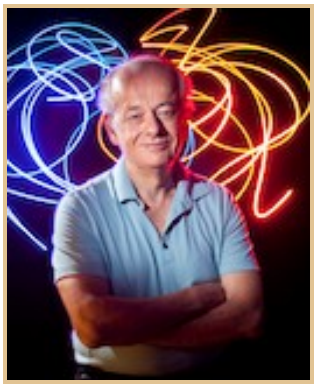
Materials-Driven Photonics: Toward Tunable and Extreme Light Control

ABSTRACT

We study tailorable and dynamically tunable properties of transparent conducting oxides (TCOs) and transition metal nitrides (TMNs) for applications in all-optical modulators and flat optics. We also investigate metal-to-insulator transition in ultra-thin TMN films operating in the so-called transdimensional regime.

PLENARY LECTURE 3

PLENARY · 35 min



Federico Capasso

Harvard University, USA

Robert Wallace Professor of Applied Physics at Harvard University. Co-inventor of the quantum cascade laser and a pioneer of metasurfaces and flat optics. **Member of the U.S. National Academies of Sciences and Engineering.** Recipient of the IEEE Edison Medal, the Balzan Prize and the King Faisal Prize for Science.

TALK TITLE

Metasurfaces: From Classical to Quantum Optics

ABSTRACT

We demonstrate a generalized Hong-Ou-Mandel effect using metasurfaces and graph theory, enabling controlled multi-photon bunching, antibunching, and entanglement across parallel matrix-encoded spatial modes. Our theoretical framework predicts the device's behavior and facilitates the design of dual graphs representing both metasurface-based multiport interferometer designs and the complex non-classical correlations they generate

PLENARY LECTURE 4

PLENARY · 35 min

Rachel Grange

ETH Zurich, Switzerland

Full Professor of Photonics at ETH Zurich (since 2025); previously Associate and Assistant Professor there. Research on integrated optics and nonlinear nanophotonics with metal-oxides — notably thin-film lithium niobate and barium titanate — for classical and quantum devices.

TALK TITLE

Quadratic Nanomaterials for On-Chip Classical and Quantum Devices

ABSTRACT

Here I will present our recent progress in top-down fabrication of lithium niobate devices and bottom-up approaches, including the assembly of randomly oriented nanocrystals and sol-gel processes, to generate nonlinear classical and quantum signals. Finally, I will describe how these platforms are suited for nonlinearities in machine learning.

PLENARY LECTURE 5

PLENARY · 35 min

Ruwen Peng

Nanjing University, China

Distinguished Professor in the School of Physics, Nanjing University, and principal investigator at the National Laboratory of Solid State Microstructures. Research in nanophotonics, metamaterials, plasmonics, photonic quasicrystals and phononic transport. Recipient of the National Science Foundation for Distinguished Young Scholars (China, 2006), the Chinese Young Women Scientists' Award (2011) and the Xie Xide Award (2013).

TALK TITLE

Metasurfaces as a Platform for Classical and Quantum Light Control

ABSTRACT

In this talk, we present metasurfaces as a platform for classical and quantum light control. The approaches achieve potential applications in optical display, data storage, information encryption, and quantum information networks.

META 2026 • PROGRAM BOOKLET

TALK TITLE

Hybrid Techniques for Inverse Design and Knowledge Discovery in Large-Scale Multifunctional Nanophotonic Devices

ABSTRACT

This talk is focused on a new class of inverse design tools for large-scale nanophotonic structures by combining rigorous gradient-based techniques with machine learning tools. By combining these two classes of design tools, dimensionality of the design space and the computation requirement can be reduced by 2-3 orders of magnitude.

KEYNOTE 2

KEYNOTE · 30 min

Girish S. Agarwal

Texas A&M University, USA

Distinguished Professor of Physics, Texas A&M. Renowned for fundamental contributions to quantum optics.

TALK TITLE

QED of Chiral Waveguides Coupled to Quantum Emitters

ABSTRACT

Waveguide QED is a quantum platform in which photons mediate long range interactions in a one dimensional channel. This talk highlights waveguide QED with quantum emitters, emphasizing quantum interference (Fano minima and transparency), chiral interactions, quantum nonreciprocity, and steady state entanglement, together with squeezed bath stabilization and dissipative phase transitions.

KEYNOTE 3

KEYNOTE · 30 min

Esther Alarcón Lladó

NWO-I AMOLF Institute, The Netherlands

Tenured Group Leader at the NWO-I AMOLF Institute and, since 2023, Professor by special appointment on Nanoelectrochemistry at the University of Amsterdam; chair of the Dutch Physics Council. She earned her PhD from the University of Barcelona in 2009, held Marie Curie and Ambizione Energy postdoctoral fellowships at A*STAR (Singapore), LBNL Berkeley and EPFL Lausanne, and in 2016 founded the 3D Photovoltaics group at AMOLF, working at the interface of optics, nanotechnology and electrochemical scanning probe microscopy.

TALK TITLE

Managing light and matter at the nanoscale for sustainable energy conversion

ABSTRACT

We realized a 1D coupled nanolaser chain enabling topologically protected bright zero modes. Our design exploits coupling sign inversion through photonic crystal barrier engineering. We present the design parameters, numerical simulation results, and preliminary experimental results from the first fabricated structures.

KEYNOTE 4

TALK TITLE

Probing Nanoscale Optical Nonlocal and Nonlinear Effects Through Free Electrons

ABSTRACT

We explore how free electrons probe nanomaterials' nonlocal and nonlinear optical responses with unmatched spatial resolution, examining harmonic generation, Kerr nonlinearities, and interference of inelastically scattered electrons, while lateral deflections from finite momentum transfers reveal nonlocal effects.

Rob Devlin

Metalenz, USA

Co-founder and CEO of Metalenz, the first company to bring metasurface technology to mass markets, with more than 150 million metasurface optics integrated into consumer devices for 3D sensing. Recipient of Optica's Kevin P. Thompson Optical Design Innovator Award (2025).

TALK TITLE

Scaling the Metasurface Market: From Flat Optics to Sensor-Integrated Intelligence

ABSTRACT

From lab breakthrough to mass-market deployment, this presentation explores the commercialization of metasurfaces at Metalenz-highlighting key drivers, technical challenges, and emerging applications. Metasurfaces are no longer just flat optical elements; they are evolving into system-level platforms for intelligent perception, enabling more perceptive, accurate, and efficient vision systems.

TALK TITLE

Topological Phononic and Photonic Modes in Optomechanic Crystals

ABSTRACT

In this work we present a theoretical investigation of structures that simultaneously support localized topological phononic and photonic modes, enabling enhanced optomechanical interactions. Two platforms are considered: (i) a one-dimensional nanobeam engineered within the framework of the Su-Schrieffer-Heeger (SSH) model and (ii) a two-dimensional honeycomb membrane.

Bert Hecht

University of Würzburg, Germany

Professor of Experimental Physics at the University of Würzburg. Research on near-field optical microscopy, plasmonics and the enhancement of light–matter interaction on the nanometer scale.

TALK TITLE

Nanorobots Steered by Light

ABSTRACT

Plasmonic nanoantennas can be used to redirect scattered light, causing momentum transfer via photon recoil. By exploiting different degrees of freedom of light, such as helicity and photon energy, several antennas can be driven selectively with minimal crosstalk to neighboring structures even at subwavelength distance.

TALK TITLE

Plasmonic HfN-Gated Monolayer MoS_2 for Giant Trion Modulation and Scalable Optoelectronic Devices

ABSTRACT

We demonstrate a chip-scale, gate-tunable light-emitting platform that integrates scalable monolayer MoS2 with a HfN plasmonic gate electrode. The favorable band alignment enables giant trion modulation, yielding a PL modulation depth of 24%.

TALK TITLE

Modeling Boundary Effects in Acoustic Metamaterials by a Relaxed Micromorphic Continuum

ABSTRACT

To accurately describe elastic wave propagation in these materials characterized by their heterogeneities or microstructures, it is essential to adopt non-local or enriched modeling approaches. In this context, we propose the relaxed micromorphic model (RMM), which effectively captures these phenomena by treating the material as continuum with enriched kinematics.

TALK TITLE

Photonic Time Crystals: Transport, Emission, Squeezing

ABSTRACT

Photonic time crystals provide a unified setting for studying wave transport, light-matter interaction, and quantum fluctuations in driven media. Here we show that seemingly different phenomena in these systems, including transport, emission, and squeezing, can be understood within a common Floquet framework that connects classical and quantum descriptions.

TALK TITLE

Chiro-optical micro-/nano-imaging and near-field interaction

ABSTRACT

We developed chiral photoinduced force microscopy (PiFM) to visualize nanoscale chiro-optical responses using circularly polarized light. Chiral and achiral plasmonic nanostructures were imaged, revealing local chiral fields and probe-induced chirality. This approach enables nanometer-scale chiro-optical imaging beyond conventional near-field techniques.

Professor at ETH Zurich (Mechanical and Process Engineering). Research in nano-optics and optomechanics, with applications from fundamental physics to biomedicine. Recipient of three ERC grants.

TALK TITLE

Meta-Optics Based Optomechanics

ABSTRACT

We discuss the use of metaoptics in optomechanics. By exploiting resonant silicon meta-atoms, we achieve enhanced optomechanical performance and deterministic control over optical forces. We show that engineering multipolar Mie resonances allows for switching between attractive and repulsive forces, directly mirroring the behavior of two-level systems.

TALK TITLE

Metamaterials at Crossroads: From Quantum to Space-Time Photonics

ABSTRACT

We discuss quantum photonics based on the recently discovered single-photon emitters in silicon nitride and the avalanche-enhanced optical modulation in silicon at single-photon intensities. Then, we show that transparent conducting oxides (TCOs) operating in the near-zero index (NZI) regime can enable extreme time-varying media.

TALK TITLE

Chirality in Light–Matter Interaction

ABSTRACT

Chiral metasurfaces enable strong control of light matter interaction at the nanoscale. Planar plasmonic architectures generate superchiral electromagnetic fields that enhance chiroptical responses beyond natural systems. These engineered platforms support enantioselective sensing, molecular spectroscopy, and quantum photonics by amplifying weak optical signatures of molecular chirality.

TALK TITLE

Electric Dipole Moments via Electromagnetic Duality

ABSTRACT

We present a duality-based framework that maps EDM physics onto Zeeman structure. Stark-induced dipoles are represented through a magnetic current description of microscopic polarization, while intrinsic dipoles remain tied to spin. A Bohr scale dipole unit and pseudo angular momentum organize dipole operators and selection rules.

TALK TITLE

Inverse designed, densely integrated classical and quantum photonics

ABSTRACT

Recent breakthroughs in photonics design, along with new nanofabrication approaches and heterogeneous integration play crucial roles in building photonics for applications including optical interconnects and quantum technologies. This design breakthrough is named photonic inverse design, and refers to efficiently searching through the space of all possible photonic device geometries.

Father of the photonic bandgap concept, who coined the term "photonic crystal". **Member of the National Academy of Sciences, National Academy of Engineering and the American Academy of Arts and Sciences.** Recipient of the Buckley Prize, the Isaac Newton Medal and the IEEE Photonics Award.

TALK TITLE

Can Physics and Optical Science Expedite Artificial Intelligence?

ABSTRACT

Artificial Intelligence (AI) requires intensive optimization calculations and is now demanding nuclear power for data centers. All the variables in an AI model must converge, to expedite the calculations. Data center energy is dominated by data communication which costs 1pJ/bit, about 6 orders of magnitude higher than the Landauer Limit.

TALK TITLE

Generating Optical Merons through Spin–Orbit Coupling in Anisotropic Metamaterials

ABSTRACT

We will discuss the enhanced spin-orbit coupling in strongly anisotropic metamaterials which provides efficient conversion of polarisation state of the transmitted light and results in meron-type topological structures of the electromagnetic field. Flexible control of polarisation and its topological properties is important for optical manipulation, communications, metrology and quantum technologies.

TALK TITLE

Optical metrology a myriad times finer than Robert Hook's and a million times faster than Eadweard Muybridge's

ABSTRACT

By training metrological estimators, employing topologically structured light, and engineering the flow of Fisher information, optical metrology can surpass conventional resolution limits by orders of magnitude-achieving atomic-scale precision at megahertz acquisition rates.

META 2026 • PROGRAM BOOKLET

Pre-Conference Workshop

COST TETRA Workshop on Biophotonics & Biometamaterials · 13–14 July 2026.

Pre-Conference Workshop

META 2026

COST · TETRA 5th Workshop on Biophotonics and Biometamaterials

Workshop Info

Dates: 13–14 July 2026 **Location:** Beckett Room, Trinity Conference Centre – Arts Building

Day 1 — Monday 13 July 2026

09:00 – 09:10 Registrations

09:10 – 09:20 **Presentation of the Workshop**
Tatjana Gric — Vilnius Tech, Lithuania

09:20 – 09:40 **COST travel reimbursement rules: presentation of the Grant Holder Manager**
Fikret Alpay Teksen — Vilnius Tech, Lithuania

09:40 – 10:30 Affinity Diagramming

10:30 – 11:00 ***Refreshment Break***

CANCER DIAGNOSTICS AND TREATMENT

11:00 – 11:30 **Wavelets–Fourier decomposition for wide-beam scattering and image-based analysis: bridging photonic metasurfaces and biomedical tissue diagnostics**
Kofi Edee — University of Clermont Auvergne, France

11:30 – 12:00 **A miniaturized implantable antenna for brain signal monitoring**
Moti Haridim — HIT—Holon Institute of Technology, Israel

IMAGING TECHNIQUES

12:00 – 12:30 **Multi-photon imaging and compositional analysis by spectral deconvolution in noninvasive vascular scaffolds**
Steve Smith — South Dakota Mines, USA

12:30 – 13:00 **Partial Mueller polarimetry for real-time diagnostic imaging of biological tissues**
Tatiana Novikova — École Polytechnique, France

13:00 – 13:30 **Aggregated plasmonic gold nanoparticles for surface-enhanced Raman spectroscopy**
Miklos Veres — HUN-REN Wigner Research Centre for Physics, Hungary

13:30 – 13:40 Group Photo

13:40 – 15:00 ***Lunch Break***

NOVEL METAMATERIALS

15:00 – 15:30 **Atomistic theory of hot carriers in metallic nanoparticles**
Johannes Lischner — Imperial College London, UK

15:30 – 16:00 **Metamaterials: from theory to applications**
Tatjana Gric — Vilnius Tech, Lithuania

16:00 – 16:30 **Effects of the order-to-disorder transition on plasmonic metasurfaces**
Jerome Plain — University of Technology of Troyes, France

Day 2 — Tuesday 14 July 2026

BIOPHOTONICS MEETING MEDICINE

09:00 – 09:30 **Early-stage testicular cancer detection via a multi-antenna Vivaldi sensor configuration** *(online)*
Fikret Alpay Teksen — Vilnius Tech, Lithuania

09:30 – 10:00 **Biophotonics for psychological stress measurements**
Victoria Barygina — Università di Firenze, Italy

10:00 – 10:30 **From biometamaterials to regulatory readiness: COST Action TETRA and in silico NAMs for biomedical efficacy and safety**
Ivana Vinković Vrček — Inst. of Medical Research & Occupational Health, Croatia

10:30 – 11:00 ***Refreshment Break***

FUTURE TRENDS

11:00 – 11:30 **Compact and efficient Quantum Dot based room-temperature THz sources**
Edik Rafailov — Aston University, UK

11:30 – 12:00 **Targeted gold nanorod conjugates for photothermal treatment of cancer**
Anatoliy Pinchuk — University of Colorado, USA

12:00 – 13:00 Storyboarding

13:00 – 15:00 ***Lunch Break***

15:00 – 16:00 Post-Up Activity

COST Action CA23125 — TETRA (The metamaterial formalism approach to recognize cancer)

Chirped Pulse Propagation and Control in Reverberant non-Hermitian Settings Enabled Through Complex Time Delay 260
Isabella Giovannelli, Thomas M. Antonsen, Steven Anlage

Plasmonic Nanostars: Engineering Optical Tunability for Enhanced Efficiency 262
Nicolas Pazos Perez

Copper-based plasmonic nanohole arrays for electromagnetic field enhancement 264
Madiha Amrani, Tô Nguyet, Gaëtan Lévêque, Mohamed El Ghafiani, E. H. El Boudouti, Yan Pennec, Rabah Boukherroub, Bahram Djafari-Rouhani

Metasurface□Driven Control of Quantum Emitters: From Visible Nanolasers to Telecom Photonics 266
Giovanni Mattei

Two Distinct Quasi-Bound States in the Continuum in an Amorphous Silicon Metasurface 268
Hicham Mangach, Pascal Szriftgiser, Gaëtan Lévêque, Yan Pennec, Bahram Djafari-Rouhani

Self enhanced generative metasurface inverse design 270
Mathys Le Grand, Pascal Urard, Loumi Trémas, Damien Maitre, Louis-Henri Fernandez-Mouron, Régis Orobtchouk

Spatial Fourier filtering with metagratings 272
Mahmoud A. A. Abouelatta, Karim Achouri

Foundry-Ready Multi Laser Terahertz Bandwidth Photonic Isolator via Electro-optic Synthetic Motion 273
Kyunghun Han, Yiliang Bao, Junyeob Song, David Long, Sean Bresler, Daron Westly, Jason Gorman, Thomas LeBrun, Kartik Srinivasan, Vladimir Aksyuk

Miniaturized Full-Color Waveguide Combiner for AR Headsets: Wide Field-of-View and High Resolution via Compound Metagratings 274
Oksana Shramkova

Enhancing the Sensitivity of Low-cost Zero-Reflection Metasurfaces for Clinical Translation 276
Nurten Koc, Ali Belarouci, Serap Aksu

Plasmon Assisted Up Conversion for High Performance Photochromic Smart Windows 277
Ovidio Peña-Rodríguez, Chang Woo Kim, Edgardo Gabriel Santoro, Umapada Pal, Young Soo Kang

Photonic integrated circuits on fiber tips for lab-on-fiber sensing 279
Arthur Bouamra, Pieter Vijn, René P. J. van Veldhoven, Jui-Hung Chen, Shuo-Yen Tseng, Andrea Fiore

Attosecond Extreme-Ultraviolet Skyrmion Pulses from High Harmonic Generation 280
David Marco, Luis Plaja, Carlos Hernandez-Garcia

Nanoscale Photonic Topological Insulators 282
Xiaoyong Hu

Hard and Soft: Exploiting Nanoplasmonics in Sensing Applications 283
Luca De Stefano, Valeria Nocerino, Bruno Miranda, Principia Dardano

Optical Phenomena in Time-Varying Transparent Conductors 284
Marcello Ferrera, Wallace Jaffray, Sven Stengel

Tailoring valley polarization and optical nonlinear effect in transition-metal dichalcogenides 285
Mu Wang, Ruwen Peng

Advanced Manufacturing Tools for Data□Processing Fiber Photonics Fabrication 286
Marcos D. Vozer Felisberto, Andrey Machnev, Thomas W. Burkle, Maxwell H. Jancich, Babak Seradjeh, Phillip Richerme, Alexander Gumennik

Chiral Diffraction from Quasiperiodic Monotile Lattice Based on Aperiodic Hat Tiling 289
Yuto Moritake

Silicon Nitride Photonics for High-Performance Systems 291
Frederic Gardes, Ilias Skandalos, Yaonan Hou, Dun Qiao, Huiwen Deng, X. Yu, Jaeseong Park, Chong Chen, Mingchu Tang, Michelle Paparella, Lifeng Bao, Elliot Sandell, Thalia Dominguez Bucio, Jérémy Moeyaert, Thierry Baron, Peter Smowton, Huiyun Liu, Alwyn Seeds, Stelios Simos, T. Moschos, Miltos Moralis-Pegios, Isaac Johnson, Theodore Rangarajan, James Gates, Nikos Pleros

Spatiotemporal Metasurface for Unconventional Control of Electromagnetic Waves 293

Anatoly Efimov, Chun-Chieh Chang, Simo Pajovic, Wilton J. M. Kort-Kamp, Hou-Tong Chen, Diego A. R. Dalvit, Abul Azad

Symmetry-Broken q-BIC Dielectric Metasurfaces for Enhanced Linear and Nonlinear Light-Matter Interactions **295**
Wen-Hui (Sophia) Cheng, Hung-Yi Wu, Tzu-Hsiang Liu, Hsin-Yu Shen

Femtosecond Laser Direct-Written Optical Fiber Microstructure Devices for Laser Applications **296**
Xuewen Shu

Novel Materials for UV Plasmonic Nanostructures **298**
Michael Foltýn, Tomáš Šikola, Michal Horák

Plasmonic Enhancement of Second Harmonic Generation from a van der Waals Crystal **300**
Hong Liu

3D topological photonics: 3D Chern photonic insulators and electromagnetic axions **302**
Chiara Devescovi, Antonio Morales-Perez, Maia G. Vergniory, Aitzol Garcia Etxarri

Dirac-Polariton Bose-Einstein Condensation at Room Temperature via Bound States in the Continuum in a WS□ Monolayer **303**
Bruno Miranda, Silvia Romano, Scott Duhey, Aidar Kemelbay, Arian Gashi, Vito Mocella, Ivo Rendina, Adam M. Schwartzberg, Gianluigi Zito

Manipulate Multispectral 3D Polarization Structures with Optical Metasurfaces **304**
Xianzhong Chen, Hammad Ahmed, Chunmei Zhang

Breakdown of the Kirchhoff's law of thermal radiation by a spatiotemporally modulated nonreciprocal metasurface **305**
Diego A. R. Dalvit, Anatoly Efimov, Chun-Chieh Chang, Simo Pajovic, Wilton J. M. Kort-Kamp, Dongsung Kim, Hou-Tong Chen, Abul Azad

Theory of Dispersive Space-Time Interfaces **306**
Alessandra Contestabile, Maria Antonietta Vincenti, Giuseppe Castaldi, Michael Scalora, Marcello Ferrera, Vincenzo Galdi, Carlo Rizza

Exciton Polarons in 2D semiconductors **308**
Carlos Alberto Maciel Escudero, Giuseppe Meneghini, Jamie Fitzgerald, Ermin Malic

Janus Vortex Meta-Laser **310**
Lili Gui, Yiyuan Xu, Hao Chen, Kun Xu

SPDC in Thin-Film LN: From Tunable Polarization Entanglement to Doubly-Resonant Metasurfaces **311**
Maximilian Weissflog, Saniya Shinde, Shaun Lung, Jinyong Ma, Sina Saravi, Thomas Pertsch, Andrey Sukhorukov, Frank Setzpfandt

Closed-form conditions for parametric amplification in open photonic time crystals **312**
Adrià Canós Valero, Sergei Gladyshev, David Globosits, Stefan Rotter, Egor A. Muljarov, Thomas Weiss

Cavity-Enhanced Superfluorescence and Lasing Transitions in Two-Dimensional Single-Crystal Perovskite Superlattices **315**
Jae Yong Suh

Towards Realization of Ideal Anapole Excitations **317**
Radoslaw Kolkowski, Matti Kaivola, Sagar Sehrawat, Andriy Shevchenko

Material and Device Optimizations for Wavelength-Selective Infrared Devices **319**
Tadaaki Nagao, Keisuke Watanabe, Thien Duc Ngo

Programmable Broadband Nonlinear Infrared Imaging with Dielectric Metasurfaces **320**
Ze Zheng

Shining Light on 2D Antiferromagnets **322**
Viktoriia Radovskaia, Mengxing Na, Theo H. Rasing, Alexey V. Kimel, Dmytro Afanasiev

Chiral Photonic Environments for Coherent Control of Valley Excitons **324**
Hassan Lamsaadi, Aurélien Cuche, Hugo Lourenço Martins, Vincent Paillard, Sébastien Weber, Jean-Marie Poumirol, Gonzague Agez

Optical Properties Tuning of Quantum Emitters in WSe2 Monolayers 325
Javier Martín-Sánchez

Photonic Inverse Design using differentiable electromagnetic solver for CMOS image sensors and Photonic Integrated Circuits 327
Hyunsung Park, Jaekwan Kim, Subeom Song, Junho Lee, Yongseob Yun, Sungmo Ahn, Choonlae Cho, Sooyeon Lee, Sookyoung Roh, Seokho Yun

Hybrid Photonic Crystal Platforms: Enabling High-Efficiency Photonic Devices and Novel Functionalities 328
Tae-Yun Lee, Hansol Lee, Lakjong Jeong, Heonsu Jeon

Limited Size Object Microscopy - Smaller Objects, Higher Resolution 329
Giorgio Adamo, Taeyong Chang, Eng Alk Chan, Nikolay I. Zheludev

Subwavelength metamaterials for modal and thermo-optic control in silicon interferometers 330
Aitor Villafranca Velasco, Irene Olivares, Irena Stolic, Raquel Fernández de Cabo, Alejandro Sánchez-Sánchez, Daniele Melati, Carlos Alonso-Ramos, David González-Andrade

Competing Lattice and Defect Dynamics Govern Terahertz-Driven Ferroelectricity in Quantum Paraelectric SrTiO3 332
Jingbo Qi

Advanced Contactless Manipulation of Micro- and Nanostructures: from Optical Forces to Acoustic Tweezers 334
Maria G. Donato, Silvie Bernatova, Antonino Foti, Pietro Giuseppe Gucciardi, Maria Antonia Iatì, Alessandro Magazzù, Andrea Mandanici, Onofrio Maria Maragò

Thermalization Speed of Highly Multimode Nonlinear Systems 335
Emmanouil Theodoros Kokkinakis, Konstantinos G. Makris, Demetrios N. Christodoulides

Advancements in Silicon Nitride Platform 337
Khaled Mnaymneh

Electrostatic Repulsion as a Governing Mechanism in Near- and Far-Field Optical Binding of Gold Nanoparticles 339
Marques Manuel

Foundry Enabled Chip-scale Photonics Technology and Applications 340
Yeshaiahu (Shaya) Fainman

Wide-angle Nonreciprocal Thermal Emitters with Strong Contrast Between Absorptivity and Emissivity 341
Georgios Veronis, Md Tanvir Emrose, Ming Zhou, Gabriel Nedelea, Roya Ebrahimi Meymand, Shanhui Fan

Compact High-Q Photonic Crystal Cavities with Improved Robustness to Disorder 342
Nicoletta Granchi, Camilla Gonzini, Matteo Lodde, Gabriele Calusi, René P. J. van Veldhoven, Andrea Fiore, Guillermo Arregui, Francesca Intonti

Graded-index metamaterials for on-chip control over mode exchange 344
Raquel Fernández de Cabo, Alejandro Sánchez Sánchez, Daniele Melati, Carlos Alonso Ramos, Aitor Villafranca Velasco, David González Andrade

Mechanistically Guided Plasmonic Dendrites for Selective CO□ Reduction 346
Anjalie Edirisooriya, Zelio Fusco, Ning Lyu, Christin David, Fiona Beck

Lasers that run cool on their own 348
Chun-Wei Chen, Michel J. F. Digonnet, John Ballato, Peter D. Dragic, Martin Bernier, Enkeleda Balliu

Perovskite Superfluorescence and High Temperature Macroscopic Quantum Effects 349
Kenan Gundogdu

Reversible metal electrodeposition for high-contrast active optical and metamaterials 350
Po-Chun Hsu

From Simulation to Design: AI-Solvers andAI-Optimizers for Electromagnetics 351
Raphael Pestourie

Topology Optimized High-Q Photonic Crystal Resonators for the THz Band 353
Stephen Hanham

Intelligent Nanofabrication for Nanophotonics: Quantifying and Understanding Process Variability 355
Wenhan Zhang, Ben Mills, Kevin MacDonald

Manipulating matter with vector twisted light 356
Mohamed Babiker

Programmable Nanophotonics with the Plasmonic Phase-Change Material In3SbTe2 357
Lukas Conrads, Matthias Wuttig, Thomas Taubner

Tailorable Light Driven Reaction with Phase-changing Material Metasurface 358
Ning Lyu, Anjalie Edirisooriya, Dawei Liu, Zelio Fusco, Shenyou Zhao, Fiona Beck, Christin David

Hot Carriers in Balance: Molecularly Functionalised Nanogaps Resolve Wavelength-Dependent Plasmonic Charge Generation 359
Ishaan Lohia, Santiago Rodríguez-Jiménez, Charlie Readman, Christine Joy Querebillo, Rowena Davies, Gregory Q. Wallace, Duncan Graham, Erwin Reisner, Bart de Nijs

Solution-Processed Quantum Light Sources Spanning the Visible to the Infrared 360
Jennifer Hollingsworth, Eric G Bowes, Han Htoon

Self-powered refractory NIR plasmonic photodetectors with compact, broadband, and quantitative spectroscopy 361
Eslam Abubakr, Saito Saito, Hironori Suzuki, Tetsuo Kan

Bound-State-in-the-Continuum Lasing Modes inInGaAs Nanowire Photonic Crystals 363
Bogdan-Petrin Ratiu, Ji Tong Wang, Kyle S. Netherwood, Nicolae-Coriolan Panoiu, Li Qiang, Sang Soon Oh

Circularly polarized Raman scattering for optical spin detection in silicon metasurfaces 364
Guillermo Serrera, Rasmus H. Godiksen, Lex M. Dedding, Tom T.C. Sistermans, Ershad Mohammadi, T. V. Raziman, Søren Raza, Pablo Albella, Alberto G. Curto

Boosting nonlinear optical response in resonant metal-dielectric metasurfaces at visible and UV spectrum 365
Crina Cojocaru, Shroddha Mukhopadhyay, Michael Scalora, Jose Trull

Advancements in Chiral Nanophotonics via Block Copolymer Supramolecular Assembly and Plasmonic Antenna-Reactor Catalysis 368
Dong Ha Kim

Tailoring Light-Sound Interactions in Photonic Integrated Circuits 369
Moritz Merklein

Photonic cluster state Generation from a Telecom-Emitting Quantum Dot 370
Giora Peniakov, Reza Hekmati, Johannes Michl, Mohamed Helal, Moritz Meinecke, Jochen Kaupp, Yorick Reum, Andreas Pfenning, Sven Höfling, Tobias Huber-Loyola

Liquid crystalline polymer photonics for all-optical signal modulation 372
Sara Nocentini, Daniele Martella, Francesco Riboli, Camilla Parmeggiani, Diederik Wiersma

Plasmon-Driven pn Junctions in Graphene Revealed by Raman Spectroscopy and Flexural Phonon Coupling 373
Maciej Wiesner, W. Strupinski, Jayanta Sarkar, Aleksandra Trzaskowska, Nojoon Myoung, Andriy Serebryannikov

Semiconductor Nanocrystal Optoelectronics for Classical and Quantum Light Generation 375
Emek Goksu Durmusoglu, Hilmi Volkan Demir

III-Nitrides based Integrated Nonlinear Photonics 377
Changzheng Sun, Bing Xiong, Jian Wang, Lai Wang, Zhibiao Hao, Yanjun Han, Hongtao Li, Lin Gan, Yi Luo

Optics of 3D Second-Harmonic Photonic Crystals from Colloidal Self-Assembly Templating 379
Thomas Kainz, Ülle-Linda Talts, Rachel Grange, Ullrich Steiner, Viola Vogler-Neuling

Resolving Surface Plasmon Dispersion with Fabry-Pérot-Assisted Extraordinary Optical 381

Transmission
Youssef El Badri, Hicham Mangach, Mustapha Bahich, Yan Pennec, Bahram Djafari-Rouhani, Younes Achaoui

Tunable resonances in doubly anisotropic, high-index MoS2 nanoplatelets **383**
Bingying You, Tom T.C. Sistermans, Alberto G. Curto

Near field imaging and spectroscopy of complex stacking of semiconductors **385**
Laure Tailpied, Clément Gureghian, Frederic Fossard, Jean-Sebastien Mérot, Fernando Gonzalez-Posada-Flores, Jean-Baptiste Rodriguez, Gregory Vincent, Thierry Taliercio, Baptiste Fix

All-Solid Multicore Fibre Probe for Background-Free Raman Spectroscopy **387**
Stephanos Yerolatsitis, Thomas Wright, András Kufcsák, Alexandra Adams, Tom Quinn, Sohan Seth, Kevin Dhaliwal, James Stone

Multilevel Spatial Programming of Photonic Devices with Phase-Change Materials **390**
Chirine Saadi, Capucine Laprais, Fouad Bentata, Xavier Letartre, Guillaume Saint-Girons, Patrice Genevet, Nicolas Baboux, Lotfi Berguiga, Sébastien Cueff, Ecole Centrale de Lyon

Topological Eutectic Heterostructure Plasmonic Metasurfaces for THz Lasing and Amplification **391**
Konstantinos Kouderis, Anousha Khamsavi, Kingshuk Bandopadhyay, Hamid Reza Darabian, Dorota Anna Pawlak, Chao Tang, Victor Ryzhii, Taiichi Otsuji

Long-lived subradiance via cavity-mediated collective interaction **393**
Kyu-Young Kim, Jin Hee Lee, Woong Bae Jeon, Dong Hyun Park, Suk-In Park, Jin Dong Song, Changhyoup Lee, Je-Hyung Kim

Laser Processing of Metallic Surfaces for Radiative Cooling and Autonomous Dew Water Harvesting **394**
Pablo Pou-Alvarez, Anne Mongruel, Mónica Fernandez-Arias, Antonio Riveiro, Daniel Beysens, Juan Pou

Metasurfaces for Laser Cooling and Trapping of Atoms and Integrated Cold-Atom Platforms **395**
Thu Hac Huong Le, Ryohei Takei, Sota Kagami, Akafumi Takamizawa, Yuichi Kurashima, Taisei Motomura

Polymer-Based Passive Radiative Cooling Films for Thermal Management **397**
Emma Spotorno, Paola Stagnaro, Lucia Conzatti, Roberto Utzeri, Simona Losio, Francesco Bisio, Michele Magnozzi, Maurizio Canepa

Wave Localisation in Aperiodic and Correlated Disorder Photonic Structures **399**
Marian Florescu, Alex Meek, Kriss Stokkereit

Phase nanoengineering of complex oxides for spin-wave devices **400**
Edoardo Albisetti

Micron Scale Spontaneous Parametric Down Conversion in Periodically Poled Layered Semiconductors **401**
Leone Di Mauro Villari, Andrea Alessandrini, Benjamin Braun, Simone Paganelli, Chiara Trovatello, Lee Rozema, Andrea Marini

Visible-Near Infrared Hyperbolic Polariton along Hyperbolic Metamaterials' interface **403**

Multi-Electron Effects in Free-Electron Beams: Light Generation and Electron-Electron Correlations **1194**
Valerio Di Giulio, Rudolf Haindl, Armin Feist, Claus Ropers

Free electrons shape light, light shapes free electrons **1197**
Alvaro Rodriguez Echarri

Scaling Up Light-Matter Interactions - Challenges in Fabrication **1198**
Rijil Thomas

Directional Energy Delivery at the Nanoscale: The Iris-Gated Approach for Photothermal Applications **1200**
Javier González-Colsa, Jose M. Saiz, Alfredo Franco, Dolores Ortiz, Francisco González, Fernando Bresme, Pablo Albella

Chiral Cavities Made from Lattices of Highly Electromagnetically-Chiral Scatterers 1201
Lukas Rebholz, Carsten Rockstuhl, Ivan Fernandez-Corbaton

Novel quantum effects in (Surface-Enhanced) Raman Scattering from molecular systems 1203
Adrian Juan-Delgado, Ruben Esteban, Lukas A. Jakob, Jean-Baptiste Trebbia, Shu Hu, Rakesh Arul, Roberto A. Boto, Quentin Deplano, Philippe Tamarat, Rémi Avriller, Niclas Sven Mueller, Diego Martın-Cano, Paloma A. Huidobro, Jeremy J. Baumberg, Brahim Lounis, Javier Aizpurua

Light management in high-refractive index semiconductor nanowires 1206
Nicklas Anttu

Photonic time crystals assisted by high-Q resonances 1207
Puneet Garg, Viktar Asadchy, Carsten Rockstuhl

Color Routing and Beam Steering of Single-Molecule Emission with a Spherical Silicon Nanoantenna 1209
Maria Sanz-Paz, Nicole Siegel, Guillermo Serrera, Javier Gonzalez-Colsa, Fangjia Zhu, Karol Kolataj, Minoru Fujii, Hiroshi Sugimoto, Pablo Albella, Guillermo Acuna

Theoretical characterization of tip-enhanced nanocavities for active control of vibrational signals 1211
Isabel Pascual Robledo, Philippe Roelli, Iris Niehues, Javier Aizpurua, Rainer Hillenbrand

Imaging the spatial distribution of tunneling-induced luminescence beyond the diffraction limit of light 1213
Elysé Laurent, Ricardo Javier Peña Roman, Sarah Miller, Aditi Raman Moghe, Etienne Lorchat, Séverine Le Moal, Elizabeth Boer-Duchemin, Luiz Fernando Zagonel, Stéphane Berciaud, Eric Le Moal

Nanoscale heat flow in laser-heated silicon nanospheres probed by pump-probe cathodoluminescence 1215
Saskia Fiedler, Evelijn Akerboom, Théo Soler, Loriane Monin, Hiroshi Sugimoto, Minoru Fujii, Wiebke Albrecht, Albert Polman

Infrared Magnetoplasmonics in Transparent Conductive Oxide Nanocrystals 1217
Alessio Gabbani

Surface-Enhanced Raman Scattering: Integrating Theoretical and Experimental Perspectives 1218

SERS Chemosensing of Metal Ions: Transduction Strategies and Interface Design 1219
Luca Guerrini

Time-Dependent Surface Enhanced Raman Scattering Simulations 1220
Giulia Dall'Osto, Stefano Corni

Operando SERS: From Molecular Spectroscopy to Plasmon-Driven Photochemistry 1221
Shashank Kumar Gahlaut, Ilko Bald, Radwan M. Sarhan, Biswajit Bhattacharyya

Plasmonic Nanopore Geometry Effects in Flow-Through Single-Molecule SERS 1222
Kirill Khabarov, Xinxin Liu, Ilaria Micol Baldi, Frank Niklaus, Francesco De Angelis

Materials for Surface-Enhanced Raman Spectroscopy Detection of Per- and Poly-fluoroalkyl Substances in Aqueous Film-Forming Foams 1224
Chuntao Wang, Kushal Biswas, Sangmin Jeong, Anila Bello, Dhimiter Bello, Michael Ross

From AI Design to SERS Spectral Shaping and Nanoplastics Detection with Metal Film over Nanospheres 1226
Cosmin Farcau, Ioana Cârdan, Ana Maria Mihaela Gherman, Fran Nekvapil

Simulating Surface-Enhanced Spectroscopies: The ωFQFμ Model 1228
Pablo Grobas Illobre, Tommaso Giovannini, Chiara Cappelli

Theoretical Investigation of Vibrational Imaging Induced by Electronically Forbidden Transitionsin Tip-Enhanced Raman Scattering 1230
Mamoru Tamura, Hiroyuki Ikagawa, Hajime Ishihara

Zwitterionic polymeric coacervates as plasmonic boxes for one-pot SERS biomarkers detection in biofluids 1233
Caterina Dallari, Francesca Torrini, Luisa Ponticelli, Silvia Bagnoli, Benedetta Nacmias, Valentina Bessi, Francesco Saverio Pavone, Paolo Arosio, Caterina Credi

SERS behavior of the antiepileptic drug cenobamate 1235
Lydia Federica Gervasini, Annachiara D'Urso, Emilio Ciusani, Alessia Cutri, Sebastiano Trusso, Paolo Maria Ossi, Andrea Lucotti, Matteo Tommasini

Nanoscale Phononics : Energy Transport, Light-Matter Coupling, and Emerging Applications 1237

Inelastic light scattering by metallic nanocrystals: symmetry, shape and chirality 1238
Lucien Saviot

Driving giant monochromatic THz strain waves in metal heterostructures by electronic pressure 1239
Matias Bargheer

Modeling the Acousto-Plasmonic Coupling: Raman Energy Density Framework 1241
Nicolas Large

Energy transfer from hot holes to phonons in photoexcited Germanium: ultrafast heating of Raman-active modes 1243
Jelena Sjakste, Raja Sen, Nathalie Vast

Unveiling Acoustic Phonon Dynamics via Time-Resolved Brillouin Spectroscopy of optophononic Resonators 1245
Carlos Montenegro, Elham Mehdi, Sandeep Sathyan, Edson Rafael Cardozo de Oliveira, Isabelle Sagnes, Martina Morassi, Aristide Lemaître, Norberto Daniel Lanzillotti-Kimura

Plasmon-Enhanced Brillouin Light Scattering Investigations of Acoustoplasmonic Metasurfaces 1246
Thomas Vasileiadis

Nanostructuration for Ultra-High Frequency Acoustic Wave Emission and Detection using Femtosecond Laser Pulses 1247
Arnaud Devos

Thermal Metamaterial Design for Phonon Heat Management at Low Temperature 1249
Boris Brisuda, Jon Canosa Diaz, Thierry Crozes, Jean-François Robillard, Olivier Bourgeois

Acoustic Phonons, Vibronic Coupling, and Room-Temperature Super-Radiance in Engineered, Icosahedral Virus Capsids 1251
Bogdan Dragnea

Approaching Ultimate Quality Factors in Nanomechanical Resonators Made of Silicon Carbide 1252
Eva Weig

Energy transport and switching in finite disordered networks 1254
Yann Chalopin

Non-Diffusive Nanoscale Phonon Heat Transport in 2D Materials 1256
Sebin Varghese, Jordi Tur Prats, Albert Beardo, Francesc Xavier Alvarez, Klaas-Jan Tielrooij

Anisotropic phonon dynamics at the nanoscale in a nanophononic SiN membrane 1258
Valentina Giordano, Silvia Mazzoleni, Stéphane Pailhès, Filippo Bencivenga

Surface Acoustic Waves and Spin Waves interaction in iron thin film 1259
Pauline Rovillain, Anupam Sharma, Florian Millo, Louis Christienne, Jean-Yves Duquesne, Mahmoud Eddrief, Franck Fortuna, Laura Thévenard, Catherine Gourdon, Massimiliano Marangolo

Experimental realization of Algorithm-designed Nanophononic Metasurfaces 1261
Michele Diego, Matteo Pirro, Jade Hardouin, Gabrielle Mazevet-Schargrod, Junior Rognon, Byunggi Kim, Roman Anufriev, Masahiro Nomura

Acoustic vibrations of single gold nanodisks supported on solid substrates 1263
Nathan Berrit, Clément Panais, Noëlle Lascoux, Sylvie Marguet, Natalia Del Fatti, Aurélien Crut

The optomechanics way to probe a single living cell 1265
Hilario Boggiano, Louis Waquier, Cherif Belacel, Ivan Favero

Mapping electrostatic and Casimir forces above metallic nanostructures using suspended nanowires 1266
Lucas Judéaux, Philip Heringlake, Hugo Weltz, Cattleya Dousset, Benjamin Pigeau, Olivier Arcizet

Vibrational dynamics of self-assembled nanoparticles 1269
Mohammad Imran Shaik, Nicholas Blanchard, Benoit Mahler, Jérémie Margueritat

Cavity Quantum Materials and Polaritonic Devices: From Microscopic Theory to Functionality 1272

Probing Cavity Polaritons via Scattering of Frequency-Entangled Biphoton States 1273
Andrei Piryatinski, Nishaant Jacobus, Sameer Dambal, Eric R. Bittner, Yu Zhang, Ajay R. S. Kandada

Cavity coupling of van der Waals heterostructures 1275
Gunda Kipp, Hope M Bretscher, Gaetan Membrez, Ethan Koskas, Lorenzo Graziotto, Felix Helmrich, Luca Somboli, Benedikt Schulte, Dorothee Herrmann, Kateryna Kusyak, Matthew W. Day, Sivasruthi Kesavan, Toru Matsuyama, Xinyu Li, Sara Maria Langner, Jesse Hagelstein, Felix Sturm, Alexander M. Potts, Christian J. Eckhardt, Yunfei Huang, Kenji Watanabe, Takashi Taniguchi, Angel Rubio, Dante M. Kennes, Michael Sentef, Emmanuel Baudin, Guido Meier, Christian Reichl, Giacomo Scalari, Werner Wegscheider, Marios H. Michael, James McIver, Jérôme Faist

Restoring Bloch's Theorem for Cavity Exciton Polaron-Polaritons 1278
Michael A. D. Taylor, Yu Zhang

META Quantum Nanophotonics Workshop 1280

Engineering Quantum Light with Perovskite Quantum Dots 1281
Yury Rakovich, Alexey Y. Nikitin, Virginia Martínez-Martínez, Andrey Rogach, Igor Aharonovich

Telecom-wavelength quantum nanophotonics with self-assembled quantum dots 1283
Nir Rotenberg

Subradiant entangled states in plasmonics and the quantization of radiative systems 1284
Angela Demetriadou

Quantum optical metasurfaces for photon pair generation 1287
Igal Brener

Ultrasensitive nanothermometry with single organic dye molecules 1288
Mohammad Musavinezhad, Jan Renger, Stephan Gotzinger, Alexey Shkarin, Vahid Sandoghdar

Thermalization of photons in disordered scattering media 1289
Valentina Krachmalnicoff, L. Soncin, Y. De Wilde, R. Pierrat, R. Carminati

Enhanced Plasmon-Emitter Coupling and Emission at the Single-Molecule Level 1290
R. Margoth Cordova Castro

Plasmonics and Nano-Optics 1292

Epsilon-near-zero mode in highly doped GaN thin films 1293
Julia Ingles-Cerrillo, Maria Villanueva-Blanco, Benjamin Damilano, Stéphane Vézian, Miguel Montes Bajo, Adrian Hierro

Symmetry enhanced modal design for magnetic emission from plasmonic core-satellite resonators 1296

Joshua Davis, Sébastien Bidault, Mathieu Mivelle, Mona Tréguer-Delapierre, Alexandre Baron

Nanostructured Cd(Zn)O for mid-infrared, near-field enhancement 1299
Miguel Montes Bajo, Pablo Ibañez-Romero, Javier Yeste, Eduardo Martínez Castellano, Maria Villanueva-Blanco, Andrea C. Illana, Fernando Gonzalez-Posada, Thierry Taliercio, Vicente Muñoz-Sanjosé, Adrian Hierro

Tunable coupling between conducting polymer nanoantennas and epsilon-near-zero thin films 1302
Suraya Kazi, Yulong Duan, Magnus Jonsson

Nanophotonics and Plasmonics Applications: Optical Antennas, Quantum Photonic Devices, and Beyond 1304

Switching Quantum Dot Microresonators by Ultrafast Laser Pulses 1305
Pietro Castronovo, Marco Reale, Susan A Rigter, Cherie R. Kagan, Christopher B. Murray, Salvatore Lorenzo, Erik C. Garnett, Peter Schall, Emanuele Marino, Alice Sciortino, Fabrizio Messina

Coupling-Controlled Exceptional Points in Intersubband Polaritonic Metasurfaces 1308
Beomjoon Kim, Hyeongju Chung, Gerhard Boehm, Mikhail A. Belkin, Jongwon Lee

Solving the Helmholtz equation with analog systems at telecommunications wavelengths 1311
Ross Macdonald, Andrew Naylor, Victor Pacheco-Peña

Chiral and Hyperbolic Metamaterials 1314

Inverse Faraday Effect and Gyrotropy in Time-Varying ENZ Films 1315
Domenico de Ceglia, Carlo Rizza, Michael Scalora, Maria Antonietta Vincenti, Wallace Jaffray, Sven Stengel, Marcello Ferrera

Carrier Drift Modulation and Hyperbolic Time Crystals 1318
Evgeniy Narimanov, Boris Shapiro

Metasurfaces: Flat Optics, FSS, HIS, and Beyond 1320

Reconfigurable Optical Imaging via a Wavelength-Driven Multifunctional Metasurface 1321
Hongliang Li, Yang Xiao, Yuning Ye, Jisen Wen, Xuechao Yu

SuperLattice Plasmon Mode in a Grating of 2D Electron Strips 1324
Alexey Shuvaev, A. R. Khisameeva, V. M. Muravev, K. R. Dzhikirba, A. A. Zabolotnykh, P. A. Gusikhin, M. S. Ryzhkov, D. A. Khudaiberdiev, A. S. Astrakhantseva, I. V. Kukushkin, A. Pimenov

Strong Coupling between quasi-bound states in the continuum and monolayer WS□ on a Si□N□ metasurface 1326
Yongliang Zhang, Oisin McCormack, Na Jia, Hodjat Hajian, Jack Dobie, Justin Schulz, Xia Zhang, Owen Moynihan, Brain Corbett, A. Louise Bradley

Wafer-scale fabrication of quartz-monolithic metalenses for the ultraviolet 1330
Jaewon Jang, Hui Jae Cho, Yeonsang Park

Colorimetric thermography by a long-infrared dual-band metalens 1332
Zhendong Luo, Peng Zhang, Yang Zhao, Mu Ku Chen

Passive and Reconfigurable Terahertz Logic Metasurfaces via Frequency and Orientation Multiplexing 1334
Mohammadhossein Momtazpour, Lei Xu, Dou Feng, Anjali Chaudhary, Dominic Craske, Costas Tsakonas, Cuifeng Ying, Demosthenes Koutsogeorgis, Miguel Navarro-Cía, Mohsen Rahmani

Deep-UV Photonic-Crystal Surface-Emitting Lasers with Sub-Degree Beam Divergence 1336
Philippe Tassin, Dogukan Apaydin, Hjalmar Andersson, Lukas Uhlig, Sarina Graupeter, Joachim Ciers, Giulia Cardinali, Erik Strandberg, Tim Wernicke, Michael Kneissl, Ulrich Theodor Schwarz, Asa Haglund

Tunable Emission Enhancement in Ge Filmsthrough All-Dielectric Metasurfaces 1338

Jon Schlipf, Diana Ryzhak, Giovanni Capellini, Paul Oleynik, Yuji Yamamoto, Inga Anita Fischer

Metamaterial-Based Devices 1340

Monolithic integrated meta-mirror color filter for 5K PPI OLED pixel 1341
Chi-Sun Hwang, Yong Hae Kim, Hyunsu Cho, Sunghoon Hong

Extreme field enhancement and anapoles in high-index tunable metamaterials 1343
Zoltan Sztranyovszky, Nicolas Spiesshofer, Caleb Todd, Rakesh Arul, Jeremy J. Baumberg, Angela Demetriadou

High-Efficiency Off-Grid-Positioned Metasurface Color Router for Sub-Micron CMOS Image Sensors 1346
PoHan Fu, Chin-Chuan Hsieh

Photonic Crystals and Electromagnetic Bandgap Structures 1348

Perovskite Anti-Resonant Reflection Optical Waveguide Fibre 1349
Christian Johnson-Richards, Luke Cording, Noel Healy

Effects of randomness on self-assembled photonic crystals 1352
Duanduan Wan

Emergence of Rashba Spin-Orbit Coupling in Staggered-Gyromagnetic Photonic Crystals 1353
Yao-Ting Wang, Wenlong Gao, Hua-Shin Lin

Symposia, Special-Session and Workshop Posters 1356

On-chip Neural Network for High-speed, Energy-efficient and Integrated Computation 1357
Xueyun Li, Shining Zhu, Tao Li

From Translucent to Transparent Wood 1359
Ilya Sychugov

Multiscale QM/Classical Modeling of SERS Spectra in Amino Acids and Nucleobases 1360
Sveva Sodomaco, Chiara Cappelli

Topological edge state waveguide fed antennas 1362
Shih-Hui Gilbert Chang

Gradient-Momentum Engineering in Metasurface for Continuous and Asymmetric Beam Steering 1363
Hsiu-Ping Su, Po-Sheng Huang, Pin Chieh Wu

Multiscale analysis of anisotropic composites 1365
Natalia Rylko

Spectral and Polarization Control of Smith-Purcell Radiation via Chiral Dielectric Gratings 1366
Loris Cavenaile, Thomas Delplace, Muluneh G. Abebe, Bjorn Maes

Experimental Study of Mechanically Graded Tensegrity-Inspired Cellular Metamaterials 1369
Anna Al Sabouni-Zawadzka, Adam Zawadzki, Wojciech Gilewski, Maciej Kołodziejczak

Dynamical superradiance in vibrationally dressed molecules 1371
Lukas Freter, Piper Fowler-Wright, Javier Cuerda, Brendon Lovett, Jonathan Keeling, Päivi Törmä

Surface-Enhanced Raman Spectroscopic Observation of SuFEx Processes at Metal Surfaces 1374
Aleksandra Miszczak, Justyna Grzeda, Hubert Sobiech, Jan Dudziński, Michał Barbasiewicz, Andrzej Kudelski, Aleksandra Szaniawska

Flat band Engineering in Polymer Acoustic Lieb Lattices 1376
Anusha Rehman, Riccardo Carlo Moroni, David Hutchins, Peter J. Thomas, Rudolf Roemer, Katarzyna Majewska, Stefano Laureti

Self-configuring linear diffractive optical networks for adaptive imaging through multimode fibres 1379
Jérôme Don Jayamanne, José C. A. Rocha, Unė G. Būtaitė, Joel Carpenter, David B. Phillips

Free-Electron Coupling to Surface Polaritons Mediated by Small Scatterers 1381
Leila Rocio Prelat, Eduardo J.C. Dias, F. Javier García de Abajo

Long-range coupling through photonic molecules 1383
Romina Abarca-Ramirez, Diego Roman-Cortes, Rodrigo Vicencio

Hyperbolic Super□Resonance and Long□Range Quantum Entanglement 1385
Evgeniy Narimanov, Eugene Demler

Observing Exceptional Lines in Scattering Matrices 1387
Wenzhe Liu, Jingyi Zhao, Xinhao Wang, Lei Shi, Che Ting Chan, Jian Zi

Nanopopcorn-Based SERS Nanosensors for Intracellular pH Mapping 1389
Katarzyna Bogusz, Katarzyna Wleciał, Agnieszka Girstun, Andrzej Kudelski, Aleksandra Szaniawska

Magnetic Properties and Applications of Glass-coated Ferromagnetic Microwires 1391
Valentina Zhukova, Paula Corte-Leon, Mihail Ipatov, Juan Maria Blanco, Arcady Zhukov

Beyond optical chirality density: tensor-based description of electromagnetic chirality 1393
Ilia Smagin

Programmable synthetic frequency dimension platform for on-chip topological photonics 1395
Xiaolong Su, Weiwei Liu, Bing Wang, Peixiang Lu

Angle-Induced Double Resonance of Quasi-Guided Modes for Enhanced Second-Harmonic Generation 1397
Sooseong Ji, Jaesung Kim, Jongwon Lee

3D Stokes Polarimetry of Dipolar Near-Fields 1400
Guillermo Serrera, Yael Gutiérrez, José J. Gil, Fernando Moreno

Flexible and Programmable Semiconductor Plasmonic Platforms for Near-Infrared Meta-Optics 1401
Debmalya Mukhopadhyay, Bivas Saha

A Dynamically Beam Steerable Metasurface Antenna with Sidelobe Suppression 1404
Enez Furkan Cihan, Nursel Akçam

Quantisation of polariton modes for dispersive resonators 1409
Jakub Skorka, Ben Yuen, Angela Demetriadou

Chiral sensing along dielectric waveguides: effective index splitting and mode coupling 1412
Alice de Corte, Tom T.C. Sistermans, Ankit K. Singh, Bjorn Maes, Alberto G. Curto

Parametric studies to approximate configurations optimal for asymmetrical responses 1414
Miklós Waldhauser, Ákos Sebők-Papp, Dávid Vass, András Szenes, Balázs Bánhelyi, Mária Csete

Coupled nanolaser arrays: towards the realization of bright topological lasers 1417
Amina Saadani, Kenneth Syddall, Kaiwen Ji, Juan Ariel Levenson, Kamel Bencheikh, Alejandro M. Yacomotti

Low-Contrast Bound States in the Continuum Metasurfaces Enabling Single Nanoparticle Sensing 1419
Keisuke Watanabe, Samuel Crowther, Masanobu Iwanaga, Frank Vollmer, Tadaaki Nagao

Externally Driven Quantum Dynamics in Plasmonic Nanocavities 1421
Ishita Jena, Angus Crookes, Ben Yuen, Angela Demetriadou

Time-varying Metamaterials on a Drone Rotor Blade 1424
Pavel Ginzburg, Dmytro Vovchuk, Anna Mikhailovskaya, Konstantin Grotov, Mikhail Tsukerman, Omer Tsidki, Sergey Geyman, Mykola Khobzei, Vladyslav Tkach, Toms Salgals, Natalja Muračova, Vjaceslavs Bobrovs

Metallic Nanohelices as Chiral Metasurfaces & Applications in Chiral Sensing 1426
Thu Hac Huong Le

Surface Light Localization in Topological Multilayers 1428
Eva Otero, Ivan Toftul, Yuri Kivshar, Crina Cojocaru, Jose Trull

Revolutionizing semiconducting SERS application for resistant pollutants via nanoarchitectonics 1430
Yunqing Kang, Yusuke Yamauchi, Julio Gutiérrez Moreno, Olga Guselnikova

High-performance Wide-angle Metalens for Optical Receiver 1432
Wei-Hsiang Lai, Pin Chieh Wu

Structural Coloring via Hyperuniform Arrays of Tapered Si Nanostructures on Glass 1434
Hanna Kylhammar, Mikko Kjellberg, Srinivasan Anand

Physically intuitive coupling engineering for realizing the proposed spectral response at the resonator with drop waveguide 1436
Yae Jun Kim, Yu Sung Choi, Jae Won Ahn, Jae Woong Yoon

Tunable Thermal Emissivity for Thermal Infrared Camouflage Enabled by a Zigzag Metallic Glass Structure 1438
Yu-Ching Shih, Wei-Han Wang, Chia-Hsuan Lee, Hsuen-Li Chen

Resonant dielectric metasurfaces in Silicon Nitride for enhanced third harmonic generation in the UV 1440
Shroddha Mukhopadhyay, Maria Antonietta Vincenti, Radu Malureanu, Crina Cojocaru, Michael Scalora, Jose Trull

Quantum Nanophotonic Control in Non-Perturbative Light-Matter Coupling Regimes 1442
Erika Cortese, Johannes Bürger, Simone Di Muzio, Dario Ballarini, Simone De Liberato

Effects of TE-TM splitting on bistability and nonlinear spin dynamics in resonantly driven spinor exciton-polaritons 1444
Ting Wei Chen, Szu-Cheng Cheng

Near-field observation of energy transfer in nonlocalmetasurfaces 1446
Jie Ji, Wouter Holman, Djero Peeters, Jaime Gomez Rivas

Structural diversity of pentatwinned plasmonic nanoparticles 1449
Ana Sánchez-Iglesias, Marek Grzelczak

Waveguide-Driven Nanoparticle-on-Mirror Nanocavities for Integrated On-Chip Raman Spectroscopy 1451
Daniel Arenas Ortega, Elena Pinilla Cienfuegos, Alejandro Martínez

Inverse-Designed Ultra-Compact 1 x 3 Beam Splitter on a Cladding-Free Photonic Crystal Platform 1455
Jinseong Bae, Donghyun Park, Minjin Kim, Sejeong Kim, Haejun Chung

Tunable nonlinearities of nonlocal free-electron gas in plasmonic heavily doped semiconductors 1458
Huatian Hu, Gonzalo Alvarez-Perez, Antonio Valletta, Marialilia Pea, Michele Ortolani, Cristian Ciraci

Thermally Addressable Au/PDLC Multilayer metamaterial: A Platform for Tunable Epsilon-Near-Zero Response 1460
Vimala Sridurai, Geetha G. Nair

Leveraging Stochastic Textures in Chiral Nematics for multi-modal Physical Unclonable Functions (PUFs) 1463
Mauro Daniel Luigi Bruno, Giuseppe Nicoletta, Roberto Caputo, Maria Penelope De Santo, Riccardo Cristoforo Barberi, Antonio Ferraro

Exploring the coupling of TPMSs: What utility canthey provide? 1465
Alonso Cuartero Mondoño, Andrea Bergamini

Topological Eutectic Heterostructures: Quantification of Their 2D-morphology 1467
Krzysztof Markus, Kingshuk Bandopadhyay, Andrzej Materna, Andriy. M. Gusak, Dorota Anna Pawlak

All-Dielectric Slotted-Disk Metasurface Sensor Based on quasi-Bound States in the Continuum 1469
Jack Dobie, Oisin McCormack, Yongliang Zhang, Justin Schulz, A. Louise Bradley

Mid□Infrared Metasurfaces for Exosome□Based Liquid Biopsy in Hepatocellular Carcinoma 1471

Riccardo Di Santo, Benedetta Niccolini, Flavio Di Giacinto, Marco De Spirito, Raffaella Polito, Andrea Notargiacomo, Michele Ortolani, Alessandra Di Gaspare, Fabrizio Pizzolante, Gabriele Ciasca, Marialilia Pea

Colloidal lithography for correlated disorder light-trapping structures **1473**
Laura de Almeida, Jean-Baptiste Doucet, Guilhem Almuneau, Stephane Collin, Inès Revol

Meta-devices based on liquid photonic devices **1476**
Yin Zhou, Zihan Geng, Mu Ku Chen

Breaking Reciprocity with Self-Oscillators **1478**
Alexander Stoychev, Ulrich Kuhl, Nicolas Noiray

Generalized Space-Time reconfigurable Metasurfaces in synthetic dimension **1481**
Yinglan Li, Chengzhi Qin, Bing Wang, Peixiang Lu

Inverse Designed Metasurfaces for SpatiallyIsolated Optical Skyrmions **1483**
Donghyun Park, Jinseong Bae, Jiwoo Kim, Sejeong Kim, Haejun Chung

Optimization of Broadband Sound Absorber Consisting of Helmholtz Resonator Array **1486**
Jia-Hong Sun, Yu-Shao Chang, Jin-Chen Hsu

Causality and free-space propagation for the second quantization of radiative nanophotonic systems **1488**
Luke Hands, Ben Yuen, Angela Demetriadou

Light emission from metals - photluminescence and electroluminescence **1491**
Imon Kalyan, Ieng-Wai Un, Kaiqiang Lin, John M. Lupton, Sebastian Bange, Yonatan Sivan

Phase-Change Extraordinary Optical Transmission Metasurfaces for Reconfigurable Spatial Filtering in the Mid-Infrared **1493**
Stuart Kendall, Joe Shields, Joe Pady, Carlota Ruiz de Galarreta, Jacopo Bertolotti, C. David Wright

Structural and Electronic Transitions in Pure and Au-Decorated VO2 Nanoporous Thin Films under Thermal and Photothermal Excitations **1495**
Claudia Pernilla Hallqvist, Charlotte Lea Oceane Nani, Edoardo Casadei, Cristina Mancarella, Francesco Bisio, Michele Magnozzi, Maurizio Canepa, Andrea Li Bassi

Equivalent Circuit Analysis of a Time-Varying Edge-Coupled Split-Ring Resonator **1497**
Theocharis Manassis, Guido Valerio, Theodosios Karamanos

Optimising Microwave Cavities for nonzero Helicity with Machine Learning **1500**
Emma Paterson, Jeremy Bourhill, Maxim Goryachev

Polarisation Conversion in Bulk Hyperbolic Crystals **1502**
Katherine Stevens, Rebecca Craig, Mark Cunningham, Sonja Franke-Arnold, Rair Macedo

Towards a BIC-based optomechanical polarization modulator **1505**
Chiara Brugnoni, Giuseppe Emanuele Lio, Grazia Salerno, Simone Zanotto, Alessandro Tredicucci, Alessandro Pitanti

Elasticity-Driven Wrinkled PDMS Structures for Tailoring Optical Properties Across the Hyperspectral Range **1508**
Urszula Malecka, Patrycja Wytrych, Tomasz Stefaniuk

Ultrasonic Needle Beam Generation in Water Using a Complex-Amplitude-Encoded Polymer Trapped-Air Acoustic Mirror **1511**
Hafiz Muhammad Imran, Marco Ricci, Rocco Zito, Stefano Laureti

Finite Element Simulation of Strain Measurement in Auxetic Materials via FBG Sensors **1513**
Katarzyna Majewska, Riccardo Carlo Moroni, Stefano Laureti

Fabry-Pérot and Friedrich-Wintgen Bound States inthe Continuum in a Plasmonic Double T-Cavity **1515**
Amina Rezzouk, Soufyane Khattou, Madiha Amrani, Adnane Noual, E. H. El Boudouti, Bahram Djafari-Rouhani

Auxetic Materials for Biomimicry: Designing for Tendon-Like Behavior **1517**
Riccardo Carlo Moroni, Katarzyna Majewska

Photonic Fiber Bragg Grating Sensor Network for Detection and Micro-Doppler Characterization of Small UAVs 1519
Rodions Marstupa, Aleksandrs Olins, Mykola Khobzei, Vladyslav Tkach, Serhii Haliuk, Sandis Migla, Toms Salgals, Vjaceslavs Bobrovs, Dmytro Vovchuk

Plasmonics, Nano-Optics and Nanophotonics 1521

Control of Chiroptical Response with Chiral Plasmonic Nanoparticles 1522
Ruiqian Zhang, Xiaolu Zhuo, Jianfang Wang

Harmonizing Plasmonic and Photonic Effects to Boost Photocatalytic H2 Production 1524
Tharishinny Raja Mogan, Jiajia Zhang, Li Shiuan Ng, Siew Kheng Boong, Carice Chong, JinnKye Lee, Haitao Li, Hiang Kwee Lee

Carbon Nanodot Superparticles as a new family of Optical Metamaterials 1527
Caterina Tortorici, Riccardo Rubino, Laureline Roffi, Vincenzo De Michele, Rodrigo Szostak, Fabrizio Messina, Alice Sciortino

Optical Control of Lasing Modes in Quantum Dot Superparticles 1530
Marco Reale, Pietro Castronovo, Marco Cannas, Emanuele Marino, Alice Sciortino, Fabrizio Messina

Enhanced hot-carrier generation and dissociation in porous gold nanorods 1533
Katarzyna Kluczyk-Korch, Tomasz Antosiewicz

Exciton-Plasmon Strong Coupling in Gold Nano-Bipyramid Arrays 1535
Kseniia Mamaeva, Hodjat Hajan, Jamie Somers, Teodora Faraone, Colm Delaney, Larisa Florea, A. Louise Bradley

Deterministic Photon Addition in a Waveguide Mode 1538
Kristina Malinowski, Holland Frieling, Benjamin Koltenbah, Pankaj Jha, Harry Atwater

Pole expansion of the optical scattering matrix via rescaled scattering channels 1541
Elias Fösleitner, Adrià Canós Valero, Zoltan Sztranyovszky, Egor A. Muljarov, Kirill Koshelev, Thomas Weiss

Can real motion be synthetically emulated? 1543
Kyan Louisia, Francisco J. Rodríguez-Fortuño

Probing Strongly Coupled Multi-Resonant Plasmonic Cavities and Excitons in ITR-PEEM 1545
Sacha Schwarz, Raphael Gherman, Alex Currie, Jean-François Bryche, Guillaume Beaudin, Dominique Drouin, Serge Ecoffey, François Fillion-Gourdeau, Pierre Levesque, Paul Charette, Steve MacLean

Detection and Quantification of Mid-Infrared through Raman thermometry in Plasmonic Bilayer Metasurface 1547
Anju Sajan, Christopher Sumner, Rohit Chikkaraddy

Direct Laser Writing of Ag-Au Thin Films for Plasmonic Sensing Platform 1549
Kernius Vilkevičius, Tomas Rakickas, Evaldas Stankevičius

Benchmark Study Using Machine Learning Surrogate Models for Predicting Optical Spectra of Tungsten Bronze Nanospheres Based on Mie Theory 1552
Yuanchao Lu, Ruixing Li

Enhanced Strong Coupling in Two-Dimensional Dichalcogenide Materials and a Bowtie Nanoantenna Plasmonic Array 1556
Na Jia, Bhera Ram Tak, Luke Doolan, Yongliang Zhang, Riley Gatensby, Jonathan N. Coleman, Richard G. Hobbs, A. Louise Bradley

Spatial Dispersion in Optical Properties of Planar Lattices of Plasmonic Nanoparticles Revealed by Müller Matrix Ellipsometry 1560
Eugene Bortchagovsky, Dai Fang, Monika Fleischer, Dietrich R. T. Zahn

Eigenmodes of Finite Rectangular Lattices 1563
Jussi Kelavuori, Roman Calpe, Benjamin Asamoah, Tommi Hakala, Mikko Huttunen

Single-Particle Study of Spin Crossover Compounds for Reconfigurable Photonic Integration 1565

Lucas Mascaro Burguera, Ramón Torres Cavanillas, Alejandro Regueiro, J. Ignacio Echevarría, Eugenio Coronado, Jorge Parra, Pablo Sanchis, Javier Hernández Rueda, Elena Pinilla Cienfuegos

Design of exotic plasmonic lattice dispersions **1567**
Joel Lehikoinen, Päivi Törmä

Interparticle Spacing-Driven Ultrafast Dynamics in Gold Nanoparticle Superlattices **1570**
Pietro Castronovo, Cristian Gonzalez, Giuseppe Ammirati, Shengsong Yang, Daniele Catone, Alessandra Paladini, Patrick O'Keeffe, Cherie K. Kagan, Christopher B. Murray, Antonio Emanuele, Emanuele Marino, Fabrizio Messina, Alice Sciortino, Alice Sciortino

Temporal Interfaces in a Kretschmann-Raether Geometry **1573**
Harry Donegan, Miraculous Joseph Bhaseen, Francisco J. Rodríguez-Fortuño, Anatoly Zayats

Mode and Pitch Multiplexed Guided-Mode Resonance Active Metasurfaces, for Multi-Wavelength Control **1575**
Julie Belleville, Martin Thomaschewski, Harry Atwater

Wavelength-Guided Plasmonic Control of CO□ Reduction: From Model Nanostructures to Gold Dendritic Electrodes **1578**
Anjalie Edirisooriya, Manuka Suriyage, Zelio Fusco, Ning Lyu, Shenyou Zhao, Christin David, Fiona Beck

Cd(Zn)O gap antennas on polar substrates **1580**
Maria Villanueva-Blanco, Pablo Ibañez-Romero, Julia Ingles-Cerrillo, Javier Yeste, Vicente Muñoz-Sanjosé, Maria del Carmen Martínez-Tomás, Miguel Montes Bajo, Adrian Hierro

Switchable n-type conducting polymer nanoantennas **1583**
Suraya Kazi, Pravallika Bandaru, Yulong Duan, Shangzhi Chen, Magnus Jonsson

Vortex Excited Plasmon Resonances in Metal Nanodisks Governed by Symmetry and Size **1584**

Metasurfaces as a platform for classical and quantum light control

Ruwen Peng*, and Mu Wang

National Laboratory of Solid State Microstructures, School of Physics, and Collaborative Innovation Center of Advanced Microstructures, Nanjing University, Nanjing 210093, China
*Corresponding author: rwpeng@nju.edu.cn

***Abstract*— In this talk, we present metasurfaces as a platform for classical and quantum light control. The approaches achieve potential applications in optical display, data storage, information encryption, and quantum information networks.**

***Keywords*— metasurfaces, polarization manipulation and multiplexing, transparent matte materials.**

Part I. Matesurfaces for polarization manipulation and multiplexing: from classical to quantum

It is well known that manipulating the polarization of light on the microscale or nanoscale is essential for integrated photonics and quantum optics. In this talk, we present our recent classical and quantum studies on polarization manipulation and multiplexing via optical metasurfaces. One is to break the limitation of polarization multiplexing in optical metasurfaces with engineered noise [1,2], and the other is to realize the generation, transformation and multichannel distribution of entangled photons with dielectric metasurface [3-5]. Very recently we have further carried out multiprotocol quantum key distributions based on a single metasurface [6]. The approaches achieve potential applications in optical display, data storage, information encryption, and quantum information networks.

Part II. Matte surfaces with broadband transparency

The long-standing paradox between matte appearance and transparency has deprived traditional matte materials of optical transparency. In this talk, we present the solution to this centuries-old optical conundrum by harnessing the potential of disordered optical metasurfaces [7,8]. Through the construction of a random array of meta-atoms tailored in asymmetric backgrounds, we have created transparent matte surfaces that maintain clear transparency regardless of the strength of disordered light scattering or their matte appearances. Our work introduces an unprecedented frontier of transparent matte materials in optics, offering unprecedented opportunities and applications.

From Classical to Quantum Metasurfaces for Multiphoton Interferometry

Federico Capasso
Harvard John A. Paulson School of Engineering and Applied Sciences,
Harvard University, Cambridge, MA 02138, USA

Multiphoton interference and entanglement are fundamental to quantum information science, but necessary extensions to higher-dimensional systems remain challenging due to imperfections and complexity of scaling conventional optical setups.

Here we demonstrate a generalized Hong-Ou-Mandel effect using metasurfaces and graph theory, enabling controlled multi-photon bunching, antibunching, and entanglement across parallel matrix-encoded spatial modes.[1] Our theoretical framework rigorously predicts the device's behavior and facilitates the design of dual graphs representing both metasurface-based multiport interferometer designs and the complex non-classical correlations they generate. Experimentally, we show that a single-layer metasurface induces strong multiphoton interference simultaneously across multiple Jones matrix–encoded diffraction orders—violating the classical limit and effectively implementing higher-order Hadamard interferometers.
These results highlight the potential of metasurface-based quantum graphs for scalable, low-decoherence quantum information infrastructure.

***Abstract*— We study tailorable and dynamically tunable properties of transparent conducting oxides (TCOs) and transition metal nitrides (TMNs) for applications in all-optical modulators and flat optics. We also investigate metal-to-insulator transition in ultra-thin TMN films operating in the so-called transdimensional regime. We also discuss the tailorability of 2D transition-metal carbides and nitrides (MXenes) for tailorable photonic devices.**

***Keywords*— tunable photonics, switchable materials, transparent conducting oxides, MXenes.**

Tailorable and dynamically tunable materials are crucial for advancing nonlinear and quantum optics, as well as optical technologies at large including IT, classical and quantum communication, imaging, sensing and energy conversion. Recently, transparent conducting oxides (TCOs) and transition metal nitrides (TMNs) have attracted attention for photonic applications as they exhibit enhanced light-matter interactions, particularly in their metallic/plasmonic regime and near the so-called epsilon near zero (ENZ) region. Here, we explore the static and dynamic tailorability and tunability of optical properties in TCOs and TMNs. Both homogeneous TCOs and TMNs, as well as structured devices made from them, were investigated for tunability of their optical interactions such as harmonic generation and optical modulation. We also report on investigations of ultra-thin TMN films where interesting metal-to-insulator transitions happen in the so-called transdimensional regime. We also discuss the customizability of 2D transition-metal carbides and nitrides (MXenes) to enable new pathways for tailorable photonic devices.

Precision nanogap metamaterials for tracking bioanalytes using SERS and SEIRA

Jeremy J Baumberg[1]

[1] Nanophotonics Centre, Cavendish Laboratory, Department of Physics, University of Cambridge, CB3 0US, UK

***Abstract*— Sensing of trace analytes, or of molecules at the metal interface that controls catalysis or battery electrochemistry, is challenging. Optical vibrational spectroscopies have huge potential, because they can be enhanced at nanostructured metal surfaces, but have been hard to control. I will discuss a range of recent key advances that give robust, repeatable, and recleanable nanogap plasmonic sensors, as well as midIR metamaterials enabling real-time flow electrochemistry.**

***Keywords*— metamaterials, plasmonics, sensing, SERS, SEIRA, electrochemistry, flow**

Quadratic Nanomaterials for On-Chip Classical and Quantum Devices

Rachel Grange

ETH Zurich, Department of Physics, Institute for Quantum Electronics, Optical Nanomaterial Group, Switzerland
*Corresponding author: grange@phys.ethz.ch

***Abstract*— Nonlinear materials used in telecommunications, lasers and quantum technologies are typically bulk single crystals. To access more sophisticated features in on-chip devices such as parametric or electro-optic effects, thin-film lithium niobate has recently emerged as a promising platform, albeit with significant fabrication constraints. Here I will present our recent progress in top-down fabrication of lithium niobate devices and bottom-up approaches, including the assembly of randomly oriented nanocrystals and sol-gel processes, to generate nonlinear classical and quantum signals. Finally, I will describe how these platforms are suited for nonlinearities in machine learning.**

Generating Optical Merons through Spin-orbit Coupling in Anisotropic Metamaterials

Vittorio Aita[1] , Anastasiia Zaleska[1], and Anatoly V. Zayats[1,*]

[1]Department of Physics and London Centre for Nanotechnology, King's College London, United Kingdom

*Corresponding author: anatoly.zayats@kcl.ac.uk

***Abstract*— We will discuss the enhanced spin-orbit coupling in strongly anisotropic metamaterials which provides efficient conversion of polarisation state of the transmitted light and results in meron-type topological structures of the electromagnetic field. Flexible control of polarisation and its topological properties is important for optical manipulation, communications, metrology and quantum technologies.**

***Keywords*— spin-orbit coupling, anisotropic metamaterials, optical field topologies.**

I. Introduction

Polarisation-controlled light–matter interactions underpin advanced applications in optical communication, sensing, photochemistry, and quantum optics. Precise spatial and temporal structuring of optical fields, combined with engineered material responses, enables control over spin–orbit coupling and the formation of topologically complex photonic states [1–5]. In particular, uniaxial materials support spin–orbit interactions that facilitate vortex beam generation. Uniaxial metamaterials provide enhanced anisotropy and chiral responses beyond natural media. Plasmonic nanorod-based metamaterials exhibit tunable dispersion regimes associated with epsilon-near-zero behavior and hyperbolic dispersion. In the hyperbolic regime. Although accessing extraordinary modes of the metamaterial requires oblique incidence to interact with longitudinal field components, tight focusing of structured scalar or vector beams enables excitation at normal incidence. Here, we experimentally demonstrate polarisation control of vector vortex beams using an anisotropic plasmonic metamaterial operating in hyperbolic regimes [6–9]. We observe azimuthal polarisation conversion and the formation of second-order meron-like polarisation topologies.

II. Results and Discussion

We studied experimentally and theoretically how strongly anisotropic plasmonic nanorod metamaterials interact with tightly focused vector beams to reshape their polarisation through spin–orbit coupling. In the epsilon-near-zero (ENZ) regime of the nanorod-based metamaterial, the longitudinal field component of the beam is heavily damped inside the metamaterial, resulting in the azimutalisation of the polarisation state of the beam upon transmission. Such azimuthalisation is observed for most beams except pure radial beams, for which longitudinal component is essential. Away from ENZ wavelengths, no polarisation conversion is observed. In the hyperbolic dispersion regime (wavelengths longer than ENZ), strong anisotropy enables significant spin–orbit conversion even for simple circularly polarized beams. Tight focusing produces vortex polarisation structures upon transmission, where components with opposite spin and different orbital angular momentum combine to create spatially varying polarisation. Analysis of Stokes parameters reveals synthetic polarisation textures consistent with second-order meron topologies.

III. Conclusion

We investigated how vector beams with strong longitudinal fields interact with a strongly anisotropic metamaterial and how this interaction drives spin–orbit coupling effects. The optical response depends on the dispersion regime: in the epsilon-near-zero regime, the metamaterial converts the input polarization into an azimuthal state, whereas in the hyperbolic regime it produces vortex-like polarisation patterns with second-order meron topology. This topological behavior is governed by the metamaterial anisotropy and the spin conversion of the incident beam. Combining strongly anisotropic and nonlinear metamaterials, dynamic generation of merons and control over their topologies can be achieved.

Abstract— **By training metrological estimators, employing topologically structured light, and engineering the flow of Fisher information, optical metrology can surpass conventional resolution limits by orders of magnitude—achieving atomic-scale precision at megahertz acquisition rates.**

***Keywords*— metrology, structured light, Fisher Information.**

We review recent advances in nanoscale optical metrology based on the analysis of coherently scattered light. By combining structured optical fields with optimisation of Fisher information flow, positions and dimensions of nanoscale objects can be measured with precision that reaches the atomic scale, exceeding limits traditionally imposed by diffraction and even thermal (Brownian) motion.

We further discuss the conceptual transition from high-precision parameter estimation to true high-resolution imaging, and introduce emerging principles for super-resolution imaging of finite-size objects beyond conventional optical limits. These developments establish a unified framework linking structured illumination, information theory, picophotonic localisation metrology and optical superesolution.

***Abstract*— We explore how free electrons probe nanomaterials' nonlocal and nonlinear optical responses with unmatched spatial resolution, examining harmonic generation, Kerr nonlinearities, and interference of inelastically scattered electrons, while lateral deflections from finite momentum transfers reveal nonlocal effects.**

***Keywords*— nonlinear optics, nanoscale optics, free electrons, nonlocal effects.**

We discuss different strategies for leveraging free electrons to quantify the nonlocal and nonlinear optical response of nanomaterials with unprecedented spatial resolution. In particular, we examine the ability of free electrons to probe harmonic generation as well as Kerr nonlinearities through the changes that these optical effects produce in the spectra of shaped electrons, and through the interference of inelastically scattered electron components. In addition, finite momentum transfers in the electromagnetic interaction between free electrons and nanomaterials result in lateral electron deflections that can be used to assess nonlocal effects.

***Abstract* — This work critically discusses micro- and meso-scale graded metastructures as spatial signal processing platforms, with emphasis on achieving tonotopicity, advanced control of wave propagation, and elastic energy confinement. Illustrative examples include graded micro- and meso-scale arrays and bio-inspired, cyclically symmetric phononic pseudo-crystals.**

***Keywords* — metamaterials, metastructures, rainbow effect, tonotopic effect.**

I. Introduction

Structures with self-adapting abilities must be endowed with efficient sensors sending information to systems embedded in the structures themselves, able to interpret and classify the sensed signals which are finally used to activate feedback and actuation mechanisms.

The path from sensing to adaptation is hindered in many cases from the low intensity of the sensed signals and from the lack of autonomous energy sources. The possibility to efficiently govern energy fluxes, guiding them along pre-defined paths, confining and amplifying energy in pre-defined locations represents a major step toward self-adaptive structures.

This contribution will leverage on recent results in the field of elastic metastructures which could effectively be used for controlled and efficient information transport, mechanical energy confinement and signal amplification in adaptive structures.

Among different elastic wave control mechanisms, a recent line of work employs graded arrays of resonators embedded in a host structure to manipulate wave propagation by taking advantage of the interaction between the structure and the resonators [1]-[3]. The term graded refers to the smooth variation of a particular parameter of the resonators along space, allowing to control the propagation of waves in a broadband regime. This modulation strategy promotes a wavenumber transformation that, in turn, activates a spatial decrease of the wave velocity when the wave enters inside the array [1], [2]. Array guided waves slow down as they transverse the array with different frequency components localizing at specific spatial positions, resulting in a so-called *rainbow* effect, which replicates tonotopic phenomena found e.g. in the human ear apparatus.

Examples discussed will include graded resonator arrays at micro and meso-scales, additive manufactured devices containing liquids, and bio-inspired cyclically symmetric phononic pseudocrystals exhibiting broadband elastic-wave attenuation.

II. Methods and Results

Our approach is based on the design of elastic structures in which wave propagation is spatially controlled by locally tailoring the dispersion relation. While this approach has been previously demonstrated in elastic waveguides embedding local resonators [1], in this work we exploit two additional mechanisms: (i) the coupling between elastic periodic structures and liquids, and (ii) the use of a cyclically symmetric phononic pseudocrystals.

Under the hypothesis of adiabatic variation of the effective properties of the medium, the structure is assumed to be locally periodic. Dispersion properties are therefore described by local dispersion curves obtained by imposing Bloch–Floquet periodicity conditions. Numerical analyses are performed using COMSOL Multiphysics, employing the Solid Mechanics and Pressure Acoustics modules to account for the fully coupled elastic–acoustic problem.

The presence of a fluid within the periodic elastic metastructure provides an additional degree of freedom for controlling the dispersion characteristics. Previous works [4] have shown that introducing a fluid inside cubic unit cells equipped with flexible membranes on the top and bottom surfaces allows the opening of band gaps at lower frequencies, with the membranes acting as elastic springs and the fluid contributing an added mass to the system.

In the present work, we extend this approach by introducing openings between adjacent unit cells, enabling the concurrent propagation of acoustic waves through the fluid domain. This configuration promotes strong coupling between acoustic and

elastic waves, allowing for selective transmission or attenuation of waves in the coupled fluid–solid medium.

***Abstract*—Chiral metasurfaces enable strong control of light matter interaction at the nanoscale. Planar plasmonic architectures generate superchiral electromagnetic fields that enhance chiroptical responses beyond natural systems. These engineered platforms support enantioselective sensing, molecular spectroscopy, and quantum photonics by amplifying weak optical signatures of molecular chirality.**

***Keywords*— chirality, metasurfaces, superchiral fields, nanophotonics, chiroptical sensing.**

I. Introduction

Chirality is a fundamental property of systems lacking mirror symmetry and plays a critical role in molecular chemistry, biology, and optical physics. In optical systems, chirality governs the interaction between matter and circularly polarized electromagnetic fields, producing phenomena such as optical rotation and circular dichroism. Detecting weak chiral optical signals remains challenging because natural chiroptical responses are typically small. Recent advances in nanophotonics have introduced metasurfaces composed of subwavelength nanostructures capable of tailoring electromagnetic chirality and amplifying light matter interactions.

II. Methods

The investigated platform consists of planar plasmonic metasurfaces designed to break spatial inversion symmetry. Arrays of nanoscale metallic resonators support localized plasmonic modes that generate highly confined electromagnetic fields. By controlling geometry and material composition, the metasurfaces produce resonant field distributions with enhanced optical chirality density. These superchiral electromagnetic environments increase the interaction strength between electromagnetic fields and nearby chiral molecules.

III. Results and Discussion

Both numerical and experimental studies show that planar plasmonic metasurfaces can generate intrinsic superchiral electromagnetic fields comparable to those typically associated with three dimensional chiral structures. Localized plasmonic resonances create electromagnetic hotspots where optical chirality density is strongly enhanced. Molecules placed within these regions experience amplified chiroptical interactions, leading to stronger circular dichroism signals and improved sensitivity in molecular detection. These results highlight the potential of metasurface platforms for biosensing, enantioselective spectroscopy, and nanoscale photonic control.

IV. Conclusion

Engineered chiral metasurfaces provide a powerful strategy for controlling light matter interaction through enhanced electromagnetic chirality. The generation of superchiral fields enables improved detection of molecular chirality and opens new opportunities in biosensing, nonlinear optics, and quantum photonics.

Managing light and matter at the nanoscale for sustainable energy conversion

Esther Alarcón Lladó

NWO-I AMOLF , The Netherlands

For the successful large-scale deployment of solar energy conversion technologies, whether for generating electrical power or facilitating chemical processes, we require the design of nano-architectures that effectively control light-scattering.[1] One powerful approach to achieving this control is through the design of metasurfaces, which are engineered materials with tailored optical properties. Light can be directed and distributed by precisely structuring the spatial frequencies within these metasurfaces, thereby allowing light to be guided in specific directions, absorbed at specific locations, or transmitted according to the desired outcome.[2-4]

The fine control over light-matter interactions requires fine control over nano-fabrication. At the same time, for any of these new photonic concepts to be implemented in real devices for sustainable energy generation, their fabrication must be scalable. In this talk, we will first discuss the robustness of broadband metasurface light scattering on fabrication imperfections.[3] We will then delve into the development of scalable methods for metasurface fabrication with nanoscale feature control, from deterministic top-down approaches to self-assembled methods.[5]

Kagome-Inspired Topological Photonics: From Lattice Design to Robust Control of Light

Zhigang Chen
The MOE Key Laboratory of Weak-Light Nonlinear Photonics,
TEDA Applied Physics Institute and School of Physics,
Nankai University, Tianjin, China
zgchen@nankai.edu.cn

***Abstract*— Kagome-type lattices offer a versatile platform for exploring topological photonics, owing to their unique symmetry, flatband features, and rich band topology. In this talk, I will present our recent advances in Kagome-inspired photonic lattices and their structural extensions, including super-honeycomb, breathing Kagome, disclination-based, and fractal-like geometries. These systems enable the realization of diverse topological states, such as higher-order boundary modes, vortex states carrying orbital angular momentum, and flatband-induced localization. By integrating real-space structural design with momentum-space topology, we uncover new mechanisms for robust manipulation of light. These results highlight a unifying framework for engineering complex topological photonic states, with potential applications in integrated photonics and optical information processing.**

Levitation optomechanics with meta-atoms

Adeel Afridi[1], Bruno de Melo[1], Bin Lu[1], Nadine Meyer[1], Romain Quidant[1,*]

[1]Department of Mechanical and Process Engineering, ETH Zurich, Switzerland

*Corresponding author: rquidant@ethz.ch

***Abstract*— We discuss the use of meta-optics in levitated optomechanics. By replacing silica nanoparticles with resonant silicon meta-atoms, we achieve enhanced optomechanical performance and deterministic control over optical forces. We show that engineering multipolar Mie resonances allows for switching between attractive and repulsive forces, directly mirroring the behavior of two-level systems.**

***Keywords*— Metasurfaces, dielectric nanophotonics, optomechanics, optical forces.**

I. Introduction

Traditional levitated optomechanics primarily utilizes silica nanoparticles, which are typically restricted to being "high-field seekers" (attracted to intensity maxima). Unlocking the full potential of ultra-weak force sensing and quantum state preparation, could benefit smarter particles that offer higher polarizability, and tunable interaction signs. This talk presents a new paradigm in optomechanics by utilizing meta-atoms - high-permittivity dielectric nanoparticles (such as silicon) that support strong Mie resonances. We start by introducing theoretically the specificities of trapping silicon meta-atoms. We then present experimental demonstrations of both deterministic control over the sign of optical forces on suspended metasurfaces and 'trapping in the dark' of individual Si meta-atoms.

II. Methods

The research combines rigorous analytical modeling with advanced experimental nanophotonics:

- **Theoretical framework:** We employ Mie theory and electrodynamics to model the optomechanical coupling of silicon nanoparticles. This includes calculating the complex polarizability and its dependence on laser detuning relative to magnetic and electric Mie resonances.
- **Experimental realization:** We utilize a hybrid optical platform where a metasurface, composed of engineered silicon meta-atoms, is pattern into a suspended nanomembrane and place into a standing wave.
- **Force characterization:** Optical forces are probed within a phase-controlled standing wave. Using homodyne detection and lock-in techniques, we extract the phase and amplitude of the membrane's displacement to determine the direction (attractive vs. repulsive) and magnitude of the exerted light pressure.

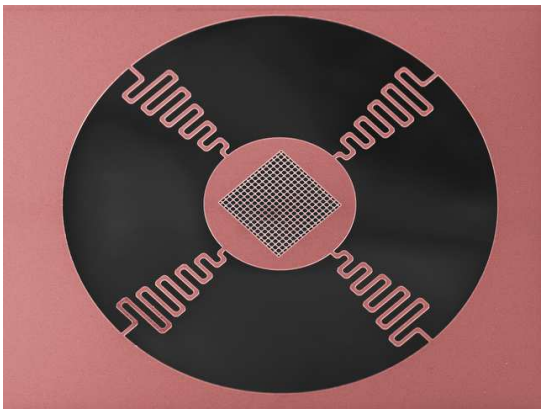

Fig. 1 SEM micrograph of a suspended array of silicon meta-atoms.

III. Results and Discussion

Our results demonstrate that meta-atoms offer several advantages over standard silica particles in levitation optomechanics:

- **Enhanced performance:** Silicon meta-atoms provide significantly higher trap frequencies and depths due to their high refractive index, facilitating easier access to the center-of-mass **ground-state cooling** regime in vacuum.
- **Sign reversal:** By adjusting the detuning of the trapping laser relative to the particle's resonances, we show that the sign of the polarizability can be flipped. This enables "low-field seeking" behavior, where particles can be trapped at intensity minima.

- **Multipolar control:** Experimentally, we confirm that by tailoring the geometry of meta-atoms to engineer the coherent superposition of multipolar modes (dipolar, quadrupolar, and octupolar), we can deterministically switch between **attractive and repulsive forces**. This mirrors the behavior of two-level systems but at a macroscopic, engineered scale.

IV. Conclusion

The integration of Mie-resonant meta-atoms into optomechanical systems represents a significant leap forward. By moving beyond the dipole approximation of simple dielectric particles, we achieve a level of control over optical forces previously reserved for atomic systems. These findings pave the way for high-precision force sensing, the study of non-equilibrium thermodynamics at the nanoscale, and the development of scalable, on-chip optomechanical devices for quantum technologies.

Scaling the Metasurface Market: From Flat Optics to Sensor-Integrated Intelligence

Rob Devlin, Co-founder and CEO, Metalenz, USA
rob.devlin@metalenz.com

Metasurfaces began as a promising academic research direction. At Metalenz, they have transitioned from lab demonstrations into over 150 million deployed consumer devices, manufactured at commercial scale in existing semiconductor foundries. This presentation examines the path from research breakthrough to commercialization and the emergence of a rapidly growing metasurface market, highlighting key milestones, technical challenges, and lessons learned along the way.

Moving beyond miniaturization, Metalenz is now co-designing metasurface hardware and perceptual AI to enable sensing capabilities that conventional optics cannot deliver. This new platform technology unlocks new information from light—bringing advanced sensing capabilities to mass-market machine vision and consumer devices for the first time.

Metasurfaces are no longer just flat optical elements; they are becoming system level solutions for intelligent perception, enabling the perceptive, accurate, and efficient vision systems that will power the next decade of intelligent machines.

Wavefront Shaping and Harnessing Coherence with Guided Mode Metastructures

Julie Belleville, Martin Thomaschewski, Komron Shayegan, Yae-Chan Lim, Gloria Halka, Arun Nagpal, Nimisha Ramprasad, Lior Michaeli and Harry A. Atwater

***Abstract*— Guided mode metastructures are key building blocks for design of electro-optic active metasurfaces for wavefront shaping, and in metasurfaces that enable spatial coherence in the far field radiation emitted from thermal radiation sources and luminescent emitters.**

***Keywords*— guided metastructures, wavefront shaping, thermal focusing, receiprocity breaking.**

I. Introduction

Active metasurfaces that enable dynamic modulation of reflection and transmission amplitude, phase, and polarization, using resonantly excited materials electro-optic active media, are powerful design elements for meta-imaging and computation. We report the design and realization of nanostructured high quality factor dielectric active metasurfaces that enable both phase and amplitude modulation. They employ perovskite electro-optic active media (lithium niobate and barium titanate) with incorporated driving electrodes that introduce local refractive index modifications in the active medium that couple to high Q factor resonant modes, in an externally applied electric field. We show that coupling of multiple spectral resonances has interesting and beneficial implications for beam steering and wavefront shaping..

Thermal radiation and luminescence emission are normally pictured as arising from the collective action of mutually incoherent sources of dipole radiation. However, by coupling thermal and luminescent emission to waveguide structures and surface-propagating modes, we can achieve considerable control over the angular and spectral properties of radiation. I will discuss several examples, including i) electro-optical phase gradient modulation for beam steering and wavefront shaping ii) thermal beaming from surface plasmon-coupled resonators, an iii) reciprocity-breaking in magneto-electric semiconductors and Weyl semimetals, and iv) optical concentration in external luminescent solar concentrators.

II. Wavefront shaping with Electro-optic metasurfaces

Electro-optically tunable active metasurfaces that enable dynamic modulation of reflection and transmission amplitude, phase, and polarization using resonantly excited materials and phenomena are powerful design elements for meta-imaging and computation. As flat, low-profile optical elements, active metasurfaces have potential serve as cascadable, programmable components in optical meta-imaging systems, such as lens-less cameras and single-photon imaging systems. In this talk, I will discuss active metasurface designs with high quality factor, local, resonant elements, tunable via electrooptic control. Ferroelectric oxides such as lithium niobate and barium titanate play a pivotal role in enabling precise electrical control of the intensity, frequency, and phase of an optical signal. Here, we report on design of visible and near infrared frequency tunable lithium niobate and barium titanate metasurfaces. Our device incorporates high-quality factor guided mode resonances for efficient beam manipulation with electrically driven, independent phase control of their constituent subwavelength elements.

III. Tailoring Thermal Emission

In metastructures that support surface waves, there is a strict relationship between the momentum or in-plane wave-vector and the energy or wavelength at which the radiation outcouples. We design and demonstrate a structure with self-focused (i.e. lensing) thermal emission with a collective resonance, the Rayleigh anomaly, which imparts long-range, in-plane spatial coherence combined with local resonances to realize a spatial phase profile across the finite aperture. We then find the optimal scatterer profile using particle-swarm optimization that produces focal points for thermal emission at varying distances and operational wavelengths.

IV. Reciprocity Breaking in Weyl Semimetals

The magneto-optic response of magnetic Weyl semimetals is characterized by non-diagonal permittivity governed by the nontrivial Berry curvature that exists between recombinant Weyl nodes. We have observed reciprocity breaking in the magnetic Weyl semimetals $Co_3Sn_2S_2$, and CoMnGa confirmed via observation of a net reflectance modulation that is nearly an order of magnitude higher than that of the typical transverse magneto-optical Kerr effect in ferromagnets, without the concurrent application of any external magnetic field, and discuss implications of these findings.

V. External Luminescent Concentrators

Finally, we report designs for metasurface-based external luminescent solar concentrators that couple luminescence excited by broadband radiation (sunlight) into surface modes and subsequently via metasurface elements into the far field, and we describe the conditions leading to net optical concentration of sunlight onto a solar cell. We model a prototype system based on II-VI semiconductor quantum dots whose emission is matched to the absorption edge of an InGaP solar cell.

Highly Nonlinear Photonic Materials Based on Metamaterials, Plasmonics, and Nanostructuring

Robert W. Boyd

The Institute of Optics, University of Rochester, Rochester, NY USA

Department of Physics, University of Ottawa, Ottawa ON Canada

robert.boyd @ur.rochester.edu

***Abstract*— This contribution reviews advances in the development of highly nonlinear materials by the combination of methods devised from the fields of metamaterials, plasmonics, and structured surfaces. We also review how these materials have led to the development of new photonics applications, including applications in quantum information technologies.**

***Keywords*— metamaterials, nonlinear optics, plasmonics, structured surfaces.**

I. Introduction

Materials with superior nonlinear optical properties are expected to play a key role in the development of future photonic devices and protocols for applications including quantum technologies, machine learning, and image acquisition and processing. revolutionized electromagnetic wave control. Recent research approaches on means to achieve these enhanced optical properties include the following: Optical materials display greatly enhanced nonlinear optical response at wavelengths for which the real part of the permittivity vanishes (this is the so-called epsilon-near-zero, or ENZ condition). Recent work stresses the development of both homogeneous ENZ materials and of metamaterials designed to display ENZ behavior at desired wavelengths. One example of this latter approach is the use of metal-dielectric multilayer stacks, with the optical materials and layer thicknesses selected to produce ENZ behavior at any wavelength in the visible range REF. Still another approach entails the fabrications of nanoscale optical cavities comprised of one linear end mirror and one nonlinear end mirror. These cavities display highly nonlinear and complex dynamic behavior because of the interplay between cavity resonances and the resonance behavior of the nonlinear cavity end mirror. The usefulness of these novel materials will be illustrated by examples of their use in several current applications.

II. Methods

One critical application of these novel photonic materials is in the field of nonlinear optics (NLO). NLO plays a key role in creating quantum states of light used in the field of light-based quantum information. A well-known example is the process of spontaneous parametric down-conversion (SPDC), which is routinely used to produce entangled photon pairs. In SPDC, an intense laser beam excites a second-order, that is, a $\chi^{(2)}$, NLO crystal. Some fraction of the photons in the incident beam split into two photons of lower energy. These daughter photons constitute an entangled photon pair; the properties of one photon are inherently linked to the properties of the other photon. This entangled state is an example of a quantum state of light, that is, a state that cannot be described using classical physics.

The relationship between NLO and the creation of quantum states of light exists at a very fundamental level. Most common light sources, such as sunlight, lasers, discharge lamps, and LED light bulbs, produce classical light. Several mathematical procedures have been developed for distinguishing classical from quantum light. For example, if the Wigner distribution function of a light field is anywhere negative, that light field is necessarily nonclassical. Classical light cannot be transformed into quantum light by means of a linear transformation. Only a nonlinear transformation can turn classical light into quantum light. There has been considerable recent interest in other situations involving quantum light and NLO. For example, the process of high-order harmonic generation (HHG) is modified when excited by quantum light [1,2]. Also, it has recently been reported that quantum states of light can be generated by the interaction of a strong pump beam with properly prepared metasurface [3].

Quantum states of light lend themselves to applications not possible with classical light. The field of quantum sensing is concerned with developing means to perform measurements more precisely through use of quantum light. A specific sort of quantum sensing is quantum imaging, a research area that seeks to produce "better" images using quantum methods. The image can be better in one of several different ways, that is, it might possess better spatial resolution, might display better

signal-to-noise ratio, or might be able to be formed using a very small number of photons.

III. Conclusion

We have reviewed recent approaches to the development of highly nonlinear materials based on a metamaterials platform. In addition, we have illustrated the utility of this approach by means of some applications that are enabled by use of these materials.

Thermal Photonics in Nonreciprocal and Time-Modulated Many-Body Systems

Philippe Ben-Abdallah[1*]

[1]Laboratoire Charles Fabry, UMR 8501, Institut d'Optique, CNRS, Université Paris-Saclay, 2 Avenue Augustin Fresnel, 91127 Palaiseau Cedex, France
*Corresponding author: pba@institutoptique.fr

Abstract— This talk explores thermal photonics in nonreciprocal many-body systems, revealing novel heat-flow control via spin-caloritronic effects. I also present a phase-tunable Floquet approach to manipulate radiative heat transfer, enabling directional flow, reversible pumping and reconfigurable flux in time-modulated networks, paving the way for programmable thermal photonic devices.

***Keywords*— Near-field radiative heat transfer, nonreciprocal media, spacetime modulation.**

I. Introduction

In the first part of this talk, I will examine thermal photonic phenomena in nonreciprocal many-body systems [1] composed of magneto-optical materials. When driven out of equilibrium by temperature gradients and spatially varying magnetic fields, these systems display unconventional radiative behaviors, including photonic analogs of condensed-matter effects such as the thermal Hall effect [2,3] and the inverse spin Hall effect [4]. These results (Fig.1) reveal new possibilities for controlling heat currents through spin-caloritronic mechanisms.

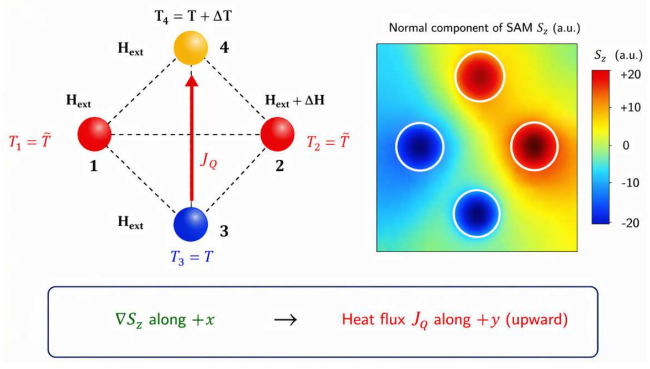

Fig. 1 Principle of inverse spin thermal Hall effect in a non-reciprocal network of C4 symmetry made with magneto-optical nanoparticles under spatially variable external magnetic field H_{ext} along the x-direction where no temperature gradient exists (T1 = T2). This spatial variation of external field induces a gradient in the same direction of light's spin angular momentum (SAM) Sz which, in turn gives rise to a transversal heat flux Jq.

In the second part, I will introduce a tunable approach to control thermal emission (Fig.2) and radiative heat transport based on Floquet interference between elastic and inelastic scattering channels arising from time-modulated permittivities [5]. By adjusting the modulation phases, one can achieve directional heat flow (Fig.3), reversible heat pumping, and reconfigurable splitting of radiative flux in many-body systems [6,7].

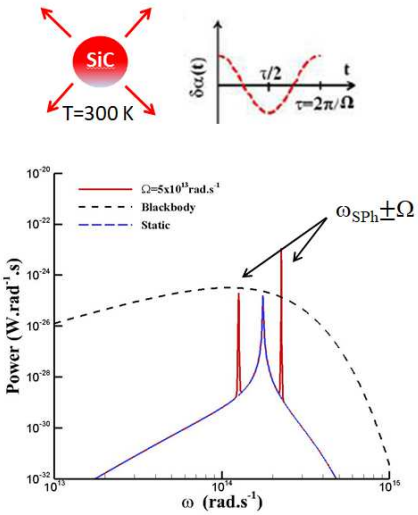

Fig. 2 Power spectrum of thermal emission at T = 300 K of a static and modulated dipole associated to a SiC nanoparticle 100 nm radius under a sinusoidal variation at the frequency Ω. The dashed line corresponds to the blackbody emission.

II. Conclusion

Together, these results reveal a unified mechanism to control radiative heat currents through spin-angular-momentum engineering and time modulation. They establish that nonreciprocity—whether induced by magnetic fields or

temporal modulation—enables transverse and programmable heat transport at the nanoscale. This opens the way toward actively controlled thermal photonic devices, where heat flow can be steered, reversed, or dynamically reconfigured using external fields and modulation protocols.

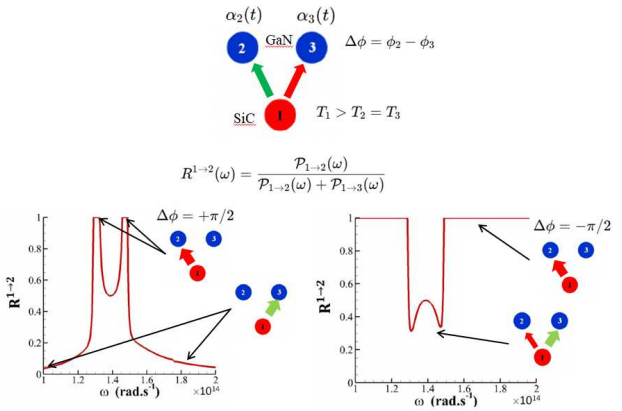

Fig. 3 Phase-controlled splitting of radiative heat flux in a three-nanoparticle SiC-GaN-GaN network. Splitting ratio R1→2, defined from the net absorbed power, with a polarizability variation $\delta\alpha = 0.1$. The SiC nanoparticle (red) acts as a hot source at T1 = 400 K, while the two GaN nanoparticles (blue) serve as colder outputs held at T2 = T3 = 300 K. Panels (left) and (right) correspond to relative modulation phases $\varphi = +\pi/2$ and $\varphi = -\pi/2$, respectively at the frequency $\Omega = \omega_{LO} - \omega_{TO}$ of GaN.

***Abstract*— Compared to magnetic materials, the dynamics of the ferroelectric order has received little attention from the scientific community. Here I review recent progress in understanding ferrons, the elementary excitations of the ferroelectric order.**

***Keywords*— ferroelectrics, domain walls, ferrons**

The duality between electric and magnetic dipoles in electromagnetism only partly applies to condensed matter. This becomes evident when inspecting the elementary excitations of the magnetic and ferroelectric orders, viz. spin and polarization waves that are quantized into magnons and ferrons, respectively. Magnons are transverse Goldstone modes at GHz frequencies that carry magnetic dipoles, while ferrons (in displacive ferroelectrics) are longitudinal Higgs modes at THz frequencies that carry electric dipoles. The ferrons and magnons have received asymmetric attention from the condensed matter community in the past [1]: While magnonics is an established and flourishing subfield in magnetism at the brink of contributing to quantum information, ferronics is still non-existent but dedicated workshops attract much interest [2].

Recent results on field-dependent heat conductance [3] as well as ballistic propagation [4,5] and diffuse transport [6] of ferrons illustrate the potential of dipole-carrying elementary excitations for applications in thermal, information, and communication technologies.

New developments include the prediction of "multiferrons" [7,8], chimera quasiparticles that emerge when ferroelectricity meets chiral phonons, as well as a polarization transfer force on ferroelectric domain walls [9] that may lead to ferron current-induced polarization switching, a new functionality in ferroelectrics that until now has been reserved for magnetic devices.

***Abstract*— Interest in exciton-polaritons for quantum devices, quantum sensing and low-threshold lasing applications continues to grow. Consequently, the realization of robust, room temperature strong-coupling systems is the subject of extensive effort. Herein, strong light-matter coupling is engineered in dielectric metasurfaces coupled with two-dimensional dichalcogenide material WS_2.**

***Keywords*— metasurfaces, strong coupling, WS_2 monolayer, Rabi splitting. quasi-bound states in the continuum**

I. Introduction

Room-temperature strong light-matter interactiion has been demonstrated in a range of material configurations using two-dimensional dichalcogenides, quantum dots and J-aggregrates coupled with dielectric and metallic metasurfaces as well as single plasmonic nanoresonators[1-5]. These systems provide complementary opportunities to access regimes of many, few or single excitons, to maximise the Rabi splitting, to control the decay rate of the coupled system or to optimize the pumping of the polariton branches. Among these materials, monolayer WS_2 is particularly well suited for room-temperature strong coupling due to its large exciton binding energy and robust A-exciton resonance in the visible spectral range.

Herein, strong coupling between the A-exciton of monolayer WS_2, located at 614 nm, and a quasi-bound state in the continuum (q-BIC) supported by dielectric metasurfaces is investigated. The metasurface is comprised of meta-atoms of disks incorporating an asymmetric slot, which enables the excitation of high-Q factor q-BIC modes with accompanying large field enhancement at the surface. Both the resonance energy and Q-factor of the metasurface can be systematically tuned by adjusting the disk height, radius, slot width, and lattice periodicity. This high degree of geometric control allows the q-BIC resonance to be engineered to tailor the radiative damping of the nanoresonator while maintaining spectral overlap with the A-exciton. Additional flexibility in controlling the strongly coupled system is achieved by modifying the local dielectric environment, for example through the introduction of a dielectric overlayer on top of the WS_2 monolayer.

II. Methods

A schematic of the slotted disk metasurface is presented in Figure 1. The lower slot edge is fixed at y_{min} = – 20 nm with respect to the disk centre. The slot width is changed by tuning y_{max}. Finite difference time domain simulations are carried out using a commercial software, Lumerical. The metasurface is simulated using a normally incident plane-wave polarized along the x-axis parallel to the slot. Periodic boundary conditions are used in the x and y directions with perfectly matched layers in z[4]. The transmittance measurements are made using normally incident white light, with the transmitted signal is fibre-coupled to a spectrometer.

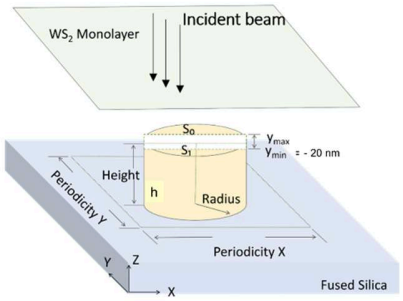

Fig. 1 Unit cell geometry of a WS_2 monolayer on top of a slotted-disk dielectric metasurface.

III. Results and Discussion

In the first instance, a TiO_2 metasurface is explored. TiO_2 has a refractive index of ~2.6 and negligible absorbance at the energy of the monolayer WS_2 A-exciton. For a metasurface suspended in air a maximum Rabi splitting of 64 meV at room temperature is observed[4]. Critical coupling is achieved when

radiative losses of the q-BIC mode match the non-radiative losses of the WS_2. It is demonstarted that this condition can be achieved, corresponding to polaritonic critical coupling in the strong coupling regime, with a maximum absorbance of 0.5 in each of the polariton branches.

In the second case, tuning of the dielectric environment for a strongly coupled system comprised of monolayer WS_2 coupled with a Si_3N_4 slotted-disk metasurface on a fused silica substrate is investigated. Si_3N_4 has a refractive index of ~2 with negligible absorbance at the A-exciton wavelength. In air a maximum Rabi splitting of 29 meV is observed. The addition of a 100 nm-thick PMMA layer on top of the WS_2 monolayer increases the Rabi splitting to 36 meV. The PMMA layer enhances the field confinement and suppresses radiative losses. Excellent agreement is observed between the experimental and simulations results.

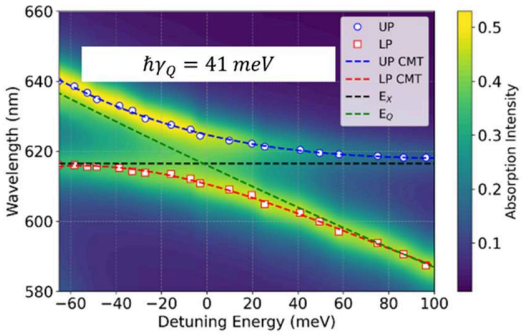

Fig. 2 Si slotted-disk metasurface: Absorbance colourmap as a function of detuning energy $\Delta = E_Q - E_X$ for a q-BIC damping rate of 41 meV. The corresponding Rabi splitting a zero detuning is 45 meV. The exciton full-width-half-maximum linewidth is 27 meV.

Si is CMOS compatible with well-established nanoscale fabrication. While it has a high refractive index of ~ 4 at the wavelength of the monolayer WS_2 A-exciton, it has non-negligible absorption ($k = 0.02$) and, consequently, has not been =explored for strong coupling applications in this wavelength range. A slotted disk metasurface on a fused silica substrate is investigated. In this case both the exciton and Si metasurface exhibit non-radiative losses. Firstly, it is demonstrated that a large Rabi splitting of 48 meV can be observed. Achieving critical coupling requires matching the total radiative and non-radiative losses in the hybridized system. Therefore, the cavity radiative losses must be tuned to match the total of the non-radiative losses. It is demonstrated that this can be achieved in the Si slotted disk metasurface with a small reduction in the overall Rabi splitting, as shown in Fig. 2. Critical coupling can be engineered and enhanced pumping of the upper and lower polariton branches realized. This works illustrates the potential of Si metasurfaces for polaritonic critical coupling.

IV. Conclusion

We have demonstrated strong coupling between the A-exciton of monolayer WS_2 and the q-BIC modes of slotted-disk metasurfaces fabricated from three different dielectric materials. The strength of the light–matter interaction, quantified by the Rabi splitting, can be systematically tuned by engineering the radiative losses of the metasurface through control of the slot width or by modifying the surrounding dielectric environment. In particular, matching the refractive indices of the substrate and superstrate reduces radiative losses and leads to an enhanced Rabi splitting.

However, the condition for maximum Rabi splitting does not correspond to the condition of optimal pumping of the polaritonic states. In many photonic systems, limited independent tunability of the resonance energy, radiative and non-radiative losses prevent simultaneous access to both the strong-coupling and critical-coupling regimes. It has been shown that polaritonic critical coupling can be engineered in both low-loss and intrinsically lossy dielectric metasurfaces at room temperature, providing maximum absorbance in the polaritonic branches. These results establish q-BIC metasurfaces aa versatile and scalable design framework for polaritonic devices, opening new opportunities for CMOS-compatible integrated platforms, low-threshold nonlinear optics, and actively engineered light–matter interactions in nanophotonic systems.

Chiro-Optical Micro-/Nano-Imaging and Near-Field Interaction

Hiromi Okamoto[1,*]

[1]Institute for Molecular Science, National Institute of Natural Sciences, Okazaki, Japan
*Corresponding author: aho@ims.ac.jp

***Abstract*— We developed chiral photoinduced force microscopy (PiFM) to visualize nanoscale chiro-optical responses using circularly polarized light. Chiral and achiral plasmonic nanostructures were imaged, revealing local chiral fields and probe-induced chirality. This approach enables nanometer-scale chiro-optical imaging beyond conventional near-field techniques.**

***Keywords*— chiro-optical effects, optical near field, microscopy, photoinduced force microscopy.**

I. Introduction

Observing the internal structure of chiro-optical responses in nano- and micro-scale materials is essential for understanding their chiral properties. We have developed near-field and far-field microscopic imaging methods based on chiro-optical effects. To visualize the geometric structure of chiro-optical responses, particularly at the nanoscale, near-field optical techniques are required. We therefore developed an aperture-type near-field optical microscopy method and achieved chiro-optical imaging of both chiral and achiral plasmonic materials. However, the spatial resolution was limited by the aperture diameter of the near-field probe, typically a few tens of nanometers.

Recently, photoinduced force microscopy (PiFM) has emerged as a new near-field imaging technique. Based on atomic force microscopy, PiFM visualizes optical near-fields by detecting forces between the sample near-field and the polarized probe, and can in principle achieve sub-nanometer spatial resolution. Using this detection principle, we developed chiral PiFM by introducing circularly polarized light and demonstrated nanoscale visualization of chiro-optical responses in chiral plasmonic materials [1].

In this report, we present chiral PiFM imaging of achiral materials to clarify the imaging mechanism. We also describe an analysis of optical forces, including gradient and scattering forces, acting on chiral materials [2], which forms the basis of PiFM.

II. Methods

A critical issue in PiFM measurements of chiro-optical effects is the elimination of photothermal effects. To distinguish optical forces from photothermal contributions, heterodyne frequency modulation (HFM) is required [3]. We employed HFM combined with frequency-modulation atomic force microscopy (FM-AFM) to selectively detect optical forces.

III. Results and Discussion

Chiral PiFM measurements near chiral gold nanostructures revealed differences in the optical forces acting on the probe under left- and right-circularly polarized light, demonstrating the feasibility of nanoscale chiro-optical imaging. Although achiral gold nanosphere dimers do not exhibit macroscopic chiro-optical effects, chiral PiFM revealed localized chiro-optical effect with positive and negative signals depending on position. Furthermore, weak chiral PiFM signals were observed even for single spherical nanoparticles, which should exhibit no intrinsic local chirality signals. This effect is attributed to probe-induced chirality arising from the probe shape and configuration.

IV. Conclusion

We demonstrated near-field chiral optical forces using chiral PiFM, enabling visualization of nanoscale chiral fields around both chiral and achiral nanoparticles. These results indicate the potential of chiral PiFM for broad applications in materials science, nanophotonics, and biochemical analysis.

QED of Chiral Waveguides Coupled to Quantum Emitters

Girish S. Agarwal[1,*]

[1] Texas A&M University, College Station, Texas 77843, USA
*Corresponding author: Girish.Agarwal@ag.tamu.edu

***Abstract*—Waveguide QED is a fundamentally quantum platform in which photons mediate long-range interactions in a one-dimensional channel. This talk highlights waveguide QED with quantum emitters, emphasizing quantum interference (Fano minima and transparency), direction-dependent interactions, quantum nonreciprocity under strong driving, and steady-state entanglement, together with squeezed-bath stabilization and dissipative phase transitions.**

***Keywords*— waveguide QED, chiral waveguides, quantum emitters, transparency, nonreciprocity, entanglement, squeezed bath, time crystals**

I. Introduction

Waveguide quantum electrodynamics provides a cavity free route to strong light matter interaction, where propagating photons in a one dimensional channel interact strongly with quantum emitters. We survey how chirality, interference, and engineered environments in waveguide platforms enable tunable transparency, direction dependent interactions, nonreciprocal transport, and steady state entanglement.

II. Many-atom Fano resonances

In the single-photon scattering theory considered here, a chain of N waveguide-coupled emitters can exhibit multiple Fano minima in reflection (equivalently, transparency peaks in transmission), with up to $N-1$ such minima as the detuning is scanned, and their positions/visibility depend strongly on the inter-emitter phase $\phi = kL$ [1]. In the analytic result, both r and t share the same collective (many-atom, spacing-dependent) denominator that encodes multiple scattering, while r has a numerator proportional to the collective interference function μ_N. Therefore, whenever $\mu_N = 0$, the reflection vanishes (a Fano minimum) and the chain becomes transparent. Since kL enters the same collective scattering factors that set this interference, changing kL strongly shifts and can even suppress these minima.

The double-emitter case allows for multiple photon transport channels, enabling destructive interference. The reflection amplitude is

$$r^{(2)} = -\frac{2ie^{ikL}\Big[\sin(kL) + \big(\Delta_k/\Gamma\big)\cos(kL)\Big]}{\big(\Delta_k/\Gamma + i\big)^2 + e^{2ikL}}. \tag{1}$$

This immediately shows a Fano minimum when the numerator is zero, i.e., $\Delta_k^{\min} = -\Gamma\tan(kL)$, so the transparency point is tunable purely by the spacing phase kL.

III. Transparency for many atoms

For a periodic chain of disparate emitters at $kL = n\pi$, the transmission coefficient is [2]:

$$t = \frac{1}{1 + i\Gamma\sum_{j=1}^{N}\big(\omega_k - \omega_j + i\Gamma_0\big)^{-1}}. \tag{2}$$

The key factor that modifies the spectrum is this additive effect of the inverse detunings. If Γ_0 is small enough to drop, Eq. (2) directly leads to the perfect-transparency condition:

$$\sum_{j=1}^{N}\frac{1}{\Delta_{k(j)}} = 0, \qquad \Delta_{k(j)} \equiv \omega_k - \omega_j. \tag{3}$$

Each emitter contributes a reflection pathway $\propto 1/\Delta_{k(j)}$; arranging detunings so these contributions cancel makes the reflected waves destructively interfere and yields $r = 0$, $t = 1$. A simple practical choice is pairwise equal-and-opposite detunings for even N. This multi-emitter transparency is distinct from the well-known EIT.

This transparency persists even under strong-field conditions [3]. In chiral waveguide QED (asymmetric coupling to forward- and backward-propagating modes), a two-qubit system can exhibit complete forward transmission and zero reflectivity, irrespective of input power, when the qubits are detuned antisymmetrically (one above and one below the central waveguide frequency) and the phase separation satisfies $\phi = n\pi$.

IV. Chiral waveguide induced interactions

A chiral waveguide (direction-dependent coupling) mediates not only collective decay but also a coherent exchange interaction between different emitters. The coherent waveguide-mediated interaction between a pair of qubits (j,l) can be written as

$$H_{jl} = -\frac{i}{2}\left[\left(\Gamma_{j\leftarrow l} - \Gamma^*_{l\leftarrow j}\right)S_j^+ S_l^- + \left(\Gamma_{l\leftarrow j} - \Gamma^*_{j\leftarrow l}\right)S_l^+ S_j^-\right]. \tag{4}$$

Here $S_j^{\pm}$ are the raising/lowering operators of qubit j, and $\Gamma_{i\leftarrow j}$ is the (generally complex and ϕ-dependent) waveguide-mediated coupling for excitation transfer from qubit j to qubit i; its direction is fixed by the spatial ordering along the 1D waveguide. Eq. (4) can be separated into a symmetric exchange channel plus an antisymmetric (chiral) channel. The

antisymmetric contribution has the form of a Dzyaloshinskii–Moriya interaction (DMI). In a nonchiral waveguide, one has $\Gamma_{\rightarrow} = \Gamma_{\leftarrow}$, and only the symmetric exchange term remains.

V. Quantum nonreciprocity and Quantum criticality

Ref. [3] studies transmission and reflection from a chiral waveguide coupled to qubits for arbitrary input powers and reports quantum nonreciprocity and a critical coupling regime. Here, nonreciprocity means that forward and backward propagation can give different transmissions. A key point is that, while a corresponding classical two-oscillator setup can remain reciprocal, in the quantum two-qubit system asymmetric detunings break reciprocity, revealing distinctive quantum nonlinear effects. In particular, for suitable asymmetric detunings and chiral couplings, forward propagation can enter a critical coupling regime for qubits where the coherent field amplitude transmission vanishes entirely at specific driving powers, while the backward transmission remains finite. This regime enables an exceptionally high degree of nonreciprocity in both coherent and incoherent parts of the transmitted field. The same quantum criticality already appears in the one-qubit case: as the input power is varied, the coherent transmission develops a pronounced dip at a critical power, approaching zero on resonance.

VI. Chiral effects due to DMI

The Dzyaloshinskii–Moriya interaction (DMI) can generate nonreciprocal quantum entanglement: with all parameters fixed and only the driven port exchanged, the steady-state two-qubit entanglement differs [4]. For representative phases and detuning patterns, forward driving exhibits a broad high-concurrence region, while backward driving is much weaker.

An especially simple limit occurs at the pure-state transparency points: the system can end up in a pure state because certain decohering channels do not participate, which also yields power-independent perfect transparency. At these pure-state transparency points, the concurrence becomes analytic. For symmetric detuning (the two qubits detuned equally), DMI is essential: it provides an additional coherent coupling channel that enables cancellation of the drive-populated "bright" component, so the dynamics stays in the "dark" manifold and the steady state becomes pure. Without DMI, the steady state remains mixed.

VII. Squeezed-bath stabilized entanglement

In an extended atomic array coupled to a squeezed vacuum, the bath fluctuations can drive the array into a pure dark state decoupled from the environment [5]. A particularly simple and striking result is that for an even number of atoms, the stabilized dark state can be a dimerized state consisting of maximally entangled atomic pairs. These pairs mimic the squeezed field by showing reduced fluctuations in one polarization quadrature and amplified fluctuations in another. Equivalently, the squeezed bath transfers its pair correlations to atoms, producing pairwise entanglement and protecting it by pushing the system into a dark manifold.

VIII. Squeezed bath and time-crystalline phase

In open (dissipative) quantum systems, continuous time crystals can appear as nonequilibrium phases with persistent oscillations even though the Hamiltonian and dissipation are time independent. In [6], the collective-spin model is coupled to a broadband squeezed vacuum reservoir. The key message is: squeezing reshapes the dissipative phase transition and the time-crystal phase. In particular, increasing squeezing can sharpen the dissipative phase transition.

IX. Conclusion

Chiral waveguides provide a unified platform to study and control quantum interference, directional photon transport, and waveguide-induced interactions at the single- and few-emitter level. We discuss how these systems also support quantum nonreciprocity and steady-state entanglement, and how engineered environments such as squeezed baths can stabilize correlations and enable time-crystalline behavior.

Plasmonic HfN-Gated Monolayer MoS_2 for Giant Trion Modulation and Scalable Optoelectronic Devices

Yu-Jung Lu[1,2*]
[1]Research Center for Applied Sciences, Academia Sinica, Taipei 11529, Taiwan
[2]Department of Physics, National Taiwan University, Taipei 10617, Taiwan
*E-mail: yujunglu@gate.sinica.edu.tw

We demonstrate a chip-scale, gate-tunable light-emitting platform that integrates scalable monolayer MoS_2 with a HfN plasmonic gate electrode. The favorable band alignment enables giant trion modulation, yielding a PL modulation depth of ~ 24%.

Abstract

Absorption in atomically thin materials remains a key bottleneck for realizing ultrathin, high-performance optoelectronics. Although many strategies have been explored to enhance light-matter interaction in two-dimensional (2D) semiconductors [1], translating these approaches into scalable monolayer devices with consistently improved performance has remained challenging. We address this issue by demonstrating wafer-scale integration of monolayer single-crystal MoS_2 photodetectors with a nitride-based plasmonic metasurface to achieve a high detectivity of 2.58×10^{12} Jones with a record-low dark current of 8 pA and long-term stability over 40 days [2]. We observed an enhancement factor greater than 100 compared to control devices, which can be attributed to the local optical field-enhanced photogating effect by the resonant HfN plasmonic metasurface. Building on this unique photogating concept, we further report a chip-scale, gate-tunable light-emitting platform that integrates monolayer MoS_2 with a work-function-controllable HfN gate electrode. Owing to the favorable band alignment, the device enables efficient charge accumulation and giant trion modulation, yielding a photoluminescence (PL) modulation depth of ~ 24% across tunable regions exceeding 5,000 μm^2 [3]. To further amplify the emission, we introduce resonant nanoparticle-on-mirror (NPoM) plasmonic cavities, achieving a 46-fold emission enhancement due to the Purcell effect while preserving the gate-tunable trion control. Finite-difference time-domain (FDTD) simulations reveal strong optical field confinement in the NPoM cavity, which facilitates efficient plasmon-trion coupling. Taken together, these results demonstrate a room-temperature, CMOS-compatible approach for realizing actively reconfigurable 2D light sources, paving the way for on-chip integrated photonics, visible light communication, dynamic display technologies, tunable emission platforms, and advanced active control of light–matter interactions in atomically thin semiconductors. Overall, these works provide unique approaches [1-4] for energy-efficient on-chip plasmonic circuitry for next-generation optical communication, computation, and quantum information processing. The detailed mechanisms and potential applications of this technology will be explored further in the presentation.

Symmetry-engineered quadromer lattices provide multiresonant qBIC control and greatly enhance four-wave mixing and nonlinear optical phenomena.**

***Keywords*— metasurfaces, quantum dots, nonlinear optics, quantum, four wave mixing, emission**

The integration of epitaxial semiconductor quantum dots (QDs) into nanophotonic architectures is a cornerstone of scalable quantum information systems, increasingly leveraging the unique capabilities of III–V semiconductor metasurfaces. Unlike plasmonic or conventional dielectric platforms, metasurfaces fabricated from high-index semiconductors enable monolithic integration of emitters—such as local-droplet-etched (LDE) GaAs QDs[1]—directly within the resonator body. Subwavelength control of light via Mie-resonant architectures and nonlocal modes maximizes modal overlap while eliminating the lossy interfaces inherent to hybrid material platforms. Beyond linear control, the field is rapidly advancing toward nonlinear optical metasurfaces, with a major focus on improving parametric processes and harmonic generation, including access to higher-order nonlinearities.

Using Huygens metasurfaces, [2] we create a position-tolerant environment that delivers a tenfold increase in collected photoluminescence, [3] while the broad resonance bandwidth simultaneously captures emission from multiple excitonic complexes. This enables a single-emitter, dual-mode source that produces both antibunched single photons ($g^{(2)}(0) < 0.5$) from neutral excitons and superbunched photons ($g^{(2)}(0) > 2$) from charged complexes under identical pumping conditions. By incorporating these design rules into a voltage-tunable heterostructure that exploits the quantum-confined Stark effect, we can tune distant QDs into spectral resonance with shared nonlocal modes, yielding an order-of-magnitude enhancement in free-space outcoupling. [4]

Future designs that control and enhance interactions between quantum dots will require tailored control over optical fields, modal structure, and the spectral placement of multiple high-Q resonances; further improvements to nonlinear and parametric processes (e.g., SPDC or FWM) in metasurfaces [5] will demand similar advances. To address these needs, we recently developed a multiresonant nonlocal metasurface design paradigm. [6, 7] We employ a symmetry-based, rational framework built around "quadromer" lattices (four elements per unit cell) that uses double band folding and selection rules to realize multiple quasi-bound states in the continuum (qBIC) resonances whose free-space polarizations, Q-factors, mode profiles, and spectral separations can be selected predictably and with strong fabrication robustness. Applying this paradigm to nonlinear processes has enabled several-orders-of-magnitude enhancement of four-wave mixing relative to unpatterned films. Together, active electrical tuning and robust quadromer design establish a scalable framework for investigating cooperative emission and advanced nonlinear optics in future photonic integrated circuits.

Photonic Time Crystals: Transport, Emission, Squeezing

Bumki Min[1]

[1] Department of Physics, Korea Advanced Institute of Science and Technology, Republic of Korea
*Corresponding author: bmin@kaist.ac.kr

***Abstract*— Photonic time crystals, whose optical properties vary periodically in time, provide a unified setting for studying wave transport, light-matter interaction, and quantum fluctuations in driven media. Here we show that seemingly different phenomena in these systems, including transport, emission, and squeezing, can be understood within a common Floquet framework that connects classical and quantum descriptions. This perspective highlights photonic time crystals as a general platform for nonequilibrium photonics, where time-periodic modulation reshapes how light propagates, interacts, and fluctuates.**

Electric Dipole Moments via Electromagnetic Duality

Michael E. Tobar[1,*]

[1]Quantum Technologies and Dark Matter Research Laboratory, Department of Physics, The University of Western Australia,
*Corresponding author: michael.tobar@uwa.edu.au

***Abstract*—We present a duality based framework that maps electric dipole moment physics onto Zeeman structure. Stark induced dipoles are represented through a magnetic current description of microscopic polarization, while intrinsic dipoles remain tied to spin. A Bohr scale dipole unit and pseudo angular momentum organize dipole operators and selection rules.**

***Keywords*— electric dipole moments, Stark effect, Zeeman effect, electromagnetic duality, equivalence currents.**

I. Introduction

Electric dipole moments (EDMs) provide exceptionally sensitive probes of discrete symmetries and are central to searches for new CP-violating physics. Intrinsic EDMs remain unobserved at current sensitivity (e.g., for the electron) [1], while induced orbital EDMs arise routinely through parity mixing in static electric fields, for example in the linear Stark effect. This work develops a symmetry-driven operator framework that maps the Stark sector onto a Zeeman-like structure under electromagnetic duality, making explicit a classical–quantum correspondence between equivalence-current methods and quantum polarization textures. The full treatment and derivations are given in [2].

II. Dual Ohanian viewpoint and magnetic probability current

Ohanian's construction expresses the spin magnetic moment in terms of an effective bound probability current derived from a microscopic magnetization field [3]. By electromagnetic duality, we introduce an electric-sector analogue based on the wavefunction's microscopic polarization $\vec{P}(\vec{r})$. A nonzero curl defines an *effective magnetic probability current density*

$$\vec{J}_m(\vec{r}) \;=\; -\epsilon_0^{-1}\,\nabla \times \vec{P}(\vec{r}), \tag{1}$$

which provides a field-equivalence (topological) representation of internal polarization textures. Importantly, the induced orbital EDM originates physically from parity mixing and charge displacement; $\vec{J}_m$ is an equivalent representation of the same internal structure rather than an additional causal mechanism. In this language, the dipole expectation can be written compactly as

$$\langle \hat{\vec{d}} \rangle \;=\; -\frac{\epsilon_0}{2}\int \vec{r}\times \vec{J}_m(\vec{r})\, d^3r, \tag{2}$$

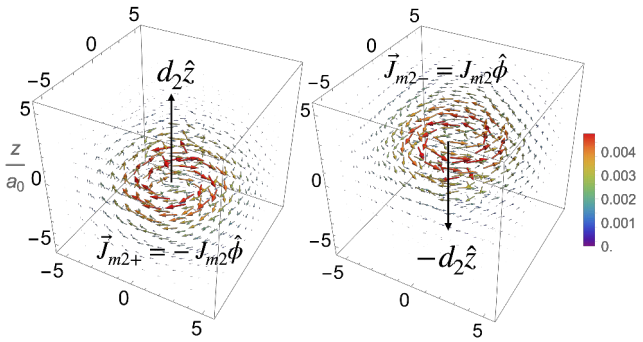

Fig. 1. Illustration of the dual-current picture: polarization textures with nonzero curl admit an equivalent magnetic probability-current representation, plotted for the $n = 2$ Stark states of the hydrogen atom

emphasizing the direct analogy with bound-current representations of magnetic dipoles. This mirrors classical equivalence-current methods in electromagnetics, where impressed electric excitations can be traded for equivalent magnetic currents that reproduce the same exterior fields.

III. Hydrogenic hidden symmetry and pseudo angular momentum

Within the hydrogenic Coulomb problem, the orbital angular momentum $\vec{L}$ and Runge–Lenz operator $\vec{A}$ generate a hidden dynamical symmetry that organizes the degenerate n manifolds. For a finite-mass nucleus, the internal (relative-coordinate) Hamiltonian is written using the reduced mass μ, and for bound states ($H < 0$) a scaled Runge–Lenz operator $\vec{A}_{\rm sc} = \vec{A}/\sqrt{-2\mu H}$ has the dimensions of angular momentum. The combinations $\vec{J}_\pm = (\vec{L} \pm \vec{A}_{\rm sc})/2$ generate the familiar $SO(4) \simeq SU(2) \times SU(2)$ structure of the Coulomb problem and satisfy standard $SU(2)$ commutation relations within a fixed n manifold. In the presence of a static electric field, the Stark interaction couples to the Runge–Lenz sector, and the relevant two- (or few-) level parity subspace can be organized by an effective angular-momentum–like degree of freedom: a *pseudo angular momentum* $\vec{J}_p$ in parity space. This pseudo angular momentum obeys the usual $SU(2)$ algebra and provides the appropriate quantum numbers for Stark eigenstates in the parabolic basis.

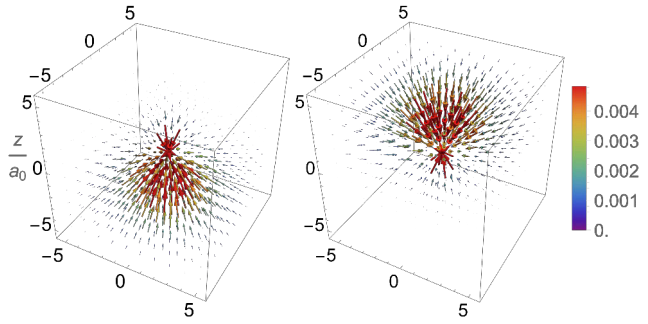

Fig. 2. Runge–Lenz structure used to construct the pseudo angular momentum in parity space for Stark mixing, plotted for the $n = 2$ Stark states of the hydrogen atom

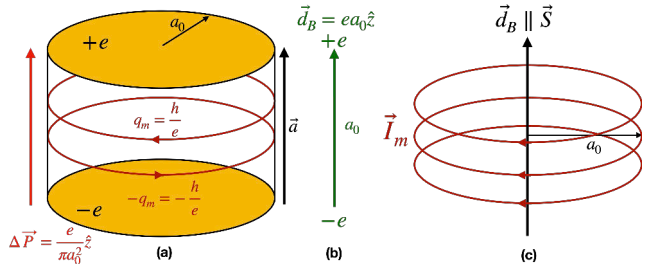

Fig. 3. Semi-classical representations of the Bohr EDM scale, $\vec{d}_B$. (a) Idealized quasi-1D "unit cell" of quantized permanent polarization, $\Delta\vec{P} = \frac{e}{\pi a_0^2}\hat{z}$, for which $\nabla \times \vec{P} \neq 0$ implies an *effective* magnetic current on the radial surface (a dual representation of the polarization texture, not a literal magnetic-charge flow). For mnemonic purposes this surface current can be pictured as two fictitious opposite magnetic charges $\mp q_m = \mp\frac{h}{e}$ circulating in opposite senses, associated with pseudo-spin (pseudo-angular momentum) in parity space rather than mechanical orbital motion. (b) Classical Bohr EDM: two point charges $\pm e$ separated by the Bohr radius a_0. (c) Schematic of an intrinsic Bohr-scale EDM connected to the position-space spin vector $\vec{S}$, represented equivalently by an effective azimuthal magnetic current $\vec{I}_m$ at radius $\sim a_0$.

IV. Bohr-scale dipole unit and orbital dipole operator

We define the natural electric dipole unit (Bohr-scale EDM) as $d_B \equiv e a_\mu$, where a_μ is the Bohr radius defined using the reduced mass. This scale is equivalent to a classical dipole formed by two charges $\pm e$ separated by a_μ, and it also matches the dipole obtained from a polarization quantum in a quasi one-dimensional "cell" picture (Fig. 3). The orbital dipole operator can be written in a Landé-like form,

$$\hat{\vec{d}}_{\rm orb} \;=\; g_E\, d_B\, \frac{\hat{\vec{J}}_p}{\hbar}, \tag{3}$$

where g_E is an electric analogue of the Landé factor determined by the hydrogenic symmetry within a fixed n manifold. As a concrete example, for $n = 2$ Stark mixing of the $2s$ and $2p_{m=0}$ orbitals produces states with permanent induced EDMs $\langle d \rangle = \pm 3 d_B$, corresponding to $g_E = 3$ for that parity doublet.

V. Broader relevance

Beyond atomic physics, the same dual-current language naturally connects to "impressed source" formulations used in engineered resonant and radiating structures. In particular, modified axion electrodynamics can be expressed in terms of effective impressed polarization and magnetization backgrounds, which in turn generate equivalent current sources [6]. Within the present framework, the $\vec{E}\cdot\vec{B}$ interaction admits dual magnetic-current signatures that mirror those appearing in the Stark-sector representation, suggesting a common symmetry-informed viewpoint for electric-dipole responses driven by weak background fields. The dual formulation also gives a new basis to describe magneto-electric couplings between Zeeman and Stark states.

VI. Conclusion

We presented a symmetry-based electromagnetic-duality formulation for EDMs that casts Stark-induced orbital dipoles into a Zeeman-like operator structure. A Bohr-scale dipole unit and a pseudo angular momentum in parity space organize orbital dipole operators, while the magnetic probability-current description provides a compact dual representation of internal polarization textures. The approach is intended to be pedagogical and symmetry driven, and may be useful wherever current-equivalence ideas are routinely employed in quantum and classical electrodynamics.

***Abstract* — In this work we present a theoretical investigation of structures that simultaneously support localized topological phononic and photonic modes, enabling enhanced optomechanical interactions. Two platforms are considered: (i) a one-dimensional nanobeam engineered within the framework of the Su–Schrieffer–Heeger (SSH) model and (ii) a two-dimensional honeycomb membrane.**

***Keywords* — Topological phononics and photonics, Optomechanics, localized modes, nanobeam cavities, SSH model.**

I. Introduction

In recent years, significant interest has emerged in the design of optomechanical (OM) cavities exhibiting high quality factors, and strong OM couplings due to their potential for information processing and communication technologies [1]. ~~This~~ Our work primarily focused on the design of cavities embedded in nanobeam phoxonic crystals, where the localization of acoustic and optical modes occur, respectively, in the few GHz and in the telecom wavelength (1550nm) range, and the OM coupling rates can achieve about 0.5 MHz [2-4]. In parallel, topological concepts have enabled the realization of robust, localized edge states in both photonics [5-6] and phononics [7-10], offering enhanced resilience against fabrication imperfections or structural disorders. In this work, we aim to bridge these two approaches by proposing structures that simultaneously host topological phononic and photonic localized modes. By engineering the spatial overlap of their electromagnetic and mechanical fields, we demonstrate a platform for achieving strong and robust optomechanical interaction.

II. Topological Structures and Localized Phononic and Photonic Modes

We discuss two types of topological structures, namely (i) a one-dimensional (1D) nanobeam where a Dirac gap is created by using the dimerization scheme of the well-known Su-Schrieffer-Heeger (SSH) model [10] and (ii) a 2D honeycomb membrane where a Valley-Hall Dirac gap originates from the breaking of the C_{3v} to C_3 symmetry.

The initial 1D OM device is constituted by a cavity inside a periodic nanobeam. The latter is made of a Si-based array of holes and stubs where proper engineering of the geometrical parameters produces acoustic and optical bandgaps, respectively in the GHz and telecom range. Several conventional cavities have been designed in this type of nanobeam [2-4, 12]. In this work, we propose to extend such designs to topological cavities inspired by the SSH model. In this model, the original unit cells are paired by making long and short distances between neighboring unit cells (Fig. 1). The dimerized structure exhibits a Dirac bandgap where two different topologies can be distinguished depending on whether the super-cell is built from long-distance or short-distance initial unit cells. Then, an association of two crystals with different topologies creates an interface that can support a localized (cavity) mode inside the Dirac gap. This scheme can be applied to both phononic and photonic band structures to create the topological OM cavity. Two types of interface profiles are considered, namely a step profile at the junction of the two crystals, or an adiabatically graded interface where the parameters are gradually changed from the center towards both sides. The optical and acoustic frequencies for both profiles are very close to each other, however the progressive variation of the parameters allows to achieve high optical quality factor and stronger OM coupling. An example is illustrated for a 7 GHz acoustic mode, an optical mode at 1546nm with a quality factor of 6.2 10^4, and an OM coupling rate of $g/2\pi$= 785 kHz. Finally, we have checked the robustness of the topological OM cavity against imperfections and disorder, in comparison to a conventional cavity. From several realizations of disorder, it can be concluded that the topological cavity exhibits a much better stability and reduced fluctuations of resonance frequencies, quality factors and OM coupling rates.

A second structure consists of a periodic silicon-based honeycomb two-dimensional membrane to realize the analog of the quantum valley Hall effect (QVHE) for both photonic and phononic band diagrams [9]. The lattice is constituted by an array of triangular holes embedded within hexagons and circular holes located at the vertices (Fig. 2). Both phononic and photonic modes that are symmetrical with respect to the mid-

plane of the membrane exhibit Dirac cones at the K/K' point of the Brillouin zone. Introducing an asymmetry in the size of the holes breaks the spatial normal mirror symmetry of the structure and gives rise to the opening of Dirac gaps, occurring respectively at 0.332 THz and 8.85 MHz, whose widths increase with the amount of asymmetry (Fig. 2). We investigate the Berry curvature distributions and Chern numbers of the bands as a function of the asymmetry. Then, robust photonic and phononic interface states are predicted to exist at the boundary of two topologically different crystals. We study the propagation of the localized interface modes at the junction of the two crystals. By considering different interface configurations, such as bearded and zigzag, we demonstrate the robustness of the topological modes at sharp bends through the analysis of the Fourier components of the forward and backward waves. We also emphasize that the output interface connecting the waveguide to the surrounding environment can have a significant impact on backscattering and cannot be overlooked in practical applications.

Modeling boundary effects in acoustic metamaterials by a relaxed micromorphic continuum

Angela Madeo[1,*]

[1] TU Dortmund University, Germany
*Corresponding author: angela.madeo@tu-dortmund.de

***Abstract*— Exploring the dynamical response of mechanical metamaterials within the framework of elastic wave propagation has gathered increasing attention in recent decades. To accurately describe elastic wave propagation in these materials – characterized by their heterogeneities or microstructures – it is essential to adopt non-local or enriched modeling approaches. In this context, we propose the relaxed micromorphic model (RMM), which effectively captures these phenomena by treating the material as continuum with enriched kinematics. A crucial micro-mechanical effect addressed by this model is the presence of band gaps, for which waves with specific frequencies cannot propagate through the material. Our previous studies have demonstrated that the RMM adequately describes the bulk behavior of mechanical metamaterials. Challenges arise, however, when considering finite-size metamaterial blocks, where boundary effects can significantly influence behavior due to reduced dimensions. Consequently, it becomes necessary to enhance the relaxed micromorphic model framework to account for these boundary effects. We will illustrate how incorporating boundary forces facilitates accurate modeling of finite-size metamaterial specimens within the framework of micromorphic elasticity.**

Hybrid Techniques for Inverse Design and Knowledge Discovery in Large-scale Multifunctional Nanophotonic Devices

Reza Marzban, Jamshid Hassanpour, Jiu Chang, Hamed Abiri, and Ali Adibi

School of Electrical and Computer Engineering, Georgia Institute of Technology

Abstract: This talk is focused on a new class of inverse design tools for large-scale nanophotonic structures by combining the unique features of rigorous gradient-based techniques (e.g., topological optimization) with machine learning tools. It is shown that by combining these two classes of design tools, the dimensionality of the design space as well as the computation requirement for training the algorithms can be reduced by 2-3 orders of magnitude. This will result in a powerful tool for not only designing large-scale and multifunctional nanophotonic devices but also obtaining helpful insight into the device operation and the importance of different design parameters in achieving the desired performance measures.

Bio: Ali Adibi is the director of Bio and Environmental Sensing Technologies (BEST) and a professor and Joseph M. Pettit chair in the School of Electrical and Computer Engineering, Georgia Institute of Technology. He is also a member of the Winship Cancer Research Center at the Emory University. His research group has pioneered several structures in the field of integrated nanophotonics for both information processing and sensing. He has also pioneered new sensing solutions for medical diagnosis as well as AI algorithms for diagnosis and prognosis in medicine. He is the author of more than 260 journal papers and 600 conference papers. He has served as the editor, conference chair, and technical committee members in over 30 different conferences and journals. He has also led several multidisciplinary research teams in the areas of integrated optics and metaphotonics for sensing, interconnection, and imaging. He is the recipient of several awards including Presidential Early Career Award for Scientists and Engineers, Packard Fellowship, NSF CAREER Award, and the SPIE Technology Achievement Award. He is also a fellow of OSA, SPIE, and AAAS.

Chiro-Optical Microscopy — Near-Field and Far-Field

Hiromi Okamoto[1,*]

[1]Institute for Molecular Science, National Institute of Natural Sciences, Okazaki, Japan
*Corresponding author: aho@ims.ac.jp

***Abstract*— Chiro-optical microscopy enables spatially resolved analysis of material chirality. This tutorial reviews near-field and far-field chiro-optical microscopic techniques, including aperture-type methods, photoinduced force microscopy, and high-precision CD imaging, and summarizes their applications to nano- and micro-scale chiral materials.**

***Keywords*— chiro-optical effects, microscopy, near-field microscopy, photoinduced force microscopy.**

I. Introduction

Chiro-optical effects provide valuable information on the chirality of materials and are widely applied in chemistry, materials physics, biosciences, and related fields. Chiro-optical spectroscopy, typified by circular dichroism and optical rotation, is therefore recognized as a powerful tool for analyzing material chirality. Despite its high potential, the application of chiro-optical spectroscopy is sometimes limited because of generally weak signals and interference from linear-polarization effects; consequently, only a few studies have reported chiro-optical imaging of inhomogeneous anisotropic samples. Nevertheless, the development of chiro-optical microscopic imaging methods is expected to have a significant impact on a wide range of research fields related to chiral materials. In this tutorial, fundamental techniques of chiro-optical microscopy are reviewed, and applications to nano- and micro-scale materials, such as plasmonic materials and microcrystals, are summarized.

II. Methods of Chiro-Optical Microscopy

A few different types of microscopic techniques have been employed to achieve chiro-optical microscopy, depending on the detection method and the spatial resolution required.

Aperture-type near-field optical microscopy: With aperture-type near-field microscopy, circular dichroism (CD) imaging using circularly polarized light [1], as well as polarimetric imaging using linearly polarized light [2], can be achieved. In the former case, the sample is illuminated with far-field radiation modulated between left- and right-circular polarization, and the response field near the sample is collected by a near-field aperture probe and detected in intensity. Lock-in detection yields the difference between the responses under left- and right-circularly polarized illumination, providing the CD signal. Near-field CD images are obtained by scanning the sample relative to the probe. In the latter case, the sample is illuminated with a linearly polarized field through the near-field aperture, and the forward-scattered light is detected in the far field. The ellipticity and polarization rotation angle are measured using polarization optics, and scanning the sample yields near-field ellipticity and optical rotation images. Using these methods, spatial resolutions of several tens of nanometers have been achieved.

Photoinduced force microscopy: As an alternative near-field approach, photoinduced force microscopy based on atomic force microscopy (AFM) was developed recently. In this method, both the sample and the probe are illuminated with light, and the force exerted on the probe due to light-induced polarization is detected by the AFM mechanism. Chiro-optical images can be obtained by introducing left- and right-circularly polarized illumination [3]. Spatial resolutions of several tens of nanometers have been demonstrated, and resolutions of a few nanometers, or better, are anticipated in principle.

Far-field high-precision CD microscopy: Even with conventional far-field optics, precise and accurate CD imaging free from linear dichroism is not straightforward for non-uniform anisotropic samples, and only a few reliable reports exist. A major source of linear dichroism artifacts is the use of a photoelastic modulator (PEM), which is commonly employed in conventional CD spectrophotometers. To achieve reliable CD imaging, we developed a new method of circular polarization modulation instead of using a PEM. With this approach, we achieved reliable high-precision CD microscopic measurements of non-uniform anisotropic chiral materials [4].

***Abstract*—Gold nanoislands are hybridized with a titanium dioxide thin film combining visible light absorbing structures with UV absorbing photocatalysts for light-induced water splitting. A custom reactor is built to measure the amount of hydrogen generated. Design considerations and first hints to the generation of green hydrogen are presented.**

***Keywords*— green hydrogen, plasmonic photocatalysis, nanoislands, thin films.**

I. Introduction

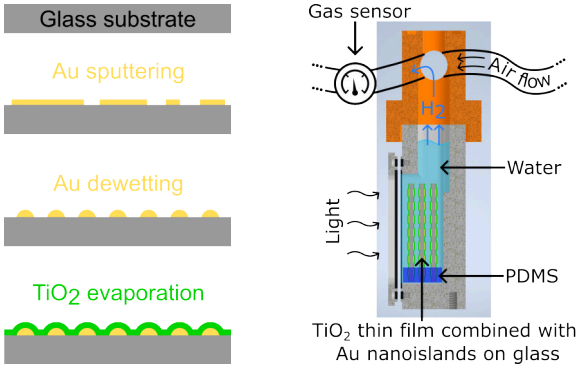
Annually only about 1% of the 100 million tonnes of hydrogen (H_2) production worldwide is environmentally sustainable. Green H_2 can be generated directly from solar energy via water splitting in plasmonic photocatalysis, holding the potential to be more efficient than industrially used, indirect H_2 generation methods including e.g. electrolysis.
High-energy charge carriers in plasmonically excited metal nanostructures can drive chemical reactions via charge transfer and an increase in temperature [1]. Titanium dioxide (TiO_2) generates charge carriers upon photo-absorption of UV light, but they can recombine before taking part in redox reactions. Combining TiO_2 with gold (Au) nanostructures, UV and visible light is absorbed, more charge carriers form through energy transfer, and an electric field originating from the space charge region reduces charge recombination and promotes their separation [2].

II. Methods

After sputtering of Au on glass substrates, a dewetting process at 360 °C for 33 min leads to the formation of Au nanoislands. Next, a TiO_2 thin film is evaporated (see Fig. 1a). Several samples fabricated in this manner are mounted vertically in a polydimethylsiloxane (PDMS) base. The resulting highly absorbing array is submerged in a closed reactor and irradiated by a halogen lamp through a window. Generated H_2 is carried by an airflow to gas sensors able to detect H_2 (see schematic in Fig. 1b).

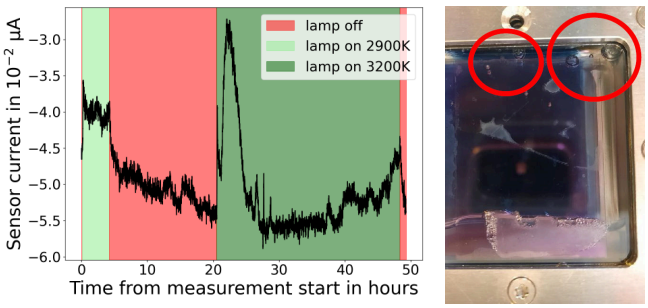
III. Results and Discussion

Scanning electron microscope measurements show Au nanoislands with sizes from 10 nm to 20 nm. Transmission



(a) (b)

Fig. 1: Schematic drawing of the fabrication process (a) and the reactor setup (b)



(a) (b)

Fig. 2: Sensor current during an H_2 measurement with the halogen lamp turned on and off (a) and accumulated H_2 bubbles inside the reactor most likely preventing continuous H_2 measurements (b).

UV-Vis spectroscopy yields absorbance peaks at roughly 610 nm. In Fig. 2a the sensor response shows enhanced signals while the lamp is illuminating the reactor. During the second illumination phase with enhanced light intensity (highlighted with a darker green area) the signal drops again after roughly 2 h. One possible explanation is an accumulation of H_2 bubbles

inside the reactor chamber, which can not be transported to the gas sensors by the air flow (see Fig. 2b).
As further design considerations, annealing the TiO_2 could enable transitions from amorphous to crystalline anatase films and improve water splitting rates [3]. An evaporation and dewetting process of platinum can lead to the formation of platinum nanoislands acting as cocatalysts improving H_2 evolution [4].

IV. Conclusion

We have demonstrated the fabrication of a hybrid system combining Au nanoislands exhibiting plasmonic responses with visible light and photocatalytic TiO_2 thin films. First traces of H_2 generation are observed. Future work will extend the design to improve H_2 detection and generation.

Very-large scale reconfigurable surfaces for dynamic control of THz and millimeter waves

Said Ergoktas[1,2]

[1]Department of Physics, University of Bath, UK
[2]Center for Photonics, University of Bath, UK

In this talk, I will go through brief history of our research on graphene-based terahertz (THz) devices leading to our latest work on very large-scale reconfigurable surfaces for dynamic control of THz and millimeter-wave.[1]

Keywords: graphene, terahertz, spatial light modulator, mm-wave

Reconfigurable intelligent surfaces (RIS) that can program terahertz (THz) and millimeter-wave fields in real time are a key missing hardware layer for next-generation wireless links, sensing, and non-invasive imaging. Progress has been limited by the scarcity of efficient, electrically tunable THz materials and by the challenge of scaling from single devices to large, densely addressable arrays. Here we present a very-large-scale programmable THz surface that merges graphene electro-optical modulators with mature thin-film transistor (TFT) active-matrix backplanes. The resulting platform implements >300,000 individually addressable, subwavelength pixels over a large area, enabling spatially structured control of transmission and reflection across the THz/mm-wave spectrum. We demonstrate electronically generated transmission patterns and masks with high uniformity and reproducibility and show millisecond-scale switching suitable for dynamic operation. In reflection mode, the multilayer architecture is engineered to operate near a reflection singularity, providing strong amplitude and phase reconfiguration and enabling large phase excursions associated with a topological transition in the complex reflection response. To highlight functionality beyond static patterning, we demonstrate (i) single-pixel mm-wave imaging of concealed metallic objects using structured masks and computational reconstruction, and (ii) dynamic beam steering and beam shaping via reconfigurable diffraction patterns, including vortex-beam generation. These results establish a scalable route to real-time, software-defined THz wavefront control for imaging and emerging THz communication systems.

***Abstract*— We describe a platform for single-crystal plasmonic nanomaterials and metasurfaces enabling engineered local field enhancements and new opportunities in nanophotonics, sensing, and energy harvesting. Engineered hot spots, metasurfaces and optically active nanostructures provide tailored fields, large SERS sensing response, controlled scattering for flat optics, and improved photo- and electro-catalytic activity.**

***Keywords*— single-crystal noble metals, engineered hot spots, metasurfaces, optical activity**

I. Introduction

Material quality plays a critical role in the performance of nanometer-scale plasmonic structures and represents a significant hurdle to large-scale device integration. Progress has been hindered by the challenges of realizing scalable, high quality, metal deposition strategies, and by poor pattern transfer and device fabrication yields characteristic of most metal deposition approaches, which yield polycrystalline metal structure. Here we highlight a novel, scalable and versatile platform to deposit ultrasmooth, single-crystal (SC) gold films ideal for subtractive patterning of nanostructures through ion beam milling, and high definition, sub-wavelength SC nanostructures through lithographic patterning methods to yield SC metasurfaces[1,2]. Here we describe complementary strategies to achieve enhanced local fields from SC plasmonic structures where we utilize the geometry and crystallinity of SC gold metasurfaces to manipulate the wavelength-dependent optical responses and plasmonic local near-field distributions of metallic nanostructures.

II. Results and Discussion

We employ a solution deposition method in the presence of anionic additives to give shape-controlled, single-crystal plasmonic gold nanostructures on Ag(100) and Au(100) substrates. Together with lithographic patterning. this chemistry yields metal deposition with precise geometry and location control to provide SC, plasmonic gold metasurfaces with tailored optical response that leverages their individual and collective responses. SC Au(100) metasurfaces comprised of square pyramidal nanostructures with dominant Au(111) facets have been fabricated to tailor the local plasmonic fields to provide resonant enhancement of the surface enhanced Raman scattering (SERS) spectra (Fig. 1). Finite Difference Time Domain (FDTD) simulations guide the design of the metasurfaces through nanostructure size and periodicity to provide local field enhancement resonant with the 785 nm laser employed for SERS measurements. This resonant enhancement provides significantly larger SERS response from Raman marker molecules such as benzoic acid (BA), compared to the SERS response from BA-covered SC gold surfaces comprised of SC square pyramids of random disposition.[3]

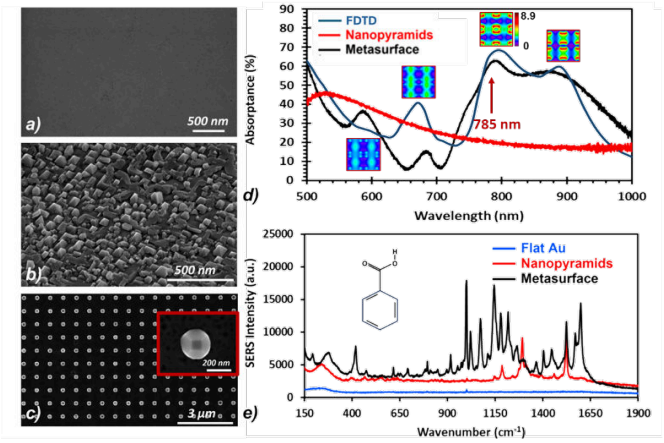

Fig. 1 SEM images of (a) flat Au, (b) randomly distributed square nanopyramids resulting from Au deposition in the presence of sulfate additives, and (c) a 250 nm diameter truncated square pyramid, 700 nm period, gold metasurface. (d) Experimental absorptance spectrum of the benzoic acid-coated randomly distributed nanopyramids (red), and the experimental (black) and FDTD simulated (blue) absorptance of the benzoic acid-coated metasurface shown in panel (c). Insets show the FDTD unit cell electric field distributions of the optical resonances appearing at 580, 680, 785, and 900 nm. (e) 785 nm SERS response from the benzoic acid-coated surfaces displayed in panels (a)–(c).

While it is common wisdom that metal-supported metasurfaces display poor SLR quality factors due to rapid dissipation of plasmonic excitation into the bath of electron density provided by the supporting metal surface, we are currently developing new strategies to produce SC metal-

supported, plasmonic metasurfaces with large surface lattice resonance (SLR) response.

One popular approach to achieve large local field enhancement is via the un-patterned deposition of solution-grown plasmonic nanocrystals onto a substrate. This approach relies on the fortuitous formation of hot spots that are not easily predictable but can give rise to enormous local field enhancements that drive large SERS response, that in some cases afford single-molecule sensitivity. Here, we describe our attempts to access more reproducible and quantitative SERS responses through the engineering of "hot spots" in single-crystal metal films through focused ion beam and helium ion beam milling. We design optical cavities, resonant antennas, and structures with nanometer-scale gaps through Finite Difference Time Domain (FDTD) simulation software, pattern high-quality SC metal films to create the desired engineered hot spots and employ SERS response as a measure of local field enhancement.

SC films of plasmonic metals and their alloys have also been employed for water splitting and CO_2 reduction reaction (CO2RR) electrocatalysis. We have identified optimal PtAu(100) and PtAg(100) alloy compositions for the hydrogen evolution reaction (HER) and shown that Au:Cu(100) SC alloy composition controls the CO2RR product distribution, yielding large (~60%) faradaic efficiency for C_2H_4 reduction products. Deposition of high surface area materials shows that these electrocatalytic processes can be enhanced through light exposure via plasmon-assisted electrocatalysis.

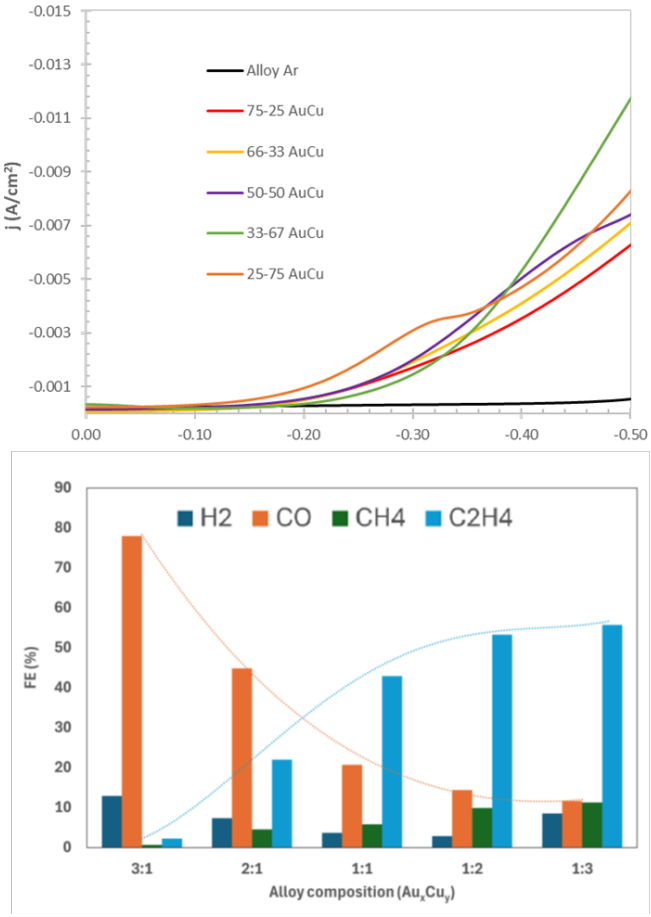

Fig. 2 Top: Linear sweep voltammograms of SC AuCu(100) alloy films of varying composition. The results show composition-dependent electro-chemical current production and overpotential. Bottom: SC AuCu(100) alloy product distributions. The results show composition-dependent.Faradaic efficiencies. Higher carbon content CO2RR products are correlated with alloys of higher copper content.

III. Conclusion

We have demonstrated a versatile and enabling platform for single-crystal plasmonics and nanophotonics applications. SC metals provide superior materials properties with reproducible and predictable, high-fidelity pattern transfer and tailored, enhanced local fields for SC metasurfaces, engineered hot spots and optically active nanostructures, with application in nanophotonics, sensing and energy harvesting.

***Abstract*— We demonstrate how thermal energy distribution within excited plasmonic metasurfaces can be used for local modification of chemical functionalization for biosensing applications.**

***Keywords*— Thermoplasmonics, pump-probe spectroscopy, Surfaced enhanced Raman spectroscopy, plasmonic biosensors.**

I. Introduction

Through several projects, we have studied plasmonic couplings, between propagative (SPP) and localized surface plasmons (LSP) in nanostructures [1,2,3]. The coupled mode has demonstrated interest in biosensing applications, notably in SPR and SERS (Raman spectroscopy) [3,4]. In addition, metal nanoparticles behave as heat sources by absorbing and converting light into thermal energy, resulting [5,6] in an interesting new pathway to manipulate at the nanoscale chemical functionalization.

II. Methods

We measured the transient reflectivity of a metasurface consisting of a 2D array of nano-cross shaped particles using pump-probe spectroscopy. These were compared with numerical simulations based on the Three-Temperature Model [6,7], which accounted for non-thermal electron ballistic displacement to determine the relative contribution of non-thermalized (N), thermalized electrons (T_e) and lattice temperatures (T_l). Additionally, the potential sensing performance was evaluated using a custom SPRI setup and TERS instrument [4,5].

III. Results and Discussion

We showed experimentally and numerically that non-thermal energy density and temperature inside the two arms of the nano-crosses can be controlled with the polarization of the pump pulse [7]. We then exploited the repartition of the three different energy baths (N, T_e, T_l) to degrade the chemical functionalization on the nanoparticles with a spatial resolution as low as 20 nm. We extended our study to several shapes of nanoparticles to optimize the control of the electronic temperature distribution on and around the gold nanostructures.

IV. Conclusion

We have demonstrated control at the nanoscale of the electronic and lattice temperatures and used it to locally modify the chemical functionalization of plasmonic biosensors. Future work will extend toward biosensing applications as well as understanding relative contribution of non-thermal and thermal effects on chemical modification. A complementary analysis based on thermopolymers is underway [8] to offer new understanding of ultrafast thermoplasmonic phenomena.

***Abstract* — Active and hybrid Fano-resonant plasmon induced transparency (PIT) metasurfaces are identified as an emerging technology in terahertz optics. Here, we introduce Fano-resonant liquid crystal integrated PIT metasurface for terahertz slow- and fast-light switching. Our findings support active Fano-resonant metasurfaces as compelling candidates for state-of-the-art nonlinear and slow- and fast-light devices.**

***Keywords* — active metamaterials, terahertz physics, liquid crystal photonics, plasmon-induced transparency, fast light, slow light.**

I. Introduction

The resonance phenomenon was revealed by Galileo Galilei in 1602 as he examined musical strings. It was later found that a variety of resonances, including mechanical, acoustic, and electromagnetic, are prevalent features of numerous classical and quantum systems. Typically, the spectral lineshape of these resonances is articulated through the Lorentzian formalism, with its dynamic variables originating from a basic linear differential equation [1]. In 1961, Ugo Fano encountered a remarkable resonance phenomenon while investigating the autoionizing states of atoms, which has been subsequently termed the Fano resonance [2].

In contrast to the Lorentzian resonance, the Fano resonance occurs when a discrete quantum state engages with a continuum of states, resulting in a unique shape in the absorption spectrum, σ(E), which adheres to the specific pattern outlined by the well-known Fano formula [3,4]:

$$\sigma(E) = D^2 \frac{(q+\Omega)^2}{1+\Omega^2} \quad (1)$$

where E represents the energy, $q = cot\delta$ is the Fano parameter, δ denotes the phase shift of the continuum. Additionally, the parameter Ω is defined as: $\Omega = \frac{2(E-E_0)}{\Gamma}$, where Γ and E_0 denote the resonance width and energy, respectively. Finally, the value D^2 can be expressed as $D^2 = 4sin^2\delta$ [4].

Current technological developments are advancing towards the incorporation of these attributes for application in plasmonics, and the progress in metaphotonics has led to numerous instances of resonant optical phenomena associated with the physics of Fano resonances [5,6]. Fano-resonant metamaterials have attracted considerable attention as an efficient and highly precise toolkit for designing innovative photonic chips with exotic functionalities, unveiling a wide range of applications in sensors, laser technology, switching mechanisms, as well as nonlinear and slow-light devices [7-9]. Interestingly, under specific circumstances, a Fano resonance can be seen as the plasmonic counterpart of plasmon-induced

transparency (PIT) [1,5-7]. These circumstances involve: (i) a sufficiently small frequency detuning between the two resonances being coupled; (ii) significant differences in resonance linewidths; and (iii) appropriate resonance amplitudes[5-7]. Hence, the emergence of Fano resonances is attributed to the interference among two or more oscillators, giving them a natural susceptibility to variations in geometry or the surrounding environment.

In consideration of the broad spectrum of opportunities and the ongoing evolution of Fano-resonant metamaterials that rely on the PIT effect, there is a current lack of multifunctional platforms that facilitate the management of both slow- and fast-light effects throughout a wide spectral range. Hence, it is critical to pursue further advancements in this sector.

In light of the previously mentioned limitations, we hereby introduce the notion of an active and hybrid Fano-resonant terahertz PIT metamaterial that facilitates the management of both slow- and fast-light effects over an extensive spectral range.

II. Hybrid and Active Plasmon-Induced Transparency Fano-Resonant Metamaterial

The spatial distribution and geometric dimensions of PIT microstructured metamaterial is shown in Fig. 1(a). The whole structure is composed of unit cells having a square shape with sides measuring 100 µm. A top-view image of the fabricated metasurface is presented in Fig. 1(b). To achieve fast and reproducible spectral tuning of PIT peaks, the metamaterial was hybridized with a 20-µm-thick layer of 1825 nematic liquid crystal (NLC) mixture, as shown in Fig. 1(c).

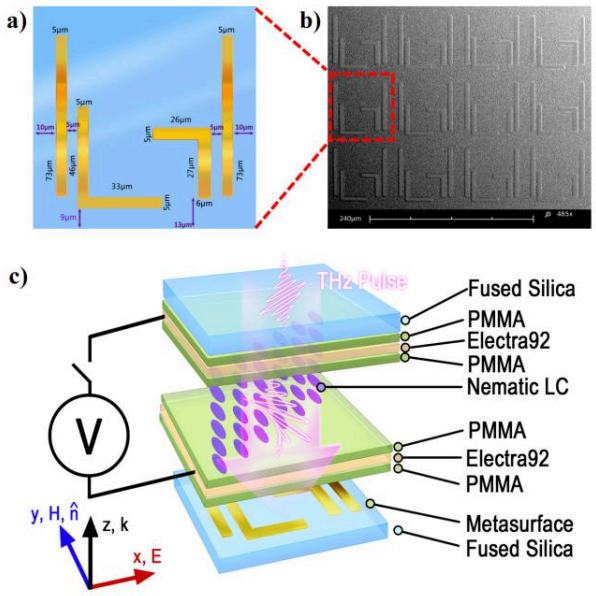

Fig. 1. Hybrid and active Fano-resonant PIT metamaterial. (a) Unit cell geometry. (b) SEM image of fabricated microstructured Fano-resonant metasurface. (c) Scheme of the liquid crystal integrated metamaterial cell.

III. Results and Discussion

Our efforts began with the design and optimization of the metasurface architecture, employing numerical simulations. To provide an explanation for the origin of the two PIT peaks, we first executed simulations of the individual meta-atoms that constitute the foundation of the final Fano-lineshape metasurface, as seen in Fig. 2.

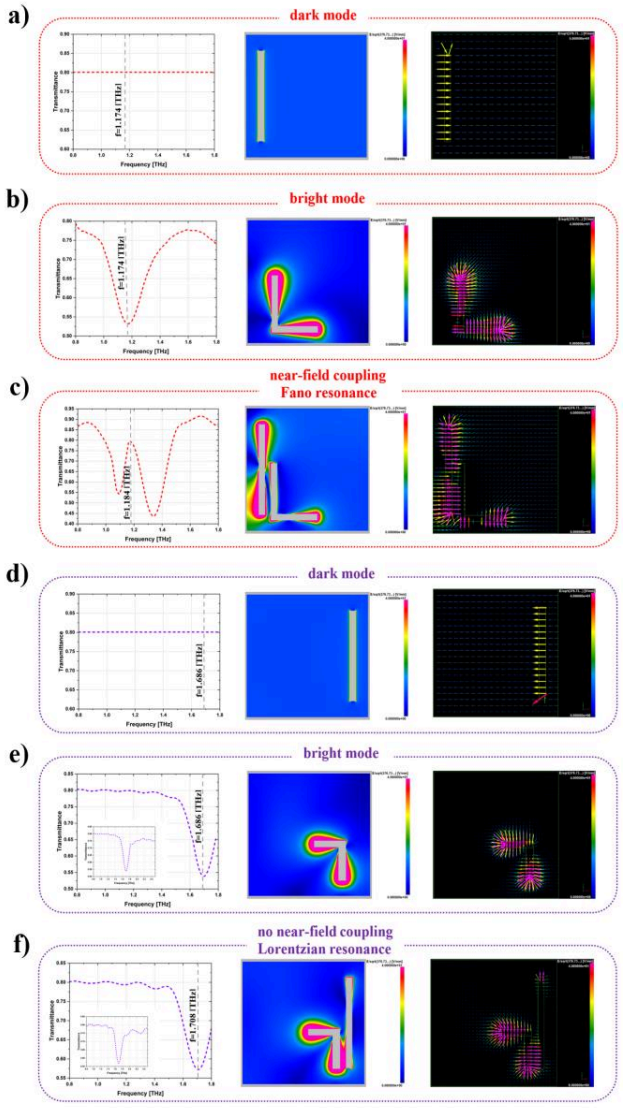

Fig. 2. Simulated transmittance amplitude and corresponding electric as well as vector field distribution at resonance frequency of (a) the sole left bar, (b) the sole left L-shaped element, (c) both left elements, (d) the sole right bar, (e) the sole right L-shaped element, and (f) both right elements.

It has been proven that the first Fano-resonant peak of plasmon-induced transparency (PIT1) results from the near-field coupling between the dark and bright meta-atoms, which are represented by the sole left bar, and the sole left L-shaped element, respectively. On the contrary, the meta-atoms located on the right do not exhibit near-field coupling, which results in a collective response that takes the form of a Lorentzian resonance. As a result, the PIT2 peak is produced from the interference of the Fano-resonant response (PIT1) and the

aforementioned Lorentzian resonance.

Significantly, our approach combines simulation, optimization techniques, and experimental insights. A comparison of the simulated and experimental results for the Fano-resonant PIT metamaterial is shown in Fig. 3. Figure 3(c) provides the group delay, calculated by:

$$t_g = \frac{d\varphi(\omega)}{d\omega} \qquad (2)$$

A heightened phase dispersion is observed around the transparency windows, resulting in a greater group index (n_g), which can be expressed as:

$$n_g = \frac{c}{h}\frac{d\varphi(\omega)}{d\omega} \qquad (3)$$

where, c is the velocity of light in free space, h is the substrate thickness and φ is the transmission phase of the MM structure. In Fig. 3(d), we have represented the group index value as a function of frequency to allow for a quantitative interpretation of the group index values within the transparency windows. It is evident from the figure that the normal dispersion of the group index is paired with anomalous dispersion surrounding the transparency windows. Crucially, group index (n_g) changes from a positive to a negative value depending on THz frequency, thus affirming the occurrence of slow- and fast-light effects.

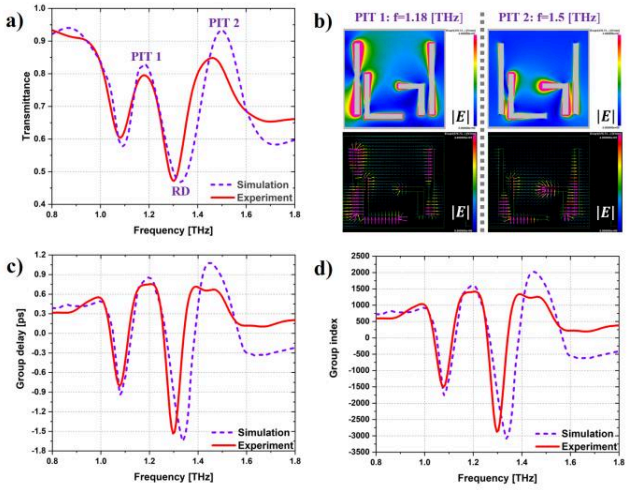

Fig. 3. A comparison of simulated and experimental outcomes. (a) Transmittance amplitude of the Fano-resonant PIT metamaterial. (b) The distribution of electric and vector fields at the resonance frequencies for both PIT1 and PIT2. (c) Group delay and (d) group index.

In the final section of the study, we utilized the sensitivity of the LC to an external stimulus, specifically an electric field, which enabled us to reorient the molecules within the LC mixture. This approach allowed us to assess the tunable parameters of the Fano-resonant metamaterial at THz frequencies. The chosen outcomes are displayed in Fig. 4. The experimental data evidently reveal that the Fano-lineshape PIT metamaterial can be effectively adjusted, achieving an intensity change of as much as 2.5% and a spectral range of up to 22 GHz, merely by varying the magnitude of the AC bias voltage, as depicted in Fig. 4(b). These values approach the theoretical limits of 5.5% for intensity tunability and 30GHz for spectral tunability [see Fig. 4(a)].

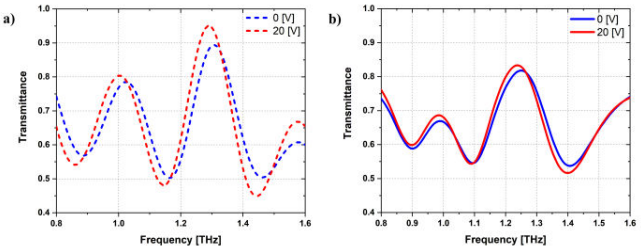

Fig. 4. Fano-resonant PIT metamaterial (a) simulated and (b) experimental transmittance amplitude tunability for off- (0[V]) and on-state (20[V]).

Following the outlined methodology, we also established the tunability of both terahertz group delay (t_g), and group index (n_g).

IV. Conclusion

We have introduced a concept of Fano-resonant PIT THz metamaterial for active control of both terahertz group delay (t_g), and group index (n_g). Notably, the group index varies from a positive to a negative value depending on THz frequency, thus corroborating the manifestation of slow- and fast-light effects. The results of our study endorse active Fano-resonant metasurfaces as noteworthy candidates for leading-edge nonlinear devices, including those designed for slow and fast light functionalities.

***Abstract*— We present a hybrid integrated platform based on patterned 3R MoS_2 enabling compact visible second harmonic generation. Band edge localization and counter propagating excitation provide efficient vertical emission from nanoscale nonlinear regions, supporting scalable integrated nonlinear and quantum photonic architectures.**

***Keywords*— nonlinear photonics, 2D materials, integrated waveguides, second harmonic generation, quantum photonics.**

I. Introduction

Two dimensional transition metal dichalcogenides exhibit exceptionally strong second order nonlinear susceptibilities enhanced by excitonic resonances and reduced dimensionality [1], [2]. Integrating these materials into dielectric waveguides enables ultracompact frequency conversion platforms operating in the visible spectral range. However, strong absorption near excitonic transitions imposes strict constraints on device geometry and field localization.

Hybrid integrated architectures combining silicon nitride waveguides with resonant MoS2 nanoelements offer a route toward efficient nonlinear interaction within nanometric volumes. The present work investigates a band edge engineered structure capable of maximizing pump localization while enabling vertical extraction of the generated second harmonic.

II. Methods

The device consists of a Si3N4 ridge waveguide patterned with 11 periodically spaced 3R phase MoS_2 resonators positioned above a SiO_2 substrate (Fig. 1). Counter propagating pumps at 890 nm excite a band edge resonance that localizes the fundamental field inside the MoS_2 elements while minimizing propagation losses. The generated second harmonic at 445 nm radiates vertically through leaky modes supported by the hybrid structure.

Full wave electromagnetic simulations are performed using a nonlinear polarization model under the undepleted pump approximation. The MoS_2 nonlinear susceptibility is taken from experimentally reported resonant values [3]. Device parameters are optimized to balance absorption, field enhancement, and phase interference between distributed nonlinear sources [4].

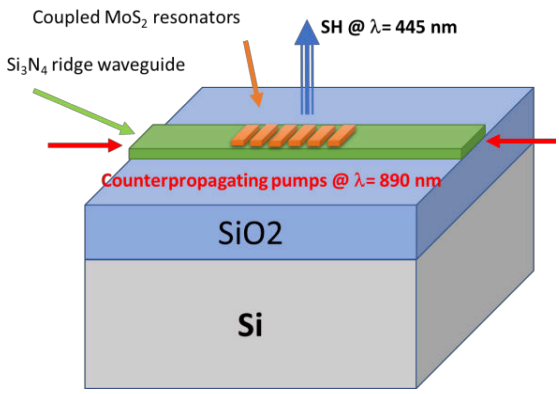

Fig. 1 Sketch of the Hybrid Si_3N_4 waveguide with coupled MoS_2 resonators excited by counter propagating pumps. Vertical radiation corresponds to the generated second harmonic.

III. Results and Discussion

The optimized structure achieves efficient frequency conversion within an interaction area of approximately 1 µm². Simulations predict second harmonic conversion efficiencies approaching 0.004 percent at moderate (300 MW/cm^2) peak pump intensities. The band edge resonance produces strong spatial confinement of the fundamental field, enhancing the effective nonlinear interaction length despite the atomic scale thickness of MoS_2.

The optimized structure consists of 11 MoS_2 stripes, each 30 nm thick and 100 nm wide, separated by 102 nm air gaps. The field distributions associated with the corresponding band edge mode are shown in Fig. 2. The fundamental pump field exhibits strong longitudinal localization inside the MoS2 array, forming a standing wave pattern that maximizes the nonlinear polarization. The generated second harmonic displays efficient vertical radiation and spatial confinement consistent with coherent emission from the coupled resonators.

Directional emission control emerges from coherent interference between distributed nonlinear sources. Figure 3

shows the upward and downward normalized radiated second harmonic power as a function of MoS_2 spacing. Results were normalized to a single MoS_2 patch having the same total MoS_2 width as the device to quantify the effect of band-edge enhancement. The response remains broadband over tens of nanometers, supporting ultrafast excitation and robust tolerance to fabrication variations.

These features indicate compatibility with spontaneous parametric down conversion and correlated photon generation in visible integrated platforms.

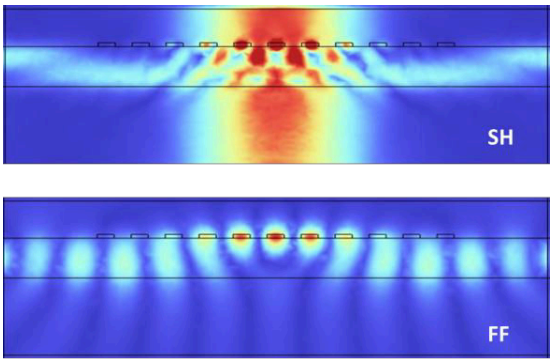

Fig. 2 Simulated electric field intensity distributions for the optimized structure composed of 11 MoS_2 stripes separated by air gaps. The fundamental frequency (bottom) is strongly localized within the array, while the generated second harmonic (top) radiates vertically from the interaction region.

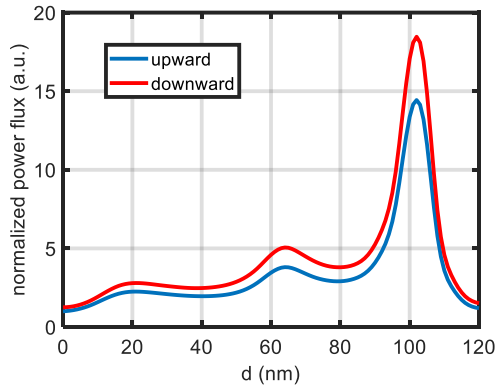

Fig. 3 Upward (blue) and downward (red) radiated second harmonic power as a function of MoS2 element spacing.

IV. Conclusion

We demonstrate a hybrid resonant photonic architecture capable of ultracompact visible second harmonic generation using patterned 2D materials. The platform supports directional emission control, nanoscale nonlinear interaction, and compatibility with CMOS fabrication. These results establish a pathway toward scalable visible frequency nonlinear and quantum photonic circuits based on resonant 2D materials.

***Abstract*—Photonic structures with phase singularities are studied theoretically and experimentally for sensing applications. Our theoretical framework provides a better understanding of the phase behaviour near critical coupling. We demonstrated that the sensitivity and detection limit of the Goos-Hänchen sensor can be improved theoretically by a factor of 100 000.**

***Keywords*— Photonic sensors, phase singularity, Goos-Hänchen shitf, Tamm plamon photonic crystal, Bloch Surface Wave.**

I. Introduction

Photonic sensors are a rapidly growing area of scientific research, driven by demand in fields such as health, safety, the environment and food. In the health sector, early diagnosis remains critical for many diseases, including cancer, infectious diseases, cardiovascular diseases and autoimmune diseases. Therefore, developing sensitive photonic sensors capable of detecting molecules with low molecular weight and/or present in low concentrations remains a technical and scientific challenge. In nanophotonics, resonant metasurfaces have been studied and developed for their ability to amplify light locally and thus improve the detection of biomolecules on their surface. Photonic structures with phase singularity are sensors that lead to a very low limit of detection. Two interrogation methods exploiting phase singularity are currently in use: i) phase interrogation using polarimetric or interferometric methods [1], or ii) the Goos–Hanchen effect, which involves measuring the lateral displacement of the reflected beam [2]. This paper explores photonic sensors with phase singularity theoretically and experimentally, providing new insights into sensors with phase interrogation as well as those using the Goos–Hanchen effect when critical coupling and its phase singularity are approached.

II. Methods

In this paper, a phenomenological approach with Temporal Coupled Mode Theory is used to model the reflectivty of photonic structures. Deduced analytical equations describing the sensitivity for sensor interrogated in phase or by the Goos-Hänchen effect have been established[3–5]. The physical parameter that describe the phase sensitivty and the Goos-Hänchen are established and allow to predict the limit of detection versus the physical parameters.

III. Results and Discussion

The phase sensitivity S_ϕ and the Goos-Hänchen sensitivty S_{GH} are described by the following two equations:

$$S_\phi = \frac{2}{\lambda_{res}} \frac{Q}{r_{min}} S_\lambda \quad and \quad S_{GH} = -\frac{3\sqrt{3} a \lambda_{res}}{8\pi^2 c} \left(\frac{Q}{r_{min}}\right)^2 S_\lambda \tag{1}$$

The sensitivities are governed by the quality factor Q, the sensitivity in wavelength S_λ, the wavelength resonance λ_{res} and for Goos-Hänchen effect by the dispersion in angle $a = \frac{d\omega_{res}}{d\theta}$, with ω_{res} the pulsation at resonance. The phase sensitivity and Goos-Hänchen sensitivity explode when the minimum of reflectivity at resonance r_{min} tends toward zero in other words when the critical coupling is approached. For phase sensitivity this variation is linear with the ratio Q/r_{min} and for Goos-Hânchen this variation is squared.

Experimental measurements are performed using an interferometric setup with holography [6] on Tamm plasmon nanostructures. Critical coupling was achieved during nanofabrication by tuning the grating geometry to the nanometre scale. The phase sensitivity relation has been verified.
Using the same experimental setup and photonic structures, the Goos–Hanchen shift can be estimated by Fourier imaging. This shows that a giant Goos–Hanchen shift is possible (up to 2 mm). This also allows us to verify the validity of our theoretical framework concerning the Goos–Hanchen shift versus Artmann's usual equation [7].

IV. Conclusion

With the developed theoretical framework, we pointed out that for metasurface with phase singularities, sensitivity and limit of detection can be pushed at very high value and at very low level respectively. We explored phase singularity and we showed experimentally the link between the phase of the reflected light and the Goos-Hänchen shift thanks to Fourier imaging. Theoretically with Goos-Hänchen sensors the sensitivity and limit of detection can be pushed by 5 orders of magnitudes. It is possible by a better understanding of the Goos-Hänchen shift behavior around the critical coupling.

Flexible and Stackable Stickers to Prepare Quasi-3D Metasurfaces

Shunsuke Murai[1,*], Koichi Okamoto[1]

[1]Department of Physics and Electronics, Graduate School of Engineering, Osaka Metropolitan University, Japan
*Corresponding author: murai@omu.ac.jp

***Abstract*— We present a strategy for preparing quasi-three-dimensional metasurfaces using flexible and stackable metasurface stickers. By integrating periodically arranged metasurface structures with incoherent light sources, the angular radiation distribution can be effectively controlled, enabling highly directional emission. The flexibility and stackability of the polymer-embedded metasurface stickers allow facile assembly of multilayer architectures, providing additional degrees of freedom for tailoring optical responses. Potential applications include directional light sources and other functional photonic devices based on reconfigurable quasi-3D metasurfaces.**

***Keywords*—Metasurface stickers; Directional emission; Polymer-embedded nanostructures**

I. Introduction

Metasurfaces enable compact control of light through subwavelength nanostructures, yet most implementations remain limited to rigid, two-dimensional platforms. Extending metasurface functionality toward three-dimensional configurations while maintaining simplicity and reconfigurability is highly desirable, particularly for controlling emission from incoherent light sources. In this work, we propose flexible and stackable metasurface stickers as a practical route to realize quasi-3D metasurfaces and directional light emission.

II. Methods

The metasurface structures were designed as periodic nanoantenna arrays to engineer the angular radiation characteristics through collective lattice effects. The nanostructures were fabricated on a sacrificial substrate and subsequently embedded into a flexible polymer layer, forming a freestanding metasurface sticker. These stickers can be attached to light-emitting substrates or stacked in multiple layers to create quasi-3D configurations. Optical characterization was performed by measuring far-field emission patterns under incoherent illumination, allowing direct evaluation of the angular radiation distribution and directionality.

III. Results and Discussion

A single metasurface sticker significantly modified the emission pattern of an incoherent light source, producing enhanced intensity in specific angular directions. Stacking multiple stickers provided additional control over the radiation distribution, indicating effective out-of-plane structuring through layer stacking. This approach enables angular emission engineering without complex fabrication or precise alignment, while preserving mechanical flexibility and reconfigurability.

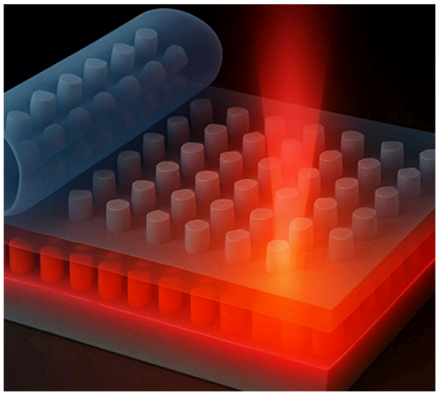

Fig. 1: Sketch of the metasurface-based directional lightsource; an emitter sandwiched between two metasurfaces [4].

IV. Conclusion

Flexible and stackable metasurface stickers provide a simple and scalable platform for preparing quasi-3D metasurfaces. The demonstrated control of directional emission from incoherent light sources highlights their potential for compact directional lighting and other reconfigurable photonic applications.

***Abstract*— We demonstrate nonlinear metasurfaces utilizing nonlinear geometric phase, providing accurate phase control of nonlinear signals via adjusting the orientation of metasurfaces. Demonstrated metasurfaces could be used as thin coatings for nonlinear applications benefitting of dispersion fine-tuning, such as for frequency conversion of ultrashort pulses using very thin nonlinear materials.**

***Keywords*— nonlinear metasurfaces, geometric phase, dispersion engineering, ultrafast optics.**

I. Introduction

Dispersion engineering is instrumental in many ultrafast applications, such as frequency conversion/characterization of ultrashort pulses using very thin nonlinear materials [1]. Nonlinear metasurfaces are emerging as a promising candidate to provide new possibilities for fine-tuning the dispersion engineering capabilities of existing technologies dominantly based on chirped mirror coatings [2]. Here, we discuss and present our latest work to develop metasurface-based coatings enabling fine-tuning of dispersion.

II. Methods and Results

The approach is based on earlier work on phasematching metasurfaces using multipass cell configuration [3]. Here, we extend the concept and study a stack of two metasurfaces, consisting of randomly positioned three-bladed gold nanogears (Fig. 1a). Due to the symmetry (C_{3v}) of nanogears, their linear response is isotropic, but second-harmonic generation (SHG) response exhibits an orientation-dependent geometric phase [4]. By rotating the second metasurface, the phasematching curves of SHG responses shift (Fig. 1b), demonstrating the phase control. Extracted phase is shown in Fig. 1c, demonstrating up to 2π phase control.

III. Conclusion

We have demonstrated nonlinear metasurfaces utilizing nonlinear geometric phase, providing accurate and up to 2π phase control of nonlinear signals via adjusting the metasurface orientations.

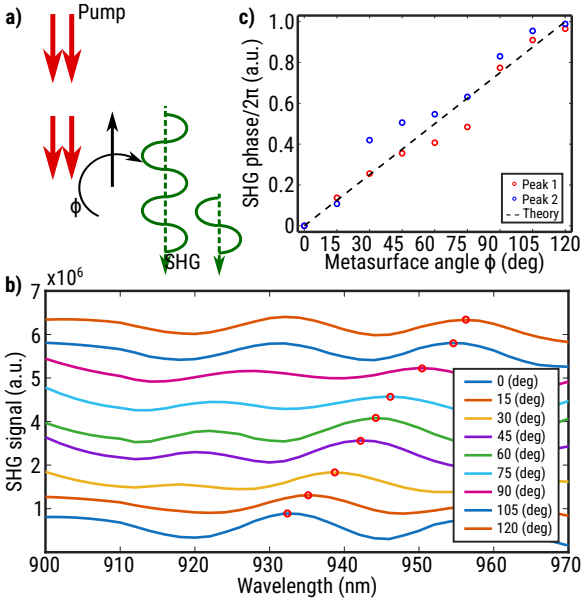

Fig. 1 a) Schematic of the experiment showing a stack of two metasurfaces of varying relative orientation. b) Measured SHG intensities as functions of pump wavelength and 2nd metasurface angle φ. c) Extracted relative phases of the SHG peaks with pump beam near 930–960 nm (highlighted with red circles in b) and 920–940 nm.

Polarization-resolved nonlinear chiroptical scattering

Ventsislav K. Valev[1,*]

[1]Department of Physics, University of Bath, United Kingdom
*Corresponding author: v.k.valev@bath.ac.uk

***Abstract*— Recent reports of nonlinear chiroptical scattering include hyper-Rayleigh, hyper-Mie, hyper-Tyndall and hyper-Raman optical activity. All were observed as differences in scattered light intensity that depend on the handedness of incident light and of the scatterers. Here, we demonstrate that the polarization state of the scattered light constitutes an independent set of chiroptical observables.**

***Keywords*— metamaterials, nanophotonics, chirality, nonlinear scattering, nanomaterials.**

I. Introduction

Although nonlinear optical activity in scattered light was theoretically proposed in 1979,[1] its experimental realization has emerged only in the past few years. Light scattering is conventionally classified into three regimes determined by the ratio of particle size to wavelength: Rayleigh scattering for subwavelength particles, Mie scattering for particles comparable to or larger than the wavelength, and the intermediate Tyndall regime. These classifications extend naturally to nonlinear optics. Because in nonlinear optics the light-matter interactions are governed by *hyper*polarizabilities, when scattering occurs at harmonic frequencies of the incident field, the processes are termed hyper-Rayleigh, hyper-Mie, and hyper-Tyndall scattering.

If the scatterers are chiral – that is, they lack mirror symmetry – the scattered light can exhibit *optical activity*. Here, optical activity refers to any change of light properties that is directly related to chirality. In 2019, we reported the first experimental observation of hyper-Rayleigh optical activity at the second harmonic.[2] This effect was observed as a difference in the intensity of second-harmonic light that depends on the chirality of the scatterers. Because even- and odd-order nonlinear processes obey different selection rules and probe distinct material responses, extending these studies to third-harmonic hyper-Rayleigh optical activity constituted a significant advance.[3] We subsequently demonstrated hyper-Mie optical activity, again as a change in detected intensity (at third-harmonic frequency).[4] We also reported hyper-Tyndall optical activity.[5]

The scattering phenomena described above are elastic, conserving energy within the light–matter system. In contrast, Raman scattering is inelastic, involving energy exchange with material excitations. When such inelastic scattering occurs in conjunction with nonlinear frequency conversion, the process is termed hyper-Raman scattering. We further showed that chiral nanoparticles can induce effective chirality in otherwise achiral molecules, giving rise to both Raman and hyper-Raman optical activity.[6] In both cases, the chiroptical effects were recorded as changes in the detected intensity.

II. Results and Discussion

Here we present several recent advances. First, while hyper-Rayleigh, hyper-Mie and hyper-Tyndall optical activity were so far only demonstrated at up to three wavelengths, we now show second- and third-harmonic spectra that extend over hundreds of nm, thereby establishing these effects as spectroscopic tools.

Next, we show that nonlinear chiroptical scattering is encoded directly in the polarization state of the generated harmonic field. Rather than relying on intensity differences between left- and right-handed excitation, we resolve how chirality governs the polarization of the scattered harmonic light itself. Remarkably, strong enantiomorph-dependent polarization signatures persist even under linearly polarized excitation, where chiroptical effects are often presumed negligible. In symmetry terms, our work extends harmonic optical activity beyond intensity-based metrics, analogous to the conceptual shift from conventional Raman optical activity to dual circular-polarization detection.

***Abstract*—Multipolar modes can be used to generate superchiral fields in the vicinity of plasmonic resonators. However, small systematic shape errors can produce linear polarization effects that can propagate in the CD to produce a spurious signal. Polarimetry allows estimating the sensitivity limits to the detection of chiral molecules.**

***Keywords*— metasurfaces, optical activity, plasmonics.**

I. Introduction

Chirality is central to the reactivity of biological molecules, with its characterization traditionally relying on the differential absorption of right- and left-circularly polarized light—an effect known as circular dichroism (CD). This approach enables the monitoring of both the configuration of simple molecules and the conformation of complex systems such as peptides or proteins. However, the weak interaction of light with these molecules severely limits detection sensitivity, particularly in studies of chiral object-surface interactions.

To enhance this interaction, photonic resonators, especially those based on localized surface plasmon resonances, have been proposed. These resonators engineer local electromagnetic fields at resonance, generating so-called superchiral fields. To date, such fields have primarily been produced using chiral resonators, but their use can introduce strong artifacts that may be mistaken for the presence of chiral molecules near the resonators [1]. In contrast, we propose the use of metasurfaces containing achiral resonators for chiral molecule detection. In this approach, superchiral fields are controlled by the polarization of the excitation light [2,3,4], offering a promising alternative for artifact-free chiral sensing. However, even such metasurfaces may exhibit irreducible artifacts.

II. Methods

Achiral plasmonic resonators can generate local chiral fields even under linear polarization excitation, as illustrated in Fig. 1 [2,3]. These fields are proposed to significantly enhance the interaction between light and chiral matter, enabling detection through variations in far-field CD [5,6].

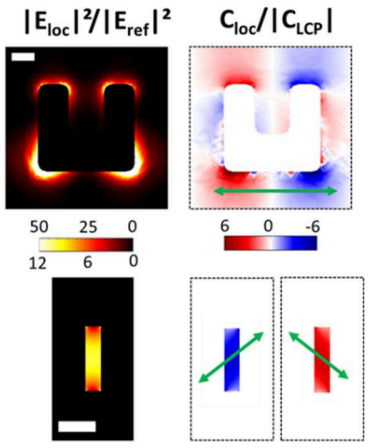

Fig. 1 Calculated near field intensity and chirality density of arrays of U-shaped resonators and nanoslits. The scale bar is 50 nm, the orientation of the linear polarization of the exciting light is indicated by a green arrow.

The resonators are typically fabricated using lithography techniques, which provide precise control over their shape. However, systematic fabrication errors may still occur, introducing residual linear birefringence and dichroism. These artifacts can propagate into the measured CD signal, producing an apparent CD effect known as LBLD. The impact of LBLD can be quantitatively assessed through full polarimetric characterization of the resonators [1].

III. Results and Discussion

Arrays of U-shaped gold resonators and nanoslits in gold films were fabricated using conventional e-beam lithography,

as shown in Fig. 2(a) and (b). Despite the apparently ideal resonator shapes observed in SEM images, the measured Circular Dichroism (CD) could never be fully suppressed (Fig. 2(c) and (d)).

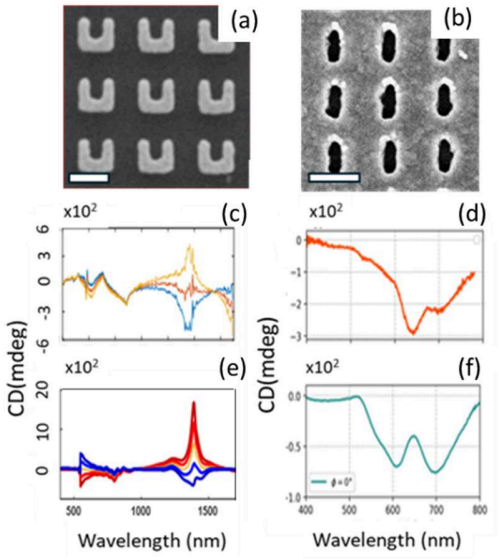

Fig. 2 SEM images of (a) U-shaped resonators and (b) nanoslits. The scale bar is 200 nm. Measured CD (note the x10^2 factor) for (c) U-shaped resonators and (d) nanoslits. In (c), different azimuthal angles (in steps of 0.1°) have been tested. Calculated CD for (e) asymmetry in arm length of 1 nm, (f) skew of 1 nm in nanoslit shape.

To investigate this discrepancy, numerical simulations of shape asymmetries were conducted using RCWA [1,7]. For U-shaped resonators, asymmetries in arm length, width, and base tilt were systematically tested. The best agreement with experimental measurements was achieved for an arm length asymmetry of just 1 nm (Fig. 2(e)). Similarly, for nanoslits, a skewness deviation of only 1° from the ideal shape was sufficient to reproduce the observed residual CD magnitude (Fig. 2(f)).

These effects are attributed to the LBLD phenomenon, which propagates into the CD signal [1]. While the calculated shape deviations are too subtle to be detected in SEM images, they are sufficient to induce spurious CD signals on the order of hundreds of millidegrees—larger than the typical CD values of most chiral biomolecules (usually a few millidegrees). Although the noise in the measurements (Fig. 2(c-d)) remains low, detecting CD variations caused by a chiral analyte would require a single, metasurface and a highly controlled experimental setup. Even minor deviations in measurement conditions could lead to significant fluctuations in spurious CD (Fig. 2(c)).

IV. Conclusion

We have demonstrated that even simple achiral metasurfaces can generate strong superchiral near fields, showing great promise for the detection of chiral biomolecules. However, conventional lithography techniques used to fabricate these metasurfaces can introduce systematic shape errors. These imperfections result in spurious CD through the LBLD effect, with magnitudes significantly exceeding those expected from interactions with chiral analytes. Numerical simulations reveal that shape deviations as small as a few nanometers, too subtle to be visualized using standard imaging techniques, are sufficient to induce these artifacts. In contrast, polarimetric measurements prove highly sensitive to such deviations, offering a means to identify and characterize the origin of spurious CD signals. This stresses the importance of precise fabrication control and comprehensive polarimetry measurement techniques in developing reliable chiral sensing platforms.

***Abstract*— We demonstrate the existence of a new type of surface plasmons supported by arrays of gold nanohelices. A spin Hall effect is observed in the free-space outcoupling of these surface plasmons, revealing a spin-dependent deflection in the emitted radiation. These results highlight the chiral nature of the plasmonic modes sustained by nanohelix arrays and provide new opportunities for controlling spin-dependent light–matter interactions in plasmonic systems.**

***Keywords*— Nanohelices, helix-array, surface plasmons, chirality, helicity, surface wave, spin-hall effect, metamaterials.**

Helical plasmonic structures exhibit remarkable chiroptical properties and have attracted significant interest in nanophotonics and metamaterials. Arrays of metallic helices have been shown to operate as broadband circular polarizers [1] and to exhibit negative refraction under large wave illumination [2]. When locally excited, these systems can also support the propagation of optical analogs of magnetic spin waves along the helix axis [3]. In these configurations, the observed response arises from volumetric plasmonic modes within the helix arrays.

Here, we demonstrate the existence of surface plasmons propagating on top of a helix array, whose electromagnetic fields decay along the helix axis both within the array and in the free space above it.

Through finite-difference time-domain simulations, we first predicted the optical properties of the chiral surface plasmons, including their dispersion relation. To demonstrate the existence of these surface waves experimentally, we fabricated homochiral arrays of six-turn gold-coated carbon helices. The helix cores were produced by focused ion beam-induced deposition of carbon, followed by the deposition of a thin gold layer to support plasmonic excitations.

Using a custom optical setup enabling far-field observation along the propagation direction of the surface plasmons in the metamaterial (horizontal axis), the array was illuminated normal to the surface (vertical axis) with a tightly focused laser beam at wavelengths in the telecommunication band. Under these conditions, we observed the free-space outcoupling of the surface plasmons, revealing a pronounced spin Hall effect and highlighting the intrinsic chiroptical nature of the plasmonic wave.

***Abstract*— Enhancing single-photon sources efficiency via optically resonant nanostructures is crucial for quantum communications. High-refractive-index dielectric nanostructures offer appealing optical properties through Mie resonances, with reduced absorption, and compatibility with CMOS technology. This study explores experimentally and numerically how silicon nanoantennas and metasurfaces influence the spontaneous emission and directionality of model quantum emitters.**

***Keywords*— dielectrics, nanoantennas, metasurfaces, single photon, quantum emitters.**

Improving the brightness and efficiency of single photon sources by the mean of optically resonant nanostructures is a major stake for the development of efficient nanodevices for quantum communications.
For a couple of decades, these resonant nanostructures have mainly been made of noble metal that sustain strong localized plasmon resonances (LSPR) that can be used to manipulate, concentrate or redirect visible light. Such properties have led to numerous actual or potential applications in integrated optics, sensors, nonlinear optics, field-enhanced spectroscopies, or photovoltaics. Recently, an alternative emerged with high refractive index dielectric nanostructures, which offer the same range of applications as plasmonics by manipulating Mie optical resonances instead of LSPR [1].

These resonances can be efficiently tuned by modifying the size, shape, and material of those nanostructures (e.g. silicon, n ~ 4) [2]. Furthermore, high index dielectric nanostructures offer several key advantages when compared to their metallic counterparts: absorption losses are far weaker for wavelengths longer than the direct band gap, access to semiconductor (CMOS) technology for nanostructure fabrication, and presence of intrinsic strong magnetic and electric resonances, providing an unique opportunity to spatially separate and redistribute the energy of the magnetic and electric parts of the electromagnetic field in the near field, otherwise inextricably connected in the far field [3].

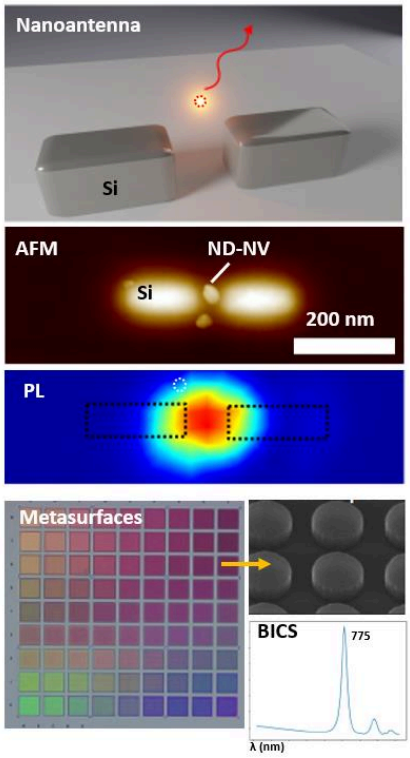

Fig. 1 Top: illustration of a Si nanoantenna coupled to a quantum emitter (ND-NV), and corresponding characterizations [5]. Bottom : metasurfaces made of Si nanodiscs.

In this work, we examine how both simple and complex high-index dielectric nanoantennas influence the spontaneous emission and directional properties of model quantum emitters. In particular, color centers in nanodiamonds are an ideal model system exhibiting single photon emission properties at room temperature [4], making them particularly suitable for proof-of-concept experiments in quantum nano-optics. By modifying the LDOS through nanostructuring, we use time-resolved photoluminescence measurements and Fourier imaging to show that the photodynamics and the directivity of these emitters can

be significantly enhanced when coupled to a nanoantenna, even at the single-photon level. Our experimental results are in good agreement with multipolar analysis and numerical simulations based on the Green Dyadic Method – GDM [6]. Additionally, we numerically investigate the potential of two-dimensional silicon nanostructure arrays, known as metasurfaces, for controlling these photodynamic processes.

***Abstract*— Silver nanostructures offer superior optical response over gold at a lower cost. However, scalable aqueous synthesis with precise size and shape control remains challenging. This talk presents advances in aqueous synthesis and robust functionalization, demonstrating how these scalable silver nanoplatforms can match or exceed gold's performance in real-world applications.**

***Keywords*— plasmonic nanoparticles, silver nanostructure, scalable synthesis.**

Silver nanostructures are exceptional candidates for next generation plasmonic, catalytic, and sensing applications, offering superior optical response, higher conductivity, and better cost-effectiveness than gold. While the polyol process enables scalable synthesis, it often limits size and shape precision and complicates functionalization. Achieving similar scalability in aqueous systems remains a significant challenge due to the difficulty of regulating the seed facets that govern growth. Furthermore, robust functionalization is essential for integrating these sensitive materials into advanced platforms. This talk presents recent advances in the scalable aqueous synthesis of silver nanoparticles, focusing on strategies to control seed facets, morphology, and surface chemistry across large batches. We also highlight scalable functionalization approaches that ensure reliable integration into high-performance systems. Finally, by comparing silver and gold counterparts, we demonstrate how silver nanostructures can match or exceed the efficiency of gold in real-world applications.

***Abstract*—We present dielectric metasurface nanolasers leveraging non-local lattice resonances and band-folding to achieve high-Q electric quadrupole modes with superior field–gain overlap. Via Pancharatnam–Berry phase encoding, we enable low-threshold, directional, circularly polarized lasing, offering a compact, full-polarization-controllable source for quantum photonics and sensing.**

***Keywords*— metalaser, nonlocal metasurfaces, PB phase, low-threshold, directional lasing.**

I. Introduction

Addressing the bottlenecks of limited integrability in traditional semiconductor lasers and high optical losses in plasmonic nanolasers[1], we present a novel architecture for dielectric metasurface micro/nanolasers based on non-local lattice resonances. By employing a Brillouin zone band-folding strategy, we precisely lock the high-Q modes of tightly bound in-plane electric quadrupole lattices into the spectral region above the light cone yet below the Rayleigh anomaly[2]. This approach maintains an ultra-high quality factor while achieving significant spatial overlap between the near-field and the gain medium, fundamentally overcoming the challenges of field-gain separation inherent in out-of-plane magnetic dipole Bound States in the Continuum (BIC) modes and the difficulties of integrating gain materials within nanopores[3].

Furthermore, we demonstrate in-situ encoding of Pancharatnam-Berry (PB) geometric phases[4] via translational and rotational perturbations of diatomic unit cells. This establishes a critical pathway from efficient near-field light-matter interactions to far-field highly directional circularly polarized emission. Ultimately, this work provides a new paradigm for light sources characterized by high Q, low power consumption, superior beam quality, full-polarization controllability, and ease of integration, paving the way for next-generation intelligent sensing and quantum photonic systems.

Chirality-Induced Response in Chiral Inorganic Materials

Yoshihiko Togawa[1,*]

***Abstract*—Chirality-dependent generation, propagation, and transfer of angular momenta of the chiral phonons are demonstrated with chiral quartz crystals under the steady heat flow.**

***Keywords*— Quartz, Chiral Phonon, Angular Momentum**

I. Introduction

It has been clarified that the spin polarization phenomena initially found in chiral organic molecules occur even in chiral inorganic crystals. The spin signals appear in a variety of chiral materials from molecules to crystals irrespective of electrical conductivity ranged from metals to insulators. As a manifestation of chirality, which corresponds to time-even pseudo scalar, works as a microscopic chiral term in driven chiral media and hybridizes translational and rotational degrees of freedom, a polarization of angular momenta appears under charge or thermal flow. In this study, we investigate chirality-dependent generation, propagation, and transfer of angular momenta of the chiral phonons with chiral quartz crystals under the steady heat flow [2].

II. Methods

Quartz is an insulative and diamagnetic material which has a trigonal crystal structure with the space group of $P3_121$ (No. 152) or $P3_221$ (No. 154). The former has a right-handed helical arrangement of SiO_4 tetrahedrons along the c axis, while the latter has the left-handed one. A quartz sample is set on a heat bath with a resistive heater on the other end for the thermal power apply, as used in the conventional setup for the steady-state thermal conductivity measurement. For the signal detection via an inverse spin Hall effect, two electrodes of tungsten (W) or platinum (Pt) were deposited by a sputtering method in the center part of the quartz, which is located between the heater and thermal bath.

III. Results and Discussion

The temperature dependence of the detected signal coincides with those of the thermal conductivity and Seebeck coefficient. The signals change the polarity with regard to the handedness of quartz. In addition, they show the opposite polarity when replacing the detection electrode from W to Pt. Furthermore, a dependence of the signal intensity on the electrode thickness is consistent with that expected for the inverse spin Hall effect. These results indicate that chirality-dependent angular momenta are generated and carried by the thermally driven chiral phonons in the quartz crystal and could be extracted from the quartz as a spin signal.

IV. Conclusion

We have demonstrated that heat flow can generate the spin signal in chiral quartz. A comprehensive understanding of these nontrivial features will clarify the mystery of chirality-induced dynamical responses such as chirality-induced spin selectivity (CISS).

Self-assembled Plasmonic Metamaterials with Hyperbolic Dispersion for Applications in Sensing

Anastasiia Zelaska, Mayela Romero-Gomez, Anatoly Zayats and Wayne Dickson*

Department of Physics, King's College London, London, UK
*Corresponding author: wayne.dickson@kcl.ac.uk

***Abstract*— Plasmonic metamaterials with hyperbolic dispersion are characterized by a transition from elliptic to hyperbolic dispersion at a tunable epsilon-near-zero frequency. Their self-assembled fabrication provides unique opportunities for tailoring their constituents, but importantly, hybridizing them with functional layers for ultrasensitive sensing.**

***Keywords*— metamaterials, plasmonics, sensing.**

I. Introduction

Plasmonic metamaterials based on self-assembled arrays of gold nanorods have demonstrated excellent sensitivity to a range of stimuli, including biological molecules[1], ultrasound[2] and hydrogen[3]. The flexibility of the electrochemical fabrication approach not only enables the constituent plasmonic material to be varied [4], but also allows the morphology of the meta-atoms comprising the metamaterial to be tailored, for example, to maximize the electromagnetic field enhancement[5]. In this work we will summarise the development of these plasmonic metamaterials for applications in ultra-sensitive sensing, with a particular emphasis on how the underlying plasmonic metamaterial can be hybridized with suitable transduction layers for sensing targets in the gas phase.

II. Methods

The plasmonic metamaterials are fabricated using electrochemical growth of metallic nanorods within nanoporous aluminium oxide templates, producing highly quasi-ordered self-assembled arrays with tunable geometry and composition. This scalable approach enables the realization of nanorod metamaterials based on different plasmonic materials, including gold, copper, and aluminium, providing either stability (gold), additional functionality (copper) (Fig. 1a–c), or bringing the epsilon-near-zero (ENZ) response into the deep ultraviolet (Fig. 1d–f). Post-fabrication electrochemical modification provides an additional mechanism to both tailor the optical response of the metamaterial and provide sensitivity to different stimuli for applications in sensing. In the case of hydrogen sensing, electrochemical functionalization with palladium provides a reversible sensing mechanism, while copper can readily be anodized (Fig. 1b-c) to create Cu_2O or CuO shells for VOC detection.

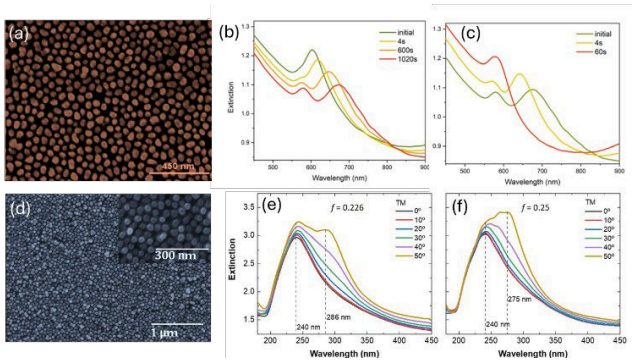

Fig. 1. Plasmonic Metamaterials comprised of copper (a-c) or aluminium (d-f). The electrochemistry of copper enables both wide tunability of the ENZ condition (b, c) with a controllable shell-thickness of copper (II) oxide while aluminium metamaterials bring the ENZ into the deep ultraviolet (e, f).

III. Results and Discussion

These self-assembled nanorod metamaterials can be engineered to provide highly sensitive detection of a range of stimuli. This work will focus on their functionalization with palladium for high-specificity hydrogen detection, metal oxides for VOC detection, and intrinsic deep UV sensitivity to biological molecules.

IV. Conclusion

This work demonstrates the flexibility of self-assembled metamaterials for adaptation to a wide range of stimuli for ultrasensitive sensing.

Broadband Infrared Unidirectional Absorption by non-Hermitian Multilayer Structure

Wakana KUBO*

[1] Department of Electrical Engineering and Computer Science,
Tokyo University of Agriculture and Technology,
*Corresponding author: w-kubo@cc.tuat.ac.jp

***Abstract*—We demonstrate a non-Hermitian four-layer structure exhibiting broadband unidirectional absorption in the infrared region. By precisely designing layer thicknesses, directional absorption is achieved over a wide spectral range. This approach offers a promising route toward thermal management applications, such as infrared heat-shielding and thermal smart window technologies.**

***Keywords*— Non-Hermitian photonics, Unidirectionality, Infrared region, Multilayer, Thermal smart glass**

I. Introduction

Non-Hermitian photonics has emerged as a powerful platform for realizing strong light–matter interactions, enabling unique phenomena such as optical unidirectionality and the non-Hermitian skin effect.[1] These distinctive optical phenomena open promising opportunities for applications in the visible and infrared (IR) spectral regions, including optical isolators, asymmetric absorbers, and thermal radiation control.

Representative demonstrations of non-Hermitian unidirectionality have been reported in photonic structures in the visible light region.[2] Furthermore, non-Hermitian unidirectionality has also been explored beyond the visible regime. However, the reported unidirectional responses are typically restricted to narrow spectral bands or specific operating wavelengths. For applications in thermal control, unidirectional absorption must be achieved over a broadband spectral range that follows the blackbody radiation spectrum. To date, broadband unidirectional infrared absorption based on non-Hermitian multilayer structures has not yet been reported, particularly in a form compatible with blackbody radiation spectra.

In this study, we design and experimentally demonstrate a non-Hermitian unidirectional multilayer structure spectrally matched to blackbody radiation using the transfer-matrix formulation. We further investigate the thermal radiation shielding effect of the proposed non-Hermitian structure to discuss its potential application as a functional thermal smart window.

II. Methods

A multilayer structure composed of alternating calcium fluoride (CaF_2) and bismuth (Bi), serving as low-loss and high-loss materials, respectively, was employed to realize non-Hermitian optical responses in the infrared (IR) region.

To achieve unidirectionality of the multilayer structure, the thicknesses of the four layers were designed using the electromagnetic transfer-matrix formulation.

$$\mathrm{M} = \prod_{j=1}^{N} \begin{pmatrix} cos\beta_j & isin\frac{\beta_j}{q_j} \\ iq_j sin\beta_j & cos\beta_j \end{pmatrix},\ j = 1, 2, 3, \cdots N$$

Here, β_j is the phase thickness of the *j*-th layer defined as

$\beta_i = k_0 n_j d_j cos\theta_j$. Eq. (3)

The optical admittance q_j depends on the polarization of the incident light.

$q_j(\mathrm{TE}) = n_j cos\theta_j$, $q_j(\mathrm{TM}) = \frac{n_j}{cos\theta_j}$, Eq. (4)

where n_j, d_j, and k_0 are the refractive index, the thickness of the *j*-th layer, and the wavenumber in vacuum.

III. Results and Discussion

Figure 1(a) presents a schematic of the four-layer structure designed to match the blackbody radiation spectrum at 373 K. Figure 1(b) presents the calculated absorption spectra of the four-layer structure under forward (red line) and backward (black line) illumination.

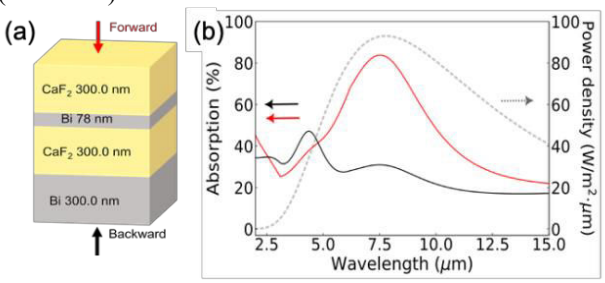

Fig. 1 (a) Schematic of the four-layer structure designed to match the blackbody radiation spectrum at 373 K. (b) Calculated absorption spectra of the four-layer structure under forward (red line) and backward (black line) illumination. The gray dashed line presents the blackbody radiation spectrum at 373 K.

The absorption spectrum under forward illumination showed an absorption of 83.9% at a wavelength of 7.5 μm and showed good agreement with the blackbody radiation spectrum at 373 K (gray dashed line). In contrast, the absorption spectrum under backward illumination exhibited an absorption of 30.9% at 7.5 μm, indicating that the absorption difference between forward and backward illumination was 53.0%. These results demonstrate that broadband infrared unidirectionality was numerically realized through transfer-matrix formulation and appropriate selection of high-loss and low-loss materials.

To realize broadband infrared unidirectional absorption, we fabricated a four-layer structure on Cu substrate using thermal evaporation. Figure 3(a) shows a photograph of the fabricated four-layer structure. The left and right samples correspond to film stacks of forward and backward structures, respectively.

Figure 3(b) presents the cross-sectional SEM image of the four-layer structure. The measured film thicknesses of the forward structure were 194 ± 80 nm (bottom Bi layer), 377 ± 93 nm (CaF_2 layer), 77 ± 2 nm (Bi layer), and 319 ± 45 nm (top CaF_2 layer), respectively.

Figure 3(c) presents the measured absorption spectra of the sample under forward (red line) and backward (black line) illumination. Two peaks of nearly perfect absorption were observed, with absorption values of 99.1% and 98.4% at 4.7 and 7.2 μm. In contrast, the absorption under backward illumination at these wavelengths was 27.1% and 20.4%, indicating a modulation depth of 52% at 4.7 μm.

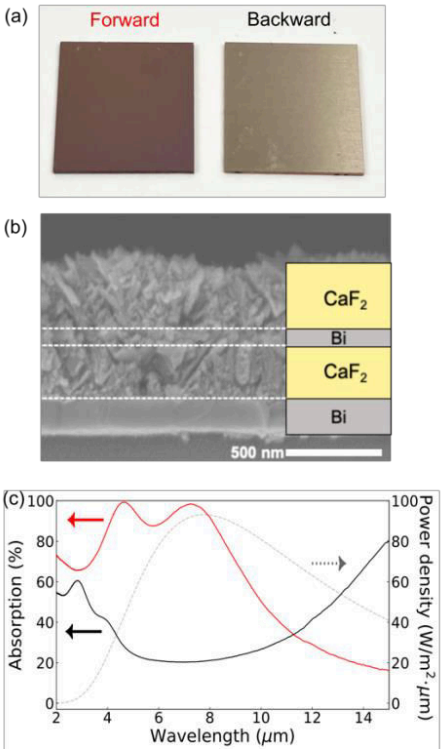

Fig. 2 (a) Photograph of the fabricated four-layer structure. The left and right samples correspond to film stacks of forward and backward structures, respectively. (b) Cross-sectional SEM image of the four-layer structure. (c) Measured absorption spectra of the sample under forward (red line) and backward (black line) illumination. The dashed line presents the blackbody radiation spectrum at 373 K.

This result demonstrates broadband infrared unidirectional absorption for the first time.

Finally, we examined the functionality of the four-layer structure as a smart glass for shielding thermal radiation. The forward and backward structures were heated using a hot plate, and the resulting temperatures were monitored by an IR camera (Fig. 3(a)). Owing to nearly perfect absorption of thermal radiation from the heat source, the forward structure exhibited a higher temperature of 64.9 °C. In contrast, the backward structure reflected a portion of the incident thermal radiation, resulting in a lower substrate temperature of 62.8 °C compared with the forward structure. These results suggest that the non-Hermitian structure exhibiting broadband infrared unidirectional absorption can function as an effective thermal shielding glass.

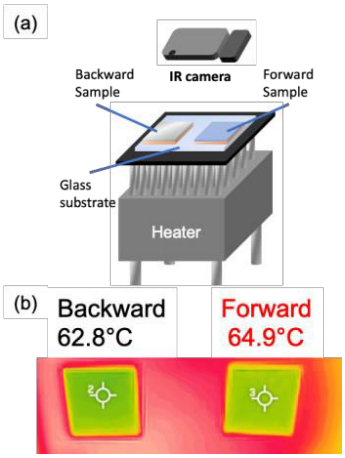

Fig. 3 (a) Experimental setup for observing the thermal shielding effect of the four-layer structure. (b) Infrared (IR) camera images of the non-Hermitian structures with forward (right) and backward (left) film-stack configurations.

Conclusion

In summary, we proposed and experimentally demonstrated a non-Hermitian four-layer structure that exhibits broadband unidirectional absorption in the infrared region.[3] By designing the individual layer thicknesses based on the transfer-matrix formulation, the absorption peak under forward illumination can be spectrally matched to the blackbody radiation spectrum at different temperatures, while the absorption under backward illumination is strongly suppressed. These results suggest potential applications in thermal smart windows.

***Abstract*— Progress in plasmonic chemistry demands reliable model reactions to elucidate energy transfer, mechanisms, and materials discovery. We show PNTP azo coupling on Au nanoparticles is unsuitable, as plasmonic heating induces Au–S cleavage and thiol oxidation. We propose alkoxyamine homolysis, offering simpler kinetics, identifiable products, and robust mechanistic interpretation for catalysis.**

***Keywords*— plasmon catalysis, azo-coupling, alkoxyamine, photocatalysis**

I. Introduction

Plasmonic catalysis relies on model reactions to understand energy transfer mechanisms and guide materials discovery. The azo coupling of 4-nitrothiophenol (PNTP) has been widely used as a model reaction; however, uncertainties remain regarding its mechanistic simplicity and reliability under plasmon excitation. This work reassesses its validity and proposes a more suitable alternative..

II. Methods

Gold nanoparticles coated with PNTP were subjected to laser-induced plasmon excitation. Reaction progress and surface chemical changes were monitored using Raman spectroscopy and X-ray photoelectron spectroscopy (XPS), focusing on N 1s and S 2p spectral regions to track bond changes and oxidation processes.

Local temperature effects during plasmon excitation were evaluated experimentally and theoretically to determine whether heating could induce ligand desorption and surface chemical transformation.

To identify a more suitable model reaction, alkoxyamine homolysis was investigated as an alternative system, monitored via electron paramagnetic resonance (EPR) spectroscopy due to its well-defined radical products and established kinetic behavior.

III. Results and Discussion

Experimental observations reveal:

• Successful PNTP azo coupling confirmed by Raman and XPS analysis

• Significant Au–S bond cleavage during irradiation, evidenced by S 2p spectral changes

• Concurrent thiol oxidation detected in N 1s spectra

• Plasmonic heating raises local temperatures above thiol desorption thresholds

• Reaction kinetics involve multiple competing pathways rather than a simple mechanism

These findings demonstrate that PNTP coupling involves ligand desorption and oxidation processes, complicating mechanistic interpretation and violating requirements for a simple model reaction.

In contrast, alkoxyamine homolysis proceeds via a single bond-cleavage event, producing identifiable radicals with well-understood kinetics, enabling reliable mechanistic analysis.

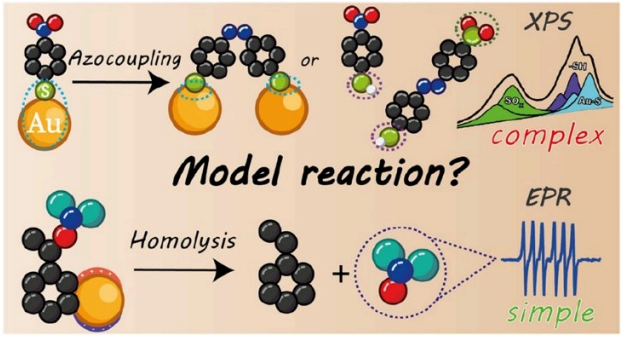

Figure 1. Comparison of PNTP azo coupling and AA homolysis as model reactions for plasmon catalysis fundamental studies.

IV. Conclusion

The PNTP azo coupling reaction is unsuitable as a universal model reaction for plasmonic catalysis because plasmonic heating induces surface bond cleavage and complex reaction pathways. Alkoxyamine homolysis offers a simpler, kinetically well-defined alternative suitable for mechanistic studies. Adoption of reliable model reactions will accelerate progress in plasmon-driven catalysis.

***Abstract*— We demonstrate a proof of concept for artificial protein assemblies as programmable scaffolds for the selective positioning of quantum emitters that opens new avenues for engineered light–matter interactions in nanophotonics.**

***Keywords*— self-assembly, protein origami, quantum emitters, collective emission.**

I. Introduction

In nature, the spontaneous process of protein self-assembly, driven by specific intermolecular interactions, leads to the formation of highly symmetrical and periodic structures such as viral capsids and cytoskeletal filaments, demonstrating nanometer-scale precision and remarkable structural reproducibility [1]. Such precision and periodicity are particularly attractive for nanophotonics, where accurate control over emitter positioning is essential for enhancing light-matter interactions and enabling engineered optical properties beyond those achievable with disordered materials [2]. However, the use of natural proteins in nanophotonic applications remains challenging due to their limited stability, structural fragility, and restricted tunability. To overcome these limitations, we demonstrate the concept of artificial protein origami as a platform for the selective and controlled arrangement of quantum emitters that can result in plethora of optical phenomena.

II. Methods

The strategy of protein origami is based on the assembly of small and stable artificial α-helical repeat proteins (α-Rep) that serve as modular building blocks.[3] To induce controlled assembly, we mix two types of proteins: “bricks” and “staples” (Figure 1a) [4,5]. Each brick consists of a central region (green region) containing a defined number of α-helical repeats and two distinct α-Rep termini (red and blue). Staples proteins (Fig. 1a, orange) are small proteins that are designed to recognize and bind selectively to complementary interfaces on the blue and red termini of two adjacent bricks thus driving the formation of a superhelical structure (Fig. 1a, right). By bridging neighboring bricks, staples effectively lock and stabilize them at a predetermined orientation and distance. The resulting superhelices can further interact with each other and assembling into more complex 3D structures such as chiral fibers, sheets, and multilayer structures with Moiré patterns [4,5].

Notably, the original protein sequences are designed with amino acids that do not contain any thiol groups. Subsequent introduction of cysteine residues enables site-specific functionalization, creating anchoring points for covalent attachment of various quantum emitters, such as fluorescent gold clusters, quantum dots, and molecular dyes.

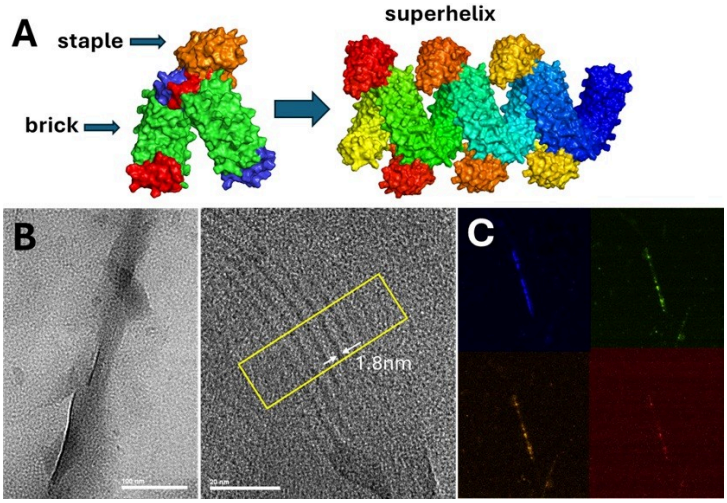

Fig. 1: (A) the model of brick and staple assembly forming a superhelix. (B) TEM of assembled protein origami with attached gold clusters. (C) FLIM images of origami with luminescent gold clusters. Blue and partially green regions represent proteins’ autofluorescence, while green, orange and red regions correspond to the PL of clusters.

III. Results and Discussion

We employed functionalized bricks in which four cysteine residues were introduced into the middle of the inner surface of the central region (Figure 1a, green). In this configuration, the attached emitters are positioned and confined within the

internal cavity of the superhelix. Upon complete binding of emitters to the bricks, a densely packed one-dimensional chain of emitters is expected to form along the helix axis. Owing to the small diameter of the superhelical inner cavity (~4 nm), glutathione-stabilized gold nanoclusters were selected as emitters. Gold clusters were first attached to the bricks via ligand exchange, followed by induction of self-assembly through the addition of staples. Transmission electron microscopy (TEM) images (Figure 1b) confirm the formation of assembled protein origami structures where individual helices are organized into extended sheet-like architectures.

Fluorescence Lifetime Imaging Microscopy (FLIM) was performed to verify cluster attachment. The gold clusters exhibit broad luminescence (FWHM ≈ 90 nm) in the 500–700 nm range, with a maximum at 600 nm. Emission was recorded in four spectral channels (Figure 1c). The blue and partially green channels correspond to protein autofluorescence, enabling localization of the protein structures, while the green-orange-red channels arise from gold cluster emission. As shown in Figure 1c, the cluster luminescence is strongly colocalized with the protein structures, confirming their successful attachment.

IV. Conclusion

We have demonstrated proof of concept for using artificial protein assemblies as scaffolds for the selective positioning of quantum emitters. By selecting appropriate brick designs, the inter-emitter distance and periodicity can be precisely controlled at the nanometer scale. This programmable spatial organization enables the formation of ordered emitter arrays within well-defined 3D architectures. The presented concept opens new pathways for applications in nanophotonics, including engineered light-matter interactions, collective phenomena, and the development of functional photonic nanomaterials.

Ultrafast Switching from Strong to Weak Coupling in a Hybrid Plasmonic-Photonic Microcavity

Benedict S. Morris[1,*], Sergeï Kostcheev[2], Luis Santos[1], Khanh-Van Do[1], Anna Rumyantseva[2], Shuwen Zeng[2], Renaud Bachelot[2], and Bruno Palpant[1]

***Abstract*— Ultrafast optical absorption can modify gold nanoparticle optical properties. We exploit this subpicosecond reversible change to explore strong coupling physics in a plasmonic-photonic microcavity. We show that our hybrid system can be tuned from strong to weak coupling by all optical pumping, opening new pathways for sensing applications.**

***Keywords*— Rabi splitting, plasmonic nanoarray, pump-probe spectroscopy, femtosecond laser, sensing.**

Metallic nanoparticles, through the localised surface plasmon resonance (LSPR) phenomenon, exhibit distinct optical absorption that depends on particle geometry, volume, material, environment, and spatial distribution. This resonance can be altered by a small perturbation in the environment of the particles; hence, they are used for efficient sensing applications. Despite the considerable detection sensitivity that can be achieved [1], there is still a need for a short-timescale detection of light molecules in dilute conditions.

To address this sensing challenge, we pursue a new hybrid technology [2], [3] by coupling gold nanorods (AuNRs) to a photonic cavity composed of two Bragg mirrors. This novel approach combines the sensitivity of plasmonic and photonic devices allowing us to propose a new generation of optical sensors.

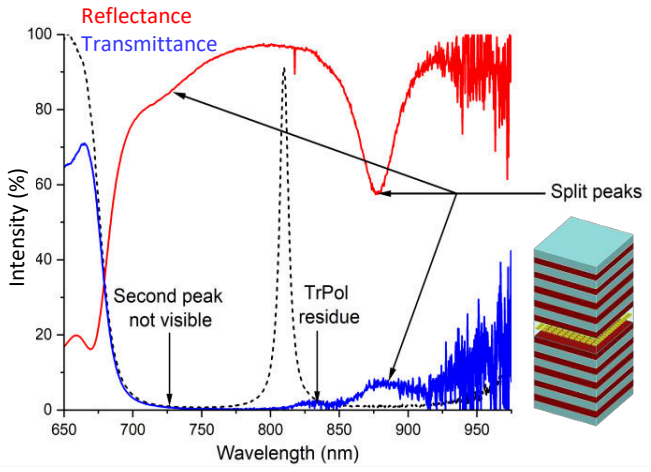

Fig. 1: Bare cavity transmittance (black dotted line) compared to hybrid cavity transmittance (blue line) and reflectance (red line) where the Rabi splitting is clearly visible.

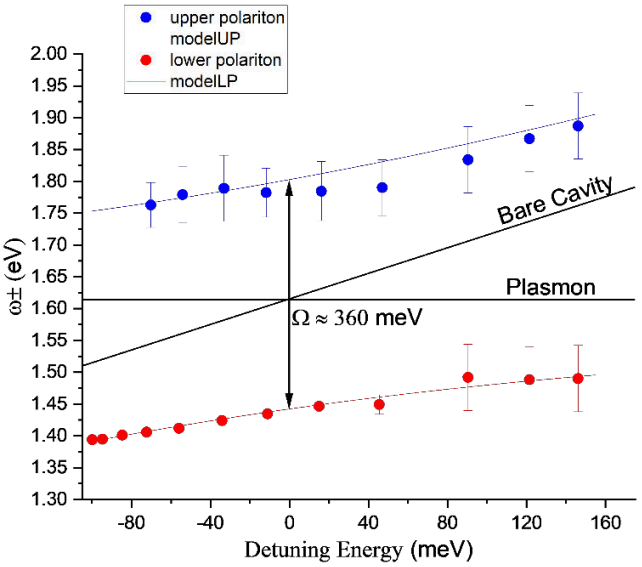

Fig. 2: Anti-crossing curve of our hybrid cavity showing large Rabi Splitting at zero detuning.

Within this hybrid framework, the strong and ultrastrong coupling regimes emerge as rich domains of electromagnetic interaction, where a large diversity of physical phenomena is enabled. To experimentally explore these regimes, we fabricate a plasmonic metasurface placed at the anti-node of a first-order Bragg microcavity, through electron-beam lithography and evaporation. We achieve robust, strong coupling (coupling strength $g \approx 0.10$), at ambient room temperature conditions. Then, after validating the stationary FDTD simulations with experimental results, the simulations are used to investigate the effects of the metasurface filling factor and position in the cavity on the coupling to the photonic resonance.

The coupling regime between our two resonators is highly dependent on each individual oscillator. Therefore, any change in the plasmonic resonator will have repercussions on the system's overall response. On the other hand, due to the LSPR dependence on the nanoparticle optical properties, any change in the dielectric function of the particles affects the plasmon resonance. Incidentally, when subject to subpicosecond laser pulses, high absorption in gold nanoparticles can lead to an ultrafast modification of the gold's dielectric function [4], therefore leading to a transient change in the plasmon resonance.

We therefore study, through pump-probe measurements, the effect of the AuNRs' transient modulation after absorption of short laser pulses on the coupling regime. We demonstrate that the reversible ultrafast modification of the AuNRs' complex permittivity results in a subpicosecond switch in coupling regimes. The spectral and time-domain signatures of these coupling regimes are both sensitive to the AuNR environment, opening a new pathway for high sensitivity sensing due to additional information compared to conventional stationary spectral data alone.

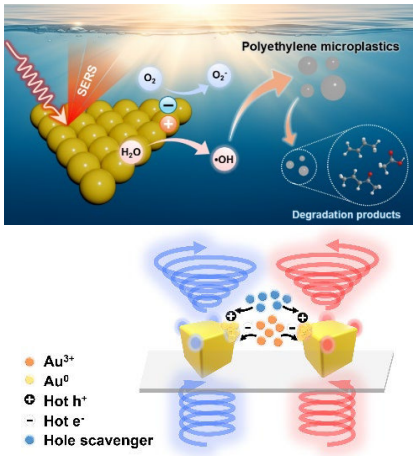
***Abstract*— Plasmonic hotspots generate hot carriers that drive chemical transformations, while enhanced fields enable in situ SERS readout. We demonstrate visible-light degradation of polyethylene microplastics by Au nanoparticle clusters and CPL-driven chiral growth from achiral Au nanocubes, arising from asymmetric hot-electron distributions and validated by CDS and SEM.**

***Keywords*— Hot carrier, Plastic degradation, SERS, Chirality.**

I. Introduction

Plasmonic metal nanoparticles (NPs) can efficiently merge the reactivity and energy harvesting abilities with enhanced plasmonic performance for sustainability. In this presentation, I will introduce the ability of plasmonic nanostructures to induce efficient energy transfer for plasmonic catalysis based on hot electron-mediated chemical reactions. Colloidally assembled nanostructures, e.g., Au particle-in-a frame and bimetallic assembled Au@M (M=Pd, Pt) nanostructures with catalytically active metals, exhibited superior performance over their constituent nanostructure counterparts in plasmonic sensing, surface-enhanced Raman scattering (SERS), and plasmonic catalysis. These model systems allow us to study the synergy effect of hot spots in plasmonic catalysis. The assembled NPs with hot spots can induce efficient light-to-chemical energy conversion as increasing non-radiative plasmon decay to the catalyst surface. We monitored the plasmon-mediated chemical reactions using SERS and dark-field scattering spectroscopy to study hot carrier-induced chemical conversion. Also, we thoroughly investigated the chirality transfer from circularly polarized light (CPL) to achiral Au nanocubes with hot carrier-mediated chemical reactions without involving any chiral molecule stimulators. Theoretical simulations, including hot-electron surface maps combined with experimental growth time and wavelength dependence of the chiral growth, reveal that the plasmon-induced chirality transfer is mediated by the asymmetric distribution of hot electrons on achiral Au nanocubes under CPL excitation. We expect these studies to provide a new direction for developing efficient plasmonic catalysts.

II. Results and Discussion



III. Conclusion

Plasmonic hot carriers provide a versatile route to drive chemical reactions, while plasmon-enhanced spectroscopy directly tracks the underlying pathways. By employing plasmonic nanostructures, we demonstrate visible-light microplastic degradation and CPL-induced chirality transfer, establishing design principles that connect hot-carrier generation, and nanoscale chemical and structural evolution.

Locally asymmetric plasmonic photocatalysis driven by light's polarization

L. V. Besteiro[1*]

[1]CINBIO, University of Vigo, Campus Universitario de Vigo, Lagoas Marcosende, 36310 Vigo, Spain

[*]corresponding author: lucas.v.besteiro@uvigo.es

***Abstract*: Light-to-matter chirality transfer can modify achiral plasmonic structures illuminated with circularly polarized light, inducing chiral growth on achiral plasmonic seeds by photocatalytically imprinting the reduced symmetry of the local fields onto the nanoparticle. We will discuss how different energy-transfer mechanisms can drive such asymmetric geometric transformations, discussing recent experimental demonstrations.**

Plasmonic nanostructures offer strong resonant responses in the UV-to-IR spectral range, which has led to their use in many optical and energy-related applications. Plasmonic photocatalysis stands as a prominent example of the latter, with plasmonic nanostructures serving as nanoscale antennas funneling radiant energy into their local environment. This talk will cover a particular subset of plasmonic photocatalytic setups with two defining characteristics: (i) the light-driven process modifies the geometry of the plasmonic nanoparticle or the optical properties of its immediate environment, and (ii) does so preserving local asymmetries induced by impinging circularly polarized light (CPL). This creates chiral features in initially achiral shapes, hence transferring chirality from light to the nanostructures, and contrasting with common strategies yielding chiral plasmonic systems, where chirality is seeded from molecules or introduced through top-down fabrication methods. The presentation will cover theoretical considerations underpinning light-to-matter chirality transfer in plasmonics,[1] a discussion about the physical energy-transfer mechanisms driving this phenomenon,[2,3] as well an overview of experimental work going from pioneering examples[4,5] to recent progress.[6,7]

Circular Dichroism Enhancement via CPL-Induced Chiral Growth of Core–Shell Plasmonic Particles

Koichiro Saito[1,*], Yoshie Ishikawa[1]

[1]National Institute of Advanced Industrial Science and Technology (AIST), Japan
*Corresponding author: koichiro.saito@aist.go.jp

***Abstract*— Synthesizing chiral plasmonic nanoparticles under circularly polarized light avoids the need for chiral molecules. However, their g-factors have remained low. Here, we achieve an approximately eightfold enhancement of the g-factor by inducing chiral Ag growth on MnO_2-coated gold nanorods.**

***Keywords*— chirality, plasmonic nanoparticles, circularly polarized light, colloidal synthesis**

I. Introduction

Chiral plasmonic nanoparticles with intrinsically asymmetric morphologies hold great promise for applications such as chiral sensing and asymmetric catalysis. Synthesizing chiral plasmonic nanoparticles using circularly polarized light (CPL) as the chiral source offers the advantage of not requiring any chiral molecules. We previously demonstrated that circularly polarized light can drive a photochemical reaction that deposits silver onto gold nanorods (AuNRs) dispersed in solution, yielding rod-shaped chiral plasmonic nanoparticles (AuNR@Ag) that exhibit circular dichroism (CD) [1]. Although such colloidal synthesis is suitable for large-scale production, the resulting g-factors have remained relatively low.

In this study, we synthesized AuNR@MnO_2 by inducing chiral deposition of manganese oxide around colloidal AuNRs under circularly polarized light. We then deposited Ag onto these AuNR@MnO_2 structures under CPL irradiation to obtain AuNR@MnO_2@Ag. The colloidal solution of the core-shell nanostructures exhibited a g-factor approximately eight times larger than that of conventional AuNR@Ag.

II. Methods

AuNR@MnO_2 were synthesized by irradiating left- or right-handed circularly polarized light (CPL) from a red LED ($\lambda \approx 630$ nm) onto a dispersion of Au nanorods (AuNRs) containing citrate and permanganate. Subsequently, AuNR@MnO_2@Ag was obtained by adding citrate and silver nitrate to the AuNR@MnO_2 dispersion and irradiating CPL under the same conditions. Based on the absorbance and CD spectra of the dispersions, the g-factor values were calculated.

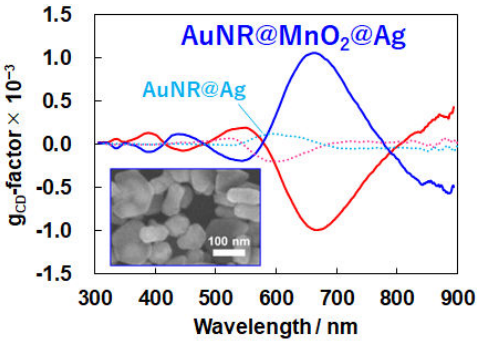

Fig. 1 CD spectra of AuNR@MnO_2@Ag synthesized under left-handed (red) or right-handed (blue) CPL. Inset: SEM image of the AuNR@MnO_2@Ag sample prepared under right-handed CPL.

III. Results and Discussion

The AuNR@MnO_2@Ag structures were predominantly rectangular in shape, although a small number of plate-like particles were observed due to excessive silver overgrowth. The maximum g-factors of AuNR@MnO_2@Ag and AuNR@Ag synthesized under right-handed CPL were 1.06×10^{-3} and 0.13×10^{-3}, respectively (Fig.1). The MnO_2 between the AuNR cores and the deposited Ag likely acts as a nanoscale spacer, potentially resulting in plasmonic coupling. This plasmon coupling could lead to a significant increase in the g-factor compared to AuNR@Ag.

IV. Conclusion

We achieved a large CD enhancement through CPL-induced chiral growth in core–shell plasmonic nanoparticles. Further chiral growth of these structures is expected to yield even greater enhancements. In the future, catalytic or sensing functions could be incorporated into these chiral structures by appropriately selecting material combinations.

***Abstract*— We present a novel approach for a chiral dark-field spectromicroscopy that enables high-throughput, artifact-free measurements of plasmonic nanostructures at the single-particle level. This method reliably quantifies the intrinsic chirality of nanoparticles and elucidates plasmon-coupled circular dichroism in hybrid plasmonic systems.**

***Keywords*— circular dichroism, circular differential scattering, plasmon-coupled circular dichroism, chiral plasmonics.**

I. Introduction

Engineering the chirality of plasmonic nanostructures is essential for applications in biosensing, chiral catalysis, and enantioselective separation. Because optochirality is strongly regulated by nanostructure morphology, establishing reliable structure–chirality relationships remains challenging. Single-particle measurements could overcome this obstacle by resolving sample heterogeneity. Dark-field scattering (DFS) microscopy has emerged as a promising technique for measuring circular differential scattering (CDS) from individual nanoparticles; however, its accuracy is often compromised by artifact signals.

II. Methods

We have developed a custom-built DFS microscope with hyperspectral imaging capability that enables high-throughput, artifact-free measurement of CDS spectra from single plasmonic nanostructures. This method employs unpolarized excitation to maintain circular polarization at the sample plane and detection optics comprising a broadband quarter-waveplate and a Wollaston prism. (Figure 1) A sequential measurement by manipulating quarter waveplate orientation allows us to identify the intrinsic CDS signal while eliminating the artifact signal originating from linear dichroism. [1]

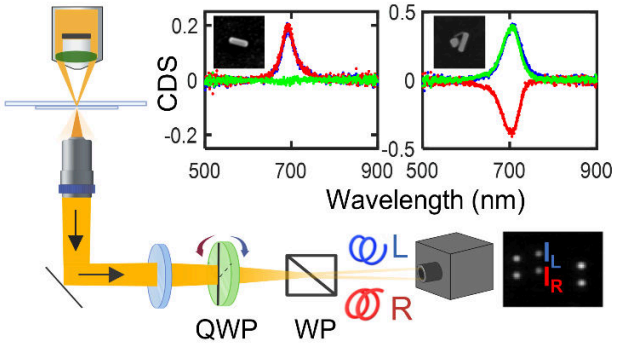

Fig. 1 Schematics of custom-built chiral DFS microscope.

III. Results and Discussion

Experimental results show:

- Measurements of intrinsic CDS of single chiral nanostructures.
- Identification of artifact CDS signal in uncoupled achiral Au nanorods.
- Observation of plasmon-coupled circular dichroism of single hybrid nanostructures composed of Au nanorods and DNA.

IV. Conclusion

We have demonstrated a precise measurement of the CDS of single achiral and chiral nanostructures. Additionally, the plasmon-coupled circular dichroism of DNA-functionalized Au nanorods is also unambiguously probed.

Plasmonic Nanosensor for Force Sensing in Live Cells

Won Park

[1]Department of Electrical, Computer & Energy Engineering, University of Colorado, Boulder, CO, USA

*Corresponding author: won.park@colorado.edu

***Abstract*— This paper presents a novel force sensor based on plasmonic modulation of upconverted luminescence. The short-range nature of plasmonic interaction enables high sensitivity. The nanosensor was used to monitor the cell-substrate interaction in live cell culture. It reveals mechanical forces in sub-cellular resolution.**

***Keywords*— surface plasmon, upconverted luminescence, biosensing, force sensing.**

I. Introduction

Upconverting nanoparticles (UCNPs) are excited by infrared light and emit visible and ultraviolet photons. The use of infrared excitation is attractive for chemical and biological sensing as it is absorbed minimally by water and many organic compounds and does not induce any background autofluorescence, leading to superior signal-to-noise ratio [1]. Compared to other frequency upconversion mechanisms such as two-photon fluorescence and high harmonic generation, UCNPs show far greater efficiencies [2], Furthermore, UCNPs do not photobleach or blink, making them ideal agents for imaging and sensing [3]. Considering these advantages, it is unsurprising that research on UCNP-based sensors has been steadily increasing over the years [4].

In this paper, we present a sensing platform based on the Purcell effect, which influences the emission process. Since the optical interaction responsible for the Purcell effect is a short-range interaction with strong distance dependence, any changes in the distance between the UCNPs and the nanoresonator modifies the luminescence properties. To build a sensor based on this mechanism, one should employ a molecule or a material that changes its length or volume in response to the environmental conditions or analytes one wants to detect. In this work, we report a straightforward yet powerful example of this sensing scheme which allows optical detection of mechanical forces. Sensors capable of quantitatively measuring physical forces are critical for a wide range of fields such as biology, medicine, and robotics. In biology and medicine, the interplay between physical forces and cell functions has long been a fundamental subject of research. Physical forces play an important role in many biological processes such as stem cell differentiation, initiation of transcriptional programs, morphogenesis, cell migration, malignancy, and wound healing. In robotics, high quality tactile sensing would enable more delicate and complex operations such as grasp control, dexterous manipulation or object recognition.

II. Sensing Principle

Our nanosensor is composed of a gold nanodisk, a polydimethylsiloxane (PDMS) layer and UCNPs (Fig. 1a). The UNCPs are $NaYF_4:Yb^{3+},Tm^{3+}$ nanoparticles which, under 980 nm excitation, emit multiple luminescence bands, as shown in Fig. 1(b). In this work, we use the two strongest emission bands centered at 645 and 800 nm. The finite-difference time-domain (FDTD) simulations showed that a gold nanodisk with a diameter of 150 nm and a thickness of 30 nm is the best choice. As shown in Fig. 1(b), the nanosensor structure exhibits a main plasmonic peak centered at around 770 nm and a smaller peak near 610 nm. The resulting Purcell enhancement of 645 and 800 nm emission results in exponentially decaying intensity ratio as a function of distance. This distance dependent PL intensity ratio provides the basis for the force sensing.

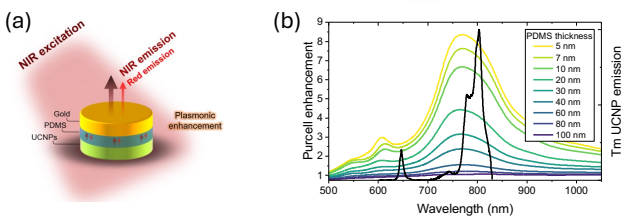

Fig. 1 (a) Schematic of the nanosensor composed of a gold nanodisk, a flexible polymer (PDMS), and UCNPs. (b) Calculated Purcell enhancement factor for various PDMS thicknesses. The size of the gold nanodisk is chosen to exhibit a large enhancement at 800 nm and minimal enhancement at 645 nm. That is, the gold disks are 150 nm in diameter and 30 nm in thickness.

III. Results and Discussion

To make the nanosensors, we developed a novel fabrication process that combines laser interference lithography (LIL), self-

assembly of UCNPs, pattern transfer and dry/wet etching. A detailed description of the fabrication process is given in a recent publication [5]. Fig. 2 shows the samples at various stages of the fabrication process.

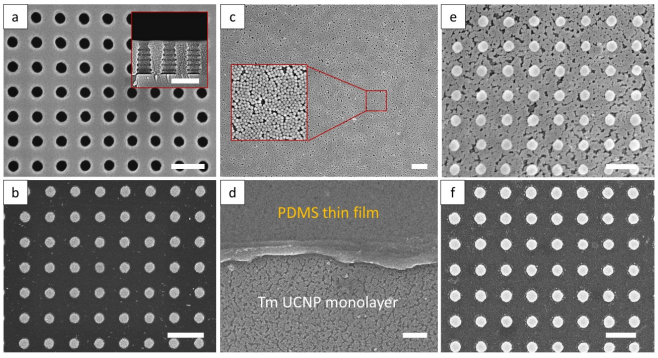

Fig. 2 Scanning electron micrographs (SEMs) of (a) nanohole array on a negative photoresist produced by laser interference lithography (Inset: cross-sectional view of the nanoholes revealing the modulated sidewall profile due to the interference pattern), (b) gold nanodisk array obtained by gold evaporation on the nanohole array shown in (a) and a subsequent lift-off, (c) monolayer of UCNPs obtained by the interfacial self-assembly method (Inset: a higher magnification view of the self-assembled monolayer), (d) PDMS thin film deposited on the UCNP monolayer shown in (c). Here, we deliberately etched the PDMS layer partially to reveal the underlying UCNP monolayer for better visualization. (e) Gold nanodisks transferred onto the PDMS surface after dry etch and (f) the final sensor array after etching away the extra UCNPs outside the gold nanodisks. All scale bars indicate 500 nm.

The fabricated nanosensors were characterized by a custom-built force characterization setup in which the nanosensors were strained by a pressurized gas. Fig. 3 shows the sensor response as a function of applied force. The PL intensity ratio increases gradually in the force range of 70 ~ 740 nN. It was not clear whether the nanosensor reached saturation at ~740 nN, because that was the maximum force we could generate using the gas pressure chamber. The force sensitivity (defined as the ratio of signal change per applied force change) obtained from the slope of Fig. 3 was 2 μN^{-1}. This corresponds to a pressure responsivity of 35 GPa^{-1}, which is two orders of magnitude larger than that of the alkaline earth UCNP force sensor [6].

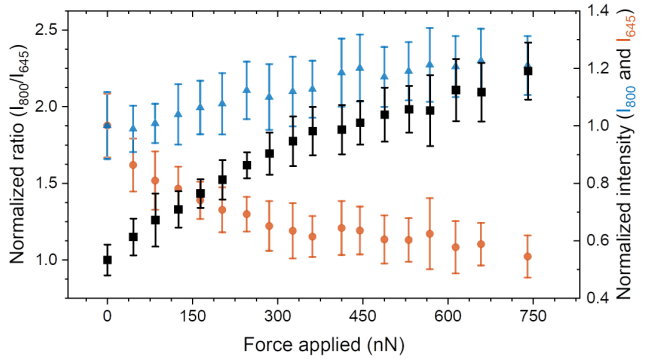

Fig. 3 PL intensity ratio as a function of applied force.

Finally, we performed force sensing experiments in live cell cultures. For these experiments, cells were grown on top of the nanosensor array and the fluorescence signal was imaged by a two-photon microscope. The results revealed that the cell-substrate adhesion force is around 20-30 nN and it varies spatially as the cells divide and migrate. This is the first direct measurement of cell-substrate mechanical interaction.

IV. Conclusion

We present a novel force sensor based on the plasmon modulated upconversion luminescence. By exploiting the short-range nature of plasmon interaction, the nanosensor is responsive to nanoscale deformations, which in turn allows for precise sensing of small forces. Since the near-infrared light interacts minimally with biological tissues, the use of near-infrared excitation makes the nanosensors well suited for biosensing applications. Furthermore, the new nanosensor employs a ratiometric sensing scheme in which one luminescence band serves as the signal while the other one acts as reference. The ratiometric sensing is much robust against environmental variations than the fluorescence intensity-based sensing scheme. The nanosensors are also very small, ~150 nm in diameter, and fabricated in a massive array. This enables sensing with high spatial resolution. This feature is particularly attractive for tactile sensing in robots where most tactile sensors lack high spatial resolution.

Abstract

We demonstrate a real-time, all-optical method for tuning optical activity in chiral metasurfaces without altering the metasurface geometry. By employing tightly focused circularly polarized Laguerre–Gaussian beams carrying different combinations of spin and orbital angular momentum, we achieve dynamic control of the dichroism through selective excitation of optically dark multipolar modes.

Keywords— metasurfaces, orbital angular momentum, chirality, vortex beams.

Enhanced Photoluminescence through Excitation - Surface Lattice Resonance Coupling in Aluminum Metasurfaces

***Abstract*—We demonstrate high photoluminescence (PL) enhancement from colloidal quantum dots (QDs) using aluminum (Al) metasurfaces by matching excitation wavelengths to Surface Lattice Resonances (SLR). By tuning lattice periods, we prove excitation-SLR coupling is the dominant mechanism. These findings provide a robust framework for designing high-efficiency, QD-based nanophotonic devices.**

***Keywords*— metamaterials, Aluminum, Surface Lattice Resonance, Photoluminescence enhancement.**

I. Introduction

Plasmonic metasurfaces supporting **Surface Lattice Resonances (SLRs)** have emerged as a premier platform for tailoring light-matter interactions at the nanoscale. These collective modes arise from the diffractive coupling of localized surface plasmons, resulting in high quality-factor resonances associated with significantly extended near-field confinement compared to isolated nanoparticles[1]. Such properties are highly appealing for enhancing the optical response of weak emitters.

Strategies to amplify the **photoluminescence (PL)** of colloidal **quantum dots (QDs)** have prioritized emission matching[2][3], where the metasurface resonance is spectrally aligned with the peak emission wavelength of the QDs. However, this approach often isolate the critical role of the absorption rate. Recent theoretical studies[4] suggest that the local field enhancement at the excitation wavelength may be the dominant contributor to the overall PL signal. In this work, we utilize **aluminum (Al) nanodisk arrays** to experimentally investigate this mechanism. Al is an ideal material for this study due to its low cost, and plasmonic response across the UV-visible spectrum. By precisely engineering the lattice periodicity, we demonstrate that matching the SLRs to the specific excitation laser wavelengths results in **high PL enhancement** of blue and green emitting perovskites QDs used in our study. Our findings shift the focus from emission to excitation matching, providing a more effective rule for high-brightness nanophotonic devices.

II. Methods

The Al nanoparticle arrays were fabricated using standard **Electron Beam Lithography (EBL)**, resulting in a samples with lattice periods ranging from **200 nm to 500 nm**. Following the synthesis of the **colloidal QDs** via room temperature method[5], they were deposited onto the arrays by **spin-coating** to ensure a uniform emitter layer. The collective optical response of the arrays was characterized using **extinction spectroscopy**. Finally, **Fluorescence Lifetime Imaging Microscopy (FLIM)** was employed to measure the **PL increase** and **lifetime reduction** of the QDs on the SLR-excitation matched arrays relative to the background.

III. Results and Discussion

The **FLIM** measurements demonstrate that **fluorescence lifetimes are maximally reduced** specifically when the **excitation wavelength is matched to the SLR mode**. Under this resonance condition, we achieve interesting brightness gains, with **PL enhancement factors of up to 3.7 for green emitting perovskites QDs (515 nm) and up to 10 for blue emitting perovskites QDs (466 nm)**

relative to the background. These findings confirm that excitation-SLR matching is the dominant driver for maximizing emission in Al-based metasurfaces.

IV. Conclusion

In conclusion, we have experimentally demonstrated that **excitation-SLR coupling** is the primary mechanism for achieving **PL enhancement** in Al metasurfaces. By selectively matching the lattice periodicity to the excitation wavelength, we achieved high PL intensity and significant **lifetime reduction** for blue perovskite quantum dots. These results redefine the rules for high-performance nanophotonic platforms, shifting the focus toward excitation-matched resonances to maximize the efficiency of colloidal quantum emitters.

Van der Waals metasurfaces from strong coupling to topology

Andreas Tittl[1,*]

[1]Nano-Insitute Munich, Faculty of Physics,
Ludwig-Maximilians-Universität München, Germany
*Corresponding author: andreas.tittl@physik.uni-muenchen.de

***Abstract*— Van der Waals metasurfaces are redefining the landscape of nanoscale light-matter interaction by merging structural design flexibility with deterministic atomic-layer assembly. Leveraging quasi-bound states in the continuum (qBICs), we demonstrate a progression from high-Q visible resonators to intrinsic strong coupling and ultralow-power nonlinearities in heterostructure metasurfaces. Finally, we show how material anisotropy enables topological charge splitting for robust polaritonic flatband formation.**

***Keywords*— van der Waals materials, metasurfaces, bound states in the continuum, intrinsic strong coupling, topology.**

I. Introduction

The emergence of van der Waals (vdW) materials has unlocked a new paradigm for materials engineering, characterized by the ability to isolate individual crystal planes and restack them into customized vertical heterostructures. Unlike conventional semiconductors, these crystalline solids allow for the assembly of artificial structures without the constraints of lattice matching or dangling bonds, providing unparalleled control over their optoelectronic properties. By patterning these layered stacks into resonant metasurfaces, we can combine the rich physics of 2D semiconductors, such as stable room-temperature excitons and high refractive indices, with the precise radiative loss management of bound states in the continuum (BICs). This monolithic integration transforms the vdW crystal into an active optical cavity, enabling the exploration of complex light-matter interactions and exotic topological phases within an atomically engineered platform.

II. Methods

Our methodology combines mechanical exfoliation of bulk vdW crystals (hBN, WS_2, ReS_2) onto fused silica substrates with top-down nanofabrication. Standard processes include electron-beam lithography (EBL) to define resonator geometries and reactive ion etching (RIE) for pattern transfer. For heterostructure metasurfaces, dry transfer techniques are utilized to stack atomic layers prior to nanopatterning. Optical characterization is performed via white-light transmittance microscopy and angle-resolved Fourier-space spectroscopy

III. Results and Discussion

We first demonstrate that nanostructured vdW materials can support high-quality (Q) resonances over the full visible spectrum. Using low-index ($n \approx 2$) hBN, we realize qBIC metasurfaces with experimental Q factors above 300 spanning wavelengths from 400 to 1000 nm [1]. We then extend this concept to excitonic vdW materials, demonstrating intrinsic strong light-matter coupling in self-hybridized bulk WS_2 metasurfaces with a Rabi splitting of 116 meV [2]. Moving to vertically integrated heterostructures, we show that patterning an hBN/WS_2/hBN stack into a BIC-driven metasurface allows for the atomic-layer assembly of optical cavities. These heterostructure metasurfaces exhibit exceptional nonlinearities, with the strong-coupling regime saturating at excitation fluences three orders of magnitude lower than conventional cavity systems [3]. Finally, we demonstrate that material-intrinsic anisotropy in ReS_2 can be harnessed to fundamentally transform the photonic topological landscape. By splitting integer topological charges into momentum-separated half-integer singularities, we drive the formation of robust, polarization-controllable photonic and polaritonic flatbands [4].

IV. Conclusion

Our results highlight the potential for the monolithic integration of metasurfaces and 2D materials to achieve unprecedented control over light-matter interactions. These findings pave the way for low-threshold polariton lasers and topologically protected quantum photonic circuits operating under ambient conditions.

***Abstract*— Hybrid plasmonic photonic metasurfaces enable strong field confinement with reduced optical losses, but scalable implementations remain challenging. This work presents colloidal photonic crystal slabs as a versatile platform for engineering hybrid modes. Applications ranging from charge transfer and photocatalysis to surface-enhanced Raman scattering and biosensing are demonstrated.**

***Keywords*— colloidal metasurfaces, hybrid plasmon-photon modes, photonic crystal slabs, surface enhanced Raman scattering, biosensing.**

I. Introduction

Plasmonic nanostructures provide extreme electromagnetic field confinement but are inherently limited by optical losses, whereas dielectric photonic structures offer low-loss propagation with reduced nanoscale localization. Hybrid plasmonic-photonic geometries combine these complementary advantages, enabling strong and spectrally selective field enhancement with improved energy efficiency.

Most hybrid metasurfaces rely on top-down fabrication, which limits scalability. In contrast, template-assisted self-assembly (TASA) offers a bottom-up alternative that enables large area fabrication with nanoscale precision. Colloidal photonic crystal slabs (cPhCs) based on directed nanoparticle assembly on thin waveguides have therefore emerged as a general platform for hybrid plasmon photon mode engineering, with relevance to sensing and energy conversion [1].

II. Methods

CPhCs were fabricated by TASA of gold nanoparticles into periodic 1D lattices on dielectric waveguides. Interference lithography and wrinkle-assisted patterning were employed to define templates over centimeter-scale areas [1-3]. Recently, confinement-based printing was used to enable rapid and reproducible pattern transfer onto a variety of substrates [3].

Optical characterization was performed using angle-resolved ultraviolet-visible-near-infrared spectroscopy and confocal Raman spectroscopy under normal and oblique incidence [1,5]. Charge transfer and photocatalytic activity were assessed using two-terminal electrical measurements and dye degradation assays [2,3]. Finite-difference time-domain simulations were used to model electromagnetic field distributions and hybrid-mode dispersion [1,4,5]. The concept of hybrid plasmon-photon mode formation in colloidal photonic crystal slabs, along with the corresponding scalable fabrication workflow, is summarized schematically in Fig. 1.

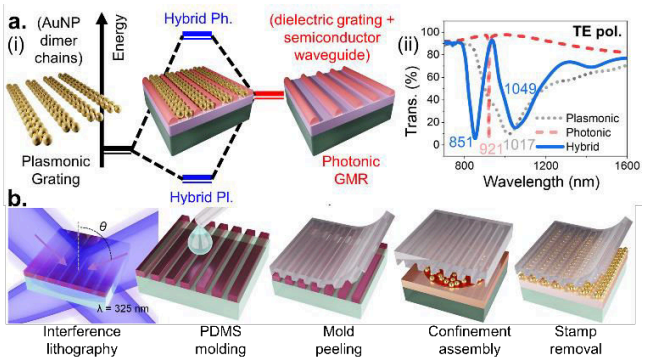

Fig. 1 Hybrid plasmon-photon mode concept and fabrication. (a) Schematic of mode hybridization between plasmonic nanoparticle gratings and photonic guided-mode resonances, with representative TE-polarized transmission spectra [1]. (b) Scalable fabrication via laser interference lithography, PDMS molding, and nanoparticle stamping.

III. Results and Discussion

Periodic colloidal nanoparticle lattices on waveguides serve as efficient optical couplers, giving rise to hybridized waveguide plasmon-polariton modes with well-defined dispersion relations [1]. Unlike conventional metallic gratings, nanoparticle chains enable excitation of hybrid modes for electric field components both parallel and perpendicular to the lattice direction, significantly expanding polarization

accessibility.

Figure 2 provides an overview of the applications of linear AuNP chain assemblies fabricated via TASA, covering both hybrid plasmon-photon and purely plasmonic functionalities. These hybrid modes facilitate efficient energy funneling into the waveguide, enabling broadband photo-enhanced charge injection in Au TiO_2 heterostructures [2]. Large-area devices exhibit measurable photocurrents and enhanced photoresponsivity under guiding conditions, while ultrafast spectroscopy reveals polarization-dependent charge-transfer dynamics influenced by nanoparticle ligand shells. Imprint-based colloidal printing further enables narrow-linewidth hybrid modes and plasmon-induced hot-electron-driven photocatalysis on the centimeter scale [3].

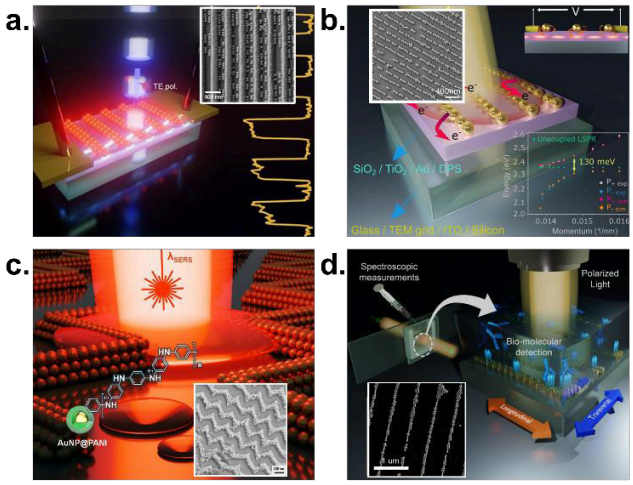

Fig. 2. 1D/2D AuNP chain assemblies fabricated via TASA. (a, b) Hybrid plasmon-photon architectures based on nanoparticle chains coupled to waveguide modes, towards plasmonic charge transfer/ photodetection as well as photocatalytic activity [1-3]. (c, d) Plasmonic chain assemblies supporting surface-enhanced Raman scattering and biosensing through strong localized field enhancement and polarization-dependent response [4, 6].

Purely plasmonic supracolloidal assemblies fabricated via wrinkle-based templates exhibit strong interparticle coupling and isotropic optical responses, enabling tunable plasmonic resonances for SERS applications [4]. However, integrating colloidal nanoparticle lattices into photonic crystal slabs yields low-loss hybrid plasmon-photon metasurfaces optimized for surface-enhanced Raman scattering. Angle-resolved SERS excitation reveals hybrid guided mode resonances and mode degeneracy, while systematic variation of lattice periodicity and nanoparticle concentration demonstrates robust performance against structural disorder. Maximal Raman enhancement is achieved when hybrid resonances spectrally coincide with the excitation wavelength [5].

Finally, linear nanoparticle assemblies fabricated via both interference lithography and wrinkle-assisted patterning exhibit pronounced polarization-dependent refractive index sensitivity. Proof-of-concept biosensing experiments demonstrate the detection of tumor necrosis factor alpha, highlighting the potential of hybrid plasmonic modes for scalable biointerfaces [6].

IV. Conclusion

Colloidal photonic crystal slabs provide a scalable, versatile platform for engineering hybrid plasmon-photon modes with controlled dispersion, reduced losses, and enhanced robustness. By bridging fundamental hybrid-mode physics with applications in energy conversion, spectroscopy, and biosensing, this approach establishes general design principles for large-area hybrid nanophotonic metastructures.

***Abstract*—We present hybrid nanomaterial platforms that combine permittivity engineered dielectric media with tunable photonic metastructures to control excitonic interactions. Near-zero epsilon environments enable dramatic enhancement of nonradiative energy transfer between quantum emitters, while multiresonant microcavity arrays support room-temperature exciton polaritons in colloidal nanoemitters with strong coupling and tunable light-matter interactions.**

***Keywords*— hybrid nanomaterials, epsilon-near-zero (ENZ) media, energy transfer, exciton polaritons, microcavity metastructures.**

I. Introduction

The ability to control excitation energy flow and light–matter interactions at the nanoscale is central to the development of advanced photonic and optoelectronic technologies. Here, we present two complementary strategies for engineering excitonic interactions in hybrid dielectric media [1,2] containing nanomaterial systems of (i) tunable photonic metastructures supporting room-temperature exciton–polariton formation and (ii) permittivity-engineered dielectric environments enabling ultrahigh nonradiative energy transfer.

II. Methods

Förster-type nonradiative energy transfer between excitonic nanostructures was systematically analyzed using an analytical electrodynamic framework describing dipole–dipole interactions in complex dielectric media [2]. Donor–acceptor systems consisting of quasi-zero-dimensional quantum dots and quasi-two-dimensional quantum wells were modeled to derive the dependence of the transfer rate on the background medium permittivity. The dielectric screening factors governing the interaction were obtained from the electric field generated by excitonic dipoles in the surrounding medium. Parametric sweeps of the complex permittivity were performed to identify resonant conditions in epsilon-near-zero regimes and quantify the resulting enhancement of energy transfer. The resulting FRET rates were calculated using the expression:

$$\gamma_{trans} = \frac{2}{\hbar}\mathrm{Im}\left[\int dV\left(\frac{\varepsilon_A(\omega)}{4\pi}\right)\mathbf{E}_{in}(\mathbf{r})\cdot\mathbf{E}_{in}^{*}(\mathbf{r})\right] \quad (1)$$

where the integration is across the acceptor volume, $\varepsilon_A(\omega)$ is the dielectric function of the acceptor, and $E_{in}(\boldsymbol{r})$ is the effective electric field created by an exciton at the donor side.

Exciton–photon coupling in the microcavity system was analyzed using a coupled oscillator model describing the interaction between cavity photon modes and excitonic transitions in colloidal quantum wells[1]. The photonic dispersion of the multilayer cavity was calculated using a transfer-matrix formalism, while the excitonic response was modeled as a Lorentz oscillator. Diagonalization of the coupled system yields the upper and lower polariton branches and their Hopfield coefficients, allowing extraction of the Rabi splitting, detuning dependence, and strong-coupling conditions.

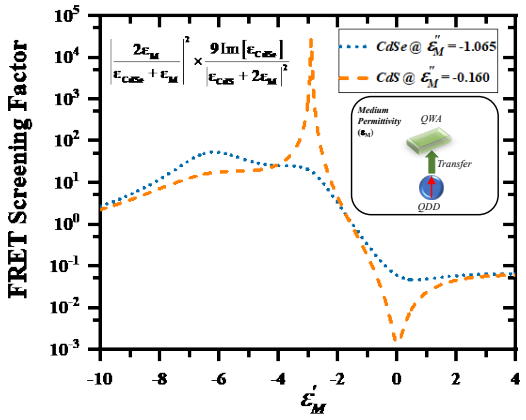

Fig. 1 Schematic representation of FRET from donor quantum dot to acceptor quantum well. FRET screening factor for CdSe (blue line, $\varepsilon_M'' = -1.065$) and CdS (red line, $\varepsilon_M'' = -0.160$) as a function of the real part of the medium permittivity.

III. Results and Discussion

Here, we investigated Förster-type nonradiative energy transfer (FRET) between semiconductor nanostructures embedded in complex dielectric media with engineered permittivity. Analytical derivations of the FRET rate for donor–acceptor pairs composed of quasi-0D quantum dots (QDs) and quasi-2D quantum wells (QWs) reveal that the transfer efficiency can be dramatically enhanced when the background medium approaches epsilon-near-zero (ENZ) conditions. In this regime, the dielectric screening factor exhibits a resonance when the denominator approaches zero, leading to a singular enhancement of dipole–dipole coupling. Using realistic material parameters achievable through digital metamaterial implementations (e.g., effective permittivity ε_M=-2+i), the FRET rate can be enhanced by more than two orders of magnitude, reaching enhancement factors up to 229-fold for QD donor-QD acceptor (QDD–QDA) pairs and 321-fold for QD donor-QW acceptor (QDD–QWA) configurations relative to vacuum.

Complementary to this near-field control mechanism, we also demonstrated tunable strong coupling between excitons and cavity photons in a multiresonant microcavity metastructure platform fabricated using binary lithography and reflow (BLR). This architecture enables nanometer-scale control of cavity length variations (<5 nm) across arrays of microcavities on a single chip. The platform was integrated with gradient core–crown CdSe/$CdSe_xS_{1-x}$ colloidal quantum wells, which exhibit enhanced photostability and large exciton binding energies (~200 meV). Angle-resolved spectroscopy reveals clear exciton–polariton formation at room temperature with a Rabi splitting of ≈ 50 meV and a Rabi quality factor Q_R ≈ 3.3, confirming a robust strong-coupling regime.

IV. Conclusion

With these results, we show that combining permittivity-engineered dielectric media with tunable photonic metastructures provides a powerful approach for controlling excitonic interactions and hybrid light–matter states. Such hybrid platforms open new opportunities for efficient excitonic energy transport, tunable polaritonic devices, and integrated photonic architectures for sensing, light generation, and energy-harvesting applications.

***Abstract*— We present our research activity on hybrid oxide heterostructures, in particular combining strongly anisotropic molybdenum trioxide, MoO_3, with thermochromic vanadium dioxide, VO_2. The integration of these two materials required careful control of the deposition sequence and interface quality in order to preserve both the polar dielectric properties of MoO_3 and the phase-change behavior of VO_2. By combining α-MoO_3 with VO_2 in multilayer architectures, we demonstrate reversible thermal modulation of the infrared optical response, leading to dynamic tuning of phonon-polariton resonances supported by the α-MoO_3 layer.**

***Keywords*— polar materials, thermochromic materials, phase-change, heterostructures.**

I. Introduction

Controlling electromagnetic radiation in the mid-infrared (mid-IR) spectral region is crucial for a wide range of emerging technologies including thermal emission engineering, chemical sensing, infrared imaging, and free-space optical communications. In this context, polar dielectric materials capable of supporting phonon polaritons have attracted increasing attention due to their ability to confine and manipulate infrared radiation at sub-wavelength scales.

Among them, the van der Waals crystal α-MoO_3 is particularly interesting because of its strong in-plane optical anisotropy and the presence of multiple Reststrahlen bands that enable polarization-dependent propagation of phonon polaritons [1]. These properties make α-MoO_3 an attractive material for mid-IR photonic components and metasurfaces. However, the realization of large-area thin films that preserve the intrinsic anisotropic optical response remains challenging.

At the same time, achieving dynamic tunability of infrared optical properties represents a key step toward adaptive photonic systems. Phase-change materials such as vanadium dioxide (VO_2) provide a promising solution, as they exhibit a reversible metal–insulator transition (MIT) accompanied by significant changes in their optical constants [2].

In this work we investigate large-area oxide thin films and their integration into hybrid heterostructures combining α-MoO_3 and VO_2. By coupling a polaritonic material with a thermochromic phase-change layer, we develop a platform capable of dynamically modulating the infrared optical response through temperature control.

II. Methods

Large-area, hybrid heterostructures were fabricated by integrating α-MoO_3 layers with VO_2 thin films using pulsed laser deposition (PLD). The growth parameters were carefully optimized by tuning substrate temperature, oxygen partial pressure, laser fluence, and deposition rate in order to obtain films with high crystalline quality and uniform thickness over centimeter-scale substrates. In these multilayer systems the thermally induced phase transition of VO_2 will enable reversible modulation of the optical response of the structure.

III. Results and Discussion

The optical response of the deposited films was investigated by Fourier-transform infrared spectroscopy (FTIR). Measurements performed at near-normal incidence revealed the characteristic Reststrahlen bands associated with the α-MoO_3 crystal structure [3]. In particular, three phonon-related spectral regions were identified: the x-Reststrahlen band (approximately 820–972 cm^{-1}), the y-Reststrahlen band (545–851 cm^{-1}), and the z-Reststrahlen band located between 962 and 1010 cm^{-1}, indicating that the polaritonic properties of the material are preserved in the multilayer configuration.

Furthermore, temperature-, polarization-, and angle-dependent FTIR measurements were performed to investigate the interaction between the phonon-resonances of α-MoO_3 and the phase-dependent optical properties of VO_2.

When α-MoO_3 and VO_2 are combined into multilayer heterostructures, the phase transition of VO_2 leads to measurable changes in the infrared spectral response of the

system. In particular, temperature-resolved FTIR spectra reveal a modulation of the phonon-polariton resonances associated with the α-MoO_3 layer when the VO_2 film switches from the insulating to the metallic phase.

This thermally induced modulation demonstrates that the interaction between anisotropic phonon polaritons and phase-change materials can be exploited to get a strong dynamic range of mid-IR optical properties of the resulting heterostructure. The ability to control phonon-resonances over large areas represents an important step toward practical reconfigurable infrared photonic devices.

IV. Conclusion

In summary, we investigated oxide thin films and hybrid heterostructures combining α-MoO_3 and VO_2 for tunable mid-infrared photonics. Optimized pulsed laser deposition enabled the realization of large-area α-MoO_3 films with clearly observable Reststrahlen bands. The integration of VO_2 phase-change layers provides an effective mechanism for active control of the infrared optical properties through the thermally driven metal–insulator transition. Furthermore, the use of tungsten-doped VO_2 allows tuning of the transition temperature toward room temperature, enabling more practical operating conditions [4-5].

Our results demonstrate that coupling anisotropic polar materials with phase-change oxides offers a versatile approach for the development of dynamically reconfigurable photonic components in the mid-infrared, including tunable emitters, adaptive metasurfaces, and polarization-dependent optical devices.

***Abstract*— We report an innovative approach for fabricating large-area, silicon-based plasmonic metasurfaces without engineered nanostructures. We show that hyperdoped polysilicon layers annealed under out-of-equilibrium conditions, exhibit enhanced light–matter tunable interactions. These remarkable optical properties originate from naturally formed metal–dielectric interfaces at grain boundaries, which support localized surface plasmon resonances.**

***Keywords*— nanoplasmonics, doped semiconductor, coupled dipoles**

I. Introduction

Advances in nanofabrication enabling subwavelength metasurfaces have been central to the success of plasmonics. However, despite rapid progress, the widespread commercialization of plasmonic metasurfaces remains hindered by challenges in scalable manufacturing and deployment in real-world devices.

II. Results and Discussion

Hyper doped polysilicon films were obtained by laser thermal annealing of a 23 nm phosphorus doped silicon-on-insulator substrate. In such extremely out-of-equilibrium conditions, concentrations of electrically active dopants beyond the equilibrium solid solubility limit can be achieved in localized regions[2]. Automated Crystal Orientation Mapping in TE performed on the samples annealed above full-melt conditions, reveals that the polycrystalline layer consists of randomly oriented nanograins separated by grains boundaries with grain size distribution ranging from 5 nm to 50 nm (see insert fig.1). Fourier-transform infrared spectroscopy shows that on these polycrystalline samples the shape of the transmission is strongly altered and the transmission minimum is no longer localized at zero frequency as it is the case for doped Si monocrystal[1]. This is a clear sign that the optical signature is no longer dominated by free carriers. Using electrodynamics simulations we confirmed that surface plasmon resonances can emerge intrinsically from unpatterned polysilicon layers composed of nanometric grains, without the need for any external nanostructuring.

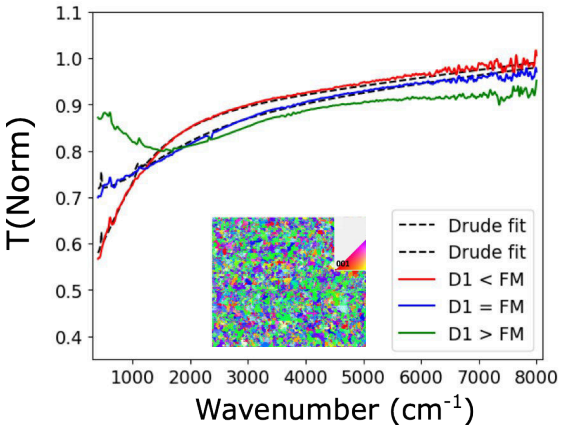

Fig. 1 Normalized transmittance. Continuous lines, measured on unpatterned hyper- doped Si layers bellow full melt, at full melt and over full melt. Insert ACOM images (orientation maps)

III. Conclusion

This behaviour, which cannot be achieved in polycrystalline noble metals, arises from the strong dielectric contrast between metallic-like silicon grains and dielectric grain boundaries. The resulting high packing density promotes strong dipole–dipole coupling, which dominates the plasmonic response of the material. Ultimately, near-field coupling elevates the size-distribution of doped nanograins to a central parameter controlling the plasmonic response, even if grain dimensions lie nearly three orders of magnitude below the excitation wavelength.

***Abstract*—We harness the anisotropic nature of Calcite to modify and control the light-matter interactions in the mid-IR. We introduce hyperbolic Calcite as a polar dielectric with in-plane anisotropic permittivity as a platform that supports cavity-like volume phonon polaritons (vPhPs) with significant modal volume compression due to the Calcite's hyperbolic dispersion.**

***Keywords*— metamaterials, hyperbolicity, nanostructuring, anisotropy, calcite.**

I. Introduction

The study of phonon polaritons (PhPs) in polar dielectrics is essential for advancing mid-infrared (mid-IR) radiometry, λ ~ 3-30 μm, for sensing, vibrational spectroscopy, black-body radiation sources, and other photonic applications [1-9]. Polar dielectric materials support PhP modes within the "reststrahlen band", the spectral region between the material's transverse and longitudinal optical Transverse and Longitudinal optical phonons [10]. Compared to plasmon polaritons, PhPs have much longer scattering lifetimes, resulting in lower optical losses making them attractive materials platforms for infrared photonics [11]. Hyperbolic polar dielectrics have a unique optical dispersion which arises when the permittivity tensor have both a negative (metallic-like) and positive (dielectric-like) component leading to hyperbolic shaped isofrequency dispersion curves. Due to the unbounded nature of the hyperbola shaped isofrequency dispersion, the physics supports coupling in very high-k limit which leads to subwavelength optical volume confinement. Hence, hyperbolic polar dielectrics can support PhP resonances with very high figure of merit which has been experimentally shown in a myriad of material platforms including hBN, β-Ga2O3, and InGaAs [12-17]. Hyperbolic materials can be found naturally or engineered as metamaterial. Current work focuses on understanding and controlling aspects of hyperbolic resonators such as physical attributes and crystal orientation to allow for the manipulation and emergence of interesting polariton behavior [14,18,19]. Developing in-plane anisotropy, where both the "metallic" and "dielectric" axis lie in-plane, is a unique geometry that is difficult to realize experimentally because it is very challenging to fabricate using conventional methods for creating metamaterials [20]. Although research has been done using 1D BNNTs and 2D hBN to study in-plane anisotropy, process and applications are limited by the difficulty of engineering microstructures into hBN based nanomaterials [21].

Recent studies show the first experimental observation of hyperbolicity in calcite, which is unique because its optical properties are highly dependent on the crystalline plane normal to the optical axis. Hence, we can easily achieve in-plane anisotropy by cleaving the crystal surface on the <100> plane [22-24]. Hyperbolic materials with in-plane anisotropy are a rare property, in part because they cannot be produced artificially using conventional methods for creating layered optical metamaterials. This makes Calcite particularly flexible material platform for studying novel hyperbolic optical physics and may have niche applications for novel mid-infrared photonic devices such as thermal radiation sources, sensors, spectrometers, waveguides, and polarizers.

II. Methods

In this work we use FTIR spectroscopy and COMSOL Finite Element Analysis (FEA) simulations to explore the exotic behavior of resonators in hyperbolic Calcite with extreme in-plane anisotropy. We experimentally show that engineering the permittivity tensor of Calcite resonators can tune the resonant frequency of strongly confined volume PhP modes in the mid-IR. Here we present a successful theoretical model which describes the hyperbolic dispersion relation, poynting vector, and selection rules for light coupling to polar dielectric resonators with extreme in-plane anisotropy.

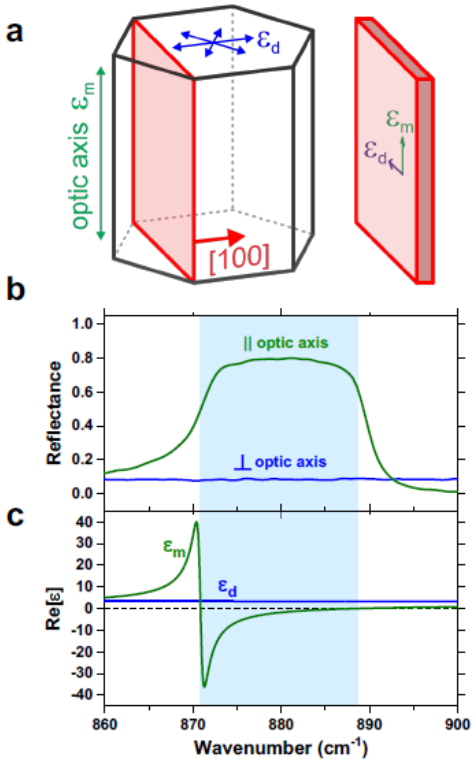

Fig. 1: Optical properties of bulk calcite. (a) Illustration depicts how the (100) sample is cut from hexagonal crystal unit cell. (b) Reflectance measurements of (100) calcite polarized parallel (green curve) and perpendicular (blue curve) to the optic axis (green curve), demonstrating optical anisotropy in the sample plane. (c) real part of the in-plane permittivity measured for (100) calcite along the optic axis (green curve) and perpendicular to the optic axis (blue curve), revealing the metallic-like and dielectric nature of the permittivities for each respective axis in the sample plane.1 Unit cell geometry of the proposed metamaterial.

Strongly coupled resonator structures in calcite supports PhP modes in its lower Rhestralen band (850-900cm-1) and its upper Rhestralen band (1350-1600cm-1) depending on the orientation of the incident polarization relative to the crystalline axis (supplemental figure 1) [19,22]. For this study we will focus on the lower Rhestralen band due to its unique behavior supporting volume PhP modes. Reports using the <001> surface of Calcite show that the "metallic-like" extraordinary axis is pointed into the substrate, hence the in-plane permittivity is isotropic and shouldn't have any polarization dependance; this represents the most studied hyperbolic crystal geometry. Our experiments using <100> plane of Calcite showed that the R-band reflectivity acquired using FTIR has a strong polarization dependance. Our results show the lower R-band the incident light is most strongly coupled when the polarization is parallel to the extraordinary axis, as shown in figure 1a. From the experimental data in figure 1ab, the lower R-band's bulk calcite, which is highlighted in blue, reveals Calcite's Type I Hyperbolic character which will support volume PhP modes. In figure 1b, we further explored the polarization dependance of bulk Calcite by recording the polarization dependent reflectivity in the middle of the R-band, ~879cm-1, on both <001> "isotropic" plane (red) and <100> "anisotropic" plane (black). Our results revealed a natural Malus' law trend for the anisotropic plane which validates our theory that the in-plane anisotropy is a direct cause of its polarization dependance.

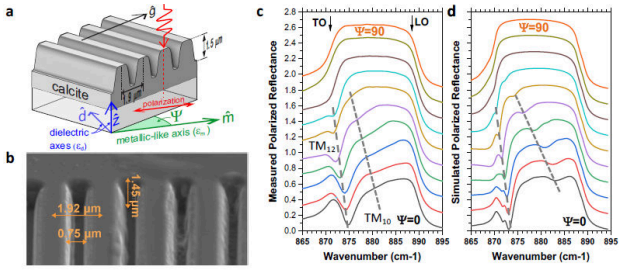

Fig. 2: Figure 2: Tuning of hyperbolic modes within 1D resonators. (a) Illustration of resonator geometry where resonators have a fixed pitch of 1.9 mm and height of 1.5 mm and are rotated with respect to the calcite optic axis (green arrow) by the angle Y. The orientation of the incident polarization for the measurements shown in subsequent panels is indicated by the red arrow. (b) Scanning electron microscope image of resonator grooves etched into (100) calcite. (c) Measured and (d) simulated polarized reflectance

III. Conclusion

Our study achieved novelty through validated hypotheses and established the influence of in-plane anisotropy on the behavior of Volume PhP modes supported by hyperbolic polar dielectrics such as Calcite. We confirmed that modal conservation and k-vector selection rules are independent of permittivity orientation, with the isofrequency surface oriented by the permittivity tensor and the k-vector selected by resonator geometry. Additionally, our validated characteristic equation allows predictability of modes given knowledge of resonator geometry and permittivity in one orientation, enabling derivations for other rotations. We comprehensively demonstrated the polariton physics within hyperbolic polar dielectrics with extreme in-plane anisotropy, showcasing its influence on frequency dependence based on resonator size, shape, and orientation. Furthermore, our findings revealed how in-plane anisotropy can manifest large changes in power flow direction from a small shift in resonator orientation relative to the in-plane extraordinary optic axis. We foresee Anisotropic Calcite as a valuable materials platform for investigating unconventional anisotropic hyperbolic materials and metamaterials. Leveraging its bulk properties for nanostructuring distinguishes it from 2D polar dielectric materials, while its low-loss characteristics for strong, high-Q resonances differentiate it from more lossy plasmonic hyperbolic materials. These attributes suggest potential applications for spectrometers and beam splitters using hyperbolic materials in various fields.

Our future work will utilize our novel physical model and cavity-resonance physics to establish a framework for enhanced power flow control, frequency tuning, and increased resonance lifetime (Q-value) for Volume PhP modes in 2D resonators and unconventional geometries. Additionally, our research aims to delve deeper into the relatively unexplored physics of surface

PhPs in the Upper R-band, particularly with extreme in-plane anisotropy. Overall, our study paves the way for further exploration and practical applications in the realm of anisotropic materials, offering insights and possibilities for advancements in various technological domains.

***Abstract*— Metasurfaces provide powerful opportunities for tailoring the spectral and angular properties of thermal radiation, which is crucial for improving the efficiency of thermophotovoltaic (TPV) energy conversion. In this work we investigate a metasurface designed for photon management in TPV systems. The structure operates as a spectral filter that suppresses undesired thermal radiation while transmitting photons within the useful spectral range of a low-bandgap photovoltaic cell. Numerical electromagnetic simulations reveal resonant field localization near 1.8 µm associated with modes supported by the periodic nanostructure. The resulting transmission spectrum demonstrates selective filtering in the near-infrared region relevant for TPV operation. These results highlight the potential of metasurface-based optical filters for improving photon utilization in high-temperature thermophotovoltaic systems.**

***Keywords*— dielectric metasurfaces, thermophotovoltaics, energy.**

I. Introduction

A significant fraction of the energy consumed in high-temperature industrial processes is dissipated as waste heat. Recovering even a modest portion of this energy represents a major technological and environmental challenge [1,2], with the potential to reduce both primary energy demand and CO_2 emissions. For example, in cement production, processes operating at temperatures between 800 and 1400 °C generate large radiative heat fluxes that remain largely underutilized.

Thermophotovoltaic (TPV) conversion represents a particularly promising approach in this temperature range [1-4]. By converting thermal infrared radiation into electrical power through low-bandgap photovoltaic cells, TPV systems enable direct radiative heat-to-electricity conversion. In principle, their efficiency can exceed that of thermoelectric generators under similar conditions. In practice, however, TPV performance is strongly limited by the spectral mismatch between the broadband thermal emission of hot surfaces and the narrow spectral response of the photovoltaic cell. Sub-bandgap photons are not converted and therefore contribute to thermal losses, while supra-bandgap photons generate excess heat through carrier thermalization. Both mechanisms reduce the overall conversion efficiency.

Metasurfaces offer a powerful approach to address this limitation by enabling spectral and angular control of thermal radiation. In this work, we investigate a metasurface designed for photon management in thermophotovoltaic systems. The classical approach to improve TPV efficiency relies on the use of a selective emitter, that is, a metasurface designed to emit in a selected wavelength range when heated [5-8]. Here, the proposed structure operates as a spectral filter that suppresses unwanted thermal radiation while transmitting photons within the useful spectral range of the photovoltaic cell. By tailoring the geometry of the metasurface unit cell, the spectral response of the structure can be engineered to improve the overlap between thermal emission and the spectral sensitivity of the TPV cell.

The spectral selectivity arises from resonant electromagnetic modes supported by the periodic nanostructure. These resonances produce strong localization of the electric field within the metasurface unit cell, leading to enhanced interaction between the incident radiation and the nanostructured material [9-11]. As a result, the transmission spectrum exhibits pronounced spectral features in the near-infrared region around 1.8 µm, which is close to the bandgap wavelength of typical InGaAs photovoltaic cells used in thermophotovoltaic systems.

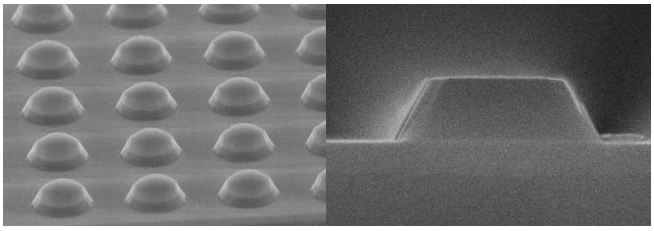

Fig. 1 SEM image of the large scale fabricated metasurface (left) and closer view on unit cell geometry (right). Size of the pillar in the unit cell is 1 µm at the top and 1.2 µm at the bottom. The structure was fabricated on Si substrate, then covered with 300 nm of SiC layer. Bottom part of nanopillar is SiO_2 and upper part is from SiC both with 300 nm thicknesses. Lattice period is 2 µm.

II. Results and Discussion

Fabrication was performed on double-side polished 4-inch intrinsic silicon wafers using contact photolithography followed by physical vapor deposition (PVD) and lift-off processes. This approach allows patterning of centimetre-scale metasurface areas while remaining compatible with scalable and cost-effective manufacturing techniques.

The metasurface in form of a square array of dielectric nanopillars was formed from several dielectric materials chosen for their optical performance and compatibility with high-temperature operation. The lower part of the resonator consists of a SiO_2 section that forms the base of the nanopillar, while the upper part is composed of a SiC layer. The thickness of both layers is approximately 300 nm. In addition, a continuous SiC layer with a thickness of 300 nm is deposited on the substrate, providing both optical functionality and improved thermal robustness. Silicon carbide is particularly attractive for thermophotovoltaic applications due to its high thermal stability and favourable optical properties in the near-infrared spectral range [11,12].

The resonators show a truncated-cone geometry, with a top diameter of approximately 1 µm and a bottom diameter of about 1.2 µm, which results from the lithography and lift-off process. The lattice period of the array is 2 µm. Scanning electron microscopy (SEM) characterization shown on Figure 1 confirms that the fabricated geometry closely matches the design parameters used in the numerical simulations.

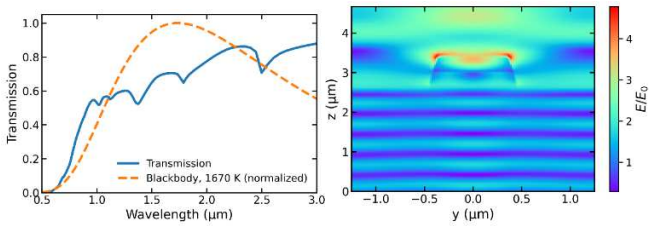

Fig. 2 Electromagnetic response of the metasurface. (left) Calculated transmission spectrum of the metasurface in the near-infrared spectral range relevant for thermophotovoltaic conversion. (right) Simulated near-field distribution at the resonance wavelength of approximately 1.8 µm, showing strong field localization near the metasurface structure.

The periodic arrangement of these dielectric resonators enables the excitation of resonant electromagnetic modes in the near-infrared spectral region as shown on Figure 2. These resonances play a key role in shaping the spectral transmission of the metasurface and form the basis for the photon-management functionality targeted in thermophotovoltaic systems. Simulated spectral response of the optical metasurface revealing selective transmission in the near-infrared range which is important for thermophotovoltaic conversion. The simulated near-field distribution shown in Fig. 2 (right panel) demonstrates strong localization of the electromagnetic field at the resonance wavelength. The electric field is concentrated in the vicinity of the nanopillar structure, indicating the excitation of resonant modes supported by the metasurface. This field confinement enhances the interaction between the incident radiation and the nanostructured material, enabling effective spectral filtering of the incoming thermal radiation.

III. Conclusion

The presented metasurface demonstrates the potential of nanophotonic structures for photon management in thermophotovoltaic systems. By engineering the spectral response of the metasurface, it is possible to selectively transmit photons within the useful spectral range of the photovoltaic cell while suppressing unwanted radiation. Such metasurface-based filters represent a promising platform for improving photon utilization and enhancing the overall efficiency of thermophotovoltaic energy conversion systems.

***Abstract*— Chiral molecules can have different biological functionalities depending on their handedness. Identifying chirality, however, is limited by low sensitivity, restricting detection to high concentrations and large volumes. We present several experimental and theoretical examples of dielectric metasurfaces and waveguides to enhance the sensitivity of chiral molecular detection.**

***Keywords*— circularly polarized luminescence, circularly polarized Raman scattering, circular dichroism, metasurfaces, integrated photonics, waveguides.**

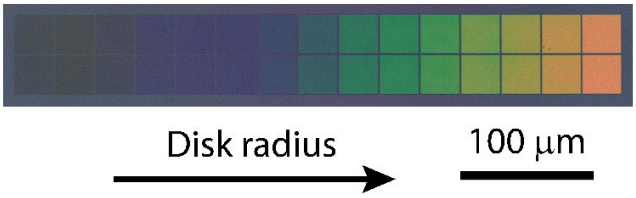

Fig. 1 – Metasurfaces made of crystalline silicon on glass.

Chirality is omnipresent in biochemistry, where molecules with opposite handedness can have markedly different biological functionalities. Detecting molecular chirality, however, is plagued by low sensitivity, limiting its use to high concentrations and large volumes. In this presentation, we introduce three examples of dielectric nanophotonic structures for chiral sensing, in particular, silicon metasurfaces and dielectric waveguides.

By sustaining optical resonances of electric and magnetic dipole origin, high-index metasurfaces can strongly enhance the sensitivity of chiral molecular detection in small volumes [1-3]. First, we will discuss our experimental results on enhancing circularly polarized luminescence from chiral molecules using crystalline silicon metasurfaces. Our results combine fluorescence enhancement [4] with controlled circular polarization. To this end, we developed a microscope with polarization modulation and photon-counting capabilities to measure smaller chiral analyte volumes than are possible with commercial systems.

Second, we will present enhanced circularly polarized Raman scattering in silicon metasurfaces. Our experimental results agree with a tensorial theory of polarized Raman scattering, demonstrating the relevance of the multipolar Mie resonances in metasurfaces for controlling excitation and emitted polarizations.

Last, we introduce a theoretical framework for predicting both optical rotation and circular dichroism induced by a chiral analyte, incorporated either as a coating or within the core of a cylindrical dielectric waveguide, for sensing applications. Our approach incorporates the Pasteur parameter into a mode solver to predict an effective index splitting explained by mode coupling theory. We explore the waveguide parameter space to identify optimal radii and refractive indexes to maximize optical rotation and circular dichroism.

Overall, both metasurfaces and waveguides open exciting paths to reach previously unmeasurable sensitivities for chiral optical spectroscopies at lower molecular concentrations and smaller analyte volumes.

***Abstract*— Chiral nanomaterials enable advanced optics, sensing and catalysis, yet laboratory fabrication of non-mirror-symmetric structures often demands delicate, equipment-intensive steps. We present simple, efficient routes to tunable plasmonic chirality by assembling achiral nanoparticles with abundant chiral biomolecules. These bio-guided assemblies transfer and amplify**

chirality, yielding switchable chiral responses without complex lithography.

***Keywords*— metamaterials, plasmonic chirality, nanoparticle assembly**

I. Introduction

Traditional plasmon-coupled circular dichroism (PCCD) suffers from inherently weak signals due to the size mismatch between chiral molecules and achiral nanoparticles[1,2]. Consequently, researchers have long attempted to enhance PCCD via the creation of strong plasmonic hotspots; however, such approaches have yielded limited improvements, and PCCD intensity still remains far below that of structural circular dichroism (CD)[3].

II. Methods

In our work, we shift the focus from engineering plasmonic hotspots to investigating the conformation of chiral molecules. By applying a simple yet effective strategy—namely, the in-situ stretching of biomolecules anchored to plasmonic nanoparticles (Fig 1)—we achieve a substantial enhancement of PCCD, with a circular dichroism of 1.18 degree and a dissymmetry factor of 0.2.

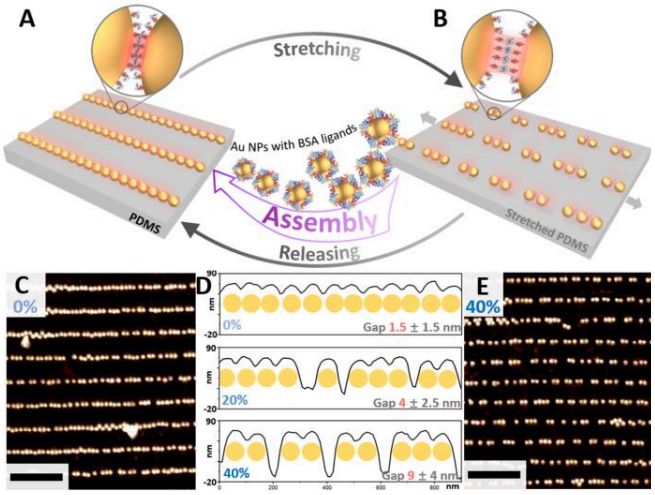

Fig. 1 Novel 1D chiral assembly of Au nanoparticles coated with BSA protein, which can be stretched due to the elastic PDMS substrate (A,B). During stretching the distance between nanoparticles increased gradually (C-E).

III. Results and Discussion

The enhanced PCCD originates not from intensified plasmonic hotspots, but from the conformational modulation of biomolecules bridging adjacent nanoparticles. In-situ stretching redistributes asymmetric electrostatic fields, amplifying chiral near-field interactions and producing a CD signal of 1.18° with a dissymmetry factor of 0.2 (Fig 2A). This lever-like mechanism enables reversible switching over 100 cycles (Fig 2B), demonstrating dynamic and tunable chiroptical activity beyond conventional hotspot-based strategies.

Molecular dynamics simulations (Fig 2C-E) indicate that the enhanced PCCD arises from stretching-induced recovery of protein secondary structures, which leads to a substantial amplification and directional alignment of molecular dipoles along the extension axis, thereby strengthening asymmetric near-field coupling.

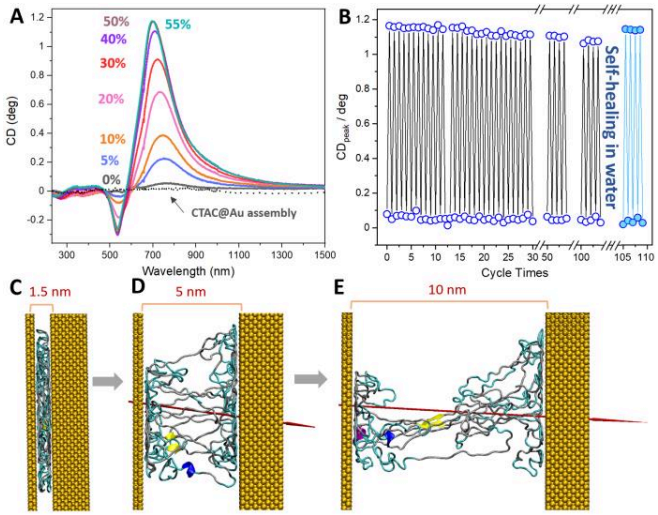

Fig. 2 Conformation-induced enhancement and switching of PCCD in BSA@Au assemblies. (A) CD spectra of BSA@Au assemblies under different stretching ratios. (B) Reversible PCCD switching over 100 cycles. (C–E) Molecular dynamics simulations illustrating protein stretching between nanoparticles accompanied by secondary structure recovery and dipole amplification along the extension direction.

IV. Conclusion

Our findings establish molecular conformation control as a new paradigm for plasmonic chirality amplification, enabling robust, reversible and stimuli-responsive chiroptical activity beyond conventional structural asymmetry.

***Abstract*— It is shown that linearly polarized light can generate and control chiral near fields in geometrically achiral gold nanotriangles. Using plasmon-assisted 2-photon polymerization, near fields are recorded as permanent polymer structures. Polarization and wavelength tuning reveal transitions between achiral and chiral configurations linked to different plasmonic modes and symmetry breaking.**

***Keywords*—nanoplasmonics, chirality,2-photon polymerization.**

I. Introduction

In nanoplasmonics, chirality plays a crucial role in the interactions between light and matter. While the majority of research has focused on the interaction of chiral nanostructures with chiral light, recent studies reveals that achiral plasmonic nanostructures can exhibit chiral near fields under linearly polarized excitation.[1]

II. Methods

To study this effect, we employed plasmon-assisted 2-photon polymerization as a tip-free near-field recorder that converts near fields into permanent 3D polymer nanostructures,[2] enabling direct readout of the near-field and its evolution with incident polarization angle and wavelength (see Fig. 1)

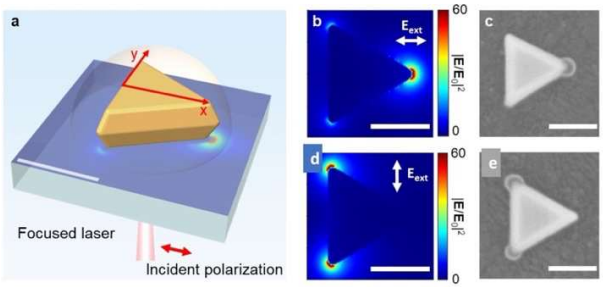

Fig. 1 a) Schematic diagram of plasmon-triggered 2-photon polymerization method. b),d) FDTD-simulated intensity maps at λ=780 nm under different incident polarizations directions (white arrows). c);e) corresponding SEM images of individual gold nanoprisms after irradiation.

III. Results and Discussion

On C3v-symmetry gold nanotriangles (NT), 2D symmetry breaking was quantified through the in-plane chirality factor V_{min}, defined from the loss of mirror symmetry of the polymer with respect to the three mirror planes of the NT and evaluated from both SEM images and FDTD simulations. Near-field dissymmetry maps derived from simulations and AFM topographies further resolved the redistribution of chiral hot spots. By jointly tuning polarization and wavelength, we revealed a controllable transition between achiral and chiral polymer configurations correlated with the modal composition of the plasmonic response (dipolar versus edge-dominated higher-order modes).

IV. Conclusion

These results establish a practical route to engineer and permanently record polarization-tunable planar dissymmetry in achiral nanoantennas, with implications for chiral sensing, enantioselective photochemistry, and nanophotonic devices.

The Interaction of Vortex Light with Chiral Assemblies

Thierry Verbiest[1,*], Weizhen Liu[1], Yovan de Coene[1]

[1]Department of Chemistry, KULeuven, Belgium

***Abstract*— In this work we investigated the interaction of vortex light carrying orbital angular momentum with chiral nanomaterials.**

***Keywords*— nanomaterials, vortex light.**

I. Introduction

Although the optical properties of a material can be understood using the more than 150 years old Maxwell's equations, the fundamental structure-property relationship between light and matter remains very relevant. Particularly interesting are the optical properties of chiral materials, a class of materials that is of fundamental importance in all scientific fields. Chiral molecules are molecules that are not superimposable on their mirror image. They exist in two different forms that are mirror images, called enantiomers. The standard procedure for differentiating between enantiomers is to evaluate and compare their interaction with circularly-polarized light. Whereas the real part of the refractive index of a freely moving chiral molecule imparts a phase retardation between the left- and right-hand circularly polarized field components, the complex part informs on the handedness-dependent light losses in the material. The most convenient experimental methods to evaluate these effects are circular dichroism (CD) and optical rotation (OR).

Maxwell's equations tell us that electromagnetic radiation carries both energy and momentum along its trajectory. Apart from linear momentum along its trajectory, light can carry a nonzero angular momentum. When light is circularly polarized, the photons carry a spin angular momentum (SAM) of $\sigma\hbar$ where σ can either be +1 (for left-circularly polarized light) or -1 (for right-circularly-polarized light). Less well known is that photons can also carry orbital angular momentum (OAM) of $l\hbar$ where l can be any integer number. For example vortex light or Laguerre-Gaussian light carries orbital angular momentum. The total angular momentum is then the sum of a spin part depending on polarization and an orbital part with a certain spatial distribution of the momentum vector [1]. In this context, helical dichroism (HD) has been introduced as the OAM analogue of CD [2]. It quantifies the differential optical response of chiral structures when illuminated with vortex beams of opposite angular momentum.

II. Results and Discussion

Helical dichroism is defined as

$$\mathrm{HD} = 2\frac{\mathrm{R}_{+l} - \mathrm{R}_{-l}}{\mathrm{R}_{+l} + \mathrm{R}_{-l}}$$

where R+ℓ and R−ℓ represent the transmission, reflection, or scattering intensities of right- or left-handed structures under a vortex beam with topological charge |ℓ|.
We present here a series of experimental results of helical dichroism on chiral nanostructures.

Several chiral nanostructures were investigated using vortex light and reflection measurements. The samples were either composed of gold or polymer.

Helical dichroism on the order of 10% were observed, much higher than what is usually found in CD, and highly dependent on the topological charge used. In this presentation we will discuss the influence of beam size, size of the nanostructures and other experimental variables that affect helical dichroism.

***Abstract*— Harnessing plasmonic near-fields, we grow molecularly imprinted nanolayers exactly where light probes matter. The resulting chiral plasmonic interfaces enable absolute enantioselective sensing with sub-femtomolar sensitivity.**

***Keywords*— sensor, chirality, SPR, MIP, photopolymerization.**

I. Introduction

The ability to discriminate molecular enantiomers with high sensitivity and absolute selectivity remains a major challenge in bioanalysis, pharmaceutical chemistry, and asymmetric synthesis. Here, we introduce a plasmon-driven near-field photopolymerization (NFPP) strategy enabling the *in situ* growth of molecularly imprinted polymer (MIP) nanolayers directly onto gold-coated plastic optical fibers (POF@Au).

II. Results and Discussion

By harnessing the strongly confined electromagnetic near-field generated under surface plasmon resonance (SPR), polymerization is spatially restricted to the nanometric sensing volume. This self-aligned process ensures nanometer-scale control over film growth, perfectly matched to the plasmonic probing depth. Using S-propranolol as a model chiral target, the resulting POF@Au@MIP sensors exhibit an ultralow limit of detection of 0.34 fM and complete enantioselectivity, with no detectable response to the opposite R-enantiomer.

Importantly, the detection dynamics and sensitivity can be finely tuned through irradiation time, directly linking optical excitation conditions to structural and analytical performance. The ultra-thin nature of the imprinted layer, combined with the intrinsic sensitivity of SPR to refractive index changes within its evanescent field, explains the sub-femtomolar detection limit. The formulation strategy and photochemical polymerization route further ensure negligible non-specific adsorption, enabling quantitative detection of a target enantiomer even in the presence of a 100-fold excess of its mirror image.

Beyond this proof of concept, the NFPP approach provides a scalable and versatile platform for engineering chiral plasmonic interfaces with molecular precision. Because molecular imprinting relies on target-directed templating, the methodology is inherently adaptable to a wide range of analytes by tuning monomer composition and stoichiometry.

III. Conclusion

This work establishes near-field-controlled polymer growth as a powerful route toward next-generation enantioselective plasmonic sensors and functional nanophotonic interfaces.

***Abstract*— Broad LSPRs in noble-metal nanostructures are engineered by arranging nanoparticles into well-defined arrays, where scattered light couples into plasmonic lattices. Self-assembly, transfer, and laser treatment of chemically synthesized nanoparticles onto thin films enable wave-guided SLRs with multiple high-Q-factor modes, thereby enabling applications in photonics, sensing, and anticounterfeiting.**

***Keywords*— Surface lattice resonance, self-assembly, nanoparticle transfer, laser treatment.**

I. Introduction

Resonant absorption and scattering in plasmonic nanostructures find numerous applications from optical sensing to photocatalysis, but their further development and exploitation might be limited as localized surface plasmon resonance (LSPR) is broad in its nature. Arranging plasmonic material nanoparticles into well-defined periodic arrays enables coupling of the scattered light into the pitch-determined Rayleigh anomalies, resulting in high-Q-factor modes known as surface lattice resonances or plasmonic lattices [1]. Clean room technologies deliver high-resolution patterning, but related vacuum thin film deposition has some drawbacks in material microstructure and roughness. Whereas wet colloid synthesis delivers nearly ideal nanostructures that are also reasonably monodispersed under careful synthesis condition control [2]. The experimentally measured LSPR-related extinction spectra of colloids are directly related to the deviations in size and material properties, which were traced back to the size distribution employing a deep neural network (DNN) based spectral analysis [3],[4]. Lithography methods define pattern dimensions at the design stage directly, whereas template-based assembly allows tailoring of the plasmon resonances via deposition of different average size nanostructures, deposition of multimers [5], or via additional laser treatment of nanoparticles [6].

II. Methods

The PDMS deposition templates were soft lithography replicated from the clean-room-made silicon masters. The silver and gold nanoparticles were synthesized using seeded-growth colloidal chemistry. Gold and silver nanosphere size distributions were analyzed using a DNN trained with theoretically simulated data. Nanoparticles were assembled in PDMS templates via capillarity-assisted particle deposition (CAPA) and transferred onto different substrates via an established process employing water-soluble PVA film [7]. The laser treatment was carried out via motorized sample translation with respect to the Yb:KGW femtosecond laser beam. Optical response of the nanoparticle lattices was analyzed under a darkfield microscope and in the angular resolved UV-Vis-nIR transmission spectroscopy. Electrochemical performance was tested as the photoelectrochemical response in the three-electrode configuration. Experimental findings were compared with numerical simulations.

III. Results and Discussion

Size distributions of the Ag [3] and Au [4] colloids of different average-sized spherical nanoparticles were analyzed with the developed DNN software and revealed the significance of the dielectric function dispersion and its size dependence. The silver nanocubes were deposited in the template and transferred onto the different thickness TiO_2 layer of fused quartz substrate, exhibiting multiple W-SLR resonances red shifting with the increasing thin film thickness. The angular resolved polarized light transmission measurements identified the hybridized TM and TE W-SLR modes in the waveguide structure. Gold nanoparticle arrays were transferred onto electrically conductive ITO substrates and demonstrated photoelectric response in the visible spectra that was attributed

to the presence of the hybridized optical resonances. Carefully adjusting the laser power used to treat gold nanoparticle arrays resulted in different colors being seen under the dark field illumination, which was attributed to different effects, including remelting of multimers into bigger nanoparticles, fracturing of the particles into the smaller ones, and others. Local laser treatment changed the SLR position as well as enabled micrometric resolution patterns from nanoparticles applicable for anticounterfeiting applications.

IV. Conclusion

Chemically synthesized nanoparticle colloids with template-based particle self-assembly enables origination of plasmonic metasurfaces with tailored optical properties and deliver a manifold of practical applications where optical resonances are in play.

***Abstract*— We study both esperimentally and theoretically arrays of plasmonic patch antennas, exhibiting ultra thin surface lattice resonance modes. Those modes will be coupled to quantum dot in order to engineer their fluorescence.**

***Keywords*— plasmonics, surface lattice resonance, quantum dots, fluorescence**

I. Introduction

On a plasmonic nano cylinder grating, Surface Lattice Resonance exhibit ultrathin absorbance peaks. We propose to combine those resonance with the emission of quantum dots embedded in antennas, in order to control and enhance their emission,

II. Methods

On a plasmonic nanocylinder grating, Surface Lattice Resonance are modes which propagate along the surface, hybridizing the large width local surface plasmon resonance, with the Rayleigh anomaly (corresponding to the diffracting mode propagating along the surface) [1,2]. SLR mode have very thin width which can be used to engineer the fluorescence of quantum dots.

A patch antenna made of a thin dielectric layer between a gold layer and a thin nanocylinder **Erreur ! Signet non défini.**gold patch has demonstrated and its capabilities to control both dynamics and directivity of quantum dots embedded inside the dielectric layer [3,4] thanks to a large Purcell factor.

We aim to realise arrays of patch antennas in order to combine surface lattice resonances and the high resonance of patch antenna in order to reach strong coupling of the quantum dots within such structure.

III. Results and Discussion

We perform (figure 1) simulation for arrays of patch antennas exhibiting for incident white light illumination ultra thin peaks, whose width is one order of magnitude thinner than the antenna patch resonance, and with similar amplitude. Experimental realization of arrays of antennas without the quantum dots show under white light normal incidence exhibit thins peaks in the absorbance characteristic of surface lattice resonance

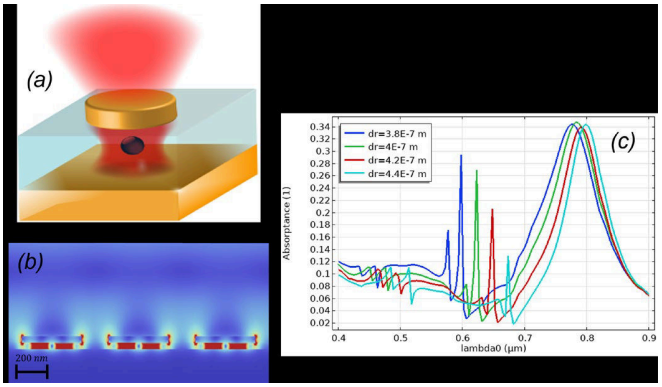

Fig. 1. a) Schematics of a single patch antenna. b) field amplitude for an array of patch antennas with a period dr. c) absorbance of the patch antenna array under white light illumination under normal incidence

IV. Conclusion

We demonstrated experimentally and theoretically surface lattice resonance for arrays of patch antennas. Ongoind work is devoted to the study of the coupling of quantum dots within these arrays.

***Abstract* — We developed a thermopolymerizable formulation that polymerizes above 130°C. Using continuous wave and femtosecond laser regimes, we generated millimetric polymer dots (collective heating) and nanometric shells (confined heating) on dense gold nanoparticles. Surprisingly, on colloidal nanotriangles, directional polymer lobes were formed, challenging the assumption of uniform temperature distribution within nanoparticles.**

***Keywords*— thermoplasmonics, gold nanoparticles, polymerization**

I. Introduction

Localized surface plasmon induced polymerization of free-radical acrylate monomers is an efficient, smart, and versatile method for preparing metal/polymer hybrid nanoparticles (NPs) with accurate control of the thickness and spatial distribution of the polymer on the NP surface. Through decay processes, the plasmon emitted light, hot charge carriers and heat. While the photochemical pathway is well known for generating hybrid NPs,[1] thermoplasmonic effects have not been used in this context.

Yet, accurately controlling and observing the temperature distribution generated by illuminated gold nanoparticles (NPs), i.e. thermoplasmonics, is critical for diverse applications. In biology, it enables photothermal therapy [2] while in chemistry, it drives catalysis [3], NP reshaping [4], and solar energy production [5].

Here, we investigated thermoplasmonic route to graft polymer onto gold NPs. The polymer (i.e. thermopolymerizable formulation), acting as a thermal probe, will be used to characterize thermoplasmonics heat generation effects at the macroscopic scale and at the single NP scale.

II. Methods

We developed a thermopolymerizable formulation combining a thermal initiator (DIAMS) and a triacrylate monomer (PETA). This formulation remains transparent in the visible range and only polymerizes above 130°C [6].

The experimental principle is the following: a droplet of the thermopolymerizable formulation is deposited on the gold NPs sample. Then the sample is illuminated with controlled power, exposure time and polarization. The sample is then rinsed with ethanol. If the polymerization threshold temperature has been reached (or exceeded), polymer is on the sample. If not, no polymer is observed.

First, we validated the thermopolymerization principle for thermoplasmonics using a high-density gold NP sample (prepared by gold evaporation followed by thermal dewetting). Illumination at 532 nm, close to the plasmonic resonance, was performed using two laser regimes: continuous wave (cw) and femtosecond (fs) pulses (pulse duration 60fs with 5 kHz frequency). While polymer dots are visible to the naked eye at the macroscale, nanoscale experiments were conducted on TEM grids and further characterized on high resolution TEM (ARM200F JEOL).

We then applied the same process to colloidal gold nanotriangles (NTs), using fs-pulses illumination at 800 nm (Ti:Sapphire 140 fs with a repetion rate of 80 MHz).

III. Results and Discussion

First, we investigated thermopolymerization using two distinct laser regimes: a continuous wave and fs pulses laser illumination (see figure 1), on dense gold NPs samples. In cw laser illumination, 100-µm thick polymer dot are observed. While its size might be surprising compared to the nanometric size of the NPs, this observation aligns with collective heating effect [7], already well-known theoretically. When multiple NPs are illuminated with a cw laser, the temperature rises homogenously across the illuminated area.

In contrast, fs pulses laser illumination generates polymer with a totally different behavior. The polymer is visible to the naked eye due to the change of color induced by the shift of the plasmon resonance in the polymerized area (Fig. 1, below).

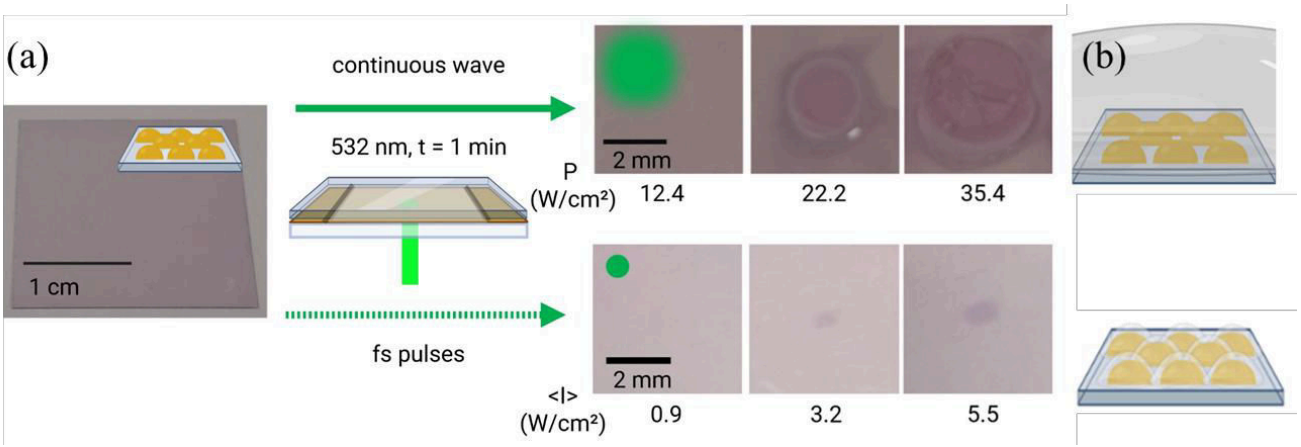

Fig. 1 (a) Experimental results obtained in cw (on top)[2] and fs pulses (below) illumination for various irradiance and (b) associated illustration of the polymerization obtained. [8]

To determine the polymer distribution at the nanoscale, experiments on TEM grids were conducted (Fig. 2), revealing nanometric polymer shells around individual NPs. Here, the heat is confined at the vicinity of each NPs.

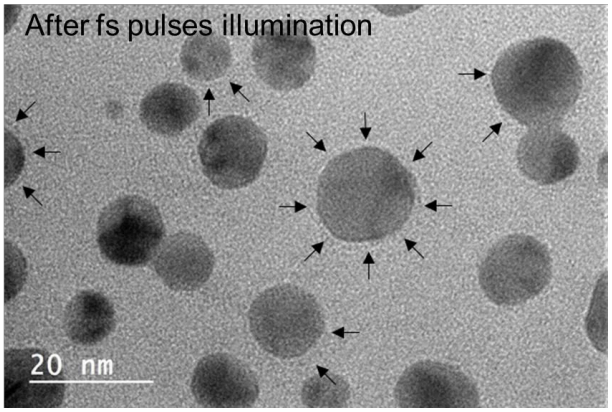

Fig. 2 TEM images of the gold NPs after fs pulses illumination at 5.5 W/cm² with the thermopolymerizable formulation. [8]

By tailoring the laser regime on the same gold sample, we demonstrate the ability to control the heat generation between collective and confined heating through the generation of polymer structures ranging from millimetric to nanometric scales through thermoplasmonics. Notably, the same thermopolymerizable formulation was used in both cases, confirming its ability to polymerize at a defined temperature threshold at the macroscale and at the nanoscale. [8]

Building on this result, which provides us with a temperature probe functional at the nanoscale, we applied this method to colloidal NTs, illuminated near their plasmon resonance at 800 nm. Surprisingly, directional polymer lobes, along the tip or the edge of the NT excited by the incident polarization, were observed (Fig. 3). [9] This experimental result was unexpected from a theoretical point of view, which instead predicted a homogeneous temperature distribution. [7] The interpretation of this observation remains under discussion, given the three mechanisms following the plasmonic excitation (field enhancement, hot electrons and heat generation). We emphasize here that the thermopolymerizable formulation exhibits no absorption in the visible range,ruling out any photochemical pathway. Regarding hot electrons, their contribution to the polymerization process is unlikely, as the thermal iniator molecules (DIAMS) are diluted in a dielectric matrix (i.e. the monomer), preventing efficient transfer to trigger a reaction via this mechanism. Thus, only heat generation might explain these polymer lobes.

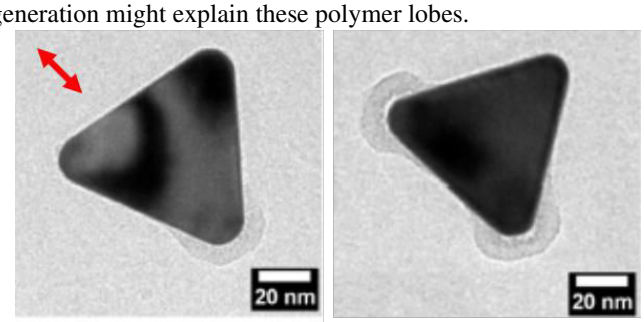

Fig. 3 TEM images of nanotriangles after their illumination at 0.53 mW at 800 nm in the presence of the thermopolymerizable formulation. The red arrow depicts the polarization direction. [9]

IV. Conclusion

In conclusion, by addressing the laser regime in a specific way, it is possible to generate nanometric to almost millimetric polymer through thermoplasmonics, opening new pathway for grafting thermoresponsive materials accross scales. Furthermore, validating a temperature probe based on polymerization, functional at both macroscopic and nanometric scales will enable deeper exploration of the thermoplasmonic of nanoparticles.

***Abstract*— Photothermal heating of metal layers, especially gold, is often neglected given gold is a poor light absorber, and good heat conductor. This picture is, however, not always true, and we have recently shown, both experimentally and theoretically, that photothermal heating of gold films can have unexpected behaviour and effects when working at the micro to nano-scale.**

***Keywords*— Photothermal heating, Nano-scale temperature measurement, Quantitative Phase Imaging.**

I. Introduction

Up to now, most photothermal studies have been focused on Nanoparticle-based systems, mainly because of a many applications in nanomedicine, nanofabrication, nanocatalysis,… Recently, however, more and more applications rely on light interaction with a metal film (SPR, SERS, Plasmonic trapping,…) where photothermal effects are often overlooked, mostly for two reasons. First, because it is generally assumed that, if any light could be absorbed by the gold film and converted into heat, its exceptional thermal conductivity would quickly disperse the heat, leading to a negligeable temperature increase. Second, because measuring temperature at the nanoscale remains quite challenging, and only few techniques allow a precise and accurate measurement.

Combining optical microscopy and numerical reconstruction, Quantitative Phase Microscopy has recently emerged as an easy-to-implement, label-free, and calibration-free technique to measure temperature at the nanoscale with sub-Kelvin accuracy. Using this technique, we studied photothermal effect on various thin metal film geometry and plasmonics nanostructures and we will discuss the origin of the light-to-heat conversion in this case, as well as potential ways to better control it. Finally, we'll discuss the potential effects of photothermal effect on metal layer considering the case of plasmonic trapping.

II. Methods

Quantitative Phase Microscopy (QPI) regroups an ensemble of optical imaging techniques which give access to both the intensity and the phase/shape of the wavefront of light. Thanks to its sensitivity in phase, QPI has been shown to be able to detect temperature variation at the nanoscale thanks to the so-called mirage effect. Indeed, upon heating, the refractive index of the medium - either a liquid, or a polymer - decreases, and induces a variation in the phase of the transmitted light (Fig.1). Using numerical reconstruction, this variation of phase can then be converted into a 3D temperature map, with nanometric resolution, and sub-Kelvin accuracy [1].

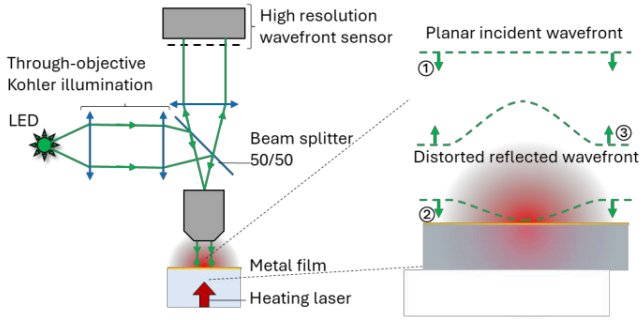

Fig. 1: Principle of wavefront sensor-based QPI measurement of temperature. The laser-induced temperature profile is illuminated with a planar wavefront. Because of refractive index variation, this wavefront is distorted and imaged onto a high resolution wavefront sensor.

Being label-free, QPI-based temperature measurement does not require calibration and can work over an extended temperature range (several hundred of °C), making it an easy and accurate way to measure temperature increase in solution.

Using this technique, we experimentally measured photothermal heating on metal layers, either plasmonic or non-plasmonic (Fig.2a)) and developed a set of numerical tool to allow easy retrieval of the 3D temperature map from the 2D phase images (Fig.2b-d) (available free of charge as supplementary material of [2]).

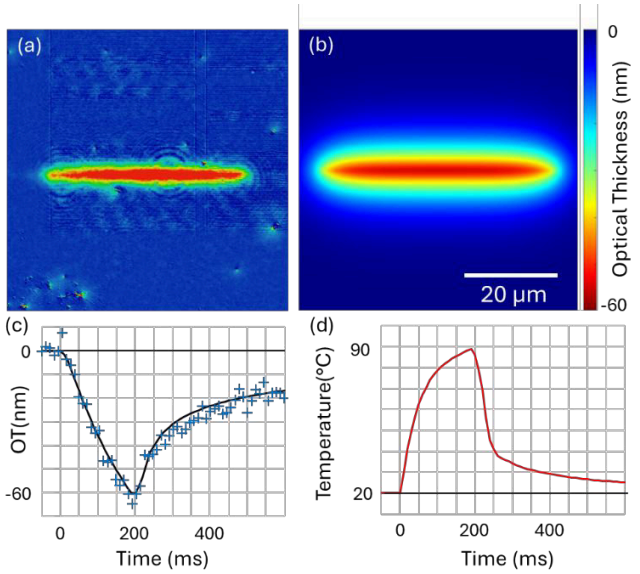

Fig. 2: Heating of a metal layer with a 200-ms line-shaped laser pulse. (a) Experimental optical thickness (OT) at the end of the laser pulse (200 ms). (b) Best-fitting simulated OT. (c) Comparison of the experimental (dots) and simulated OT. (d) Corresponding temperature determined from the simulation.

III. Results and Discussion

We then study more specifically the case of plasmonic trapping. Here, a 5 mW infra-red laser is focused on a plasmonic nano-aperture, and the resulting plasmonic field enhancement allows optical trapping of nanoparticles down to a few nanometer in diameter.

In this configuration, the general belief is that, even though light absorption near the nanohole is enhanced due to plasmonic resonance, the relatively thick gold film (100 nm or more) should quickly dissipate the heat, and limit the temperature increase to a few degrees. Our experimental measurement however showed a temperature increase of several tens of degrees (Fig.3). Using the previously developed numerical models, we were able to attribute this high temperature increase to (1) absorption not on the gold film nor on the plasmonic nanostructure but on the adhesion layer, (2) “not so efficient” heat dissipation by the gold film.

The main consequence of this local heating was the formation of a long-range (several tens of micrometers) thermal trap, governing the diffusion of nanoparticles around the nano-aperture localized plasmonic trap. This thermophoretic effects could be stronger than the optical trap itself, and allowed us to explain the otherwise unexplainable effects of nanoparticule coating on trapping efficiency [3,4].

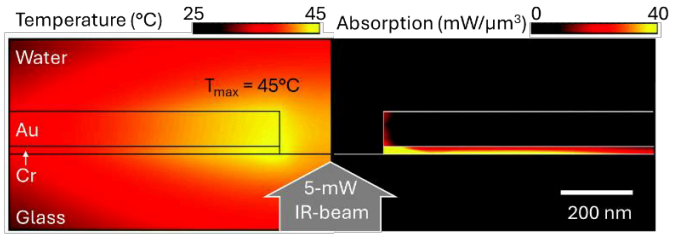

Fig. 3: Temperature increase (left) and local power density absorbed (right) when a 5 mW laser beam (1064 nm) is focused onto a 200 nm diameter nanohole on a 100 nm thick gold film with 13 nm Cr adhesion layer. Most of the absorption happens within the adhesion layer, leading to high temperature increase.

These results helped us understand how to control the photothermal heating to reduce its unwanted effects, or even take advantage of it.

IV. Conclusion

We have presented an easy-to-implement and accurate method to measure temperature at the nanoscale based on QPI, as well as numerical tool to retrieve and/or predict photothermal heating on metal layers. We used these tools to study local heating induced in plasmonic trapping experiments and showed that heat generation on, and near metal layer can have major effects on the system behavior, and should therefore not be overlooked. We hope these tools will help better understanding some still unexplained phenomena observed when in application based on light-metal layer interaction.

Operando Quantification and Mapping of Interfacial Charge-Transfer Efficiency in Hybrid Materials

Olivier Henrotte[1]*

[1]Nanoinstitute Munich, Ludwig-Maximilians-Universität München, 80539 München, Germany

*Corresponding author: O.henrotte@lmu.de

***Abstract*— Hybrid semiconductor–metal photocatalysts often show strong activity, yet the fraction of photogenerated carriers that reaches the solid–liquid interface and drives redox chemistry remains poorly quantified. Herein, I will present operando, spatially resolved quantification of interfacial charge-use efficiency across hybrid systems.**

***Keywords*—metal-semiconductor, scanning electrochemical microscopy, quantum efficiency, interfacial charge-transfer.**

I. Introduction

Photocatalytic performance at solid–liquid interfaces is governed by coupled processes spanning multiple length and time scales: light absorption and carrier generation, ultrafast relaxation and trapping, charge transport through heterogeneous media, and finally interfacial charge transfer to solution-phase species. Standard bulk metrics (e.g., rates, apparent quantum yields, product selectivity) generally convolve these steps, complicating mechanistic interpretation and limiting rational design. This becomes particularly severe in hybrid semiconductor–metal architectures, where interfacial states, junction energetics, and nanoscale morphology can introduce spatially varying reactivity and multiple parallel pathways.

A central, often implicit quantity is the interfacial charge-use efficiency—the fraction of photogenerated carriers that (i) survive recombination, (ii) reach the solid–liquid interface, and (iii) execute productive redox chemistry. While optical spectroscopies can reveal excited-state dynamics, they do not necessarily report on the chemically useful carrier flux at the interface under operando conditions. Conversely, purely electrochemical measurements typically lack the spatial resolution needed to separate heterogeneous regions. Bridging this gap requires correlative, operando measurements that link local structure and illumination conditions to spatially resolved redox activity, enabling a quantitative view of which parts of a hybrid architecture actually "use" photogenerated charge in solution.

Here, I present an operando strategy aimed at extracting and mapping interfacial charge-use efficiency across a hierarchy of hybrid material systems with increasing architectural complexity: (i) a 2D MoS_2 monolayer as a geometrically well-defined model interface; (ii) planar arrays of Au or Pt nanoislands on a semiconductor film (TiO_2) to probe how metal identity and morphology modulate interfacial reactivity; and (iii) a one-dimensional junction geometry based on a TiO_2 nanotube decorated only at the tip with Au nanoislands, which enables direct tests of axial charge transport and spatial separation of solution-phase redox processes.

II. Methods

Our methodology combines structural and optical mapping with operando scanning electrochemical microscopy (SECM) and reaction–diffusion modelling to quantify interfacial charge-use efficiency in hybrid photocatalysts. Morphology is characterized by SEM, optical response by scanning spectrophotometer microscopy, and local photochemical activity by light-coupled SECM (Figure 1.a,b). A calibrated diffusion model converts the SECM probe signal into the corresponding surface reaction rate, enabling extraction of external and internal quantum efficiencies.[1], [2]

III. Results and Discussion

Using operando light-coupled SECM on a monolayer MoS_2 model interface, we quantified where photogenerated charges become chemically productive at the solid–liquid interface. Oxidation signatures remain confined to the illuminated region, whereas reduction products are detected far from the excitation spot (Figure 1.c), consistent with long-range lateral electron transport (up to ≥80 μm).[1]

Beyond spatial mapping, we revealed that the A-exciton internal quantum efficiency (IQE) exceeds the C-transition IQE, even though EQE may still be larger for C when absorption is stronger. Collectively, these results show that MoS_2 activity cannot be rationalized solely by "defect = active site"; rather, carrier transport and extraction geometry determine where oxidation vs reduction occurs, and excitation energy selects which carrier population is most chemically productive.[1]

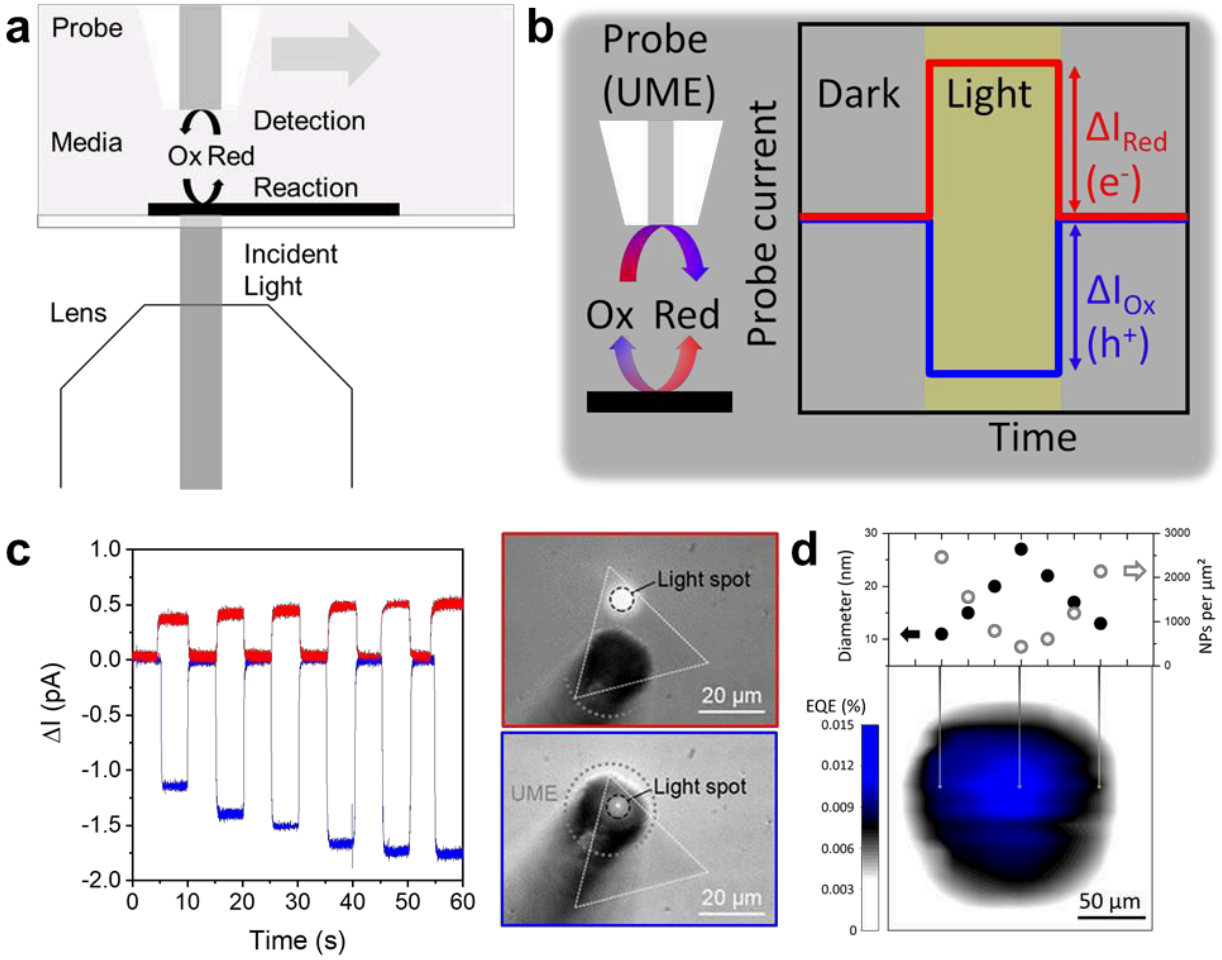

Figure 1. (a) Schematic of the light-coupled scanning electrochemical microscopy (SECM) configuration. (b) Conceptual diagram illustrating signal acquisition for either a reduction (red) or oxidation (blue) process occurring at the investigated material and detected at the probe. (c) Unaligned (Top) and aligned (Bottom) excitation–detection measurements on a MoS_2 monolayer, highlighting the spatial separation of reduction (electron-driven; red) and oxidation (hole-driven; blue) sites as a function of light-excitation position and power. (d) Top: Au nanoparticle population along the array centerline (diameter, left axis, filled symbols; number density, right axis, open symbols). Bottom: external quantum efficiency (EQE) map of the Au nanoparticle array measured by SECM. Experimental conditions: (c) λ_{LED} = 660 nm, r_T = 0.1 µm, RG = 25, Z = 5 µm; (d) λ_{LED} = 595 nm, r_T = 5 µm, RG = 5, Z = 20 µm. Electrolyte: 1 mM ferrocene dimethanol in 0.1 M KCl.

We extended this methodology to semiconductor-metal hybrid systems via Au nanoisland arrays on planar TiO_2. The Au/TiO_2 arrays exhibit peak EQE at the plasmon resonance (around the ~595 nm region for the studied arrays), and the measured EQE varies systematically with nanoisland statistics (size distribution and number density) (Figure 1.d). Wavelength-dependent analysis supported by theory indicates that the dominant carrier channel changes with excitation: interband ("d-hole") contributions dominate at shorter wavelengths, while plasmonic hot holes dominate at longer wavelengths.[2] This provides a direct explanation for why optical absorption alone is not predictive— greater absorption does not necessarily translate into higher chemical yield unless the relevant carrier population is efficiently extracted and coupled to interfacial charge transfer.

Applying nanoscale SECM to a tip-decorated TiO_2 nanotube bearing Au nanoparticles, we observed a bipolar, nanodiode-like behavior: oxidation is confined to Au-decorated regions (consistent with hot-hole-driven chemistry), while reduction products emerge in spatially distinct locations, consistent with hot-electron injection into TiO_2 followed by transport and interfacial transfer elsewhere. In other words, a single illuminated hybrid structure can sustain spatially separated oxidation and reduction zones through engineered charge separation and transport. [2]

IV. Conclusion

Across these three platforms—2D MoS_2, planar semiconductor–metal nanoisland arrays, and 1D nanotube-based junctions—I aim to show that interfacial charge-use efficiency is not a bulk property but an architecture-dependent, spatially heterogeneous quantity that must be measured operando. In MoS_2, oxidation and reduction are spatially separated and IQE depends strongly on excitation channel (A

exciton vs C transition), demonstrating that productive photochemistry is governed by transport and extraction geometry rather than absorption alone. In Au/TiO_2 nanoisland arrays, we established a quantitative workflow linking morphology and optical response to chemically specific reactivity maps, and we demonstrated that wavelength selects distinct hot-carrier pathways—explaining why absorption is an incomplete predictor of chemical yield. Finally, the plasmonic nanodiode concept shows that geometry can encode spatially programmed redox chemistry, and the tip-only Au design demonstrate this principle in a cleaner and more quantitative ways.

Taken together, these studies support a practical design message for hybrid photocatalysts: improving performance requires engineering not only light harvesting, but also the routes by which specific carrier populations reach the solid–liquid interface and react with solution species—and validating these pathways through operando, spatially resolved quantification.

Molecular Bridges in MXenes: Tunable Charge Transport and Chemiresistive Sensing

[1]Yudhajit Bhattacharjee

[1]Leibniz-Institut für Polymerforschung Dresden e. V. ; bhattacharjee@ipfdd.de

Abstract: MXenes, a family of 2D transition metal compounds, have emerged as promising materials due to their tunable surface chemistry and exceptional electrical properties, making them ideal candidates for flexible electronics and sensor applications. In this work, we present a versatile strategy to adjust interlayer spacing and interfacial interactions within $Ti_3C_2T_x$ - MXenes through molecular cross-linking, achieved by sequential ligand exchange with homologous diamines. Initially, oleylamine ligands were employed to exfoliate and stabilize MXene flakes in organic solvent, facilitating their uniform dispersion. The delaminated flakes were then reassembled into thin films through controlled cross-linking using diamines with varied aliphatic chain lengths, enabling precise modulation of interlayer spacing. Grazing incidence X-ray scattering (GIXRD/GIWAXS) revealed a systematic increase of interlayer distance with increasing chain length, while density functional theory (DFT) calculations corroborated these results, indicating precise tunability based on a molecular length scale. We performed charge transport measurements of the resulting films, demonstrating a strong correlation: as the interlayer spacing increases, the electrical conductivity shows a distinct trend. Notably, longer ligands led to more separated layers, which introduced broader tunneling barriers, while shorter linkers improved inter-flake coupling, increasing conductivity.[1] Beyond conductivity, the cross-linked MXene films exhibited promising chemiresistive sensing behavior. When exposed to volatile organic compounds and water vapor, they responded with significant resistance changes. A pronounced selectivity towards H_2O was observed. This selectivity is attributed to the modified interfaces of MXenes, where molecular cross-linkers act as both spacers and functional moieties, facilitating the adsorption of polar analytes and enabling rapid, reversible chemiresistive responses. By strategically tuning interlayer spacing, interface structure, and surface chemistry through molecular cross-linkers, this work demonstrates how molecular design directly influences both electronic transport and chemiresistive sensing properties in MXene systems.[1]

Controlling Polaritonic Contributions to Material Properties

Matthew Sheldon[1,*]

[1]Department of Chemistry, University of California, Irvine, USA
*Corresponding author: m.sheldon@uci.edu

***Abstract*— We show that engineered plasmonic cavities can control how light matter coupling contributes to material behavior. Across recent studies, cavity symmetry and optical state density reshape polariton character, radiative energy transport, and thermoelectric response. These results establish photonic design as a route to tuning spectroscopy, chemistry, and charge transport.**

***Keywords*— plasmonic nanocavities, polaritons, vibrational strong coupling, local density of optical states, thermoelectric response.**

I. Introduction

Optical cavities are increasingly viewed not only as spectroscopic environments but as platforms for controlling material behavior. In plasmonic nanocavities, the local density of optical states, radiative damping, and mode symmetry can all be engineered on subwavelength length scales. These features make plasmonic systems especially attractive for studying how light matter interactions contribute to chemical and physical properties under both weak and strong coupling conditions.

This presentation synthesizes three recent studies from our laboratory that together support a unified picture. First, the symmetry of a plasmonic cavity can change the radiative character of the hybrid states formed under vibrational strong coupling. Second, resonant cavities can modify a thermally driven chemical transformation by enhancing localized radiative energy transfer. Third, photonically structured plasmonic environments can alter the apparent thermoelectric response of a metal nanostructure. Taken together, these results argue that polaritonic and near polaritonic contributions to material properties can be intentionally controlled through photonic design.

II. Results and Discussion

Our first study addressed a basic question in polariton science: which states become optically bright or dark after strong coupling, and how does that depend on cavity symmetry. Using subradiant quadrupolar plasmonic resonators, we found that the usual expectation from bright cavity systems can be inverted. In these structures, the hybrid polariton states acquire subradiant character, while the collective molecular states that are usually spectrally hidden become comparatively accessible. This result shows that cavity symmetry directly shapes the optical character of the coupled states and opens a route for probing molecular contributions that are often difficult to observe in conventional cavity geometries.

Our second study connected this state engineering perspective to chemical reactivity. We examined the thermal dehydration of copper sulfate pentahydrate on resonant plasmonic nanocavity substrates and found that vibrational coupling lowered the onset temperature of dehydration by as much as fourteen degrees Celsius. Spatially resolved Raman mapping showed that the strongest modification occurred in regions of highest optical state density near the nanocavity hotspots. These observations support a mechanism in which resonant electromagnetic modes enhance radiative energy exchange between the cavity and the molecular film, reducing local thermal resistance and changing how thermal energy is delivered to the reacting material. In this study, weak and strong coupling modify the intrinsic thermal transfer properties of the chemical system itself, changing how energy is exchanged, transported, and ultimately used to drive reaction.

Our third study extended this broader idea beyond chemistry and into electronic transport. In structurally uniform gold nanowires placed adjacent to plasmonic nanodisk antennas, we observed spatially correlated photovoltage signals that tracked the local photonic environment. Because the devices were designed to minimize known structural sources of Seebeck coefficient variation, the results point to a photonic contribution to the apparent thermoelectric response. The data are consistent with a photothermoelectric mechanism in which the engineered photonic landscape modifies the effective Seebeck coefficient through photon electron interactions. This finding suggests that photonic structure can be used not only to control optical absorption and local heating, but also to tune electronic transport behavior in metals.

Across these three studies, several common themes emerge. The first is that mode symmetry matters because it determines whether coupled states are radiative, subradiant, or spectroscopically silent. The second is that local density of optical states matters because it defines where light matter interaction is strongest and where modified behavior is most likely to appear. The third is that photonic modes can influence material properties through transport phenomena, not only through static spectral signatures. These themes provide a coherent framework for understanding how optical cavities

contribute to spectroscopy, chemistry, and charge transport in plasmonic systems.

III. Conclusion

Across these three studies, several common themes emerge. The first is that mode symmetry matters because it determines whether coupled states are radiative, subradiant, or spectroscopically silent. The second is that local density of optical states matters because it defines where light matter interaction is strongest and where modified behavior is most likely to appear. The third is that photonic modes can influence material properties through transport phenomena, not only through static spectral signatures. These themes provide a coherent framework for understanding how optical cavities

***Abstract*— We recently introduced the concept of all-optical arithmetic and logic units (ALU) in single plasmonic cavities. The first prototype showed the sub-optimal addition of two 1-bit numbers and all 2-input logic gates. In the absence of an established design theory for such holistic devices, we have developed a new hybrid AI approach that optimizes the design beyond the performances of the initial intuitive demonstrator and paves the way to more complex optical Boolean computing.**

***Keywords*— optical computing, plasmonics, hybrid AI, non-linear optics.**

I. Introduction

Photonics has revolutionized information transfer, but processing and computing remain provided by microelectronic solutions that face fundamental limitations, including the interconnect bottleneck: circuits of smaller switching devices need longer and narrower interconnects, where most energy is dissipated.

We recently proposed a new concept of micrometric, all-optical and interconnect-free, reconfigurable Arithmetic and Logic Units (ALU) of increasing computing capacity. The shape of a 2D single crystalline gold microcavity defines a set of plasmon modes to be used as reconfigurable computation channels.[1,2] The plasmonic landscape, optically excited by N Boolean inputs encoded into two polarization states of focused fs-pulsed laser spots, generates a remote optical Boolean calculus at the ALU output ports. The arithmetic or logic function is directly realized by the relationship between the inputs and outputs. Unlike all information paradigms that rely on concatenated switching devices to realize logic gates, Shannon's theory of information does not apply to our holistic devices and we need to uncover the specific rules governing our ALU design and operation for given Boolean functions. The first prototype to demonstrate experimentally this concept, though sub-optimally, was a cavity with a double hexagon (DH) shape.[1,2] To improve the device performance, we have created a hybrid AI (HAI) tool able to propose candidate cavity shapes as well as optimal excitation/detection condition and successfully shown that they outperform the DH prototype in realizing the 1-bit Full-Adder function.

II. Methods

A robust Boolean function is achieved in plasmonic modal ALU devices when the transmittance, probed here as the non-linear photoluminescence (NPL) transmittance, between the input and output ports obeys the truth table with a high Boolean contrast (i.e. a large difference between '0' and '1' output values). This condition can be expressed for any Boolean function and used to identify where and when an output signal fulfils it.[2] We have created a purpose-conceived hybrid AI framework that that comprises two genetic algorithms to tests millions of cavity shapes and excitation/detection schemes, check the viability of the proposal based on a specific set of ontologies [3] and assesses the optical response of the cavity with a 30 000x acceleration factor compared to standard simulation tools to finally provide most promising solutions.[4]

III. Results and Discussion

Within a few computation days, this DALHAI tool has identified optimal coherent drive conditions for the DH cavity and a set of 5 cavities with increasing overall Boolean contrast for the joint (AND, XOR) Boolean function that implements the 1-bit Full-Adder function. As Fig. 1 shows, the performance is increased by a factor of 200% compared to the optimized DH case.

Experimental realization and testing of such plasmonic ALUs and the effective assessment of the computation quality was carried out and will be introduced but detailed in a separate contribution. In particular, the cavity shapes are realized, from the geometrical description by the HAI, by focused ion beam (FIB) milling of single crystalline gold microflakes. The optical Boolean computation is obtained by implementing the coherent 2-beam excitation of the cavity [5] and controlling the

excitation parameters (beam positions, linear polarization set encoding the Boolean inputs and relative phase-shift between the two incident fs-pulsed beams).

We will also discuss the extension and generalization of our approach towards more complex Boolean functions taking the 2xN-bit Full-Adder as a user case requiring 2N inputs and N+1 outputs.

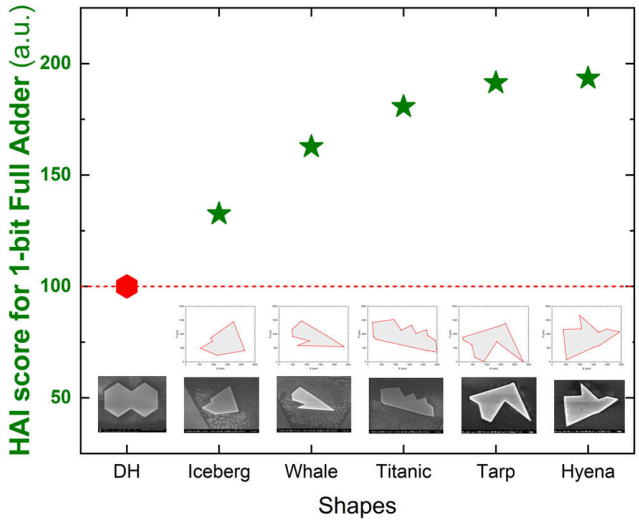

Fig. 1: Optimal 1-bit Full-Adder Boolean contrast (normalized to the one of the DH cavity) for the series of HAI-design plasmonic cavities. Each simulated score corresponds to a specific set of excitation conditions (input locations, linear polarization set, phase shift between exciting pulses). In inset: geometric shape provided by the HAI (top row) and SEM images of the nanofabricated cavities from single crystalline flakes (bottom row). [6].

IV. Conclusion

Our hybrid AI tools successful uncover better performing cavities achieving the targeted 1-bit and 2-bit Full-Adder functions. These results are extremely promising as no established criteria for shaping a cavity and operation scheme for a chosen Boolean function is available. In the process, we have identified several limitations that suggest improvement steps to further generalize our approach in order to reach more complex Boolean functions.

I. Introduction

The development of integrated optical computing architectures is a central challenge in modern nanophotonics, driven by the need to overcome the fundamental limitations of electronic processors [**1**]. While transistor performance has continued to improve, signal routing through metallic interconnects has emerged as the dominant bottleneck, imposing severe constraints in terms of power consumption, footprint and clockrate at advanced technology nodes [**2**]. Optical approaches offer an attractive alternative, benefiting from high bandwidth and low dissipation, yet conventional photonic platforms remain limited by diffraction and bulky interconnect architectures [**3**].

Plasmonic nanostructures provide a promising downsizing route for optical computing by confining electromagnetic fields below the diffraction limit. In this context, nonlinear photoluminescence (NPL), arising from hot-electron dynamics in metals, offers a powerful virtual local probe of plasmonic mode localization and interference.[**3**] Understanding and controlling the spatial distribution of NPL is therefore crucial for encoding and reading out Boolean logic states in plasmonic devices [**4-6**].

Recent demonstrations of plasmonic logic gates within single cavities have highlighted the potential of interconnect-free optical computation. The Boolean output contrast delivered by these demonstrators are nevertheless modest as not optimization procedure has been applied, thereby highlighting the need for an optimal design approach towards viable Boolean scalability [**5,6**]. We have recently elaborated a new a hybrid artificial intelligence (HAI) framework that predicts optimal cavity geometries and excitation parameters for the 2x1-bit Full-Adder and associated 1-input logic gates.[**7**,**8**] In this work, we experimentally benchmark the performances of the HAI proposals by nanofabricating the HAI-inverse-designed cavities, explore the determinant coherent conditions to generate a contrasted output and establish the performance roadmap of this new series of optical computing devices. By jointly optimizing the cavity geometry and the excitation conditions, we realize reconfigurable all-optical plasmonic arithmetic and logic units, culminating in the experimental demonstration of a cascade-free 1-bit optical full adder within a single plasmonic cavity with a 200% output contrast improvement.

II. Methods

2D plasmonic cavities were fabricated by focused ion beam milling chemically synthesized single-crystal gold microflakes deposited on a transparent glass substrate with a 10-nm nominal conductive indium tin oxide layer. [**5,6**] The milling of the polygonal shapes of the cavities was directly implemented from the Hybrid AI output files by simply adjusting the ion dose to

Proceedings of META 2026 · Dublin, Ireland · 14–17 July 2026 · ISSN 2429-1390 · pp. 224–226

the microflake thickness.

HAI approach was employed to optimize both the excitation conditions and the geometries of the plasmonic cavities. In our setup, two laser beams coherently illuminate each cavity at distinct positions, and the logical information is encoded in the polarization of each beam (810 nm, 140 fs, 80 MHz), representing "0" or "1," as illustrated in **Fig.1**, which shows both the experimental instrument and the cavity irradiation scheme. With two beams and two polarization states, four input configurations are possible (00, 01, 10, 11).

In this work, we focus on a 2×1-bit full adder, which requires a XOR gate to perform the sum and an AND gate to generate the carry. To perform an addition correctly, both the XOR and AND gates must operate simultaneously for the same input configuration. The Boolean contrast (ε), defined as the measure of distinguishability between the logical states "0" and "1" based on their output intensities, was enhanced through HAI-guided optimization (**Fig.1.b-c**). The AI proposed several optimized cavity shapes, and the Boolean contrast of the 2×1-bit full adder was systematically compared between AI-predicted simulations and experimental measurements, demonstrating excellent agreement and validating the effectiveness of the AI-driven design framework.

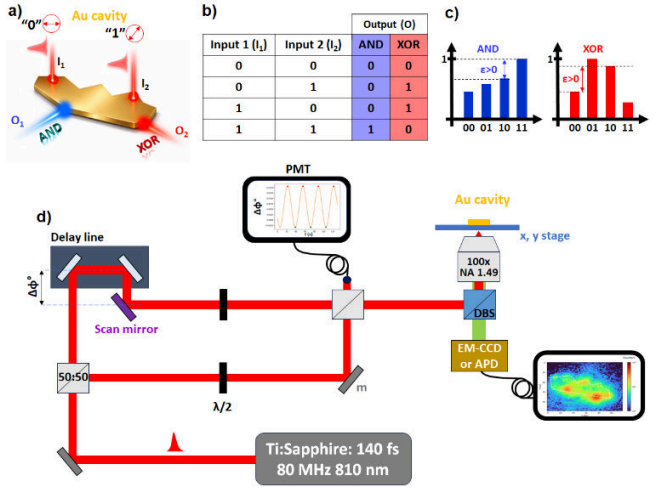

Fig.1: (**a**) Conceptual schematic of the plasmonic cavity. (**b**) Combined truth tables of the output positions simultaneously implementing AND and XOR logic (full-adder operation) within a single plasmonic cavity. (**c**) Bar-plot representation of the AND and XOR logic gates, highlighting a positive Boolean contrast (ε). (**d**) Schematic of the experimental setup used for optical characterization of the full-adder.

III. Results and Discussion

First, the geometry and excitation conditions (polarization, beam positions, and relative phase shift between the two irradiation beams) of the plasmonic cavities were optimized for logic-gate operations using an AI-driven framework that combines accelerated simulations with evolutionary algorithms. Five geometries (Whale, Mountain, Titanic, Hyena, and Tent) outperformed the reference double-hexagon (DH) design [**3**], achieving up to a twofold improvement (**Fig. 2**). SEM images of the AI-designed structures are shown in **Fig. 2**.

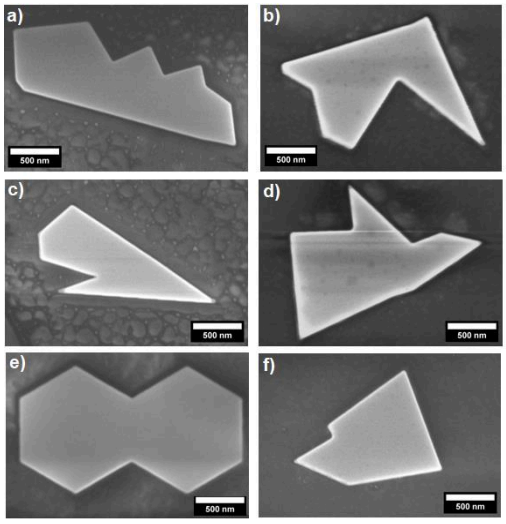

Fig. 2: SEM images of the studied structures: titanic (**a**), tent (**b**), hyena (**c**), whale (**d**), mountain (**e**), and double hexagon (**f**).

The experimental implementation of the AI-predicted excitation conditions demonstrated that these structures achieve Boolean scores (**Fig. 3**) up to four times higher than those obtained from designs based on experimental intuition [**6**]. As an illustrative example, the Titanic geometry exhibits both logic gates of the adder at a phase shift of 40°, with a contrast of 77% for the AND gate and 22% for the XOR gate, resulting in a Boolean score of 22%, compared to only 3% reported in our previous studies [**6**]. The logic-gate locations are clearly spatially separated, which facilitates their identification. Furthermore, **Fig. 3** demonstrates the realization of a fully optical, interconnection-free 2×1-bit adder.

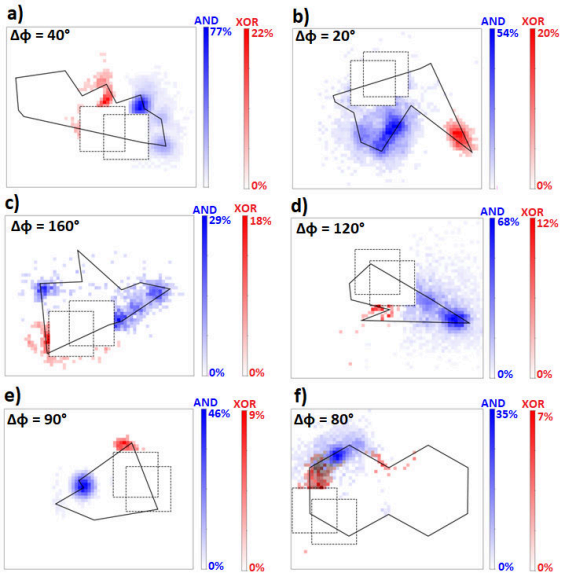

Fig. 3: Optimal 1-bit adder maps obtained experimentally under the excitation conditions predicted by the AI, for the studied structures: titanic (**a**), tent (**b**), hyena (**c**), whale (**d**), mountain (**e**), and double

hexagon (**f**).

Moreover, we demonstrate that the position of the logic gate can be controlled by tuning the phase shift between the two beams. **Fig.4** presents an example of the variation of the Boolean score of the Titanic geometry as a function of the phase shift, highlighting the reconfigurability of the plasmonic-cavity-based adder. Interestingly, the experimental trends of the Boolean scores for the XOR and AND gates are in good agreement with theoretical predictions.

These cavities exhibit phase-dependent reconfigurability, where $\Delta\varphi$ controls beam interference, enabling switching between AND and XOR functions without altering the geometry. For example, in the Titanic structure, $\Delta\varphi \approx 0°$ favors AND, while $\Delta\varphi \approx \pm 120°$ favors XOR.

IV. Conclusion

In conclusion, AI-driven optimization enables the design of plasmonic cavities with high performance and reconfigurability. NPL generation is governed by confined cavity transport modes and strongly depends on beam polarization and position, with sharp corners serving as efficient output points. The optimized geometries outperform the reference double-hexagon design, achieving up to twofold improvement in Boolean contrast. Phase-dependent control allows dynamic switching between AND and XOR gates without changing the cavity, while long-range plasmon propagation and local hot-electron transport explain the observed NPL patterns. These results confirm the accuracy of AI predictions and highlight a physical performance plateau set by intrinsic plasmonic constraints, demonstrating that AI-assisted inverse design is a powerful strategy for creating robust, high-performance, and reconfigurable plasmonic logic devices.

All-Dielectric Photo-Thermo-Optical Metasurfaces for All-Optical Spatio-Temporal Wavefront Control

Gopal Narmada Naidu*, Giulia Tagliabue

Laboratory of Nanosciene for Energy Technologies, EPFL, Switzerland
*Corresponding author: gopal.naidu@epfl.ch

***Abstract*— All-dielectric photo-thermo-optical metasurfaces could enable high speed all-optical spatiotemporal wavefront control. We demonstrate reconfigurable metasurface optical responses driven by thermo-optic nonlinearities and present an inverse thermal design framework for programmable temperature profiles. Together, these capabilities advance dynamic meta-optics, photothermal catalysis, and next-generation spatial light modulation for photonic and energy applications.**

***Keywords*— photo-thermal, thermo-optic, all-dielectric metasurfaces, inverse design, temperature shaping, reconfigurable, wavefront control.**

I. Introduction

Precise spatiotemporal control of optical wavefronts is central to emerging technologies including imaging, optical communications, holography, and laser processing. Conventional spatial light modulators based on liquid crystals are limited by millisecond response times, restricting their applicability in high-speed optical systems. Metasurfaces composed of subwavelength nanoresonators provide a compact platform for manipulating amplitude, phase, and polarization with high spatial resolution. However, achieving rapid and fully optical reconfigurability remains a major challenge. Thermo-optic nonlinearities and photothermal effects in high index dielectrics provide a promising route toward all-optical high-speed modulation.[1], [2], [3]

II. Methods

Combining electromagnetic simulations, topology optimization, and machine learning based design strategies, we efficiently explore high-dimensional design spaces, achieving optimized wavefront control while overcoming the computational limits of traditional iterative approaches. We further develop an inverse thermal design framework for dielectric metasurfaces composed of amorphous silicon nanoresonators, wherein a precomputed library of absorption spectra as a function of geometry and temperature is constructed using full wave electromagnetic simulations and target temperature distributions are mapped onto metasurface layouts. Coupled optical and thermal simulations are performed to evaluate steady state and transient temperature fields under optical illumination.

III. Results and Discussion

Silicon exhibits a strong thermos-optic coefficient, enabling substantial refractive index modulation with modest temperature variations. Coupled optical and thermal simulations of silicon dielectric metasurfaces reveal that optical and thermal dynamics can be partially decoupled, enabling optical modulation faster than thermal relaxation.[4] Motivated by these findings, we developed an inverse thermal design framework that maps target temperature profiles onto metasurface layouts, enabling precise nanoscale thermal control. We demonstrate that thermo-optical nanoresonators enable dynamic reconfigurability through wavelength or intensity multiplexing without complex unit cells. Furthermore, we show that engineered thermal distributions enhance photo-thermocatalytic performance by exploiting nonlinear temperature-dependent reaction kinetics to improve catalytic efficiency, while more broadly providing a general framework for optimizing other photothermal processes including solar evaporation and separation technologies.[5] Finally, this work aims to extend these concepts to realize fully reconfigurable all-optical metasurfaces with independent amplitude, phase, and polarization control.

IV. Conclusion

We present an inverse designed all-dielectric photo-thermo-optical metasurface platform for high-speed all-optical spatiotemporal wavefront control. The combination of thermo-optic nonlinearities and programmable temperature shaping establishes a scalable strategy for dynamic meta optics, photothermal catalysis, and next generation spatial light modulation.

Near-Field Coupling in Plasmonic Nanoarrays: Tailoring Radiative and Non-Radiative Losses Through Gap Engineering

Benedict S. Morris[1, *] and Bruno Palpant[1]

[1] LuMIn, Université Paris-Saclay, CNRS, ENS Paris-Saclay, CentraleSupélec, Gif-sur-Yvette, France

***Abstract*— Absorption losses in plasmonic nanoparticles limit their performance in many optical and photonic applications by dissipating energy as heat and damping resonance strength. Using finite-difference time-domain simulations (FDTD), we demonstrate that near-field coupling in dense, periodic nanoparticle arrays can significantly mitigate these losses.**

***Keywords*— Critical coupling, finite-difference time-domain (FDTD) simulations, electric field enhancement.**

When interparticle distances are small, for the free carriers inside a given particle, the field enhancement of neighbouring particles reduces the effect of the field enhancement at the tip of the particle under study. As a result, the internal electric field—and thus the associated Ohmic losses and optical absorptance—are substantially reduced (Fig. 1), despite intense field enhancement in the narrow interparticle gaps. By comparing our results to analytical theory of electric dipole arrays [1], we show that engineering the gaps in periodic arrays allows fine tuning of the non-radiative to radiative losses ratio [2]. In addition to this tailoring of losses, we show that near-field coupling can induce both red- and blue-shifting of the plasmon resonance wavelength. This interplay between the near-field enhancement and the electric field inside the nanoparticles suggests a route to exploit densely packed plasmonic arrays for optical devices, achieving high resonance strength and field enhancement while minimizing thermal losses and associated damping.

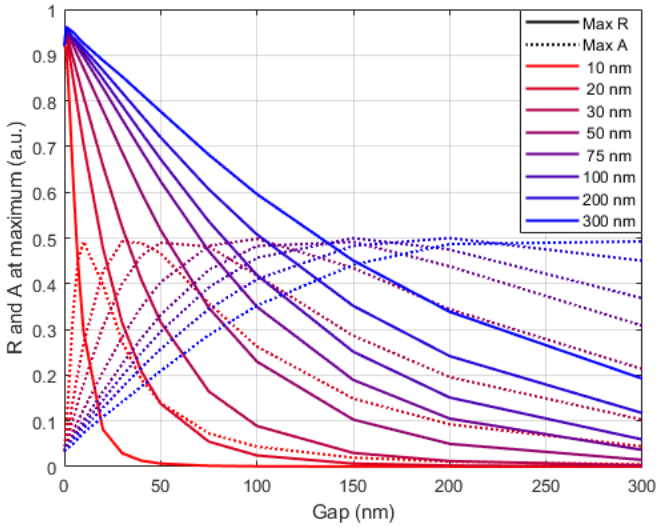

Fig. 1: Maxima of reflectance (solid lines) and absorptance (dotted lines) for different nanorod lengths (in nm) as a function of gap. The nanorods are 10 nm wide by 10 nm high.

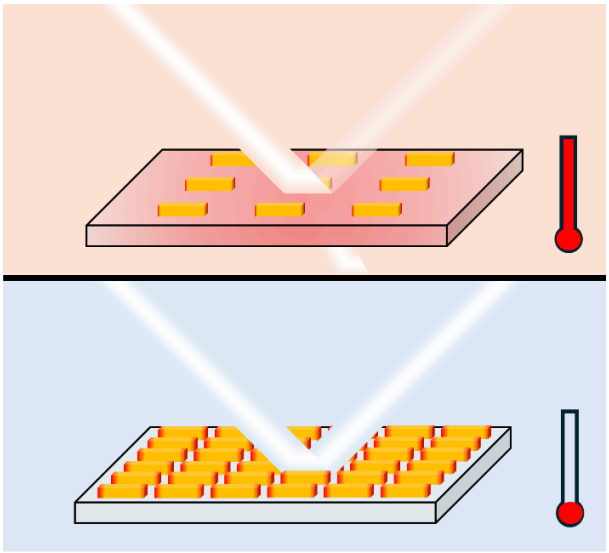

Fig. 2 : Small interparticle gaps lead to mirror-like behaviour with high values of enhanced near-field and reduced thermal losses.

Single plasmon transport in 1D nanowire

Gérard Colas des Francs

Laboratoire ICB UMR 6303 CNRS/Université Bourgogne Europe, Dijon, France

gcolas@ube.fr

***Abstract*—Waveguide quantum electrodynamics (wQED) explores the interaction between emitters and guided modes in *e.g.* optical nanofibers and plasmonic nanowires. We develop a dedicated formalism that naturally introduces coupling constant into a non Hermitian effective Hamiltonian. This facilitates the physical interpretation of plasmon transport including the role of propagation losses.**

***Keywords*— quantum plasmonics, wQED, non Hermitian.**

I. Introduction

Waveguide quantum electrodynamics (wQED) exploits evanescent coupling to mediate photon-photon interactions—otherwise weak—in direct analogy to cavity quantum electrodynamics (cQED). Quantum emitters coupled to a plasmon waveguide have been demonstrated to implement single-photon optical transistors [1], two-qubit entanglement [2], [3], long-range energy transfer [4], and nanowire lasers [5].

Theoretical treatments of wQED generally follow two complementary approaches. Effective Hamiltonian models describe emitter–waveguide interactions using *ad hoc* coupling constants, allowing compact expressions for single photon transmittivity [6], [7]. In contrast, continuous formulations based on the electromagnetic Green's tensor provide a description of the electromagnetic environment [2], [8]. In this work, we derive effective non-Hermitian Hamiltonians directly from the quantized electromagnetic Green's tensor of a plasmonic nanowire. This formulation naturally incorporates propagating SPPs and losses within a unified description.

II. Modulation of the single plasmon transport

The electromagnetic field is quantized within the Langevin type model [9] and we follow the procedure described by Castellini *et al* [10], but adapted to propagative modes to obtain the interaction Hamiltonian associated to a single emitter coupled to a plasmonic nanowire.

We consider a silver nanowire of radius 50 nm coupled to a single emitter located at 15 nm from its surface. We assume an emission at the telecom wavelength $\lambda = 1.5\,\mu\text{m}$, for which the nanowire supports a single mode SPP_0. The various contributions to the reflectivity and transmitivity are presented in Fig. 1. Single photon reflectivity and transmittivity achieve $R_0 = 50\%$ and $T_0 = 10\%$ at zero detuning $\omega = \omega_0$.

We extend our formalism to several emitters and demonstrate a significative improvement of the single plasmon modulation ($R_0 = 86\%$ and $T_0 = 2\%$ for 5 emitters).

Fig. 1. Modal reflectivity R_0 and transmittivity T_0 associated to the fundamental SPP_0 mode and to high order $\sum_{n\geq 1} R_n = \sum_{n\geq 1} T_n = \sum_{n\geq 1}$.

III. Conclusion

We have developed a Green-function-based effective Hamiltonian to single-plasmon transport in nanowires. The modal analysis clarifies the respective roles of guided and non-guided contributions in determining transport properties.

***Abstract*— Nanoscale noble metal structures show the effect of localized surface plasmon resonance (LSPR), based on interaction of light with conduction electrons in the metal. As the observed resonance wavelength is influenced by the refractive index, modification with specifically binding biomolecules realizes label-free biosensors, also possible in array format for multiplexing.**

***Keywords*— gold nanoparticles, biosensing, DNA hybridization, sensor arrays.**

I. Introduction

Besides composition (material) size and shape of noble metal nanostructures, also the refractive index of the surrounding influences the resonance wavelength due to the effect of localized surface plasmon resonance (LSPR). By monitoring the resonance wavelength using VIS spectroscopy, refractive index sensing is so possible. By modifying the surface with certain receptors (molecules like antibodies, aptamers or DNA, which bind a target molecule highly specifically), a molecular detection with high specificity is provided. When using arrays of gold nanostructure spots each modified with a different receptor molecule, multiplexing is possible.

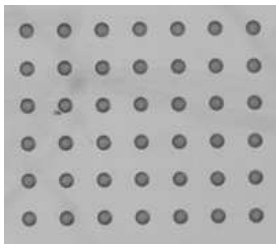
II. Methods

Chemically synthesized gold nanoparticles 80 nm diameter were spotted in an array pattern (spot diameter ca. 120 µm, center-to-center distance of 275 µm, Fig. 1) and modified by a second spotting run with various receptor molecules, such as single-stranded DNA [1, 2]. An imaging spectrometer setup using spectrally filtered light provided by 6 LEDs of different wavelengths spanning the VIS range is used to monitor the LSPR peak with a time-resolution in the lower second range upon incubation with target molecules (complementary DNA) [3]. Sensorgrams, plots of the resonance wavelength over time, are used to visualize the changing peak wavelength upon incubation with various buffers and/or target molecule solutions.

III. Results and Discussion

Experimental results show:

- Multiplexed label-free monitoring of DNA hybridization kinetics
- No significant cross-talk between different targets
- Strong agreement between simulated and measured spectra



- Fig. 1 Optical transmission micrograph of a gold nanoparticle sensor array (spot diameter about 120 µm)

IV. Conclusion

We have demonstrated a multiplexed, label-free monitoring of molecular interactions for DNA using gold nanoparticle sensor arrays with VIS spectroscopic imaging readout.

***Abstract*— Nonlinear metastructures combining nanoscale electromagnetic resonances and material nonlinearities, offer unprecedented opportunities in photonics. Here, we review our recent results in the field, where finite-element-method numerical analysis is exploited to model and design a variety of nonlinear metastructures, for the ultrafast all-optical control and THz generation.**

***Keywords*— metasurfaces, nanoantennas, hot carriers, difference-frequency generation, terahertz, ultrafast photonics.**

I. Introduction

Photonic nanostructures, including metasurfaces, made of nonlinear materials have attracted increasing interest for the unprecedented possibility of boosting and tailoring the optical nonlinearities of the constituent media. Most research in the field has focused on two main directions, depending on the kind of nonlinearity to be exploited (see for instance, [1-3] and references therein): (i) nonlinearities mediated by photoinduced hot carriers for the all-optical modulation of light; (ii) instantaneous nonlinearities for light generation at the nanoscale.

II. Results and Discussion

Semiconductor metasurfaces have been demonstrated to be all-optically reconfigurable via photogenerated hot carriers for several years [4,5]. However, most works in the field have assumed a photoinduced permittivity modulation which is either homogeneous across the structure, or spatially inhomogeneous in a way that is not actively involved in the reconfiguration process. Here, we report on semiconductor metasurfaces designed to enhance the effect of photoinduced transient spatial inhomogeneities. The key idea is to exploit the symmetries presiding over the optical response of the metastructure and to induce, via photogenerated hot carriers and the subsequent third-order nonlinearity, a transient modulation of these symmetries. We originally introduced the concept by the all-optical modulation of the left-right inversion symmetry in a nonlocal AlGaAs metasurface, leading to efficient and ultrafast (sub-picosecond) modulation of light [6]. More recently, we consider a heterostructure metasurface where the meta-atom includes two nanowires made of AlGaAs, geometrically identical but with different stoichiometric compositions. We theoretically predict the possibility to modulate the discrete translational symmetry of the system, by effectively halving the metasurface periodicity (via photoinduced hot carrier), and thus transiently suppressing the first diffracted order over a relatively broad spectral range.

Second-order processes in nanostructures made of non-centrosymmetric crystals have attracted an increasing interest in the last few years, especially for second harmonic generation (SHG) and difference frequency generation (DFG) at the nanoscale [1,2,7]. DFG in all-dielectric nanoantennas boosted by phonon-polariton resonances has been also proposed for the nonlinear generation of THz radiation from infrared pump pulses [8,9]. Following a multipolar theory approach, we report on a strong influence of the illumination scheme on the DFG process. For example, in <111>-oriented AlGaAs nanopillars an efficient control of the THz radiation pattern is enabled by acting on the polarization state of the single pump in an intrapulse-DFG scheme. When resorting to an interpulse-DFG scenario, it is possible to control the far-field pattern of a Z-cut $LiNbO_3$ nanocylinder by changing from two co-polarized to two cross-polarized infrared pumps, at almost no cost in terms of conversion efficiency.

III. Conclusion

A design strategy based on the concept of transient symmetry modulation has been proposed to exploit hot-carrier mediated third-order nonlinearities in semiconductor metasurfaces. The efficiency of this approach opens new perspectives for the design of high speed all-optically reconfigurable nanophotonic devices.

All-dielectric metastructures can also enable THz generation from infrared pumps with advanced functionalities, such as wide-angle beam steering or nonlinear routing, by simply acting on pump polarization in the DFG process. Extending this analysis to nanoantenna arrays opens the way to all-optically reconfigurable metasurfaces for THz photonics.

***Abstract*— Chiral-induced spin selectivity (CISS) is a well-known phenomenon where molecular chirality filters electron spins. This lecture proposes Plasmon-Induced Spin Selectivity (PISS) as an electromagnetic analogue. We demonstrate how chiral plasmonic fields align spins during transitions, utilizing this mechanism to drive and control spin-dependent chemical transformations in nanostructured environments.**

***Keywords*— plasmon, chiral, spin-selectivity, water splitting, ammonia production, CO_2 reduction.**

INTRODUCTION

Chiral-induced spin selectivity (CISS) is a well-known phenomenon where the structural asymmetry of chiral molecules acts as a filter for electron spins. As electrons move through these helical or asymmetric frameworks, the interaction between their motion and the molecular electrostatic field favors the transmission of one spin orientation over the other. This effect is widely utilized to improve the efficiency of electrochemical processes, such as water splitting, by suppressing unwanted side reactions. It can be utilized also in the electrochemistry, to enhance efficiency and selectivity of chemical transformations.

Commonly spin polarization is traditionally achieved using magnetic materials and in case of CISS it relies on the spin-orbit coupling of electrons within asymmetric molecular structures. Our recent studies report the observation of spin selectivity induced by chiral plasmonic field. Plasmon-Induced Spin Selectivity (PISS) emerges as a powerful alternative, utilizing chiral plasmonic fields to align electron spins. This mechanism has been proved effective in water splitting, where spin-polarized electrons favor the production of triplet oxygen over undesired hydrogen peroxide. Similar thermodynamic benefits are currently being explored for nitrogen and carbon dioxide reduction. By aligning electron spins, PISS can lower activation barriers and suppress hydrogen evolution. Controlling spin states facilitates the stabilization of key intermediates in these complex multi-electron processes, potentially enabling more efficient pathways toward ammonia synthesis and high-order hydrocarbon production.

I. METHODS

A seed-mediated colloidal method facilitated by a chiral amino acid or peptide was used for the preparation of chiral MeNPs. The 432-helicoid III particles exhibit specific chiral morphology resulting in a high value of g-factor but there are more MeNPs that can be used.

The electrodes combining a redox active layer with AuNPs were prepared by electrodeposition and drop-casting.

Evidence for PISS was established through electrochemical experiments by measuring presence of hydrogen peroxide, ammonia production and creation of C2+ products.

II. RESULTS AND DISCUSSION

Experimental results show:

- Chiral MeNPs were created with a g-factor equal to 0,2 and they were coupled with redox active layers.
- Created systems were used in electrochemical and photoelectrochemical regime for water splitting, nitrogen and carbon dioxide reduction.
- While hydrogen peroxide typically competes as a main product of water splitting, our system demonstrated a significant preference for triplet oxygen formation.
- Plasmon triggering positively affect reaction kinetics (observed for both chiral and achiral MeNPs).
- Critically, performance metrics under illumination substantially outperformed those in dark, indicating that plasmonic excitation actively mediates spin-alignment.
- Utilization of chiral plasmon apparently affects reaction selectivity and effectivity in the case of nitrogen and CO_2 reduction.

III. Conclusion

We have demonstrated an apparent impact of illumination i.e. plasmon induced spin selectivity on the amount of reaction products in the case of relevant electrochemical transformations. Light-driven enhancement confirms the efficacy of PISS in modulating reaction pathways, providing a robust experimental foundation for utilizing chiral plasmonic nanostructures to bypass conventional thermodynamic barriers in multi-electron transfer processes.

***Abstract*— Pharmaceutical contaminants in wastewater are a growing environmental concern. Electrochemical surface-enhanced Raman spectroscopy (EC-SERS) with mesoporous gold sensitively detects trace organics by electrochemically controlling analyte selective accumulation on plasmon active surface, enhancing spectral intensity, and reducing matrix interference on SERS-active nanostructures. Several model pharmaceutical pollutants to assess analytical performance.**

***Keywords* — electrochemical surface-enhanced Raman spectroscopy, mesoporous gold, wastewater, pharmaceutical pollutants, trace detection, SERS, EC-SERS, environmental monitoring.**

I. Introduction

The rapid and reliable detection of trace amounts of hazardous organic compounds in complex media remains a major challenge in modern analytical chemistry, particularly in environmental analysis. This problem is especially important for wastewater, where pharmaceuticals and other organic micropollutants are often present at very low concentrations in the presence of numerous interfering substances [1]. This matrix complexity significantly limits the applicability of conventional analytical methods and creates a demand for highly sensitive, selective, and reproducible analytical approaches [2].

In this context, EC-SERS represents a highly promising strategy for trace-level detection [3]. By combining the molecular specificity of Raman spectroscopy with the signal amplification provided by plasmonic nanostructured surfaces and the controllability of electrochemical techniques, EC-SERS enables enhanced analyte adsorption, improved signal reproducibility, and selective detection in complex media [3]. The application of an electrochemical potential can promote the preconcentration of target molecules on the substrate surface, influence their orientation and interaction with the metal, and help suppress background interference [4]. These features make EC-SERS particularly attractive for the analysis of wastewater samples containing trace organic contaminants.

This work aimed to develop and validate an EC-SERS method based on mesoporous gold substrates for the detection of trace analytes (pharmaceutical contaminants) in wastewater. Special attention was paid to diclofenac, carbamazepine, and ibuprofen, which were selected as model analytes to evaluate the analytical performance of the proposed approach. These compounds are widely recognised as important pharmaceutical pollutants due to their extensive use, persistence in wastewater, and potential environmental impact [5]. The study focused on assessing the sensitivity, reproducibility and applicability of the mesoporous gold-based EC-SERS platform developed for the determination of these pharmaceutical contaminants in complex wastewater matrices.

II. Methods

Mesoporous gold was used as the SERS-active substrate and working electrode for EC-SERS, fabricated following Lim et al. [6]. PS-b-PEO (10 mg) was dissolved in 3 mL THF, heated to 40°C, and stirred for 30 min, then 1.5 mL absolute ethanol, 1 mL 40 mM HAuCl4, and 2.5 mL deionized water were added dropwise and stirred for 1 h. This micellar solution was used for gold electrodeposition by chronoamperometry (Edc = −0.5 V, t = 1200 s) in a three-electrode cell (FTO glass working electrode, Ag/AgCl reference, platinum grid counter). After deposition, substrates were rinsed seven times with THF and deionized water to remove residual micelles.

The mesoporous gold layer was characterized by UV–Vis absorption spectroscopy (Lambda 850, UV WinLab™), SEM and EDX (LYRA3 GMU, Tescan, 10 kV, 600 pA), and XRD (Empyrean, Malvern Panalytical, Cu Kα, 8.04 keV, λ = 1.54151 Å, 45 kV, 30 mA). Surface morphology and layer thickness were additionally evaluated by AFM scratch profiling (Icon, Bruker, peak force tapping mode).

The simulated wastewater was prepared using the composition from Aiyuk and Verstraete [7]. The prepared solution was diluted ten times prior to use.

EC-SERS measurements were conducted using a closed electrochemical flow cell positioned within a DXR3 Raman Microscope (Thermo Fisher Scientific), as illustrated in Fig. 1B. Spectral acquisition was performed with a standard 10× objective, a 25 μm slit aperture, an exposure time of 10 s, and signal averaging over 10 accumulations. The laser power was

adjusted in the range of 0.5–10 mW, employing excitation wavelengths of 785 nm and 532 nm. Subsequently, the optimal deposition potential for EC-SERS was systematically evaluated within a potential window extending from open-circuit conditions (no externally applied potential) up to 0.8 V.

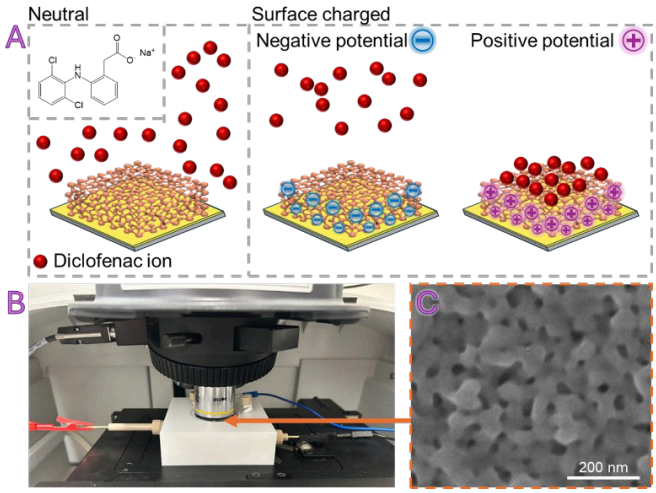

Fig. 1: (A) Schematic of the sensing mechanism via plasmon-enhanced EC-SERS on mesoporous gold; (B) electrochemical cell inside Raman spectrometer; (C) SEM of mesoporous gold (working electrode).

III. Results and Discussion

The EC-SERS method regulates the spatial distribution of analyte molecules near a SERS-active surface by applying an external electrode potential. Diclofenac, used as a model compound, is mainly anionic in solution, so its interfacial behaviour at the electrode is dominated by electrostatic interactions. Without an applied potential, diclofenac is randomly distributed in the bulk, and its interaction with the SERS-active surface depends mainly on diffusion and weak nonspecific adsorption. As a result, the analyte concentration near the surface, and thus the SERS signal intensity, remain relatively low.

When a positive potential is applied, the electrode surface becomes positively charged, electrostatically attracting negatively charged diclofenac anions to the near-electrode region. This leads to their accumulation in the electrical double layer, decreases their average distance from the metal surface, increases their probability of entering SERS-active "hot spots," and produces a strong enhancement of the Raman signal.

When a negative potential is applied, the electrode becomes negatively charged and repels diclofenac anions. This lowers the analyte concentration near the surface, suppresses adsorption, and decreases the fraction of molecules in SERS-active regions, reducing the SERS signal intensity. This concept was used for substrate regeneration, allowing the same substrate to be reused multiple times without a substantial decrease in signal. These processes are illustrated schematically in Fig. 1A.

Mesoporous gold served as the working electrode in the EC-SERS platform due to its high surface area, well-defined porosity, and excellent conductivity. These features provide many active sites for analyte adsorption, promote SERS hot spot formation, and enable effective electrochemical modulation at the electrode–electrolyte interface [8]. Its tuneable pore morphology is an additional advantage: in this study, pores of 40–60 nm may restrict penetration of larger matrix components into the inner enhancement-active regions while still allowing smaller analyte molecules to reach the surface.

Diclofenac, ibuprofen, and carbamazepine were studied as model pharmaceutical contaminants in pure water and wastewater. Diclofenac and ibuprofen were reliably detected down to 10^{-6} mol L^{-1}, whereas carbamazepine gave a much weaker EC-SERS response under the same conditions. This difference arises from their acid–base properties: at pH ~5, diclofenac and ibuprofen are mainly anionic and are strongly attracted to the positively polarised electrode, leading to interfacial preconcentration and stronger signals. In contrast, carbamazepine remains mostly neutral at this pH, experiences little electrostatic attraction, accumulates less at the interface, and therefore shows a lower EC-SERS signal.

This behaviour was clearly observed in pure water, where diclofenac and ibuprofen showed strong signals at low concentrations, while carbamazepine remained much less detectable. In wastewater, conditions are more complex because of a highly heterogeneous matrix containing many potentially interfering constituents, including natural organic matter, proteins, humic and fulvic substances, surfactants, inorganic salts, and various dissolved organic and inorganic species. At pH ~5, some of these components—especially humic and fulvic substances—carry a net negative charge and compete with the target analytes for adsorption at the positively polarised electrode surface. In addition, larger macromolecular and colloidal or aggregated species can block active surface sites or hinder mass transport to the most enhancement-effective regions of the electrode.

Mesoporous gold offers a key advantage: its tuneable 40–60 nm pore size can be adjusted during synthesis to restrict larger matrix components from reaching internal SERS hot spots, while allowing smaller analyte molecules to diffuse in and interact with the active regions. Thus, mesoporous gold serves as a conductive working electrode, a SERS-active substrate, and a structurally selective interfacial layer that improves analyte detection in complex media. The same electrode can be used for up to six consecutive measurements without noticeable performance loss, demonstrating its stability and suitability for wastewater analysis.

IV. Conclusion

In conclusion, a mesoporous-gold-based EC-SERS platform was shown to detect low concentrations of pharmaceutical organic analytes in wastewater. Diclofenac, carbamazepine, and ibuprofen were used as model compounds to evaluate performance in the presence of environmentally relevant contaminants. The combination of electrochemical control with mesoporous gold substrates enabled sensitive, reproducible, and reliable detection in complex aqueous matrices. The substrate also retained its performance over at least six measurement cycles, demonstrating high reusability.

***Abstract*— We use photo-acoustic effect do reveal scattering-free absorption signals at the nanoscale. We present microscope-enriched laser photo-acoustic spectroscopy with full tunability of a conventional chiro-optical set-up.**

***Keywords*— metamaterials, plasmonics, nano-photonics, photo-acoustic spectroscopy.**

I. Introduction

Photo-thermal techniques are still unconventional, but extremely useful in characterization of absorbed light at the nanoscale [1-3]. Direct characterization of absorption is highly important in nano-photonics and plasmonics, where nanostructured media can be tailored to resonantly enhance absorption. Moreover, characterizing different absorption of left and right circular polarizations, i.e. circular dichroism (CD), is important for the field of chiral nanophotonics.

We apply photo-acoustic spectroscopy (PAS) to convert absorption-induced periodic heating into an acoustic signal, thus enabling contactless, scattering-free, non-destructive, low-postprocessing absorption characterization.

II. Results and Discussion

We enrich PAS set-up with multiple tunable components present in conventional chiro-optical set-ups. The laser is widely tunable in the near-IR and visible range, in power, polarization, spot-size, position on the sample, incidence angle. Moreover, in PAS, tunable modulation frequency could potentially allow for depth scanning. We successfully apply it to measure absorption and chirality in different nanostructures and metamaterials [4-6].

III. Conclusion

We believe that PAS is yet to become attractive for mapping chirality at the nanoscale with multiple degrees of freedom.

***Abstract* — We demonstrate all-optical Boolean computing with an interfacial robot, BOTAI, that autonomously drives a multi-beam non-linear optical setup. The system interprets operating instructions from a hybrid artificial intelligence to position, encode and time fs-pulsed laser beams carrying the input Boolean operands onto a single 2D plasmonic microcavity and acquires the non-linear photoluminescence response that is processed in the Boolean computation result. BOTAI demonstrates the fully automated Boolean logic operations with sub-100 nm positioning accuracy.**

***Keywords* — plasmonics, non-linear optics, optical computing, robotics.**

I. Introduction

All-optical arithmetic and logic units (ALUs) represent a promising pathway toward ultrafast and energy-efficient computing. We have recently demonstrated that two-dimensional plasmonic cavities carved from ultrathin crystalline gold microplates can operate as reconfigurable all-optical ALUs, already achieving basic logic gate operations as well as a 1-bit full-adder [1-3]. To optimize their performance, we are developing a hybrid artificial intelligence (HAI) framework that predicts optimal cavity geometries and excitation parameters [4].

Experimental validation of HAI-optimized structures demands ultra-precise positioning, fast polarization flipping and temporal synchronization of the input fs-pulsed beams, which become increasingly challenging for human operators as system complexity grows. Hence, we introduce BOTAI, an interfacial robot that autonomously drives our two-beam optical bench with sub-pixel accuracy. This system establishes the foundation for scaling to N-bit ALU processors with $N \geq 2$, where manual operation becomes impractical and automation is essential for exploring complex Boolean operations.

II. Methods

Principle of single cavity All-Optical ALU

The Boolean ALU is a planar polygonal plasmonic structure (~3 × 2 µm²) nanofabricated into crystalline gold microflakes deposited on a transparent substrate. Two synchronized femtosecond laser beams (810 nm, 140 fs pulses, 80 MHz) are focused onto designated input ports on the structure perimeter. Logical input bits are encoded as linear polarization states, while the plasmonic response is controlled by adjusting the inter-pulse temporal delay, modulating the interference between excited surface plasmon modes. Since the absolute phase offset varies between experiments, the measurement protocol scans the full 2π phase range while recording the output observable encoded in non-linear photoluminescence (NPL) maps. This provides complete optical responses for all relative phase shifts. The HAI framework determines the ALU geometry and optimizes excitation conditions - input port coordinates, polarization states encoding "0" and "1" and the relative phase shift - while simulating the optical response and ensuring implementation of targeted arithmetic and logic functions.

Optical Setup

Figure 1 illustrates the dual-beam coherent excitation setup.

The laser output is split into two independent paths with equal intensity. Beam 1 is focused directly onto the first input port, while Beam 2 passes through a motorized delay line before being steered to the second input port. Both beams are focused through a 100× objective (N.A. 1.49) to approximately 300 nm diameter spots with 15-20 mJ/cm² fluence. The resulting NPL is filtered via a dichroic beam splitter and recorded as 2D spatial maps on an EMCCD camera.

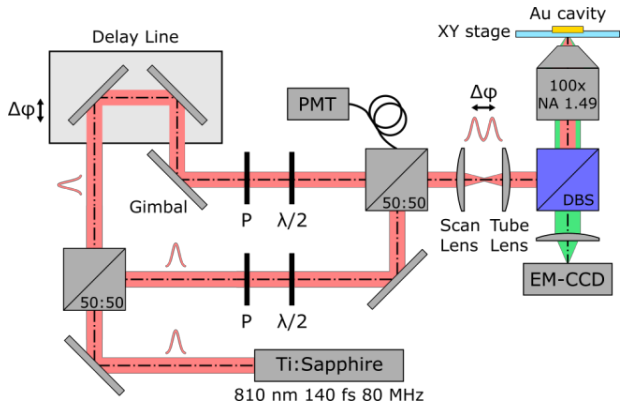

Fig. 1. Dual-beam optical setup for coherent excitation of the 2D plasmonic ALU cavities

Robotic Control and Automation

The BOTAI robot autonomously controls the experimental setup through a Python-programmed interface managing seven motorized components: Andor Luca EMCCD camera (structure recognition and NPL acquisition), Mad City Labs NanoDrive XY stage (sub-100 nm sample positioning), Newport Picomotor 8742 gimbal (two-axis beam steering), Newport DL125 delay line (pulse phase-shift modulation), Thorlabs K-Cube polarizers ×2 (Boolean input encoding), and Zurich Instruments UHF lock-in amplifier (phase monitoring and camera fire signal acquisition). BOTAI interprets optimal measurement parameters - targets structure geometry, input port locations and polarization angles encoding "0" and "1" - and autonomously executes the complete measurement sequence.

Computer Vision for Structure and Beam Detection

Automatic structure localization employs Otsu thresholding on brightfield images, followed by morphological filtering and contour extraction. Candidate structures are filtered by area and ranked via Hu moment shape matching against HAI reference geometry. The best candidate undergoes polygon alignment optimization maximizing intersection area between reference and detected contours. Critical corrections account for OpenCV's pixel-corner convention and systematic detection biases.

Laser fluorescence spot detection uses intensity thresholding, Gaussian blur, and mean position calculation of maximum-valued pixels, achieving sub-pixel accuracy. A fluorescence-to-810 nm offset correction is applied to determine the incident focus spot position.

Closed-Loop Positioning

The gimbal alignment positions Beam 2 to port I2 with respect to port I1 location through iterative error minimization (Δ = target - spot), converting pixel errors to motor steps via calibrated proportional coefficients. Iteration continues until $|\Delta| < 0.5$ pixel, with final verification via 5-frame averaging.

Once both input beams are positioned, XY stage alignment brings port I1 of the cavity to beam 1 position using the same proportional correction method, converging within 6 iterations maximum. The port I2 of the cavity is concomitantly brought to beam 2.

Automated Measurement Protocol

Upon operator selection of the target HAI-designed structure,[5] BOTAI executes the following autonomous sequence:

1. Beam 1 localization by centroid detection of laser's residual fluorescence focal spot
2. Structure detection: Computer vision identifies and localizes the selected geometry on the camera field of view
3. Beam 2 positioning: closed-loop gimbal directs the second excitation beam to port I2 relative to Beam 1
4. Structure alignment: closed-loop XY stage positions the structure such that ports I1 and I2 coincide with Beams 1 and 2 respectively
5. Optical contact search: Two-phase delay line scan (coarse then fine) determines pulses temporal overlap
6. Sequential acquisition, for each input Boolean configuration of the 2-input ALU (00, 01, 10, 11):
   a. Polarizer angles setup
   b. Structure position verification
   c. Delay Line scan starting from optical contact
   d. NPL map recording

When the output locations (for example the AND and XOR function corresponding to the CARRY and SUM of the 1-bit Full Adder) are known, direct readout of the computation result is possible. For newly designed cavities, the Boolean gate locations are automatically provided as described in [2].

III. Results and Discussion

Automated Positioning and Measurements

Closed-loop control of the XY stage and gimbal beam steering converges within a maximum of six iterations, achieving sub-pixel accuracy better than 0.5 pixel (< 25 nm) and maintaining positional stability throughout the complete four-configuration measurement sequence.

Applied to a HAI-designed plasmonic cavity (~3 × 2 µm gold monocrystal), this autonomous procedure successfully executes the full measurement protocol and enables correct simultaneous realization of XOR and AND logic gates (i.e. SUM and CARRY of a 1-bit full adder), confirming accurate beam positioning on input ports I1 and I2. This automated procedure demonstrates repeatability exceeding that achievable by manual

alignment performed by a human operator.

Limitations and Perspectives

The system currently lacks adaptive beam positioning based on NPL response. A human operator can modulate beam positions according to real-time NPL feedback, whereas BOTAI executes fixed HAI instructions. Implementation of an additional feedback loop analyzing NPL response quality could enable adaptive beam optimization.

The architecture facilitates future expansion to 4-beam configurations required for more complex 2×2-bit ALUs with 3-bit outputs ("11"+"11" = "110"), the optical setup is currently under construction.

IV. Conclusion

We have demonstrated autonomous robotic control of a complex non-linear optical setup for all-optical Boolean computing. The BOTAI system successfully interprets HAI-generated instructions, performs sub-pixel beam and structure positioning, and acquires complete NPL characterization datasets. This robot-AI integration enables systematic exploration of plasmonic computing architectures and paves the way for increased Boolean complexity through multi-beam configurations. Future developments will incorporate adaptive positioning strategies and extend to $2N \geq 4$ input beams for advanced arithmetic operations.

***Abstract*— We present a unified framework for engineering electromagnetic descriptors in plasmonic nanoantennas to control nanoscale light–matter interactions. Full-wave simulations show how geometry, symmetry, and lattice coupling tune LDOS, chirality, and decay channels. Nanogap cavities and surface-lattice-resonant arrays enable tailored emission, polarization selectivity, and vibrational sensing, validated experimentally.**

***Keywords*— Plasmonic nanoantennas, Surface lattice resonances, SEIRA, FEM, chirality.**

Plasmonic nanoantennas enable the engineering of light-matter interactions at the nanoscale by reshaping electromagnetic boundary conditions and achieving subwavelength confinement. Their capability to localize and redistribute electromagnetic energy provides controlled access to a broad variety of optical observables. These electromagnetic descriptors constitute a quantitative framework for describing nanophotonic systems, supporting prediction, comparison between architectures, and experimental design. Here, we present a computational strategy based on full-wave three-dimensional finite-element simulations in COMSOL Multiphysics to engineer key quantities such as the local density of optical states (LDOS), optical chirality density, radiative and non-radiative decay rates, field enhancement factors, and lattice-mediated coupling for realistic applications.

Particularly, we show that nanogap cavities yield strong Purcell enhancement, while symmetry-broken and intrinsically chiral nanoantennas produce polarization-selective and circular dichroic responses. In periodic arrays, surface lattice resonances (SLRs) induce spectral narrowing and collective enhancement, improving linewidth control and sensing figure of merit (FOM) [1].

These collective modes can also mediate molecular chirality transfer, enabling tunable circular dichroism in achiral nanoparticle lattices through controlled coupling with chiral molecules [2]. At the near-field level, gap-confined fields and polarization-dependent modal distributions govern hot-spot localization and plasmon-driven chemistry. Such descriptor-level control underpins enhanced refractometric sensing in nanoparticle arrays [1], SEIRA-based detection of molecular vibrational fingerprints in resonant infrared nanoantennas [3], and polarization- resolved super-resolution SERS imaging in gap-engineered systems [4].

Together, these results establish a descriptor-driven approach to nanophotonics in which geometry, symmetry, and collective effects are systematically engineered to tailor emission, chirality, and vibrational responses. The proposed models not only guide device design but also are validated by experimental realizations, reinforcing their predictive capability for advanced nanophotonic materials.

Can Surface Plasmon Carry Heat?

Jungmin Nam[1], Kuk Hyun Yun[1], Bong Jae Lee[1,*]

[1]Department of Mechanical Engineering, KAIST, South Korea
*Corresponding author: bongjae.lee@kaist.ac.kr

***Abstract*—This presentation outlines our recent endeavors in developing an efficient heat spreader made of a nanoscale metallic film, beginning with experimental investigations to demonstrate in-plane heat transfer along a thin metal film via surface plasmon.**

***Keywords*— surface plasmon, in-plane heat transfer, thin metal film.**

I. Introduction

The thermal conductivity of nanoscale thin films is significantly constrained by the classical size effect, occurring when film thickness becomes comparable to or smaller than the mean free path of primary heat carriers such as phonons and electrons. This reduction in thermal transport efficiency hinders effective heat dissipation from localized hot spots, thereby compromising the performance and reliability of highly integrated microelectronic devices. As traditional thermal management techniques reach their physical limits, there is a critical need for advanced strategies rooted in a fundamental understanding of extreme-scale heat transfer phenomena

II. Results and Discussion

In 2023, a novel heat transfer mechanism was identified involving surface plasmon polaritons (SPPs) generated at the interfaces of thin metallic films. These electromagnetic surface waves, which couple photons with free electrons, can achieve propagation lengths extending over several centimeters in the mid-infrared regime. Initial investigations demonstrated that SPPs can enhance the in-plane thermal conductivity of a 100 nm Ti film by approximately 25% [1].

Subsequent research focused on noble metals, specifically Au and Ag thin films supported by SiO_2 substrates. This work emphasized the necessity of incorporating thickness-dependent permittivity to account for electron-boundary scattering. Results indicated that such size effects reduce predicted plasmon thermal conductivity by approximately 30% compared to bulk-property models [2]. For these systems, an optimal thickness of 20 nm was identified to maximize SPP-mediated transport when utilizing a 10 nm Ti adhesive layer.

To determine the global conditions for maximum enhancement, a comparative analysis across various metals (Al, Ag, Au, Cu, and Pt) was conducted [3]. This study established that metals characterized by high plasma frequencies and low damping coefficients provide superior channels for plasmonic heat transfer.

Finally, numerical validation confirmed that while different mathematical approaches (complex-β vs. complex-ω) yield different local propagation lengths, the predicted overall thermal conductivity remains consistent, ensuring the robustness of these theoretical models [4].

III. Conclusion

This research establishes a comprehensive theoretical and experimental framework for utilizing surface plasmon polaritons as a primary heat dissipation channel in supported thin films. By optimizing material selection and film geometry, SPP-mediated heat transfer will offer a scalable and effective solution for mitigating thermal management challenges in next-generation microelectronics.

Polarization-Programmable Optics using Chiral Dielectric Metastructures

Soo Jin Kim*

School of Electrical Engineering, Korea University, Seoul, Republic of Korea
*Corresponding author: kimsjku@korea.ac.kr

***Abstract*— We demonstrate symmetry broken dielectric metasurfaces that leverage the nonlocal guided mode resonances to enable efficient spin selective polarization control and chirality resolved detection. Moreover, we propose metastructures which produce globally biased optical chirality in the near and far field regime, supported by coupled mode design rules.**

***Keywords*— dielectric metasurfaces, nonlocal resonances, chiral optics, polarimetry, Stokes parameters.**

I. Introduction

Chiral meta optics afford the spin dependent manipulation and sensing of light in a compact planar film, with applications in polarization resolved imaging, molecular detection, and integrated photonics. However, there remain several challenging issues in realizing strong chirality in a single layered dielectric metastructure. For example, strong intrinsic chirality often relies on three-dimensional geometry or loss engineering, and realizing a perfectly planar intrinsic chiral metastructure still remains elusive. Here we exploit symmetry breaking along with collective guided mode resonances to realize efficient planar intrinsic chirality and various chiroptical functions including the spin selective polarization control and chirality resolved detection. Additionally, we leverage the nonlocal resonances in periodic dielectric arrays to offer an ability to enhance chiral light matter interaction and produce globally biased optical chirality in the near and far field regime.

II. Results and Discussion

We demonstrate chirality-resolved polarization meta-optics using a symmetry-broken dielectric metasurface in which the meta-atoms are arranged in a periodic array that supports a nonlocal guided-mode resonance. In the operating spectral range, the optimal coupling of local and nonlocal resonances provides steep dispersive phase control and enhanced polarization mixing, allowing efficient manipulation of phase and wavefront together with reconfigurable conversion between orthogonally polarized components. As a result, the handedness of incident circular polarization is converted into distinguishable output polarization states, enabling chirality-resolved generation in a compact single-layer metastructure.

Using the spin-dependent polarization response, we further design a practical polarimetric detection by calibrating the relative amplitudes and phases of the transmitted polarization channels. This optimization enables discrimination of left- and right-handed circular polarization and supports Stokes-parameter retrieval without bulky free-space optics. Based on this, we investigate how symmetry breaking governs the origin of chirality by comparing in-plane and out-of-plane perturbations. In-plane asymmetry primarily produces extrinsic chiral signatures that depend on illumination geometry, whereas out-of-plane symmetry breaking enables an intrinsic chiral response that remains for normal incidence. Notably, we realize an effective planar intrinsic-chiral metastructure without three-dimensional sculpting by leveraging substrate-induced out-of-plane symmetry breaking, where the resulting hybrid resonance breaks the mirror symmetry of the near-field distribution and generates helicity-dependent features analogous to those typically associated with 3D chiral systems.

Beyond polarization control and readout, we propose metastructures that produce a globally biased optical chirality density over an extended region rather than isolated hotspots. We reveal that the collective nature of the guided-mode resonance allows the chirality bias in both near- and far-field regimes. The measured and designed responses are analyzed based on a coupled-mode theory, which provides design rules that connect resonance detuning and interference to the amplitude and phase relations between co- and cross-polarized channels.

III. Conclusion

In conclusion, we propose several chiral design strategies to realize nonlocal, symmetry-broken dielectric metasurfaces as an efficient and scalable route to planar intrinsic chirality, spin-selective polarization optics, and globally biased chirality sensing for various applications such as integrated photonics and molecular-detection applications.

Subspace-Protected Topological Phases

Masatoshi Sato

Yukawa Institute for Theoretical Physics, Kyoto University, Japan
msato@yukawa.kyoto-u.ac.jp

***Abstract*—Symmetry is a key to controlling topological phases. In this talk, I will explain that an invariant subspace, a generalization of symmetry, protects topological phases with unconventional properties. I also discuss a possible realization of such subspace-protected topological phases in metamaterials.**

***Keywords*— metamaterials, non-Hermitian Hamiltonian, invariant subspace, topology.**

I. Introduction

Symmetry is a fundamental principle for characterizing and classifying topological phases of matter. In particular, various types of symmetry provide free-fermion systems with rich topological structure, as in topological insulators and superconductors. A unitary symmetry resolves the Hilbert space into sectors, in which topological phases are individually classified on the basis of internal symmetries or crystalline symmetries. A significant characteristic of topological phases is the bulk-boundary correspondence: the nontrivial topological phases in gapped bulk involve the presence of gapless boundary modes. Nontrivial topological insulators protected by time-reversal symmetry (TRS) exhibit helical gapless modes as the Kramers pairs, and nontrivial topological superconductors can host Majorana zero modes reflecting particle-hole symmetry. In recent years, the idea of symmetry-protected topological phases has also been applied to metamaterials with and without non-Hermiticity.

While extensive research has shown that symmetry enriches the topological phases of matter, the more general principles that protect them have yet to be explored. Here, I elucidate the roles of subspaces in free-fermionic topological phases. A subspace property for Hamiltonians enables new topological invariants. It results in peculiar topological boundary phenomena, i.e., the emergence of an unpaired zero mode or zero-winding skin modes, characterizing subspace-protected topological phases. I also propose possible platforms that possess the subspace property.

II. Subspace-protected topological phase

In this talk, I show that subspaces of Hilbert spaces provide a principle for introducing a novel type of topological phases in both Hermitian and non-Hermitian systems, beyond the conventional notion of symmetry. Specifically, we consider the following condition, which we call the subspace property, for a Bloch Hamiltonian $H(\boldsymbol{k})$ acting on a Hilbert space $\mathcal{H}$ of internal degrees of freedom,

$$H(\boldsymbol{k})\mathcal{M} \subseteq \mathcal{M}', \tag{1}$$

where $\mathcal{M}$ and $\mathcal{M}'$ are subspaces of $\mathcal{H}$ independent of the wave vector $\boldsymbol{k}$. The subspace property is not reduced to group-theoretical symmetry operations. With Kenji Shimomura, Ryo Takami, and Daich Nakamura, I propose the concept of topological phases protected by the subspace property (1), dubbed *subspace-protected topological phases*, and establish the bulk-boundary correspondence in the phases [1].

As discussed in Ref.[1], the proposed subspace-protected topological phases exhibit unusual topological properties in both Hermitian and non-Hermitian systems. In particular, they may host a topological phase transition without gap closing, which has never been seen in conventional topological phases.

The realization of systems with the subspace property is not difficult in artificial quantum systems, including metamaterials. Actually, we have recently realized such a system mechanically [2].

III. Summary

In summary, we have discovered subspace-protected topological phases and established the bulk-boundary correspondence. Our work reveals that the new principle beyond symmetry may play an essential role in topological phases.

Fluctuation-induced Hall-like lateral forces in a chiral-gain environment

Daigo Oue[1,2,3,*], Mário G. Silveirinha[1]

[1]Instituto Superior Técnico–University of Lisbon and Instituto de Telecomunicações, Lisbon, Portugal

***Abstract*—We predict a fluctuation-induced lateral force on a particle near a substrate under an electrostatic bias that induces chiral optical gain. The force arises from vacuum fluctuations in a non-Hermitian environment, is governed by the Berry-curvature dipole, and enables directional momentum transfer without a magnetic field.**

***Keywords*— non-Hermitian systems, chirality, Casimir effect**

Non-Hermitian electromagnetic media, characterised by loss and/or gain, enable wave phenomena with no direct counterpart in passive systems. In current-biased conductors, a static electric field drives carrier drift that modifies the optical response and can induce polarisation-dependent gain [1]. In low-symmetry materials possessing a finite Berry-curvature dipole, such an electrostatic bias produces *chiral optical gain*, where one circular polarisation is amplified while the opposite is dissipative. Hence, both inversion and time-reversal symmetries are broken, leading to a nonreciprocal behaviour.

We have explored fluctuation-induced forces in the chiral-gain environment [2]. We consider a small polarisable particle placed near a biased substrate (Fig. 1). Unlike conventional

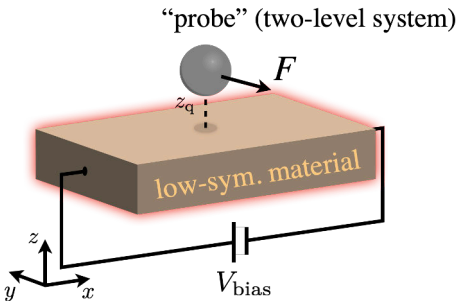

Fig. 1. A polarisable particle modelled by a two-level system placed above a low-symmetry material under an electrostatic bias.

Casimir–Polder forces, which act normal to a surface, the Hall-like lateral force arises due to the non-Hermiticity and nonreciprocity of the material. We demonstrated that the force is governed by the Berry-curvature dipole of the substrate response, establishing a link between quantum geometry and fluctuation-induced forces.

We utilised the Lindblad formalism and the Green-function-based field quantisation to obtain a reduced master equation effectively describing the dynamics of the particle. The momentum transfer between the particle and the surrounding field was evaluated at the steady state. Figure 2 depitcs the fluctuation-induced lateral force as a function of the distance z_q between the particle and the surface.

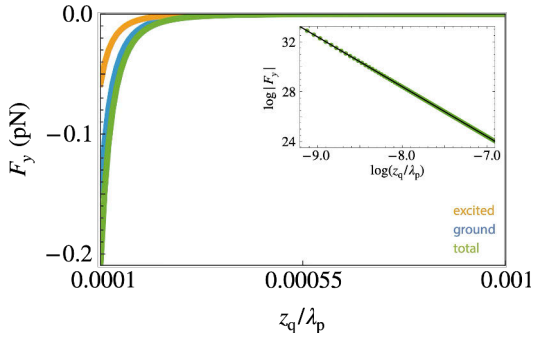

Fig. 2. Fluctuation-induced Hall-like force as a function of the distance z_q between the surface and the particle. The inset is the logarithmic plot, implying the force is proportional to $1/z_q^4$.

Our results reveal a new mechanism for engineering vacuum fluctuations using active, nonreciprocal photonic platforms.

Metasurface concepts for polarisation control

Ilya V. Shadrivov

***Abstract*— We develop metasurface based broadband polarisers and waveplates for controlling Terahertz radiation. We discuss effects of topology and mode interplay for achieving broadband operation of the proposed devices.**

***Keywords*— metamaterials, terahertz, gratings.**

I. Introduction

Efficient polarisation control in the terahertz frequency range is required in many applications, including material characterization, imaging, and polarimetry. Main devices that control wave polarisation are polarisers and waveplates, including quarter and half-waveplates, as well as Q-plates. There are several approaches and commercially available products with this functionality, but they have drawbacks. For example, the available quarter waveplates that convert linear polarisation into circular come in various designs, including subwavelength gratings, metamaterials, prism-type waveplates, natural birefringent material stacks, liquid crystals etc. However, these solutions still suffer from limited bandwidths, low transmission or other limitations.

II. Results and Discussions

In this work, we will present metal-based and dielectric gratings that aim to provide a full polarisation control for the Terahertz frequency range. For the metal gratings, we explore the effect of the shape of metal stripes on achievable transmission and extinction ratio of polarisers. We further demonstrate quarter-waveplates based on high-index dielectric gratings. A subwavelength linear grating is a fundamental building block for creating optical elements with tailored properties. Using high-order effective medium theory, a scattering-matrix formalism, and a particle-swarm optimization, we developed an efficient approach to predict and optimize grating parameters. Our simulations show that the relative frequency bandwidth of a single-layer grating is limited to about 40-50%, and that transmission characteristics can be improved by adjusting the grating profile.

To further increase the bandwidth, we stack multiple single-layer gratings with carefully selected dimensions and rotation angles. The resulting structure exhibits enhanced performance across a broader spectral range.

This work presents both simulation results and experimental demonstration of the proposed structures. Our fabrication techniques include lithography, laser micromachining and electrochemistry. They provide a scalable platform for the fabrication of polarisation devices. Figure 1 shows top view of dielectric micrograting, with the depth optimised so that the device acts as a quarter waveplate. The performance of the devices was characterized using terahertz time-domain spectroscopy system. The experimental results show excellent agreement with theory and numerical simulations, and they confirm the viability of the proposed approaches for achieving polarisation control in the terahertz frequency range.

***Abstract*— Anisotropic materials can support directional surface waves and guided modes. Their propagation direction and its angular cone depend on the optical properties of the anisotropic materials. We numerically analyze directional surface waves on tungsten disulfide metasurface, which exhibits large effective anisotropy and transparency for near-infrared wavelengths.**

***Keywords*— surface waves, metasurfaces, transition metal dichalcogenide, anisotropy.**

I. Introduction

Photonic surface waves are supported on various nanostructured systems, such as plasmonic materials or photonic crystals [1]. In particular, directional surface waves are supported on in-plane anisotropic materials and are sometimes referred to as Dyakonov surface waves.

Here, we numerically show that nanostructured transition metal dichalcogenide (TMD) metasurface (MS) exhibits large in-plane anisotropy and can support Dyakonov surface waves and related guided modes for telecommunication wavelengths at 1550 nm due to its extreme anisotropy. The TMD MS consists of tungsten disulfide (WS_2) metasurface made of deep sub-wavelength one-dimensional gratings with air gaps. Numerical analysis is performed in combination of analytical equations and the COMSOL software based on the finite element method.

II. Results and Discussion

Numerical analysis shows:

- large propagation cone, angular existence domain, of surface waves over 20 degrees for telecom wavelengths as opposed to smaller than 1 degree of natural anisotropic material (Fig. 1), and
- the deviation between effective media and real metasurface structures, affected by the thickness and the period of deep-subwavelength gratings of the metasurface.

III. Conclusion

In this talk, we present that the significant improvement of propagation cone of the directional modes can be controlled by the design of WS_2 metasurfaces, for example, its volume fraction, and thickness. Nanostructured TMD materials can be a versatile platform with high anisotropy, low loss, and synthetic properties for some specific nanophotonic applications.

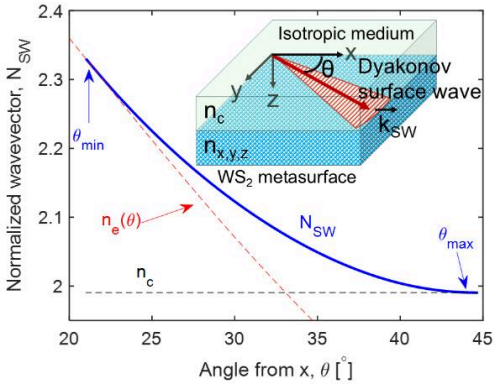

Fig. 1 Propagation direction θ from crystallographic axis x and normalized wave vector $N_{SW} = k_{SW} / k_0$, where k_{SW} and k_0 are wavenumber of Dyakonov surface wave and that in vacuum. $n_e(\theta)$ is angle dependent extraordinary refractive index of WS_2 metasurface. The inset shows the schematic illustration of WS_2 metasurface with biaxial effective refractive index components $n_x \neq n_y \neq n_z$ and isotropic layer with refractive index, n_c.

*Corresponding author: xiangpingli@jnu.edu.cn

***Abstract*— Here we report the development of metasurface based integrated optics from polarization imaging to optoelectronic Stokes logic.**

***Keywords*— Metasurface, light field manipulation, polarization camera, multidimensional imaging.**

I. Introduction

Metasurfaces [1], composed of arrays of subwavelength artificial atoms, have demonstrated capability of powerful wavefront manipulation. The ultra-thin thickness metasurfaces offer a new platform for development of integrated planar optics with multifarious functionalities. In this talk, I will present our recent research progress focused on meta-optics for multidimensional light field manipulation as well as its application in multidimensional imaging.

II. Results and Discussion

Leveraging the flexible polarization control capability, we demonstrate the encryption of two images in two arbitrary nonorthogonal polarizations without crosstalks covering the full Poincare sphere [2]. This omni-potential polarization and phase manipulation capability enables the development of monolithic polarization camera. A meta-grating-lens functioning as polarization beam splitter and imaging lens allows highly compact and full stokes polarization camera [3]. The monolithic integrated polarization camera operates at the wavelength of 940 nm with a total diffraction efficiency approaching 65% and a polarization distinguish ratio close to 10 db. We applied such camera for directly imaging of internal stress inside transparent PMMA solids as well as anti-face attack. It can clearly distinguish the polarization difference between a true human face and its planar picture attack.

Additionally, we integrated this polarization camera with a graphene photocurrent detector to implement optoelectronic Stokes logic [4]. The three mutually independent Stokes components $S1$, $S2$, and $S3$ are treated as parallel logic channel. Therefore, we establish a physical device-level route from "Stokes reconstruction" to "Stokes logic", allowing information encryption as well as the edge image calculation.

***Abstract*—We present the Dynamically Reconfigurable Unified Microresonator (DRUM), an integrated silicon photonic platform enabling tunable Hermitian and non-Hermitian coupling between counter-propagating modes. The DRUM exploits coupling-controlled feedback to access diabolic and exceptional points, inducing nonlinear hysteresis and memory effects. This enables controllable bifurcations and functions as a reconfigurable artificial neuron.**

***Keywords*— Microring resonator, Non-Hermitian system, integrated optics, neuromorphic hardware.**

I. Introduction

Integrated microring resonators architectures with counter-propagating modes are an ideal platform for implementing non-Hermitian systems. They enable precise control of light and demonstrate key phenomena such as unidirectional reflection [1], coherent perfect absorption [2], chiral mode control [3] and enhanced sensing [4]. When combined with optical nonlinearities, non-Hermitian systems exhibit rich dynamics, including self-oscillations, nonreciprocal transmission and multistability [5]. This offers a path towards neuromorphic photonic devices.

Here, we present the Dynamically Reconfigurable Unified Microresonator (DRUM): a fully integrated silicon photonic platform that enables on-demand tuning of the coupling between clockwise (CW) and counterclockwise (CCW) modes. As demonstrated in our recent work [6], the DRUM architecture, incorporating Mach–Zehnder interferometers (MZs) and phase shifters (PSs), enables controlled transitions between diabolic points (DPs) and exceptional points (EPs), dynamic spectral shaping, suppression of backscattering, and tunable system chirality. Moreover, we showed in [7] that intrinsic memory, arising from two-photon-absorption-induced carriers and thermal effects, supports multistability, path-dependent dynamics, and self-sustained oscillations. Here, we report that the DRUM exhibits a programmable firing threshold, highlighting its potential to mimic a controllable artificial neuron.

The DRUM thus provides a versatile testbed for fundamental studies of non-Hermitian nonlinear photonics and for neuromorphic computing, enabling the emulation of controllable neuronal behavior within a single device.

II. Methods

We experimentally investigate the linear and nonlinear response of a tunable DRUM. As shown in Fig. 1 (a), the device consists of a bus waveguide side-coupled to a microring resonator with two auxiliary side lobes. These lobes enable selective recirculation of the clockwise (α_1) and counterclockwise (α_2) modes. Electrical control of the coupling amplitudes and phases is provided by thermally tunable Mach–Zehnder interferometers (MZL and MZR for the left and right lobes, respectively) and phase shifters (PSL and PSR). This allows operation at both degeneracy points: DP or EP.

III. Results and Discussion

In the low-power (linear) regime, the transmission spectrum evolves with the current applied to the PSL, transforming the initial Lorentzian profile (black curve) into an almost balanced doublet at a phase of π (red curve) [6], as illustrated in Fig. 1(b).

As the optical power increases, the DRUM exhibits nonlinear behaviour driven by light–matter interactions, which are dominated by two-photon absorption (TPA). TPA generates free carriers, which lead to free-carrier absorption and dispersion. These carriers modify the refractive index of the microresonator via two competing mechanisms: absorption-induced heating redshifts the resonance through the thermo-optic effect, whereas plasma dispersion induces a blueshift [8]. The interplay between carrier dynamics and thermal effects can lead to self-sustained oscillations known as self-pulsing (SP), whereby a continuous-wave input is converted into a periodic output signal. Figure 1(c) shows the normalised transmission as a function of time with no current applied (0 phase), at the wavelength detuning indicated by the black square in Fig. 1(b). The measured signals are shown as solid black lines, while the red dashed lines represent sine waves at the fundamental SP frequency.

In the nonlinear regime, the DRUM can exhibit memory to PSL phase variations through the coupled dynamics of the energy of the two modes, the carrier density change ΔN, and the temperature change ΔT inside the microresonator. Because both ΔN and ΔT depend on the intracavity optical intensity,

Fig. 1. (a) Schematic of the DRUM. Red lines denote the optical waveguides, and triangles mark the grating couplers. (b) Linear transmission spectrum. (c) Time-resolved nonlinear transmission: the black trace shows the measured optical response, while the red dashed curve represents a sinusoid at the fundamental oscillation frequency. (d) Map of the SP frequency as a function of input power and laser wavelength for two values of the PSL phase. (e) Firing threshold power versus the PSL.

when the phase controlling energy exchange between counter-propagating modes varies slowly compared with carrier and thermal relaxation times, the final state strongly depends on the path in parameter space. Scanning the PSL in opposite directions, from 0 to 2π (forward) and from 2π to 0 (reverse), may yield distinct final states [7].

Controlling the SP states enables the emulation of biologically inspired neuronal behavior, as previously demonstrated in microresonators [9]. In contrast, the DRUM architecture permits the reconfiguration of fundamental characteristics, such as the firing threshold. Figure 1(d) presents SP maps as a function of the input laser wavelength and power. White regions denote non-oscillatory regimes, whereas the color scale represents the SP oscillation frequency. Upon tuning the PSL, not only the spectral response is modified (as illustrated above the maps), but the SP domain is also redistributed in both power and frequency (see dashed lines). The firing threshold, defined as the minimum optical power required to trigger SP, is shown in Fig. 1(e). The results of different SP maps are summarized in a single plot, showing two separate lines between the regions where the DRUM exhibits SP and those where it does not.

IV. Conclusion

The DRUM's versatility in emulating photonic systems at diabolic points (DPs) and exceptional points (EPs), while supporting self-pulsing (SP) regimes that reveal memory effects, enables its use as an artificial neuron. It can replicate a wide range of neuronal response behaviors within a single device, with a controllable firing threshold. Such precise control is crucial for scalable neuromorphic photonic systems. By combining nonlinear dynamics, non-Hermitian physics, and electrical tunability, the DRUM functions not just as an artificial neuron, but as a fully programmable neural element. This makes it a versatile platform for emulating diverse neuronal behaviors in a single device, representing an important step toward adaptive, hardware-based photonic neural networks.

***Abstract*— We present various types of optical chirality arising from the non-Hermitian nature of photonic crystals both theoretically and experimentally. First, we reveal interesting interplay between topological singularity and 3D/2D chirality in non-Hermitian photonic crystals. Second, we show our recent results on the propagating non-Hermitian skin effect in photonic crystals, and their application to generate chiral orbital angular momentum.**

***Keywords*— non-Hermitian optics, chirality, photonic crystals, metamaterials, optical angular momentum, non-Hermitian skin effect, topological singularity, exceptional point**

I. Introduction

Optical chirality has generally been discussed and utilized in non-reciprocal (magnetic) or three-dimensional (3D) chiral media and structures. However, it has been clarified that reciprocal (non-magnetic) and planar structures can exhibit various types of optical chirality for non-Hermitian systems. As one example, planar chirality has been extensively studies in 2D metamaterials, which shows asymmetric conversion in terms of the handedness of light in transmittance and reflectance. In another direction, asymmetric reflection in PT-symmetric periodically-modulated photonic crystals has been applied to generate chiral orbital angular momentum (OAM). As such, various chiral phenomena have been observed in non-Hermitian photonics where the complex refractive index plays an essential role.

In this talk, we present two different approaches to explore novel chirality arising from non-Hermitian optical systems, especially on non-Hermitian photonic crystals (PhCs) shown in Fig. 1. First, we discuss 2D/3D chirality in non-Hermitian hybrid photonic crystals, where the real and imaginary parts of the refractive index are independently controlled. By judiciously introducing the symmetry-breaking complex index perturbation, we generate and manipulate 2D and 3D chirality in the reciprocal space. We show two examples for which singular points play an intriguing role: non-Hermitian chirality originates from exceptional points (EPs) and non-Hermitian chirality arising from topological singular points (BICs, or bound states in the continuum). These results present unique controllability in achieving exotic chiral states in optical response.

For the second topic, we investigate interesting properties of reciprocal non-Hermitian skin effect in non-Hermitian PhCs, and apply it to generate orbital angular momentum (OAM) chirality. We show that OAM appears from propagating skin modes, and its chirality is determined by the chirality of the point gap. We also present our recent result of experimental observation of the point gap in radiation-based non-Hermitian PhCs, and its application to OAM generation.

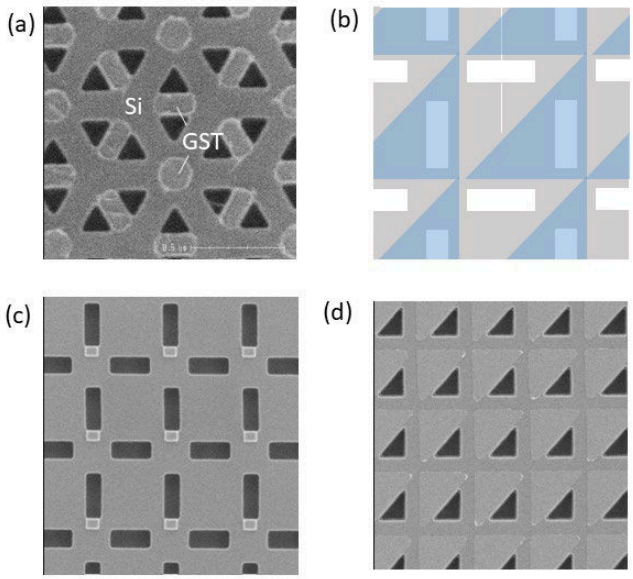

Figure 1. Hybrid photonic crystals. (a) GST-loaded PhC. (b) Graphene-loaded non-Hermitian PhC. (c) and (d) Metal-loaded non-Hermitian PhCs.

II. Chirality and Topological Singularity in Non-Hermitian Photonic Crystals

In this part, we investigate three types of optical chirality, S_3, 3D and 2D chirality in non-Hermitian systems, especially concerning the spin angular momentum, that is, polarization. First, we briefly review the S_3 chirality, which is nothing but conventional circular dichroism defined by the third Stokes parameter (S_3). It has been well clarified that the polarization chirality in far-field can be well described by the language of the singular optics. That is, the maximally-chiral point is C-point, which has a definite half-integer topological charge. In

conventional Hermitian photonic crystals, one can create various intriguing polarization states of light by manipulating topological singular points, including merging and splitting them, by breaking the crystal symmetry [1].

In this talk, we will exploit a similar scenario in non-Hermitian photonic crystals by breaking their complex symmetry. For doing so, the other two types of chirality play important roles. 3D chirality (C_{3D}) and 2D chirality (C_{2D}) are defined by the handedness-wise transmittance,

$$C_{3D} = \frac{T_{RR} - T_{LL}}{T_{RR} + T_{LL}}, \; C_{2D} = \frac{T_{RL} - T_{LR}}{T_{RL} + T_{LR}}$$

Our basic structure is a square-lattice air-hole photonic crystal, with C_{4v} symmetry, and we investigate two different approaches for manipulating polarization chirality. As is well known, the square lattice has p-like doubly-degenerate bands and two non-degenerate d-like bands for each band group. In the first approach (Fig. 1(b)), we pick up p-like degenerate bands. By applying MT-symmetric perturbation, which breaks the mirror symmetry by imaginary perturbation, one can create four EPs in the k space. Then, we break another mirror symmetry by real perturbation, leading to merging four EPs into a single 2D-chiral EP at Γ point. In the second approach (Fig. 1(c)), we pick up one of d-like bands, which is actually symmetry-protected BIC at Γ point. We split this BIC into a pair of C-points by non-Hermitian symmetry breaking perturbation. We break the mirror symmetry by real perturbation, leading to 2D chiral singular point at Γ point. For both cases, the whole processes are well explained by the topological nature of non-Hermitian singular points.

Concerning experimental demonstrations, we have recently developed a technique to fabricate so-called "hybrid PhCs", as shown in Fig. 1, where we load a patterned functional film on a host PhC to realize arbitrary symmetry breaking perturbation to a host PhC [2]. We have applied this technique to make designed non-Hermitian PhCs, and have observed some of intriguing chiral polarization properties. We will report the details at the conference.

III. Chirality in non-Hermitian skin effect

In this part, we discuss another type of chirality arising from non-Hermitian skin effect (NHSE). NHSE was first discussed in a 1D tight-binding model with non-reciprocal hopping in quantum systems based on the Hatano-Nelson Hamiltonian. This system has a so-called *point gap* in the complex frequency plane for the periodic boundary condition, and exotic localized skin modes for the open boundary condition. The existence of the point gap leads to the appearance of NHSE. These two features are strongly correlated. NHSE has attracted significant interest in various fields in physics, but experimental studies have been very limited and its application has not been clarified yet. Recently, it was found that similar NHSE can be created for a certain type of reciprocal 2D PhCs with anisotropic loss or gain. The anisotropic loss/gain plays a role of the imaginary gauge potential with the presence of finite wavevector in the direction parallel to the boundary [3].

One of the interesting aspects of this reciprocal NHSE in PhCs is the fact that this skin mode can *propagate* in the direction parallel to the boundary. This is a new degree of freedom compared to conventional 1D NHSE. We theoretically confirmed that each boundary supports unidirectional transport without backscattering, which is somewhat similar to the topological edge mode [5]. We explored various properties of this propagating skin mode, and found that one can create optical orbital angular momentum (OAM) modes when enclosing the anisotropic non-Hermitian media by open boundaries with specific directions [4]. The chirality (circulating direction) of OAM is determined by the chirality of the point gap, that is, the sign of the winding number. This means that this OAM chirality is attributed to the chiral nature of the point gap.

As for the point gap, its experimental observation has been very limited. Very recently, we have successfully observed the point gap in non-Hermitian PhCs. For this work, we first designed reciprocal and anisotropic non-Hermitian PhCs (Fig. 1(d)), which have large point gaps and exhibit NHSE. A key point is that we create anisotropic loss by managing the radiation loss, which makes experimental observation easier. We have observed point gaps in Si PhCs by the angle-resolved reflectance spectroscopy [5]. Although we could not measure the whole closed loop by the restriction of the numerical aperture, we clearly observed the existence of the point gap.

We have also designed and fabricated structures for OAM generation based on these non-Hermitian PhCs. We will report details of these studies at the conference.

***Abstract*— We show that temporal dispersion of the metal dielectric function significantly modifies the shape of scattering spectra of quantum emitters strongly coupled to surface plasmons by shifting spectral weight towards lower energy polaritonic band.**

***Keywords*— surface plasmon, strong coupling, excitons**

I. INTRODUCTION

The shape of scattering spectra of quantum emitters (QE) resonantly coupled to localized surface plasmons (LSP) in metal nanoparticles (NP) as the system transitions to the strong coupling regime has been an actively debated topic [1,2]. In general, the scattering spectrum of a hybrid system characterized by broad spectral band should be enhanced on the higher frequency side due to faster radiation rate of the upper-energy states, implying that, in the strong coupling regime, the spectral band associated with the upper-energy polaritonic state should be relatively enhanced. Such a spectral profile is consistent with the classical model of two coupled oscillators, in which one of the oscillators (LSP) couples much stronger to the electromagnetic (EM) field due to its much greater optical dipole moment as compared to the QE one [3]. However, recent experiments for excitons resonantly coupled to LSP in metal-dielectric structures [1,2] reveal the opposite asymmetry pattern characterized by enhancement of the lower polaritonic band. In this paper, we demonstrate that temporal dispersion effects in the metal dielectric function strongly affect the optical spectra of hybrid QE-LSP systems and, in the strong coupling regime, result in a pronounced shift of the spectral weight towards the lower-energy polaritonic band, consistent with the experiment

II. METHODS

We consider a hybrid system of QE located near metal NP in the external EM field $\boldsymbol{E}_0 e^{-i\omega t}$ characterized by complex metal dielectric function $\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega)$ and QE excitation frequency ω_e tuned to resonance with the LSP frequency ω_n. Using the LSP Green function for NP of arbitrary shape [4], we set up non-Lorentzian semiclassical Maxwell-Bloch equations which include the full complex dielectric function of the metal rather than using Lorentzian approximation for the LSP resonance:

$$\Omega_n \rho_n = g\rho_e + \boldsymbol{\mu}_n \cdot \boldsymbol{E}_0$$

$$\Omega_e \rho_e = g\rho_n + \boldsymbol{\mu}_e \cdot \boldsymbol{E}_0$$

where ρ_e and ρ_n are, respectively, the QE and LSP polarizations, which determine their induced dipole moments as $\boldsymbol{p}_e(\omega) = \boldsymbol{\mu}_e \rho_e$ and $\boldsymbol{p}_n(\omega) = \boldsymbol{\mu}_n(\omega)\rho_n$, and g is QE-LSP coupling. Here, $\Omega_e = \omega_e - \omega - i\gamma_e/2$ is QE detuning, where γ_e is the QE decay rate, $\Omega_n = [\varepsilon'(\omega_n) - \varepsilon(\omega)]/\varepsilon_n'$, with $\varepsilon_n' = \partial\varepsilon'(\omega_n)/\partial\omega_n$, is non-Lorentzian LSP detuning, and $\boldsymbol{\mu}_e$ and $\boldsymbol{\mu}_n(\omega)$ are the corresponding optical dipole moments. The latter is defined as $\boldsymbol{\mu}_n(\omega) = (1 / 4\pi) \int dV [\varepsilon(\omega) - 1] \boldsymbol{E}_n(\boldsymbol{r})$, where $\boldsymbol{E}_n(\boldsymbol{r})$ is electric field of the LSP mode. The full system induced dipole moment $\boldsymbol{p}(\omega) = \boldsymbol{p}_e(\omega) + \boldsymbol{p}_n(\omega)$ determines the system scattering spectrum near the LSP resonance.

IV. RESULTS AND DISCUSSION

In Fig. 1 we show the scattering spectra for a QE near an Au NP at two different LSP frequencies calculated using the non-Lorentzian model (left panel) compared to Lorentzian model of coupled oscillators (right panel). As the QE-LSP coupling increases relative to LSP decay rate, the system undergoes the transition to strong coupling regime signaled by the emergence of Rabi splitting between the polaritonic bands. The scattering spectra calculated using the non-Lorentzian model (left panel) exhibit pronounced enhancement of the lower energy polaritonic band [5], consistent with the experiment [1,2]. In contrast, for scattering spectra calculated in the Lorentzian approximation shown in Fig. 2, the upper energy polaritonic band is relatively enhanced, as predicted by the coupled oscillators model. This reversal of spectral asymmetry is traced to the effect of temporal dispersion of the metal dielectric function on the LSP optical dipole moment which results in a suppression of the LSP radiation efficiency for higher energies.

I. Summary of the work

Optical absorbing metasurfaces are two-dimensional materials composed of metal-insulator-metal (MIM) nanostructures. By utilizing a bottom metallic layer to suppress light transmission, these structures serve as highly efficient photothermal conversion devices.Electromagnetic simulations have revealed that when metasurfaces are constructed using conventional plasmonic metals such as gold (Au), silver (Ag), or copper (Cu), the optical absorption and scattering coefficients become equivalent under impedance-matching (zero-reflection) conditions. Experimental evidence further suggests that even under perfect non-reflective conditions ($T = 0, R = 0$), the emissivity does not reach 100%, implying that perfect non-reflection does not inherently equate to perfect absorption.Previous studies have shown that by increasing the thickness of a chromium (Cr) adhesion layer between the Au and dielectric layers to approximately 50 nm, the ratio of the absorption cross-section to the scattering cross-section reaches approximately 1.2. This shift toward absorption dominance enables a state near perfect absorption. However, when used as thermal radiation materials, Au/Cr multilayer structures are thermally unstable; heating causes Cr to readily diffuse into the Au, leading to structural degradation and deterioration of optical properties. To address this, we explored metallic materials where absorption is inherently dominant while maintaining the same metal layer as the plasmonic component. We focused on High-Entropy Alloys (HEAs). In a narrow sense, an HEA is defined as a metallic material composed of five or more metallic elements in equimolar ratios, characterized by the maximization of configurational entropy. While the configurational entropy of conventional binary alloys is relatively low, leading to phase separation when alloying is enthalpically unfavorable, the high entropy in HEAs acts as a driving force for mixing, allowing for the formation of stable solid solutions. HEAs are reported to exhibit superior mechanical strength, and noble-metal-based HEAs have shown significant catalytic effects compared to pure palladium (Pd) or platinum (Pt). However, their application to optical devices, including plasmonics, has not yet been fully realized. Recently, alloys have gained attention as plasmonic materials; for instance, Au-Ag-Cu systems (categorized as medium-entropy alloys) have demonstrated utility, although X-ray diffraction (XRD) analysis indicates slight phase separation between Au-Ag and Ag-Cu. In this study, we constructed an MIM metasurface using an HEA composed of Au, Ag, Cu, Pt, Pd, Al ,Mg. While the Group 11 elements (Au, Ag, Cu) and Al, Mg are useful for plasmonics, their Drude parameters suggest that scattering remains influential. By incorporating Group 10 elements (Pt, Pd), which exhibit strong damping and high absorption loss due to their dielectric constants, we expected to increase the absorption coefficient. We report that this five-element HEA system serves as an effective metasurface material across a wide mid-infrared (MIR) range. The electric permittivity of the metallic materials were determined using spectroscopic ellipsometry. To eliminate back-surface reflections, thick films (> 200 nm) were used. Measurements were performed across a broad spectrum using both UV-Vis and MIR spectroscopic ellipsometry. The data were analyzed using a Drude-Lorentz model, where parameters were optimized via the least-squares method to merge the results into a single consistent model.

Abstract— Orbital degrees of freedom provide a powerful route to engineer unconventional wave phenomena in photonic crystals. We show that p□orbital photonic lattices support finite□barrier bound states and rotation□induced flat bands. By controlling orbital orientation, multiple bands become fully degenerate and dispersionless, enabling robust mode localization and flexible photonic control.

***Keywords*— Bound states in the continue, Flat bands, p-orbitals.**

I. Introduction

Photonic crystals are commonly described using effective single□orbital models, yet realistic structures naturally host multiple orbital□like modes. By selectively enhancing p□orbital responses through material choice and structural design, orbital degrees of freedom can be isolated and exploited as an active control parameter. In this talk, we present two experimentally motivated platforms that demonstrate how p□orbitals enable qualitatively new photonic states.

II. Results and Discussion

First, we introduce a square□lattice photonic crystal with two p□orbitals per site and show that it supports boundary states trapped by a finite barrier. Despite the absence of a well□defined bulk bandgap due to finite size effect, these modes exhibit vanishing tunneling at specific wave vectors, forming finite□barrier bound states analogous to bound states in the continuum. We discuss their physical origin, tunability, and experimental observation.

Second, we study lattices hosting a single p□orbital per site, where the orbital pointing direction acts as an additional internal degree of freedom. By coherently rotating the p□orbitals within each unit cell, we induce a band□flip transition and identify critical rotation angles at which all bands become perfectly flat and degenerate across the Brillouin zone. This mechanism is robust against higher□order couplings and enables localized excitation under arbitrary sources. Together, these results establish p□orbital engineering as a versatile strategy for realizing flat bands and confined states in photonic systems.

III. Conclusion

Overall, our results establish the orbital degree of freedom as a powerful and previously underexplored mechanism for creating finite barrier bound states and flat bands in photonic systems.

***Abstract*— Complex time delay (CTD), derived from frequency domain scattering matrix data, predicts time and frequency shifts of reflected and transmitted time-domain pulses from multi-modal scattering systems. We extend these results to chirped pulses and show that the pulse time shift is a combination of real and imaginary CTD, creating new opportunities for pulse control.**

***Keywords*— metamaterials, microwave, time delay, non-Hermitian physics, chirped pulse, reflection, transmission.**

I. Introduction

It is known that transmission time delay $\tau_T = \frac{-i}{2\pi}\frac{d}{df}\ln[T]$ in non-Hermitian scattering systems is complex and encodes information about the poles and transmission zeros of the scattering matrix [1, 2]. We recently demonstrated experimentally that τ_T predicts the time shift D_t and frequency shift D_f of a transmitted Gaussian pulse with fixed center frequency [3]. Complex time delay, and its dependence on frequency, is a property of a given scattering system. However, tunable metasurfaces embedded inside the system can be utilized to modify the CTD, often quite dramatically, through the process of "cavity shaping" [4, 5]. Now the question arises, can we modify pulse propagation through complex scattering systems by means of "pulse shaping"?

II. Pulse Shaping

Chirping creates pulses whose instantaneous carrier frequency varies during the pulse, and are the basis for multiple modern technologies, and are present in various fundamental physical phenomena. This includes chirped pulse amplification, chirped pulse spectroscopy, lidar, radar, and sonar, qubit control, etc. Gaining control over the propagation of chirped pulses in reverberant scattering structures is of central importance to many scientific problems and technological applications.

We find theoretically that for narrow-bandwidth pulses interacting with a single resonance inside a reverberant scattering system, the transmitted pulse suffers a time shift given by $D_t = Re[\tau_T] - \Omega'\delta_T^2 Im[\tau_T]$, where δ_T is a measure of the duration of the pulse envelope and Ω' is the linear chirp rate. A frequency chirp effectively allows the pulse to explore the transmission properties of the system not just the center frequency, but also at neighboring frequencies, leading to a mixture of real and imaginary parts of the complex transmission time delay to contribute to the time shift of the transmitted pulse. Note that the time shift is sensitive to the sign of the chirp rate Ω' as well. Altogether, this leads to a remarkable degree of control of time shift, and to some extent the frequency shift, of the transmitted pulse, as we demonstrate experimentally.

III. Experiment and Results

Experiments are performed in transmission through microwave graphs which support a number of wide-bandwidth resonant modes. We use an arbitrary waveform generator (AWG) to synthesize the chirped pulses, and create pulses with a variety of center frequencies, pulse durations and chirp rates. The pulses are transmitted through the graphs and measured on a digital sampling oscilloscope, and the time and frequency shifts suffered by the pulses are measured.

We have explored values of the dimensionless parameter $\Omega'\delta_T^2$ between approximately -1000 and +1000 in our experiments. The results show excellent agreement with the predicted time shift D_t of the pulse and its dependence on parameters, including center frequency (which changes the real and imaginary parts of τ_T), the pulse duration δ_T, and the linear chirp rate Ω'.

IV. Conclusion

We have expanded the importance of complex time delay by showing that chirped pulses can have their propagation properties systematically varied over a considerable range through a controlled linear combination of the real and

imaginary parts of CTD. The results generally apply to all wave phenomena in multi-modal resonant settings, and serve to create new opportunities for utilization of these scientifically- and technologically-important pulses over the entire electromagnetic spectrum.

***Abstract*— We investigate the controlled epitaxial growth of silver and gold onto preformed gold nanostars, enabling precise tuning of their optical response while preserving branched morphology. Adjusting the plasmon resonance position and silver content, SERS enhancing properties can be maximized by nearly two orders of magnitude compared to conventional gold nanostars..**

***Keywords*— plasmonics, nanostars, gold nanoparticles, silver nanoparticles, SERS.**

I. Introduction

Over the last several decades, significant efforts have focused on engineering plasmonic nanoparticles that produce maximal surface-enhanced Raman scattering (SERS) signals. Although spherical gold and silver nanoparticles are widely used in SERS, their intrinsic properties typically require particle aggregation to create intense localized electromagnetic regions, or "hotspots," necessary for strong signal amplification. While such aggregation strategies can achieve very low detection limits, they often lack reproducibility, limiting their practical implementation. To overcome these drawbacks, researchers have developed controlled assembly methods that organize nanoparticles into defined architectures, including core–satellite structures.[1-4] However, in many of these systems, the electromagnetic hotspots are located within the interior of the assemblies, restricting analyte access and ultimately diminishing sensing performance.

A different strategy to circumvent these limitations involves employing single nanoparticles that inherently generate electromagnetic hotspots, such as gold nanorods and gold nanostars (NSts).[5-7] Among these nanostructures, Au nanostars stand out for their exceptional SERS performance, which arises from their numerous sharp protrusions. Each branch tip supports strongly confined and highly intensified electromagnetic fields. This distinctive morphology creates multiple readily accessible hotspots at the particle surface, promoting strong signal amplification while facilitating effective interaction with target analytes.

Although gold nanostructures are highly valued for their chemical robustness and controllable optical properties, silver nanoparticles generally exhibit stronger plasmonic responses and superior optical performance. Nevertheless, producing anisotropic silver nanostructures in a controlled and reproducible manner remains difficult, which restricts their broader implementation in SERS sensing. A widely adopted solution consists of depositing silver onto pre-synthesized gold nanoparticles.[8] This approach maintains the uniformity and defined shape of the gold templates while benefiting from the enhanced plasmonic characteristics of silver. Despite successful silver overgrowth on multiple gold nanoparticle geometries, only limited research has addressed silver deposition on gold nanostars. Furthermore, previous reports often describe silver growth occurring predominantly at the nanostar core,[9] resulting in structural modifications that diminish the branched features critical for their outstanding SERS performance.

In addition to providing stronger SERS enhancement, silver nanoparticles display plasmonic resonances at shorter wavelengths, extending into the ultraviolet (UV) range. For this reason, coating gold nanostructures with silver has become a common strategy to induce controlled blue shifts in their plasmon bands, enabling precise tuning of their optical response throughout the visible to near-infrared (Vis–NIR) region.[8]

In this work, we describe a method for the controlled epitaxial growth of gold and silver on gold nanostars (NSts), enabling accurate tuning of their optical response without compromising their branched architecture. By carefully adjusting the plasmonic response of gold nanostars, a silver shell can be grow maximizing silver content meanwhile adjusting the optical response. Notably, the process preserves the multiple sharp tips that define the nanostar morphology and sustain their intrinsic electromagnetic hotspots. SERS measurements reveal that silver-coated nanostars deliver an approximately an increase of two orders of magnitude in brightness compared standard gold nanostars.[10] Overall, these results demonstrate that silver-functionalized nanostars constitute highly effective SERS platforms with customizable optical properties, expanding their potential for advanced plasmonic sensing and molecular detection technologies.

***Abstract*— Localized surface plasmon resonance (LSPR) in copper nanoholes enhances local electromagnetic fields at the nanoscale. We investigate the effects of lattice period, hole size, and film thickness on field enhancement, analyzing both localized and propagating plasmonic modes. Optimized nanostructure designs offer potential applications in electrocatalysis and other plasmon-assisted processes.**

***Keywords*— LSPR, plasmonic structures, enhancement field.**

I. Introduction

Plasmonic nanoparticles (NPs) exhibit remarkable optical properties arising from localized surface plasmon resonance (LSPR), which corresponds to the collective oscillation of conduction-band electrons excited by incident electromagnetic radiation [1]. Under resonant conditions, LSPR can lead to strong confinement and enhancement of the electromagnetic field in the vicinity of the nanoparticle surface. This localized field enhancement plays a key role in many plasmonic phenomena, including enhanced light–matter interaction, strong optical absorption, and improved energy localization at the nanoscale. Such enhanced plasmonic fields are widely exploited in surface-enhanced spectroscopies, such as surface-enhanced Raman scattering, and are increasingly investigated for plasmon-assisted catalytic processes. The magnitude of the field enhancement strongly depends on the shape and size of the nanoparticles, as well as on the wavelength of the incident excitation.

In addition, these LSPR effects are considered promising for applications in sensing and plasmon-assisted catalytic processes. Although plasmon-driven electrochemical reactions, such as oxygen reduction, hydrogen evolution, and methanol oxidation, have been reported in recent studies [2–4], the fundamental electromagnetic mechanisms responsible for field enhancement in plasmonic nanostructures remain an active area of research.

Periodic nanohole arrays are particularly attractive plasmonic systems, because they can support both localized surface plasmons and propagating surface plasmon polaritons. In this study, we propose a triangular lattice of copper nanoholes (Cu NHs) covered with water and supported on a glass substrate. We investigate the optical response of these structures by analyzing their transmission, reflection, and absorption spectra using the finite element method implemented in COMSOL Multiphysics. A comprehensive geometrical parameter study is conducted to assess the influence of the lattice period, hole, size, and copper thickness. In addition, we examine the localized and propagating behavior of plasmonic modes as a function of these geometrical parameters in order to identify the most suitable designs for enhanced electrocatalytic applications.

II. Results and Discussion

Obviously, an enhanced plasmon mode should lead to significantly improved catalytic activity, as it is directly linked to scattering extinction (transmission, reflection, and absorption) together with the eigenfrequencies of both isolated and coupled nanoholes. An example of the Cu NH configuration is shown in Fig. 1(a), along with a corresponding experimental sample in Fig. 1(b). The structure is illuminated by a plane wave at normal incidence from the water side. Figures 1(c)–(e) display the transmission, reflection, and absorption amplitudes as functions of wavelength and lattice period. Two resonant modes are clearly observed in the visible spectral range. These modes exhibit a linear redshift with increasing period a, indicating that the plasmonic resonances can be efficiently tuned through the lattice periodicity.

An example of the optical spectra is shown in Fig. 2(a), illustrating the transmission, reflection, and absorption as a function of wavelength for a lattice period of $a = 880\ nm$. As

observed, two plasmonic modes appear as reflection maxima around 690 and 770 nm. These modes correspond to excited propagating plasmon at the water/Cu and Cu/glass interfaces, resulting from the diffraction of incident light by the nanohole (NH) array, as illustrated in the field maps of the two resonances. These resonant modes could be exploited in chemical reactions and electrocatalytic applications due to their strong field enhancement. Additionally, the proposed system may serve as a sensing platform, with its performance that could be tuned by adjusting the water height and the filling fraction

III. Conclusion

In conclusion, we analyzed the copper nanohole configuration in a triangular lattice on a glass substrate. The study revealed both localized and propagating plasmonic modes and their dependence on geometrical parameters, providing guidance for optimal design. These Cu nanostructures exhibit strong potential for plasmon-enhanced chemical reactions, electrocatalysis, and sensing applications. A detailed investigation of the properties of these plasmonic nanostructures, which demonstrate promising performance for electrocatalytic reactions, will be presented elsewhere.

***Abstract*— Engineered optical metasurfaces enable precise control of quantum-emitter radiation at room temperature. We demonstrate three platforms: metallic nanoparticle arrays for coherent visible emission, slotted-silicon metasurfaces enhancing Er^{3+} emission at 1540 nm, and VO_2 phase-change films providing active tunability. These approaches advance scalable quantum photonic sources across visible and telecom bands.**

***Keywords*— Metasurfaces, Quantum emitters, Emission control.**

I. Introduction

Optical metasurfaces offer unprecedented control over light–matter interactions at subwavelength scales. By tailoring their geometry and materials, they reshape the emission dynamics of quantum emitters placed in the near-field. This enables enhanced, directed, or actively tunable radiation at room temperature. Such capabilities open new pathways for compact quantum photonic sources across visible and telecom wavelengths.

II. Methods

The metasurfaces were designed through electromagnetic simulations using finite-difference time-domain and rigorous coupled-wave analysis to optimize resonance modes and field enhancement. Thin-film emitters and nanostructures were fabricated by electron-beam lithography, sputtering, and controlled deposition techniques. Optical characterization involved photoluminescence spectroscopy, lifetime measurements, and angle-resolved emission analysis to quantify enhancement and directionality. Electrical excitation studies employed device stacks optimized for balanced carrier injection, enabling room-temperature electroluminescence from the embedded emitters.

III. Results and Discussion

Here we present three case studies of different metasurfaces for controlling at room temperature the emission efficiency of different emitters in the visible or telecom spectral range: (i) 2D ordered arrays of Al nanoparticles coupled with dye molecules for ultralong ($\tau_c = 29 \pm 2$ ps) temporal coherent emission in the VIS range (nanolasers)[1]; (ii) slotted Si nanodisks arrays for the 3 orders of magnitude enhancement of the emission at $\lambda = 1540$ nm from Er^{3+} ions by exploiting quasi-BIC modes with Q-factor values up to 10^5 [2]; (iii) phase-change materials thin films based on VO_2 for the active control of Er^{3+} ions, whose radiative lifetime is modulated by a factor 2 between the monoclinic (room temperature) and rutile (high-temperature) VO_2 phases [3].

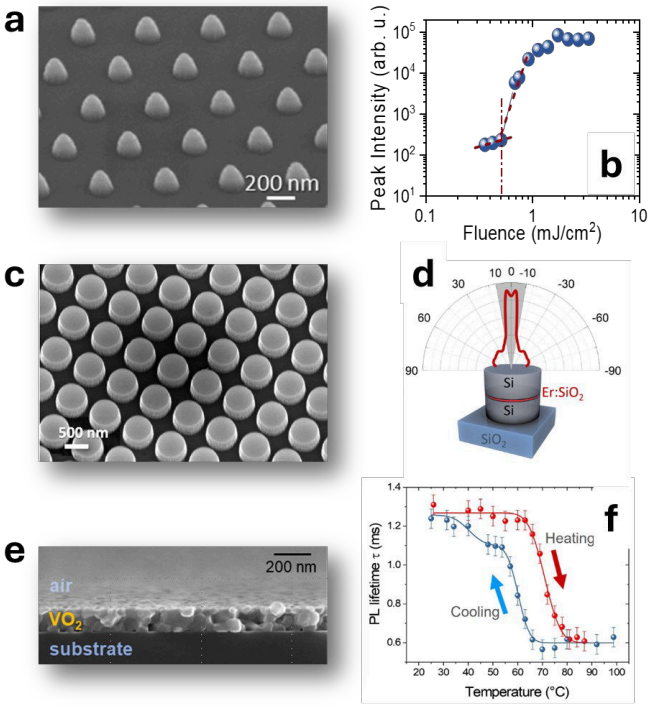

Fig. 1 (a,b) Al nanolaser: SEM image and lasing intensity; (c,d) Si nanogap array: SEM image and directional enhanced emission; (e,f) Er@VO_2: SEM image and lifetime control with temperature.

IV. Conclusion

The presented metasurface platforms demonstrate effective control of quantum-emitter radiation across visible and telecom wavelengths at room temperature. By tailoring resonant modes, field confinement, and active material responses, we achieve enhanced, directed, and tunable emission. These results highlight metasurfaces as versatile building blocks for scalable

quantum photonic devices, from nanoscale light sources to reconfigurable emitters for integrated optical technologies.

Abstract— **Quasi–bound states in the continuum (QBICs) enable subwavelength light confinement with long photon lifetimes. Here, we demonstrate accidental and symmetry-protected QBICs in an amorphous silicon metasurface. The quality factor of the accidental QBIC reaches 10^4, while the symmetry-protected QBIC approaches 10^5.**

***Keywords*— metasurface, quasi-bound states, photon lifetime.**

I. Introduction

Recently, bound states in the continuum (BICs) have enabled strong confinement of light within regions smaller than the wavelength scale [1]. Owing to their long photon lifetimes, these states have attracted significant interest for applications including high–coherence lasers, ultra-sensitive sensors, and optomechanical coupling [2-3]. However, these dark states are inaccessible due to symmetry protection or destructive interference [4]. Therefore, BICs remain outcoupled from all possible radiation channels. In order to make them accessible, two distinct mechanisms exist [5]. In symmetry-protected BICs, the mode is forbidden from radiating due to the incompatibility of its field profile with the symmetry of the lattice. Introducing a controlled symmetry-breaking along a certain symmetry plane, such as displacing or reshaping elements in the unit cell, allows partial coupling of the mode to free-space radiation [6]. This converts the ideal BIC into a QBIC with a finite photon lifetime, while the resonance remains sharp and well-defined. In contrast, the accidental BICs arise from the precise cancellation of multiple radiative channels. By slightly detuning structural parameters, such as the lattice spacing, element dimensions, or refractive index, this delicate interference is partially disrupted, allowing weak radiation leakage [7]. The resulting QBIC inherits a finite lifetime, determined by how closely the interference condition is preserved.

II. Accidental and Symmetry-Protected QBICs Engineering

We consider a dimerized rectangular resonator composed of amorphous silicon (a-Si) deposited on a glass substrate, arranged in a square lattice (Fig. 1A). The lattice period and the resonator aspect ratio are carefully tuned to perturb the modes' destructive interference, enabling energy exchange with external channels. The resulting accidental quasi-bound state in the continuum (A-QBIC) appears at a wavelength of 1390 nm with a photon lifetime of 10^4, as shown in Fig. 1D. To realize a second class of QBICs, here referred to as SP-QBICs, we introduce an a-Si bridge connecting the dimerized resonators at the center of the lattice (Fig. 1B). Because the bridge is placed symmetrically, the overall lattice symmetry is preserved, and the spectral position of the A-QBIC remains essentially unchanged, with only minor shifts in the resonance peak due to the modified a-Si filling factor. The SP-QBICs are obtained by breaking the horizontal mirror symmetry plane (XZ-plane) through a displacement of the bridge along the *y*-direction. This perturbation generates a SP-QBIC at a wavelength of 1450 nm with a quality factor of 10^5(see Fig.1 E). Both QBIC wavelengths lie in the near-infrared, close to the telecommunication bands, where materials such as a-Si exhibit low optical loss, facilitating on-chip integration. This spectral region offers additional advantages for sensing and optomechanical applications. The 1390 nm wavelength is highly sensitive to water vapor, which corresponds to a strong water absorption band, allowing the evaluation of water content in biological tissues, including porcine and human skin [8]. Moreover, the 1450 nm band is suitable for exploiting enhanced light-matter interactions to achieve strong optomechanical coupling [9]. The sample is fabricated from a 200-nm-thick amorphous silicon (a-Si) layer deposited on a 782-nm-thick silicon dioxide (SiO_2) substrate. A 1.5-µm-thick photoresist is spin-coated and patterned by electronic lithography, followed by the deposition of a 200-nm-thick nickel (Ni) hard mask for pattern transfer. The a-Si nanostructures are etched using reactive-ion etching (RIE, Plassys MU400) with an SF_6/O_2 gas mixture (20 sccm SF_6, 6 sccm O_2) at a chamber pressure of 5 mTorr and a temperature of 15 °C. The QBIC resonances are characterized using the setup shown in Fig. 2. A broadband telecom source is used to cover both resonances. The incident light is linearly polarized to align the polarization with the long axis of the dimerized resonators. Collimating mirrors ensure a nearly parallel beam before it enters an optical microscope with up to 20× magnification. The reflected spectrum is measured using a

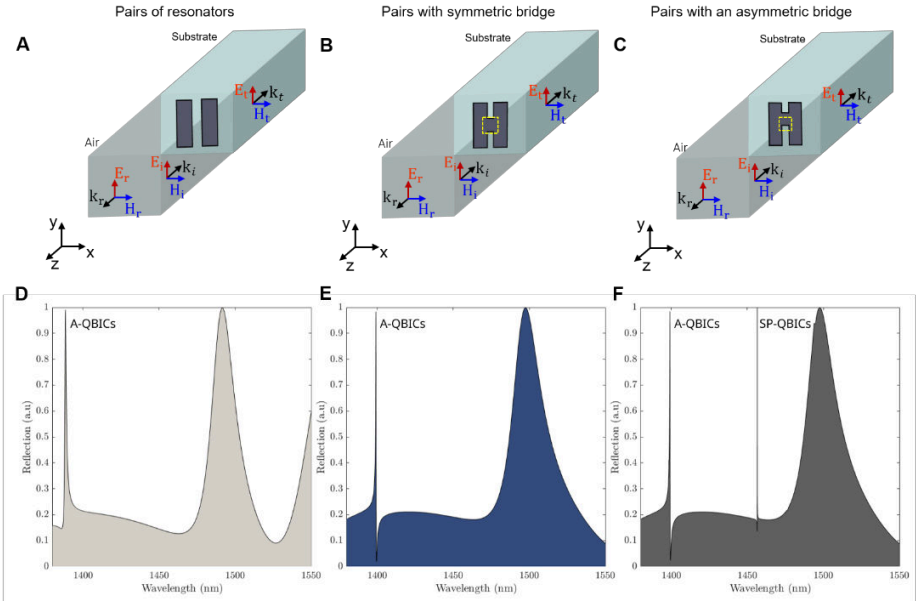

Fig 1: Illustration of QBICs formation in a-Si metasurface : (A–C) Dimerized rectangular resonators with and without a linking bridge. The A-QBIC is depicted with and without the linking bridge. The bridge is moved along the *y*-axis by 20 nm in scenario (C), for the purpose of breaking the symmetry. (D-F) Numerical simulation of the reflection spectra of the meta-designs when excited with linear polarization parallel to the resonator's long axis.

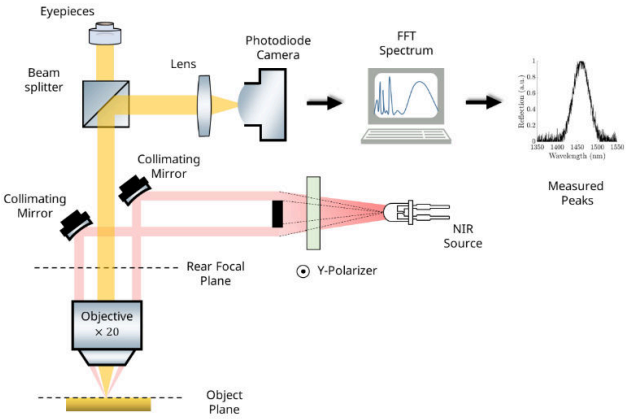

Fig 2: **Experimental Setup**: The apparatus utilizes a telecom-wavelength light source, whose output beam is first polarized, spatially filtered, and collimated using collimating mirrors to create two optical channels. The combined beam is then focused onto the sample using a 20× microscope objective (NA = 0.45), with the sample mounted on a nano-positioning stage for precise focal alignment. Reflected light is directed through a broadband beamsplitter to both a visualization eyepiece and a spectrometer equipped with a photodiode detector (600–1600 nm range).

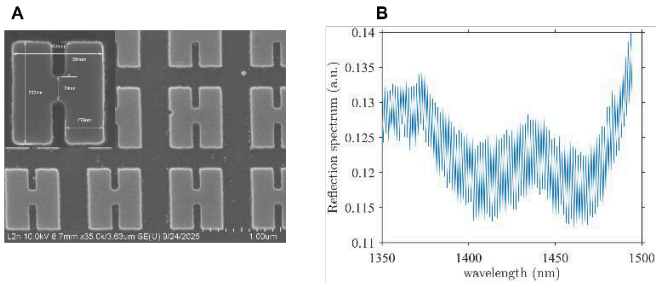

Fig 3: (A) SEM image of the fabricated sample. (B) Measured reflection spectrum indicating the existence of two resonance peaks (A- and SP-QBICs), at 1360 nm and 1440 nm, respectively.

a photodiode detector. Fig. 3(A) and (B) show the fabricated sample and the measured reflection spectra.

The spectra are not yet optimized due to the high Q of the QBIC modes and the limited spectral purity of the NIR source used. Moreover, the observed QBICs' resonance peaks shift is mainly due to manufacturing tolerance and imperfections.

***Abstract*—Inverse design of metasurfaces is hindered by complex structural-electromagnetic relationships and computationally expensive traditional optimization. While deep learning models offer solutions, they are limited by narrow training datasets. We propose using generative inverse design techniques to augment and diversify databases, significantly enhancing design space coverage and improving model generalization.**

***Keywords*— metasurface, inverse design, generative model, diffusion model, Schrödinger bridge.**

I. Introduction

Metasurfaces are subwavelength-patterned metamaterials capable of providing exquisite control over the phase, amplitude, and polarization of light [1], [2]. These capabilities have catalyzed breakthroughs in dielectric metalenses [1], [3], demultiplexers [4], and adaptive beam shaping [5], [6]. The central challenge of inverse design lies in identifying the specific physical geometries required to yield a target optical response. However, the high-dimensional nature of this design space makes exhaustive search computationally exhaustive when utilizing conventional solvers such as Finite-Difference Time-Domain (FDTD) [7], the Finite Element Method (FEM) [8], or Rigorous Coupled-Wave Analysis (RCWA) [9], all of which struggle with scalability and periodic constraints.

This work addresses the inherent "one-to-many" mapping problem where disparate physical architectures produce identical very similar far-field signatures by leveraging generative AI. We propose a recursive framework that utilizes generative models to iteratively refine training datasets, ultimately enhancing the model's ability to navigate complex design landscapes with high fidelity.

II. Generative method background

Diffusion models (DMs)[10], [11] have emerged as powerful generative frameworks capable of modeling complex data distributions through a gradual denoising process. DMs enable high-quality sample generation from simple noise distributions. Their iterative sampling procedure approximates the data distribution by sequentially refining noisy inputs, making them well-suited for inverse design tasks where mapping from desired properties to structural parameters is inherently ill-posed and multimodal.

Building upon this foundation, diffusion Schrödinger bridges (DSBs) [12], [13], [14] extend the classical diffusion framework by framing the generative process as a stochastic optimal transport problem. DSBs model the evolution between two probability distributions typically the data distribution and a prior via a controlled stochastic process that minimizes a Schrödinger-type entropy functional. In inverse design applications, DSBs facilitate more accurate and efficient navigation of the design space, capturing complex conditional distributions that arise from physical constraints and target specifications.

Together, DMs and DSBs offer high performance approaches to generative inverse design [15], [16], enabling the synthesis of structures that meet specified functional criteria while addressing challenges related to multimodality, nonlinearity, and data scarcity.

III. Initial Database

In the absence of an inverse design tool, constructing a database aligned with the anticipated far-field behavior was impractical. Therefore, the initial dataset was generated by sampling metasurface structural parameters from simple distributions primarily uniform across all parameters, resulting in 5,000 samples. Corresponding far-field responses were computed using FDTD simulations.

IV. Enhanced Database

Having established baseline generative models for both DMs and DSBs using the initial database, we employ these models to synthesize a refined dataset. This stage is designed to populate the design space with far-field patterns that are more representative of high-performance metasurface applications. To achieve this, we generated a diverse set of 5,000 target profiles consisting of complex polygonal shapes, including both solid and annular (hole-containing) geometries. This refined dataset allows the generative architectures to learn from a more functionally relevant distribution of optical responses, effectively bridging the gap between random structural permutations and intentional design targets.

V. Enhanced performance

The generatively enhanced database improves the performance of both generative inverse design models DMs and DSBs, as illustrated in Figure 1.

Another stakes is to scale the method to larger metasurface and as seen on Fig. 2 the generative enhanced database not only increase performance on the example with the same size of the database but also on larger metasurface. Moreover the performance metric performs relatively constantly from 23x23 pillars to 98x98 pillars.

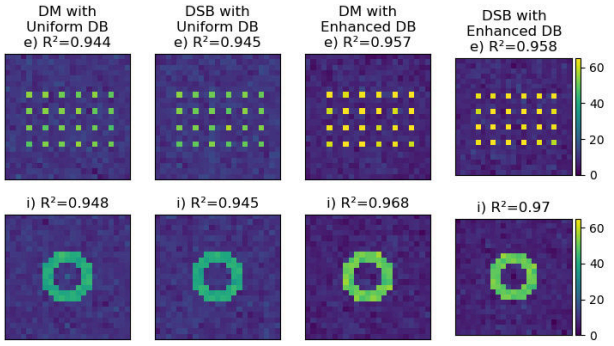

Fig. 1. Far-field distributions obtained via FDTD simulations for diffusion models (DM) and diffusion Schrödinger bridges (DSB), each trained on either the initial or the generatively enhanced database.

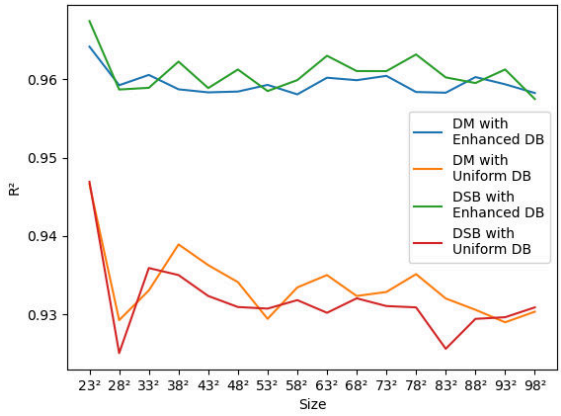

Fig. 2. R^2 metrics computed from FDTD simulations for diffusion models (DM) and diffusion Schrödinger bridges (DSB) trained on either the initial or generatively enhanced database. Inverse design was performed on metasurfaces of increasing size until simulation became computationally infeasible.

Spatial Fourier filtering with metagratings

Mahmoud A. A. Abouelatta[1,*], Karim Achouri[1]

[1]Laboratory for Advanced Electromagnetics and Photonics, EPFL, 1015 Lausanne, Switzerland
*Corresponding author: mahmoud.abouelatta@epfl.ch

***Abstract*—Traditional 4f Fourier-optics are too bulky for integrated photonics. We present the first nanostructured metagrating providing high-fidelity angular filtering five orders of magnitude thinner than lens-based systems. By engineering dipolar resonances and Kerker-like interference, we achieve efficient spatial filtering, enabling ultra-compact, lens-free optical computing across the near-infrared.**

***Keywords*— metagratings, angular filtering, spatial Fourier filtering, optical computing.**

I. Introduction

The 4f lens configuration remains the cornerstone of Fourier-optics, facilitating essential angular filtering for applications ranging from holographic data storage to adaptive imaging. However, the inherent physical volume of these refractive systems poses a fundamental bottleneck for the evolution of on-chip integrated photonics. In this work, we transcend these spatial constraints by introducing a metagrating-based architecture [1], as shown in Fig.1, capable of replicating standard Fourier filters within a sub-wavelength footprint. By precisely tailoring the angular scattering of nanostructured arrays, we eliminate the need for traditional lens-based propagation, paving the way for ultra-compact, lens-free spatial signal processing.

II. Methods

Our experimental pipeline utilizes a combination of anisotropic wet etching and controlled material transformation. We initiated fabrication by applying KOH etching to a silicon substrate through a predefined nitride mask, resulting in a series of highly ordered periodic triangular ridges. These silicon precursors were subsequently subjected to thermal oxidation, converting the framework into high-quality silica. To achieve the desired plasmonic response, we performed dual-stage oblique gold evaporation. This technique selectively deposited gold ”hat” structures atop the dielectric ridges. The resulting architecture leverages the complex coupling between two-dimensional dipolar resonances and the Kerker-like suppression of backward scattering, allowing for sharp control over the angular transmission and diffraction profiles.

III. Results and Discussion

Characterization in the near-infrared regime confirms the robust versatility of the metagrating platform. Our measurements in full spatial Fourier space demonstrate that the device functions as an efficient low-pass filter and a controllable high-pass filter. Specifically, the system achieved power suppression exceeding 30 dB for the high-pass filter and 10 dB for the low-pass filter beyond their respective cutoff thresholds.

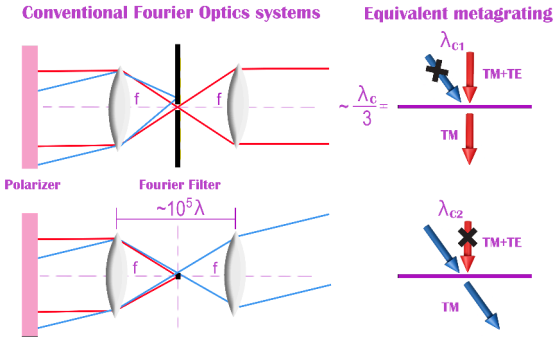

Fig. 1. Schematic representation of the nanostructured platform, providing a compact alternative to the standard 4f imaging system [1].

The gathered experimental data demonstrate excellent agreement with both our theoretical framework and full-wave electromagnetic simulations. Building on these results, we further explore the potential for a reflection-mode bandpass filter. By manipulating the diffraction cutoff conditions inherent to the periodic geometry, numerical simulations suggest the cutoff spatial frequency can be tuned based on the grating cutoff conditions, offering a pathway toward integrated reflection-domain processing that complements the experimentally verified transmission filters.

IV. Conclusion

This work demonstrates a compact metagrating alternative to the bulky 4f system, achieving extreme volume reduction while maintaining high filtering precision. The platform offers a scalable route for lens-free spatial Fourier filtering in challenging electromagnetic regimes—such as the terahertz or X-ray bands—marking a major advancement toward monolithic, high-resolution optical computing. Moreover, this architecture facilitates the simultaneous multiplexing of various spatial filtering operations at specific center wavelengths in a single step. It further broadens the scope of spatial filtering to include signals with significantly reduced coherence lengths.

***Abstract*— We demonstrate a magnet-free, intrinsically broadband photonic isolator using electro-optic traveling-wave modulation to create synthetic motion across four waveguides, realizing dynamic rotating destructive interference that continuously cancels backward-propagating light. We show ≈30 dB isolation, >24 dB isolation across a 30 nm span, and >20 dB isolation for two lasers simultaneously.**

***Keywords*— chip-scale isolator, electro-optic modulator, synthetic motion, integrated photonics**

SUMMARY

Despite recent progress, achieving nonreciprocal light propagation on chip with low-loss, high contrast and high instantaneous bandwidth remains challenging, limiting the currently available solutions for integrated isolators and circulators.

Here, we show a magnet-free, intrinsically broadband traveling-wave isolator built from foundry-compatible components. The approach, applicable from the visible to telecom, uses radio-frequency electro-optic modulation to create synthetic motion across four parallel waveguides, realizing dynamic rotating destructive interference that continuously cancels backward-propagating light while leaving forward-propagating light unaffected. We reach ≈30 dB isolation while maintaining >24 dB isolation across a 30 nm wavelength span, and show >20 dB isolation for two lasers simultaneously within 10 nm — an optical frequency range order of magnitude broader than any prior non-magnetic designs with similar isolation efficiency. Our demonstration's 770 nm to 800 nm wavelength span covers key alkali atomic transitions, enabling on-chip laser isolation for atomic spectroscopy, laser cooling, and locking applications.

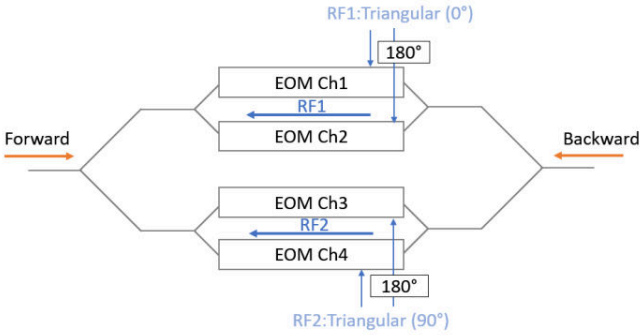

Fig. 1 Isolator schematic. Light is equally split among four channels experiencing nonreciprocal traveling wave modulation. The traveling waves shape and the relative phase offsets are engineered to apply synthetic motion resulting in continuous full destructive interference.

***Abstract*—This work presents a multi-layer metagrating design for single-waveguide near-eye displays, achieving a wide field of view (FoV) while reducing waveguide thickness. The approach enables high-resolution imaging by accommodating large lateral dimensions for the in-coupled grating, optimizing compatibility with advanced light engines.**

***Keywords*—Compound metagrating, augmented reality, high FOV, waveguide.**

I. Introduction

The demand for compact, high-performance augmented reality (AR) headsets continues to drive innovation in optical waveguide technology. Achieving a wide FoV, full-color capability, and high resolution in a miniaturized form factor remains a significant challenge. In this work, we introduce a novel multi-layer metagrating design for single-waveguide near-eye displays, enabling both ultra-thin waveguides and expanded FOV without compromising image quality.

II. Methods

Waveguide-based AR head-mounted displays (HMDs) often rely on multi-waveguide configurations to achieve full-color performance, with each waveguide dedicated to one or two specific colors [1]. However, this approach results in bulky and complex systems. Single-waveguide full-color solutions are therefore preferred for their simplicity and improved integration, but they face a critical limitation: the use of a single diffraction grating for both in- and out-coupling reduces the FOV due to dispersion effects.

Traditionally, expanding the FOV has involved employing high-refractive-index materials, which increase the internal reflection angle. Yet, these materials introduce trade-offs, such as increased waveguide thickness, added weight, and reduced efficiency. To address these challenges, diffractive metagratings offer a promising solution for achieving achromatic waveguide designs [2-5]. However, while this approach enables a wider FOV, it also necessitates larger microdisplays with higher pixel counts, which in turn requires enlarging the in-coupling grating to match the etendue. This often results in thicker waveguides to mitigate back reflection issues.

To overcome these limitations, we propose a novel approach based on polarization transformation. By enabling efficient reflection of orthogonally polarized light at the in-coupling grating, this method prevents light loss due to unintended out-coupling. This innovation allows for the use of thinner waveguides while maintaining large lateral dimensions for the in-coupling grating and accommodating the wide diameter of the in-coupled beam.

This talk introduces multilayered metasurface topologies designed for separated RGB illumination within a single high-refractive-index waveguide, achieving a diagonal FOV exceeding 70° with high uniformity and efficiency (see Fig.1). The optimized gratings transmit one polarization while reflecting the orthogonal polarization.

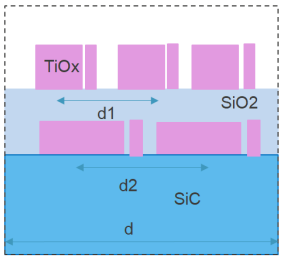

Fig. 1 Cross-sectional view of the metagrating on top of the waveguide.

III. Results and Discussion

By integrating the proposed metagratings with a sapphire retarder layer, we enable efficient light management. Sapphire layer leverages the material's birefringence to rotate the polarization of the in-coupled light (see Fig.2). When combined with a metallic mirror on the opposite side of the waveguide, this configuration further enhances performance. By integrating these gratings with retarders, we demonstrate at least a twofold reduction in waveguide thickness, enabling the development of significantly more compact AR devices.

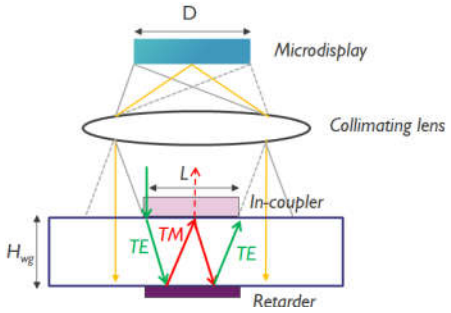

Fig. 2 Configuration of the proposed in-coupling system demonstrating polarization conversion of the in-coupled wave using a combination of an in-coupling metagrating and a retarder.

IV. Conclusion

We have demonstrated a novel approach to achieving full-color, wide-FOV AR displays using multilayered metasurface topologies within a single high-refractive-index waveguide. By leveraging polarization-selective gratings combined with a sapphire retarder and metallic mirror, we not only enhance optical efficiency and uniformity but also reduce waveguide thickness by at least half. This innovation addresses key challenges in miniaturization and performance, offering a promising pathway toward more compact, high-performance AR HMDs.

***Abstract*— Zero-reflection metasurfaces hold great promise for clinical translation. Towards this, we manufacture the metasurfaces using optimized adhesion materials with minimum optical loss. We demonstrate their large area homogenous nanofabrication using modified laser lithography and showed detection of brain metastasis relevant biomarkers in serum.**

***Keywords*— metamaterials, optical biosensing, laser interference lithography, cancer diagnostics.**

I. Introduction

Zero-reflection metasurfaces offer unmatched sensitivity but suffer from the 'adhesion-loss' trade-off. Traditional adhesion layers like Ti improve stability but kill optical performance. We identify Al as a 'best-of-both-worlds' solution. We show that Al provides near-field responses that rival adhesion-free gold films. We performed a detailed investigation determining the optimum adhesion layer. The metasurfaces are fabricated on large area using a modified laser interference lithography. The optic and metric uniformity of the nanostructures are quantified and compared against EBL fabricated ones. Finally, we demonstrate the clinical relevance of this platform through the ultrasensitive detection of proteins relevant for brain metastasis and its ability to withstand harsh environmental stress, paving the way for the next generation of robust, portable biosensors.

II. Methods

Zero-reflection metasurfaces were designed via computational modeling using Ansys Lumerical. The nanofabrication is performed using a modified laser interference lithography[1,2]. To highlight the advantages of aluminum adhesion layers in achieving perfect absorption, we utilized a narrowband metal-insulator-metal (MIM) absorber based on a nanodisc antenna architecture [1,2]. The device comprises a 100 nm Au ground plane, a 40 nm SiO_2 dielectric spacer, and a top layer of periodic Au nanodiscs (periodicity: 650 nm; diameter: 180 nm; thickness: 40 nm) on a 500 µm silicon substrate. To investigate stability and performance, 2.5 nm and 5 nm adhesion layers were integrated at the metal-insulator interfaces.

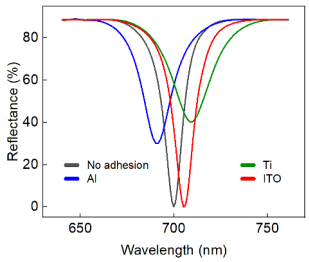

Fig. 1 The simulations showing the effect of 5 nm adhesion layer of different materials on a nanostructured perfect absorber.

III. Results and Discussion

Experimental results show that Al enhances the mechanical stability of gold nanodiscs and thin films, withstanding harsh conditions such as water flow and 40 kHz sonication. Compared to Ti, Al-based metasurfaces exhibit higher electric near-field enhancements, closely matching the performance of structures without adhesion layers. This improvement is further validated through the detection of 50 kDa proteins, where Al-based metasurfaces produce the largest refractive index-based shift, indicating superior sensing performance.

IV. Conclusion

We experimentally demonstrate that aluminum (Al) outperforms conventional adhesion material titanium for metasurface integration. Large area manufacturing enables lens free detections on metasurfaces. The relevant biomarkers as low as 1pg/ml concentrations are detected using the engineered metasurfaces.

***Abstract*— Photochromic smart windows can regulate solar radiation, but their performance is limited by the small ultraviolet fraction in sunlight. We report plasmonic yolk shell nanophosphors that convert visible light into ultraviolet emission. Integrated with tungsten oxide photochromic films, they significantly accelerate coloration kinetics and enhance optical contrast in smart windows.**

***Keywords*— smart windows, photochromic materials, plasmonic nanostructures, up conversion, nanophosphors.**

I. Introduction

Energy consumption in buildings is strongly affected by heat transfer through windows. Photochromic smart windows dynamically modulate solar radiation using light responsive materials [1,2]. However, their efficiency is limited because ultraviolet light represents only a small fraction of the solar spectrum. A promising strategy is the use of wavelength conversion materials capable of transforming visible light into ultraviolet radiation that activates photochromic layers. In this work, we develop plasmonic yolk shell nanophosphors designed to enhance up conversion efficiency through localized surface plasmon resonance [3]. These nanostructures are integrated with tungsten oxide photochromic films to fabricate fast switching smart windows with improved coloration performance (see Fig. 1).

II. Methods

Plasmonic nanophosphors with a yolk shell architecture were synthesized through a multistep wet chemical process involving:

1. Preparation of silver nanoparticles with controlled size
2. Sequential deposition of precursor shells
3. Thermal treatment to create hollow phosphor shells surrounding the plasmonic core

The resulting structures consist of a silver core inside a hollow cavity surrounded by a praseodymium doped yttrium silicate phosphor shell. The optical response of these hybrid nanostructures was analyzed experimentally and through electromagnetic simulations to understand plasmon assisted up conversion processes. For device fabrication, the optimized nanophosphors were deposited over photochromic tungsten oxide films, forming a double layer structure capable of converting visible solar light into ultraviolet radiation that activates the photochromic reaction.

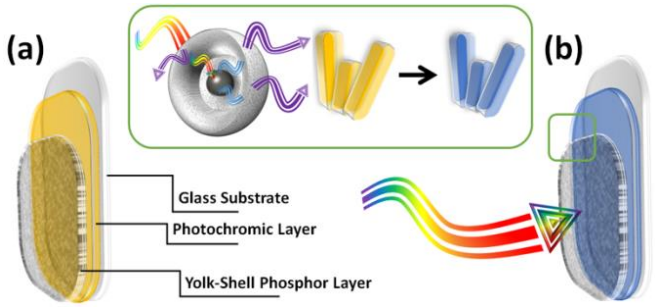

Fig. 1 Schematic illustration of up-conversion layer approach.

III. Results and Discussion

The plasmonic yolk shell geometry strongly influences the up-conversion efficiency of the nanophosphors. By optimizing the size of the metallic core, the cavity dimension and the shell thickness, the emission efficiency of the nanophosphors was significantly enhanced compared with hollow phosphor structures. The improved emission originates from plasmon assisted near field enhancement, which increases the excitation rate of the phosphor shell when the plasmon resonance of the silver core matches the excitation wavelength.

When integrated with tungsten oxide photochromic layers,

the up converted ultraviolet emission activates the photochromic reaction more efficiently. As a result, (i) the coloration rate increased by up to twenty-four times, and (ii) the kinetic constant increased by almost one order of magnitude. These improvements demonstrate that plasmon mediated up conversion can overcome the spectral limitation of conventional photochromic smart windows.

IV. Conclusion

We have demonstrated plasmonic yolk shell nanophosphors capable of enhancing up conversion through plasmon assisted electromagnetic fields. When combined with tungsten oxide photochromic films, these nanostructures dramatically accelerate the photochromic switching process. This strategy offers a promising pathway for the development of high efficiency smart windows for energy efficient buildings.

***Abstract*— We present the integration of high-Q ring resonators onto fiber tips. These sensors feature efficient coupling and high quality factors, combining the power of nanophotonics with the versatility of fiber sensing.**

***Keywords*— fiber sensors, lab-on-fiber technology, photonic integrated circuits**

I. Introduction

Integrating photonic integrated circuits (PICs) onto multicore fiber (MCF) facets bridges the gap between PIC functionality and deployable sensing. Using backside-etched grating couplers and an optimized transfer method, we achieved parallel addressing of photonic elements with −6.9 dB coupling efficiency and Q-factors up to 13,000. This scalable approach provides a robust foundation for future multi-channel, multiplexed fiber-tip sensing platforms

II. Methods

PIC design and fabrication

We used Particle Swarm Optimization (PSO) and 3D FDTD simulations to design backside couplers and ring resonators on InP membranes. PICs were patterned via electron-beam lithography and a single etch step. Alignment-controlled backside wet etching created fiber insertion apertures, ensuring membrane integrity before sacrificial layer release.

Membrane Transfer and Alignment

Membranes were integrated onto MCF tips using a transfer technique enhanced by a rotational stage. Positioning was finalized via active alignment, combining CCD monitoring with real-time transmission measurements to maximize coupling efficiency.

Temperature Compensation

To ensure stability, we integrated a reference ring resonator encapsulated in a silicon nitride (SiN) cladding. This cladding isolates the reference from the external medium, allowing the tracking of thermal fluctuations independently of the active sensing ring.

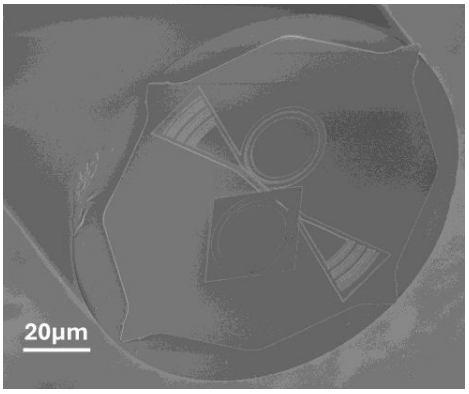

Fig. 1 SEM image of a membrane with two ring resonators, on a fiber-tip

III. Results and Discussion

Experimental results show a 20.1% (−6.9 dB) efficiency at 1478 nm for the grating couplers, a quality factor (Q) of 13,000 for the ring resonators, along with a refractive index sensitivity of 80 nm/RIU sensitivity, leading to a competitive limit of detection of 2.3×10^{-6} RIU. Additionally, temperature compensation can be achieved using the reference ring.

IV. Conclusion

We demonstrated a scalable, transfer-based method to integrate full InP PICs onto multicore fiber tips. Utilizing single-step lithography, the platform achieved high coupling efficiencies and Q-factors. Notably, the sensor reached a state-of-the-art limit of detection of 2.3×10^{-6} RIU, establishing a robust foundation for multiplexed, high-precision lab-on-fiber sensing architectures.

Attosecond Extreme-Ultraviolet Skyrmion Pulses from High Harmonic Generation

David Marco[1,2,3,*], Luis Plaja[1,2], Carlos Hernández-García[1,2]

***Abstract*—We demonstrate the generation of attosecond skyrmion pulse trains via high harmonic generation driven by an infrared femtosecond vector beam carrying fractional orbital angular momentum. Consecutive far-field harmonics around 70 eV exhibit skyrmion polarization textures whose coherent superposition yields ∼500-attosecond pulses, enabling new avenues for ultrafast control, imaging, and spectroscopy.**

***Keywords*— skyrmion, structured light, attosecond science**

Skyrmions are topological field distributions in which a spatial domain maps onto a complete spherical parameter space. Such configurations have been observed across a broad range of physical platforms, including magnetic systems and structured optical fields [1]. Optical skyrmions emerge in beams whose transverse profiles contain the full set of paraxial polarization states. These fields therefore map a planar region onto the entire Poincaré sphere, where each point represents a distinct polarization state. Their potential impact is currently being investigated in complex media, topological materials, and advanced imaging schemes [1]. However, the generation of skyrmion pulses in the attosecond regime has not yet been demonstrated, with previous realizations restricted to continuous-wave illumination or long optical pulses.

The generation of attosecond pulses has been established for over two decades through high harmonic generation (HHG) in gases, where an intense infrared (IR) laser drives the emission of a plateau of high-frequency phase-locked harmonics with comparable amplitudes. The coherent superposition of selected harmonics yields attosecond pulse trains. In contrast, spatial structuring of high-energy radiation has only become feasible recently, owing to the inefficiency of conventional optical elements at extreme energies. Most approaches therefore focus on engineering the spatial profile of the driver to control the structure of the generated harmonics, enabling extreme-ultraviolet (EUV) structured beams such as attosecond vortices [2] or EUV vector beams [3].

Designing a driving field capable of producing a desired topological structure in the attosecond regime is nontrivial. In particular, HHG efficiency rapidly deteriorates with increasing polarization ellipticity, preventing a straightforward translation of optical skyrmions into the harmonic spectrum. A scheme based on a bichromatic structured driver has been proposed to induce skyrmion patterns at the gas-jet plane, where the skyrmion topology varies across consecutive harmonics [4]. Consequently, this approach does not deliver a phase-locked harmonic comb with similar skyrmion textures, which is a prerequisite for synthesizing attosecond pulses with a temporally robust skyrmion structure. Here, we show that HHG driven by a tailored linearly polarized vector beam produces a phase-locked plateau of consecutive harmonics that exhibit nearly identical skyrmion textures in the far field. Their coherent addition therefore results in attosecond skyrmion pulse trains.

Figure 1(a) illustrates the proposed scheme, where a linearly polarized IR vector driving beam interacts with a gas jet to produce an attosecond skyrmion pulse train. The local polarization state is encoded using a color representation corresponding to points on the Poincaré sphere (Fig. 1(b)). The left- and right-circular polarization (LCP and RCP) driver components carry fractional orbital angular momenta $\ell_{l,r} = -65/132$ and $67/132$, respectively, as depicted in Fig. 1(a). The choice of these parameters follows from a simplified model (see Ref. [5] for more details). The driver can be realized experimentally using metasurfaces or spatial light modulators.

We use the structured driving field in numerical HHG simulations in an argon gas jet. Our model combines a single-atom quantum response, within the strong-field approximation, with an electromagnetic propagation scheme that accounts for macroscopic phase matching and yields the far-field harmonic distribution. The driving pulse has a central wavelength of 1.2 μm, a full width at half maximum (FWHM) duration of 11.5 fs, and a peak intensity of 1.19×10^{14} W/cm^2. By applying realistic Al and Zr filters with thicknesses of 0.2 μm and 0.3 μm, respectively, we isolate five consecutive harmonics around 70 eV. The unfiltered spectrum and the selected window (purple shaded region) are shown in Fig. 2(a). The far-field spatial profiles of these five harmonics exhibit nearly identical skyrmion textures within an annular region of 0.19 mrad radius. The far-field intensity and polarization distribution for the central harmonic are displayed in Fig. 2(b).

The coherent superposition of the harmonics produces an attosecond pulse train with individual pulse durations of approximately 500 attoseconds (FWHM). The Skyrme number N_S characterizes the topology of the skyrmion by quantifying how many times the polarization texture maps the Poincaré

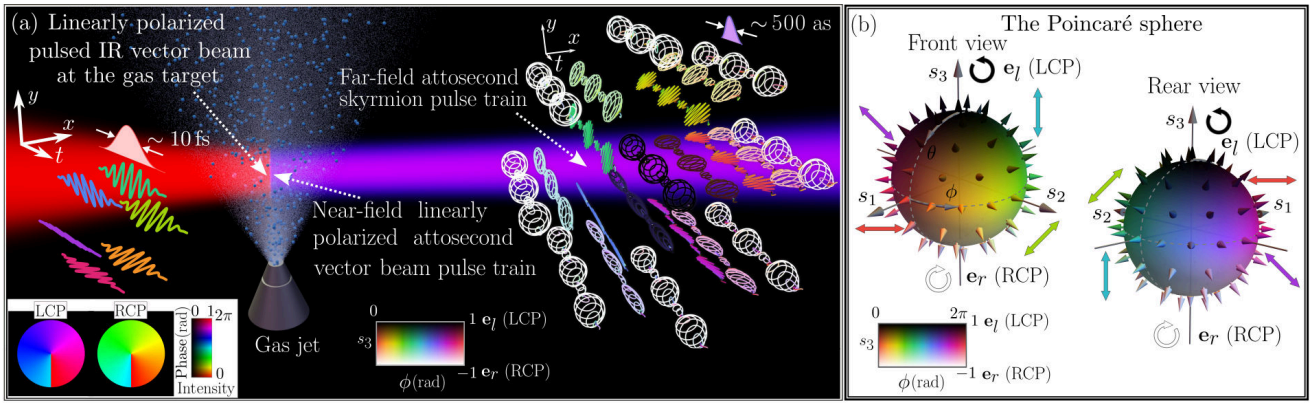

Fig. 1. (a) Illustration of attosecond EUV skyrmion pulse train generation by HHG driven by a linearly polarized femtosecond vector beam. The local polarization state of both the driver and the emitted attosecond field is represented by a color code corresponding to points on the Poincaré sphere. The driving beam consists of left- and right-circular polarization (LCP and RCP, respectively) components carrying fractional orbital angular momentum. (b) Representation of paraxial polarization states on the Poincaré sphere, where each polarization ellipse maps to a single point. The color map is defined by the azimuthal angle ϕ (twice the ellipse orientation) and the s_3 coordinate, which encodes ellipticity and handedness.

sphere [1]. Evaluated at different instants during the central pulse and within the same 0.19 mrad contour (Fig. 2(c)), N_S remains remarkably stable in time, reaching a maximum value of $N_S = 1.000$ with fluctuations limited to $\Delta N_S = 0.009$. Figure 2(d) displays the real electric-field distribution of the most intense pulse in the synthesized train, revealing a well-defined skyrmion texture that persists in time.

To sum up, we presented an experimentally viable route for generating attosecond skyrmion pulses whose topological properties are preserved in time. Such pulses open new pathways for encoding topological information into photoelectron angular and spin distributions [6], for simultaneously probing structural and anisotropic material responses in high-resolution EUV imaging [7], and for enabling ultrafast probing of magnetic helicoidal dichroism [8].

*Corresponding author: xiaoyonghu@pku.edu.cn

***Abstract*— Nanoscale photonic topological insulators, providing an excellent platform for information processing, are restricted by the experimental precise control of coupling strength between nanostructure lattices. We proposed new method of coupling strength controlling, and realized nanoscale plasmonic Aubry–André–Harper topological insulator and reconfigurable silicon micro-ring photonic topological insulator.**

***Keywords*— photonic topological insulators, photonic chips, photonic crystals.**

I. Introduction

Nanoscale photonic topological insulator provides an excellent platform for the light field manipulation and information processing chip. Owing to the challenge of precise control of coupling strength between photonic nanostructure lattices, it is very difficult to experimental realization of complicated photonic topological insulator. This has greatly restricted the practical applications of Nanoscale photonic topological insulator in nanophotonic devices and integrated photonic chips.

II. Methods

We propose an approach to address this challenge faced by nanoscale plasmonic topological insulators by integrating gold nanodisk lattices with connecting gold short waveguides. We found that the coupling strength between nanodisk lattices increases as the connecting gold short waveguide width increases. Therefore, precise control of coupling strength between photonic nanostructure lattices could be realized through adjusting the width of the connecting gold short waveguides. This makes the experimental realization of complicated Aubry–André–Harper configuration easily, even though the coupling strength varied between two different neighboring lattices.

We also proposed a method to precise control of coupling strength between two neighboring silicon micro-ring lattices by using a coupling nanostructure with a Mach–Zehnder interferometer configuration. Therefore, the coupling strength between two neighboring silicon micro-ring lattices could be precisely controlled by thermal adjusting the Mach–Zehnder interferometer.

III. Results and Discussion

We fabricated the plasmonic Aubry–André–Harper topological insulator sample by using electron-beam lithography method. The topological properties of the Aubry–André–Harper configuration are directly characterized by using photoemission electron microscopy. Excellent topological state near-field distribution was obtained. Moreover, polarization multiplexing control could be realized through exciting the gold nanodisks in odd or even positions of trivial staggered nanochains by using incident left- or rightcircularly polarized light, offering a promising method for further manipulating and refining plasmonic nanochains and their potential applications.

We also fabricated reconfigurable silicon micro-ring photonic topological insulator using electron-beam lithography method. Topological transition between trivial phase and topological phase was realized experimental for one- and two-dimensional photonic topological insulator.

IV. Conclusion

We have realized nanoscale plasmonic Aubry–André–Harper topological insulator and reconfigurable silicon micro-ring photonic topological insulator chip. This may be useful for the study of nanophotonic devices and integrated photonic chips.

***Abstract*— Optical (bio)sensors are based on materials that convert a (bio)molecular interaction occurring on, or near, their surface into a change in the values of the light impinging on them. Integrated optics, i.e. optical circuits on glass and silicon photonics, has been the main technology adopted in optical sensing until the advent of nanoplasmonics and metamaterials.**

***Keywords*— nanoplasmonics, nanoparticles, nanoisland.**

I. Introduction

Nanostructured plasmonic materials have revolutionized the design and fabrication of optical transducers and biosensors. Bottom-up and top-down approaches can be both be exploited to produce low cost, high sensitivity plasmonic devices that can be used in very different fields of application, from environmental monitoring to biomedical diagnostic [1-2].

In particular, the diffusion of nanomaterials, that could be easily combined with other substances in bottom-up approaches, has strongly changed the development frame and opened new routes to applications until now forbidden to traditional hard materials. The soft matter, polymers, liquid crystals, macromolecules, has been added of optical features that well compete with traditional emitters, lightguides and detectors. Moreover, their mechanical properties, flexibility and weaving, can be used to design and fabricate smart wearables, innovative sensors and much more [3].

II. Methods

Nanoislands, fabricated by sputtering a thin (less than 10 nm) gold film on glass and then annealed (at 560 °C) in rapid thermal oven, detected small molecules at very low concentration.

Diacrylate hydrogels have been photo-crosslinked together with gold nanoparticles in patches of different size and shape. Local functionalization and selective sensing have been proved.

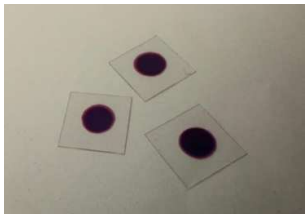

Fig. 1 Gold nanoislands (1 cm diameter) on cover slips (2x2 cm).

III. Results and Discussion

The readout of transparent devices can be simply constituted by a white light and a photodetector or a spectrum analyzer. Due to the presence of plasmonic resonances the signal no needs to be amplified and high sensitivity such as 10^{-17} M of Streptavidin in bovine serum solution in case of nanomushrooms on glass or 0.1x 10^{-12} M using a flexible hydrogel in MEF (metal enhanced fluorescence) configuration.

***Abstract*— Transparent conductive oxides operating near the epsilon-near-zero regime provide a powerful platform for ultrafast time-varying photonics. We outline a unified framework for extreme optical nonlinearities spanning field engineering, quantum emission control, ultrafast polarisation manipulation, and spatio-temporal metamaterials.**

***Keywords*— nonlinear optics, photonic metamaterials, polarization control, quantum optics, ultra-fast physics.**

I. Introduction

Transparent conductive oxides (TCOs) have emerged as a key platform for nonlinear and time-varying photonics due to their tunable carrier density and optical dispersion [1]. Near their crossover wavelength, they exhibit epsilon-near-zero (ENZ) behaviour where the refractive index approaches zero, strongly enhancing light–matter interaction and enabling nonlinear responses exceeding most solid-state platforms [2–5]. This is often linked to slow-light-like effects near the ENZ point [6], while preserving ultrafast femtosecond nonlinear dynamics suitable for near single-cycle index modulation [7]. These properties make near-zero-index (NZI) TCOs strong candidates for time-varying photonic systems controlling spectral and momentum properties of light, with impact across integrated nonlinear and quantum photonics [8,9].

II. Methods

The results discussed here are based on subwavelength TCO flat systems engineered to operate near their ENZ wavelength and optically driven by femtosecond pumping to induce transient carrier redistribution and strong refractive index modulation. By tailoring the optical excitation in its temporal profile and polarisation state, full control over the probe optical response can be achieved on ultrafast timescales, including its spatial and spectral distribution as well as local chiral, birefringent, and dichroic properties.

III. Results and Discussion

Recent experiments demonstrate the breadth of phenomena accessible in this platform, including modification of spontaneous emission and radiation patterns via coupling of quantum emitters to low-index ENZ environments [10]; ultrafast control of all polarization properties (i.e., transient birefringence, dichroism, and optical activity) in a single isotropic platform via optically induced plasma symmetry breaking [11]; and spatio-temporal structuring of NZI photonic metalattices with simultaneous control of photon energy and momentum through space–time modulation [12].

IV. Conclusion

NZI TCOs provide a versatile platform for ultrafast time-varying photonics, enabling nonlinear independent control over photon energy and momentum. The demonstrated capabilities across quantum emission engineering, polarisation control, and space–time metamaterials highlight the potential of these materials for next-generation integrated photonic.

***Abstract*— In this talk, we present the manipulation valley polarization and optical nonlinear effect in transition-metal dichalcogenides. The approaches achieve potential applications in developing low-dimensional optoelectronic materials and devices.**

***Keywords*— metasurfaces, valley polarization and optical nonlinear effect, transition-metal dichalcogenides.**

Controlling valley polarization and optical nonlinear effect in transition-metal dichalcogenides (TMDs) is essential for advancing low-dimensional devices. In this talk, we present the manipulation of valley polarization of interlayer excitons in TMD heterostructure using a dual-handedness metasurface [1]. This metasurface, composed of left- and right-handed gold nanoantenna arrays, exhibits distinct chiral optical responses. Further, we demonstrate that it enables direct and byte-invert arithmetic operations for information transmission. In addition, we show chiral second-harmonic generation in rhombohedral TMDs [2], and illustrate them as compact and multifunctional platforms for integrated photonics. The approaches achieve potential applications in developing the advanced optoelectronic materials and devices.

***Abstract*—By melt-shaping multimaterial fiber cores, we demonstrate building blocks of fiber-embedded photonics. Fiber photonics with data-processing capabilities could translate data on-the-fly across numerous computation platforms, including quantum and neuromorphic, each of which encodes data in a platform-specific form, thus enabling the integration of those platforms into the broader Internet.**

***Keywords*— fibers photonics, 3D printed silica preforms, fiber-integrated ion traps, mode-shaping fibers.**

I. Introduction

Optical fibers form the backbone of modern communication, sensing, and photonic computing technologies. Traditionally, fibers consist of simple cylindrical core–cladding structures fabricated through chemical vapor deposition or preform stacking techniques [1]. While these approaches have enabled tremendous technological progress, they impose strong constraints on achievable fiber geometries and integrated functionality.

Emerging photonic computing platforms, starting with quantum and neuromorphic, are frequently optimized to perform specific tasks with high fidelity, resulting in materials, computational protocols, and even physical implementations of data registers – bits or qubits – tailored for the desired tasks. As a result, however well each of those platforms may perform its isolated tasks, they cannot readily communicate with each other, especially when such communication must be quantum-coherent. To integrate those platforms into a harmonious network, an approach to translating data from a format understandable to the outbound platform into one understandable to the inbound platform is necessary for each such pair. The lack of a universal Quantum Interconnect (QuIC) has been acknowledged in recent years as a major bottleneck to the implementation of scalable quantum networks [2].

Recent advances in additive manufacturing of fiber preforms, fiber thermal drawing, and post-processing [3] enable a new paradigm for fiber design, in which complex device architectures are first fabricated at the preform scale and then translated into functional fibers through the draw and post-processing. These approaches enable the integration of electronic, optical, and quantum data-processing elements and systems directly within fiber-optic systems. As shown in **Fig. 1**, fibers with data-processing capabilities could solve the QuIC bottleneck, enabling on-the-fly, quantum-coherent data translation across the various material platforms comprising the network. Moreover, as further shown in **Fig. 1**, such fibers could provide efficient solutions for quantum routers and quantum coherent repeaters, further enhancing network scalability.

Here, we present our first practical steps toward implementing this concept. First, we demonstrate a fiber-integrated ions-to-photons quantum information converter that enables direct coupling between trapped-ion qubits and optical fiber modes. Second, we demonstrate light-shaping fibers fabricated from 3D-printed silica preforms, enabling arbitrary core geometries and beam shaping within the fiber platform. Additionally, since the 3D printed preforms don't need to be axially uniform, we can implement axially distributed classical integrated photonics elements in a fiber. For instance, we have successfully demonstrated a preform for a Y-splitter/multiplexer in a fiber, which is the first step toward photonic circuits embedded in a fiber, as demonstrated in **Fig. 1, Inset I**, required for quantum routing. Other elements of fiber photonics, including detectors and photonically resonant structures, have been demonstrated by us before and publicized elsewhere [1], [3], [4].

II. Methods And Results

Distributed quantum computing architectures rely on coherent transfer of quantum information between spatially separated nodes. However, many quantum hardware platforms encode qubits in stationary systems, such as trapped ions or solid-state defects, while communication channels use photonic qubits. Efficient interfaces between these systems, therefore, play a critical role in scalable quantum networks.

To address this challenge, we propose a fiber-integrated ions-

to-photons quantum information converter (IP-QIC). In this architecture, a Paul trap capable of confining ions is integrated directly into the cross-section of a functional fiber, as shown in **Fig. 1, Inset III**.

The device consists of a polymer cladding that encapsulates a quadrupole arrangement of RF electrodes forming a Paul trap. A central optical fiber runs through the device and includes an axial gap in the core where trapped ions can be positioned. Conductive carbon-black-filled polyethylene electrodes surrounding the optical fiber enable axial ion confinement via applied DC potentials.

Finite-element simulations were performed to co-design the electromagnetic fields and device geometry. These simulations evaluated RF confinement fields in the transverse direction and DC trapping potentials along the fiber axis, while also accounting for the frequency-dependent impedance of conductive polymer electrodes. The design ensures that the DC electrodes remain conductive at low frequencies while exhibiting minimal dielectric loss at RF trapping frequencies, allowing efficient penetration of RF fields into the trapping region.

The device is fabricated using Very-Large-Scale Integration for Fibers (VLSI-Fi), which combines additive manufacturing of fiber preforms with thermal drawing techniques. A 3D-printed polycarbonate preform containing the electrode channels is fabricated and annealed to remove porosity. During the draw process, copper wires and a conventional optical fiber are inserted into the preform and consolidated into a composite fiber structure.

This approach produces a fiber-based device that traps ions concentrically with the fiber's optical core, forming a continuous waveguide and enabling efficient coupling between trapped-ion emission and guided optical modes. Such architecture provides a promising pathway toward integrated quantum interconnects with integrated repeaters for distributed multi-processor quantum computing.

In addition to fiber-integrated fiber repeaters, additive manufacturing of preforms enables the fabrication of optical fibers with arbitrary internal geometries that cannot be produced by conventional fabrication techniques.

We demonstrate fabrication of light-shaping fibers derived from stereolithography-printed silica preforms. Using silica nanocomposite resins loaded with germanium oxide nanoparticles, we fabricate core structures with non-cylindrical geometries, beyond those shown in **Fig. 1, Inset II**, including circular, triangular, square, hexagonal, and cross-shaped cross-sectional optical core profiles.

The printed Germania-doped core structures are sleeved into

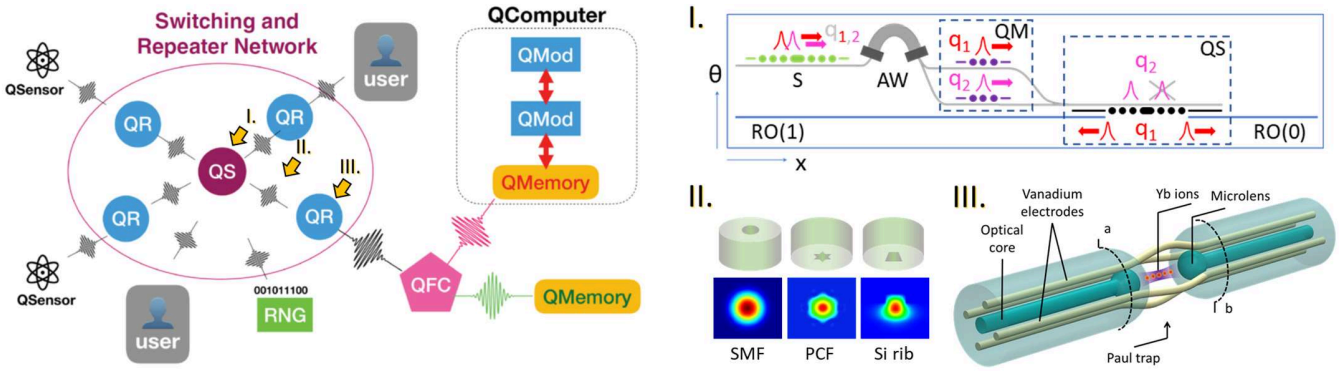

Fig. 1 Fiber photonics to address the scalability of quantum networks. Quantum computer interfacing quantum network (adapted from Awschalom *et al.* (2021) [2] and reproduced under Creative Commons Attribution 4.0. Copyright © 2021, American Physical Society. The elements of the network we aim to address at FAMES Lab using VLSI-Fi are **I.** – quantum switch (QS), **II. –** Quantum Interconnect (QuIC), **III.** – quantum repeater (QR). Other elements of the network, schematically depicted here, include a modular quantum processor (QMod), a quantum frequency converter (QFC), and a random-number generator (RNG). The QuICs are red arrows and wave packets. **Inset I** – suggested implementation of QS with photonic routing capabilities. A fiber-embedded quantum circuit is arranged circumferentially in the fiber cladding. x – longitudinal axis, θ – angular axis in cylindrical fiber coordinates. Initially continuous, cores are selectively patterned by capillary instability into a qubit source S, a quantum memory QM, a quantum all-optical switch QS, and an arrayed waveguide demultiplexer AW. Grey lines are optical cores. RO(0) and RO(1) are the single-photon readouts in superconducting nanowire cores. QS is a resonator that resonantly transmits q_1. When switched by the absorption of q_2, it gets out of resonance, and q_1 is reflected. **Inset II** – Quantum interconnect (QuIC) implemented in a fiber with adiabatic mode shapers, reshaping the long-haul communication circular mode of single-mode fiber (SMF) into a form acceptable without losses by other material platforms, such as an atomic trap in a photonic crystal fiber (PCF) with a hexagonal mode, and a quantum Si Photonics chip (Si rib) with trapezoidal mode. **Inset III** – a suggested implementation of QR with optical to ionic qubit conversion capabilities, in which a fiber-integrated Paul trap embeds an ion-array concentric with the optical mode of the fiber. It can be realized using a vanadium-quadrupole fiber, which has recently been fabricated at FAMES Lab. The Paul trap will be created by etching a gap in the fiber's silica cladding with hydrofluoric acid, which does not affect vanadium. Then the section between **a** and **b** will be heated above the softening point of SiO_2 but below the melting point of V, such that the surface tension reshapes the caps at **a** and **b** into spherical lenses. This will be done in an inert environment to prevent vanadium oxidation. Panels I, II, and III are adapted from Faccini de Lima *et al.* (2023)[5] and reproduced with permission. geometry-matched printed pure silica claddings and subsequently sintered at high temperature to produce transparent glass preforms. The sintered structures are then encased within additional silica tubing and consolidated on a glass lathe under vacuum, forming a monolithic preform suitable for fiber drawing. We have developed an improved annealing procedure to remove residual porosity introduced during 3D printing.

Thermal drawing of these preforms produces fibers with cross-sectionally scaled-down and longitudinally scaled-up versions of the original printed geometries. Electron microscopy and elemental mapping confirm that the germanium-doped cores remain well defined and compositionally uniform after drawing.

Optical characterization demonstrates effective light guidance within the engineered cores. When illuminated with a 450-nm diode source, the fibers exhibit beam profiles corresponding to the designed core geometries, confirming the ability to shape optical modes directly within the fiber. The propagation losses we measure at 1.55 µm are less than 1 dB/m. This is not on par with conventional fiber optics, yet it is more than an order of magnitude better than previously demonstrated for 3D printed silica preforms [6]. We believe that our improved preform-annealing approach enables us to further reduce propagation losses by enhancing the annealing time.

This approach provides a versatile platform for creating optical fibers with tailored modal behavior, integrated photonic components, and complex beam-shaping functionality.

III. Discussion

Together, these results demonstrate that additive manufacturing, combined with fiber thermal drawing and post-processing, enables a new class of multifunctional fibers with embedded photonic and quantum functionalities.

The light-shaping fiber platform provides unprecedented geometric freedom for engineering optical modes, while the quantum-interconnect fiber architecture demonstrates the feasibility of integrating quantum hardware components directly within fiber systems. Both approaches leverage similar fabrication principles and highlight the potential of additive manufacturing for large-scale integration of photonic and electronic structures in fibers.

Future developments will focus on reducing optical losses in printed glass fibers, refining ion-trapping architectures within fibers, and integrating additional functional elements, such as photonic cavities and single-photon sources/detectors.

IV. Conclusion

A combination of classical processing techniques, such as thermal drawing of fibers, with emerging advanced manufacturing approaches, such as additive manufacturing of preforms, is transforming the design space of optical fibers by enabling architectures that combine optical, electronic, and quantum functionality within a single microstructured glass strand. We demonstrated two complementary implementations of this paradigm: a fiber-integrated ions-to-photons quantum information converter and light-shaping fibers fabricated from 3D-printed silica preforms.

These results illustrate the potential of advanced fiber fabrication techniques to enable next-generation photonic systems for quantum communications, sensing, and computing technologies.

***Abstract*— We experimentally investigated optical diffraction from a newly discovered aperiodic structure, an aperiodic monotile. The monotile tessellates two-dimensional space using a single tile shape. We fabricated a quasiperiodic lattice on a nanophotonic platform based on this monotile tiling and observed interesting chiral diffraction response unique to the monotile geometry.**

***Keywords*— photonic crystals, quasicrystals, optical diffraction, aperiodic montile.**

I. Introduction

An aperiodic monotile is a newly discovered aperiodic tiling that was reported in 2023 [1]. In mathematics, minimizing the number of tiles required to aperiodic tessellation was a long-standing problem. The well-known Penrose tiling uses two tiles to tesselate the plane aperiodically, whereas a single-tile aperiodic tessellations (monotile) had not been found. In 2023, Smith discovered the first monotile, called “hat tile” after it shape (Fig. 1(a,b)).

Our motivation is explore physical phenomena enabled by this monotile on a nanophotonic platform. To generate lattice point from the hat tiling, we propose a “monotile lattice” as shown in Fig. 1(c). The lattice has C3 symmetry but lacks inversion symmetry, unlike conventional quasiperiodic lattices such as the Penrose tiling. While theoretical studies of monotile lattices have recently begun to emerge [2,3], experimental realizations remain elusive. Photonic crystals offer a promising platform to investigate this new lattice.

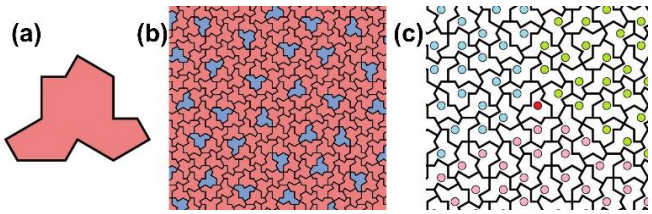

Fig. 1 (a) Geometry of the hat tile and (b) its tiling. (c) The monotile lattice generated from the hat tiling.

II. Results

We investigated diffraction from an aperiodic photonic crystal whose circular holes are positioned on the monotile lattice. The measured diffraction patterns exhibit clear, discrete peaks, indicating long-range order in the aperiodic lattice. Importantly, the patterns show sixfold rotational symmetry together with chirality. Mirror-related structures produce diffraction images with opposite handedness (Fig. 2(a,b)). We also observe an incident-helicity dependence under circularly polarized illumination [5], which is absent in conventional inversion-symmetric quasicrystals.

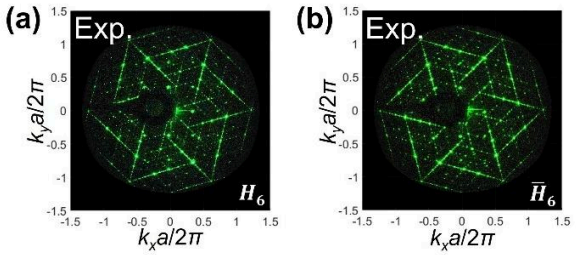

Fig. 2 Pictures of optical diffraction from the fabricated mmonotile lattice. (a) and (b) are results for the monotile lattice and its mirror-reversed structure, respectively.

III. Conclusion

Our experiments reveal unique chiral properties of monotile-based tilings. Chiral optical diffraction from quasiperiodic structures without inversion symmetry opens a new research direction in aperiodic photonics. These results also highlight the usefulness of photonic-crystal platforms for exploring the physics of newly emerging aperiodic structures.

***Abstract*— We report the first QD SOA grown on silicon coupled to silicon nitride waveguides using a monolithic integration scheme. We also report complex photonic circuit programming using UV light trimming. These developments underscore significant strides in the field, paving the way for enhanced photonic device functionality and integration.**

***Keywords* — QD SOA, QD Laser, Silicon Nitride, Monolithic Integration**

I. Introduction

Silicon nitride photonics has emerged as a critical platform for next-generation computing and communication systems due to its exceptionally low optical losses, wide transparency window spanning visible to mid-infrared wavelengths, and full compatibility with established CMOS manufacturing processes. The platform offers propagation losses of less than 0.2 dB/cm in the O-band telecommunications window, making it ideal for complex photonic integrated circuits. However, two fundamental challenges have historically limited the capabilities of silicon nitride photonics: the integration of active gain elements for on-chip light amplification, and the development of non-volatile, zero-power optical memory elements suitable for energy-efficient computing applications. In this work, we address both challenges through breakthrough technological advances in monolithic III-V integration and UV-programmable photonic memories..

II. Results and Discussion

We demonstrate the first monolithically integrated [1-3] electrically pumped semiconductor optical amplifiers on silicon substrate coupled to silicon nitride waveguides. Our InAs/GaAs quantum dot distributed Bragg reflector lasers achieve continuous-wave operation with threshold currents below 215 mA at room temperature and maximum fiber-coupled output power exceeding 2 mW. The SOA devices demonstrate net optical gain greater than 5 dB with a 3-dB optical bandwidth of 46 nm, establishing broadband amplification capability across the O-band.

The monolithic coupling strategy between III-V gain regions and N-rich SiN passive waveguides achieves coupling losses below 1.5 dB per interface with back-reflections close to -13 dB for normal incidence.

For optical memory functionality, we exploit the intrinsic photosensitivity of nitrogen-rich Si_3N_4 with a refractive index of 1.9, deposited via plasma-enhanced chemical vapor deposition on silicon wafers with 3.2 μm of thermally grown silicon dioxide. A 244 nm frequency-doubled Argon-Ion laser with 25 mW power and 14 μm spot size permanently modifies the refractive index through controlled UV exposure at fluences of 1.5 kJ/cm² [4]. This enables non-volatile programming of Mach-Zehnder interferometer switching states without requiring continuous electrical biasing or thermal tuning, eliminating static power consumption. We experimentally validate this approach through demonstration of a 4×9 wavelength-division multiplexed ternary content addressable memory bank, representing the highest-dimension photonic memory array reported to date. The system operates at 20 Gb/s with 2-bit optical words while consuming zero electrical power during steady-state operation. Characterization reveals a 15 dB extinction ratio between ON and OFF states after 20 UV exposure cycles, with bit error rates below 10^{-9} across all stored configurations. The platform demonstrates multi-million cycle endurance with stable refractive index retention and maintains wafer-scale manufacturing compatibility.

These results establish further silicon nitride as a complete platform for high-performance photonic computing, combining monolithically integrated optical amplification with non-volatile, zero-power programmable memory. This addresses the fundamental limitation of silicon's indirect bandgap while eliminating speed-power trade-offs of electronic alternatives.

***Abstract*— Lorentz reciprocity fundamentally limits the performance of photonic systems by enforcing reciprocal energy exchange between source and detector, which manifests as the symmetry of the scattering matrix. We design and fabricate a graphene-based integrated photonic structure and experimentally demonstrate nonreciprocal scattering from a metasurface modulated at gigahertz frequencies.**

***Keywords*— metamaterials, midinfrared, graphene device**

I. Introduction

In electromagnetism, the Lorentz reciprocity theorem states that a source and a detector of light can swap positions without changing the outcome of the measurement by the detector[1] . In other words, the scattering matrix is symmetric, $S_{ab} = S_{ba}$. Reciprocity assumes that light propagates in a linear, time-invariant medium with symmetric permittivity, permeability, and conductivity tensors. In reality most devices inherently operate under the regime of reciprocity, which states that the spectral directional emissivity and absorptivity of a surface are equal[2,3]: $e(\omega, \theta, \phi) = a(\omega, \theta, \phi)$, where e is emissivity, a is absorptivity, ω is (angular) frequency, and θ and ϕ are polar and azimuthal directions, respectively. In principle, a nonreciprocal system for which $S_{ab} \neq S_{ba}$, achieved by lifting one or more of the assumptions of the Lorentz reciprocity theorem. Spatiotemporal modulation has been one of the most successful approaches to nonreciprocity, having been theoretically predicted and even experimentally demonstrated in waveguides[4], antennas[5], and metasurfaces[6]. Despite the promise of mid-infrared nonreciprocity and its relevance to tailoring thermal radiation, there have been few experiments demonstrating nonreciprocal emission, absorption, or scattering in this spectral range. In this work, we experimentally demonstrate nonreciprocal frequency conversion using a spatiotemporally metamaterial (STMM) designed for operation at a wavelength of 10 μm, near the peak wavelength of room-temperature thermal radiation.

Our STMM consists of an array of 36 rectangular pixels of size 5.7 μm × 200 μm. Each pixel contains six metallic patch antennas placed on top of a graphene monolayer, which is transferred onto a dielectric stack of alumina and amorphous-germanium (a-Ge) that is backed by an optically thick metal ground plane (see Fig. 1). Monolayer graphene is used to modulate the antennas' optical response via electrically controlled charge density at 1 GHz frequency. Our metasurface is designed to generate synthetic diffraction orders in reflection around a center wavelength of about 10 μm (i.e., 30 THz) when driven with properly phase-controlled GHz RF voltage. The experiments are performed in Littrow configuration[7] using a piezo tunable mode-hop-free quantum cascade laser (QCL, Sacher Lasertechnik).

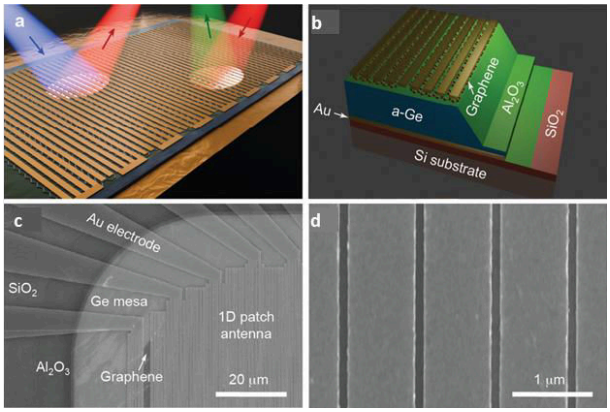

Fig. 1 . a Nonreciprocal reflection from a graphene STMM, b. Schematic layers of device, c SEM image of the fabricated device, d Expanded top-view of one-dimensional patch antenna pixels.

To perform the measurements, a 10 kHz drive voltage is applied to every third pixel of the metadevice to create a quasi-static grating for diffraction. The results of these quasi-static measurements are shown in Fig. 2 a The bright rings correspond to the transmission of a specific optical frequency at certain angles of the FPE. We then apply a spatiotemporal modulation ($\Omega/2\pi = 1$ GHz, $\Delta V = 2.5$ V) to the STMM in the 3-pixel periodic sequence $[+120°, 0, -120°]$ and obtain the 2D map in Fig. 2b. The rings are displaced to the right exactly by $\Omega/2\pi = 1$ GHz modulation frequency, demonstrating unidirectional and essentially nonreciprocal frequency conversion.

II. Results and Discussion

To understand the data, we first consider the "forward" experiment by arbitrarily choosing an input frequency of the QCL, say $\omega_{\text{in}} = \omega_0 + \Delta\omega$, where $\omega_0/2\pi \approx 31.6$ THz (wavelength 9.5 μm) and $\Delta\omega/2\pi = +0.5$ GHz. A vertical slice (solid blue line) of the map in Fig. 2b at ω_{in} cuts through one of the rings at two symmetric points (with one marked with a blue circle) located at angular positions of about $\pm 0.8°$. Following the horizontal blue dashed line, in the reference map (Fig. 2a) we find that the FPE transmission frequency is $\omega_{\text{out}}/2\pi = \omega_0/2\pi - 0.5$ GHz at these angular positions, as indicated by the yellow circle and vertical dashed line. By comparing the maps in Figs. 3a and 3b, we conclude that frequency down-conversion $\omega_{\text{out}} = \omega_{\text{in}} - \Omega$ occurred in the spatiotemporally modulated metadevice.

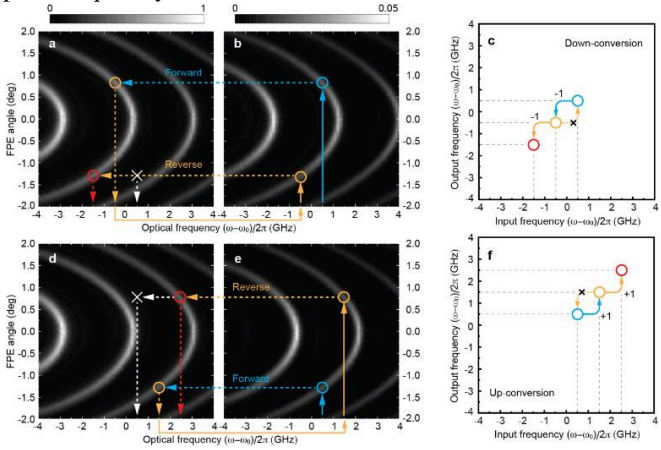

Fig. 2 The 2D maps show the transmission signal through the FPE as a function of the FPE angle and QCL frequency. Panel **(a, d)** corresponds to the case of the metasurface with no RF spatiotemporal modulation. (b) transmission for the spatiotemporally modulated metasurface for the modulation sequence [+120°,0,-120°] corresponding to frequency down-conversion (c). Panel (e, f) Same for the sequence $[-120°, 0, +120°]$ corresponding to frequency up-conversion.

We consider the "reverse" experiment while keeping the modulation protocol $[+120°, 0, -120°]$ unchanged. The Littrow configuration with colinear input and optical output modes allows us to keep the QCL laser and detector in the same positions in the reverse experiment. This leads to the same 2D optical density map depicted in Fig. 3b. We consider the previously down-converted frequency to be the new input frequency $\omega'_{\text{in}}/2\pi = \omega_{\text{out}}/2\pi = \omega_0/2\pi - 0.5$ GHz and extend a vertical slice (yellow solid line) that intersects a ring in Fig. 3b at FPE angular positions about $\pm 1.25°$ (yellow circle for the negative one). Following the horizontal yellow dashed line to the reference map in Fig. 3a we find the intersection point marked by the red circle, which corresponds to the new output frequency $\omega'_{\text{out}}/2\pi = \omega_0/2\pi - 1.5$ GHz, suggesting yet another down-conversion, $\omega'_{\text{out}} = \omega_{\text{in}} - 2\Omega$. Figure 3c schematically illustrates the two steps of the frequency down-conversion just discussed. This key observation demonstrates nonreciprocal scattering from our graphene-based spatiotemporally modulated metasurface operating at mid-infrared frequencies.

For completeness, we have also demonstrated nonreciprocal reflection in a reversed modulation sequence [-120°,0,+120°], with the 2D optical density map shown in Fig. 3e. In this case the rings are displaced to the left by the 1 GHz modulation. Following a similar procedure as above, one can show that in the forward experiment there is frequency up-conversion$\omega_{\text{out}} = \omega_{\text{in}} + \Omega$. The reverse experiment gives another up-conversion, $\omega'_{\text{out}} = \omega_{\text{in}} + 2\Omega$ and no signal at the initial input frequency is observed. Figure 3f depicts the two steps of frequency up-conversion. As before, this indicates nonreciprocal reflection from our spatiotemporally modulated metasurface. The measured efficiency of mode conversion $\omega_0 \rightarrow \omega_{\pm 1}$ is $\approx 4 \times 10^{-5}$.

III. Conclusion

In summary, we have introduced a graphene-based STMM platform modulated at GHz frequencies for experimental demonstration of breakdown of Lorentz reciprocity at mid-IR wavelengths. We have also developed a theory that relates nonreciprocal reflection with the breakdown of the spectral directional Kirchhoff's law of thermal radiation. Our work has the potential to find applications in mid-IR optical isolators, solar energy harvesting, thermophotovoltaics for waste heat recovery, active/dynamic thermal management for electronics, radiative cooling, and adaptive thermal camouflage and thermal signatures.

Symmetry-Broken q-BIC Dielectric Metasurfaces for Enhanced Linear and Nonlinear Light-Matter Interactions

Wen-Hui (Sophia) Cheng[1,*], Hung-Yi Wu[1], Tzu-Hsiang Liu[1], Hsin-Yu Shen[1]
[1] National Cheng Kung University, Taiwan
[*]corresponding author: wcheng@gs.ncku.edu.tw

Abstract: We present a dielectric metasurface supporting q-BICs induced by controlled symmetry breaking. Strong mode interference enables high-Q resonances, enhanced photoluminescence, and boosted third-harmonic generation. By balancing field confinement and radiation coupling, the design offers an efficient platform for enhancing linear and nonlinear light-matter interactions in nanophotonic devices.

Dielectric metasurfaces offer a versatile platform for manipulating light-matter interactions with low nonradiative losses and high design flexibility. In this work, we introduce a metasurface composed of biradial circular resonators that supports quasi-bound states in the continuum (q-BICs) through controlled symmetry breaking. By slightly perturbing a symmetry-protected BIC, an experimentally accessible q-BIC with a high quality factor and strong field confinement is achieved. The resonance is primarily governed by the interference between electric dipole and magnetic multipolar modes, enabling enhanced photoluminescence and robust spectral tunability. Beyond linear optical responses, we further exploit q-BIC modes to boost nonlinear light-matter interactions. By carefully balancing field confinement and radiation coupling, significant enhancement of third-harmonic generation is realized in optimized asymmetric circular array designs. Our results reveal that maximizing nonlinear conversion efficiency requires not only high-Q resonances but also appropriate radiative coupling, highlighting the critical interplay between confinement and outcoupling. This study elucidates the symmetry-driven physics of q-BIC metasurfaces and provides a practical and fabrication-friendly strategy for enhancing both linear and nonlinear optical processes, paving the way for advanced applications in frequency conversion, nanophotonics, and integrated nonlinear photonic devices.

Femtosecond Laser Direct-Written Optical Fiber Microstructure Devices for Laser Applications

Xuewen Shu[1,*] (Invited)

[1]Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, 430074, China

*Corresponding author: xshu@hust.edu.cn

***Abstract*— We report our recent progress in the use of femtosecond lasers to fabricate various microstructures within optical fibers, including gratings and interferometric devices, and discuss their diverse applications in fiber laser systems.**

***Keywords*— fiber gratings, interferometric devices, femtosecond laser direct-writing, fiber lasers.**

I. Introduction

Femtosecond laser inscription technology has emerged as an indispensable tool for fabricating intricate microstructures in a diverse range of materials. Femtosecond laser direct writing offers several distinct advantages, such as highly localized material modification and no requirement for material photosensitivity. The strong spatial confinement of the technology, combined with laser-beam scanning or sample translation, enables the creation of geometrically complex three-dimensional structures. In recent years, we have employed this technique to fabricate various fiber-optic microstructures, including gratings and interferometric devices, and demonstrated their applications in fiber laser systems. In this presentation, we provide an overview of our research progress in this field..

II. Methods and Results

Figure 1 shows an example of using the femtosecond laser line-by-line inscription technique to fabricate a small-period long-period grating (SP-LPG) and applying it to generate ultrashort pulses in a fiber laser [1]. The SP-LPG is produced with a period of 25 μm and a length of 2.5 mm. This grating has significant polarization dependent loss (PDL) in C and L bands, making it possible to use as a mode-locking device. The laser cavity has a total length of 130 m and a net cavity dispersion of -2.738 ps^2. Figure 2 shows the output characteristics of the mode-locked laser based on the SP-LPG. The central wavelength is around 1577 nm with 3 dB spectral bandwidth of 4 nm. The signal-to-noise ratio (SNR) reaches 50 dB, demonstrating excellent stability of the mode-locked pulses.

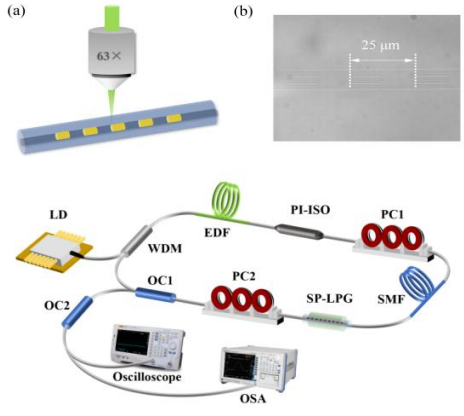

Fig. 1 (a) Schematic of the femtosecond laser inscribed process for SP-LPG; (b) CCD photograph of SP-LPG;(c) Fiber laser setup.

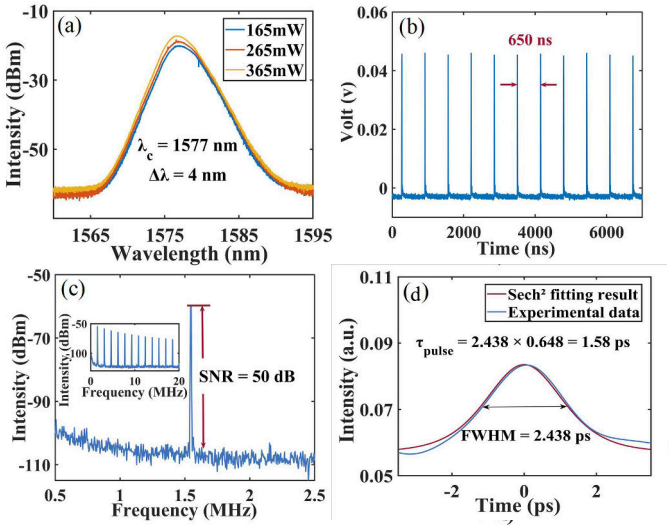

Fig. 2 Performances of the mode-locked fiber laser. (a) Optical spectrum. (b) Pulse train. (c) RF spectrum. (d) Autocorrelation trace

In another experiment, such an SP-LPG was also employed in a normal-dispersion fiber laser to generate mode-locked pulses in the L-band [2]. Other fiber grating and interferometric structures were also fabricated and applied in various laser systems, including mode-locked fiber lasers and random fiber lasers [3-6].

III. Conclusion

Femtosecond lasers can be used to fabricate various fiber gratings and interferometric devices in optical fibers, offering broad application potential in fiber laser systems.

Novel Materials for UV Plasmonic Nanostructures

Michael Foltýn[1,*], Tomáš Šikola[1], Michal Horák[1]

[1]Brno University of Technology, Brno, Czech Republic
*Corresponding author: Michael.Foltyn@vutbr.cz

***Abstract*— We present a study of novel plasmonic materials, focusing on nanostructured non-noble metals at the single-particle level. We demonstrate the spectral tunability of their localized surface plasmon resonances. In particular, we investigate gallium, bismuth, lead, and tin.**

***Keywords*— non-noble metals, nanoparticles.**

I. Introduction

Localized surface plasmon resonances (LSPRs) arise from collective oscillations of free electrons in metallic nanostructures coupled to light. They enable strong, subwavelength confinement and enhancement of electromagnetic fields, allowing control of optical processes beyond the diffraction limit, consequently bringing a wide range of applications. Although gold-based plasmonics are highly promising, their broader use is limited by high fabrication costs and a restricted plasmon energy range due to interband transitions. These limitations motivate the exploration of alternative metals such as gallium, bismuth, lead, and tin, which are theoretically predicted to provide comparable performance with a wider energy range [1]. Here, we present the plasmonic properties of gallium [2], [3], bismuth [4], [5], lead, and tin.

II. Methods

To investigate all the listed metals, we employed several complementary methods to prepare the respective nanostructures. Lens-shaped gallium nanoparticles were fabricated by depositing gallium from an effusion cell directly onto silicon nitride membranes. Bismuth nanostructures were produced by focused ion beam (FIB) lithography of thin bismuth films sputtered onto silicon nitride membranes. In addition, bismuth nanoparticles were synthesized via chemical reduction of sodium bismuthate in ethylene glycol at elevated temperature. Lead nanoparticle solutions were prepared by thermal decomposition of lead acetate in tetraethylene glycol. The resulting bismuth and lead nanoparticle dispersions were subsequently drop-cast onto silicon dioxide membranes for further analysis.

The prepared nanostructures were examined by transmission electron microscopy to determine their structural and morphological characteristics. Their plasmonic properties, including the tunability of localized surface plasmon resonances, were analyzed using electron energy loss spectroscopy [6].

III. Results and Discussion

The spectral tunability of localized surface plasmon resonances in bismuth is comparable to that of gold, showing similar size-dependent behavior. This makes bismuth a significantly more cost-effective alternative for plasmonic applications. In addition, bismuth maintains its strong plasmonic performance at energies above 2 eV, extending its usefulness into the visible and near-UV range.

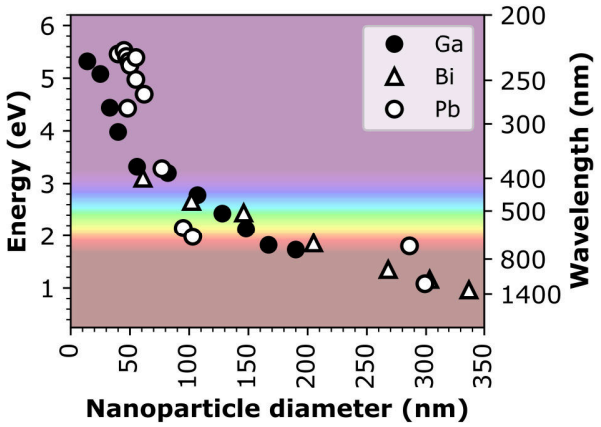

Fig. 1. Tunability of LSPR dipole mode in bismuth [5], gallium [2] and lead nanoparticles.

Lead and gallium are particularly promising for ultraviolet plasmonics. Both materials exhibit dipolar LSPR modes at energies up to 5.3 eV. Although gallium undergoes a liquid-to-solid phase transition at low temperatures, its plasmonic response remains stable, making it well suited for cryogenic surface-enhanced Raman spectroscopy and other low-temperature applications.

IV. Conclusion

We have experimentally verified the ability of lead, bismuth and gallium to support localised surface plasmon resonances, and extracted the spectral tunability of the plasmonic dipolar mode. All of the listed metals expand the spectral range to the UV spectral region, offering attractive applications, which would be inaccessible with the traditional plasmonic materials, such as gold.

***Abstract*— It has been reported that niobium oxide dichloride ($NbOCl_2$) crystal exhibits giant optical nonlinearity. We developed a plasmonic resonator insensitive to polarization to acquire strong local field amplification, which achieves fivefold enhancement of second harmonic generation (SHG) intensity. It provides a robust pathway toward high-performance, miniaturized nonlinear quantum light source.**

***Keywords*— niobium oxide dichloride ($NbOCl_2$), ferroelectrics, second harmonic generation, nonlinearity, plasmonic resonator**

I. Introduction

Layered niobium oxyhalides ($NbOX_2$, X = Cl, Br, I) have recently emerged as promising candidates for realization of efficient nonlinear light sources at nanoscale[1-2], owing to their intrinsic ferroelectricity, strong in-plane anisotropy, and large second-order susceptibility coefficients. Even though their SHG conversion is very high, which still needs to be increased remarkably to meet the requirement for practical application of quantum light sources.

II. Methods

In this work, we engineered a silver plasmonic resonator which consists of circular ring structures to amplify the local electric field upon excitation. Meanwhile, it is able to boost effective nonlinear polarization while maintaining isotropic optical response across all polarization states. Coupled with the plasmonic resonator, the van der Waals crystal of $NbOCl_2$ emits enhanced intensity of SHG.

III. Results and Discussion

Experimental results show:

- Environmental robustness of $NbOCl_2$ flakes manifested by optical property stability test
- Strong hotspot formation at the ring edges of polarization-insensitive ring resonator upon excitation at 780 nm excitation
- Fivefold enhancement of SHG intensity

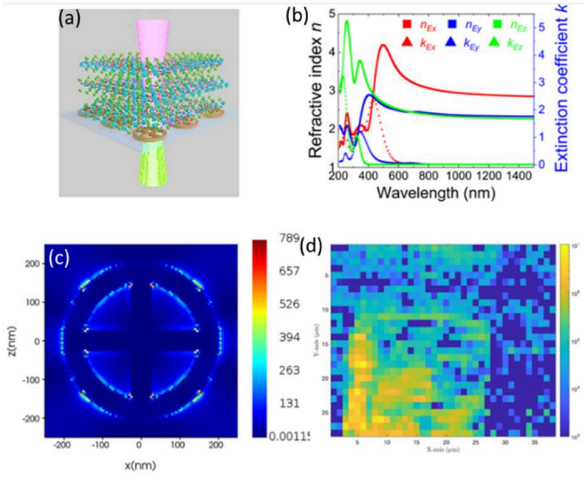

Fig. 1. The concept and experimental results. (a) Schematics of hybrid nonlinear emitter consisting of plasmonic resonator and $NbOCl_2$ flaks. (b) Optical properties measured by ellipsometer. (c) Simulated electric field of plasmonic resonator. (d) The spatial mapping of SHG intensity.

IV. Conclusion

We have demonstrated a polarization-insensitive plasmonic resonator which can significantly enhance the intrinsic SHG of $NbOCl_2$ and also validate its superior air-stability as a van der Waals ferroelectric with giant optical nonlinearity

***Abstract*— This work presents a method to design 3D photonic Chern and electromagnetic axion insulators with tunable topological properties. These structures support robust, unidirectional light transport via chiral edge and hinge states, enabling lossless photonic networks and offering promising applications in quantum technologies and axion dark matter detection.**

Inspired by the discoveries of topological phenomena in solid state systems, the study of topology in the propagation of light in photonic crystals has been the subject of much recent attention. Among all topological states of matter, time-reversal symmetry (TRS) broken topological materials, such as Chern insulators have been a particular focus due to their topologically protected unidirectional edge states with non-reciprocal propagation properties. In these systems, scattering processes from one boundary state into another are strongly suppressed, due to decoupling of counter-propagating 1D chiral edge channels.

In this contribution, we will firstly introduce a general strategy to design 3D Chern insulating (3D CI) cubic photonic crystals in a weakly TRS broken environment with orientable and arbitrarily large Chern vectors [1-2].

Secondly, will show how these designs can be used to build photonic axion insulators [3-4]. Such a 3D topological photonic crystal exhibits extraordinary properties such as half-quantized surface effects and unidirectional chiral hinge states that propagate exclusively along the edges. These chiral hinge states form intricate networks that enable light to travel without loss or interference, even when obstacles are present. This breakthrough offers a deeper understanding of exotic particles and paves the way for practical applications in quantum computing, advanced sensors or in the development of axion-like particle detectors such as axion dark matter particles [4].

***Abstract*— Room-temperature exciton–polariton Bose–Einstein condensation is demonstrated in a WS_2 monolayer using BIC-enabled Dirac-mode confinement. Strong coupling with ~60 meV Rabi splitting persists above threshold. Topological polariton superfluids, negative-mass self-trapping, discrete Dirac-gap condensates, and pump-tunable spectra enable reconfigurable, integrable quantum photonic platforms at ambient conditions.**

***Keywords*— exciton–polaritons, bound states in the continuum, WS_2 monolayers, Bose–Einstein condensation.**

I. Introduction

Exciton–polaritons in atomically thin semiconductors offer a platform for nonlinear quantum photonics at ambient conditions. However, room-temperature polariton Bose–Einstein condensation has remained inaccessible due to strong losses. Topological bound states in the continuum [1-3] (BICs) provide a route to overcome these limitations.

II. Methods

Our methodology integrates simulation, analytical non-Hermitian Hopfield model and experimental feedback. A WS_2 monolayer is coupled to a silicon nitride photonic crystal slab supporting Dirac-point BIC modes. Strong coupling and dispersion engineering are analysed using RCWA and a polariton model, combined with a driven–dissipative Gross–Pitaevskii framework:

$$i\,\partial_t\psi = (H - i\Gamma + g\,|\,\psi\,|^2 + g_R n_R)\psi,$$

validating the experimental photoluminescence mapping of the strong coupling regime and polariton lasing.

III. Results and Discussion

Experimental observations show:

- Room-temperature polariton lasing;
- Persistent strong coupling with ~60 meV Rabi splitting above lasing threshold;
- Negative-mass polariton self-trapping and discrete Dirac-gap condensate states;
- Extended spatial coherence through first order correlation function vs pump power;
- Pump-tunable blueshifts up to ~28 meV and topological charge |2| inheritance;
- All-optical dynamical reconfiguration through pump-shape profile modulation.

IV. Conclusion

We demonstrate room-temperature polariton Bose–Einstein condensation in a WS_2 monolayer enabled by Dirac BIC confinement. The BIC dispersion supports omnidirectional negative-mass polaritons that self-trap via a reservoir-induced potential, resulting from interfering Dirac modes. A general analytical model predicts the evolving loss landscape, enabling the prediction of the condensation regime. The non-equilibrium condensate is dynamically controlled through the real-time modulation of the space-variant self-trapping potential. This open-cavity platform supports condensate arrays and integration with van der Waals heterostructures and Moiré superlattices, tracing a pathway toward emerging functionalities at ambient conditions. The resulting system establishes a new scalable platform for coherent light–matter states in low-dimensional semiconductors under ambient conditions.

Manipulate Multispectral 3D Polarization Structures with Optical Metasurfaces

Xianzhong Chen[1,*], Hammad Ahmed[2], Chunmei Zhang[1]

[1]School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK
*Corresponding author: x.chen@hw.ac.uk

***Abstract*—3D polarization structures are garnering significant interest owing to their peculiar properties. We use optical metasurfaces to generate various multispectral polarization 3D structures and cascaded polarization cages, whose polarization profiles can be dynamically modulated.**

***Keywords*— optical metasurfaces, 3D polarization control, polarization cage, multispectral.**

I. Introduction

3D polarization distributions are garnering significant interest owing to their peculiar properties. Multi-color polarization manipulation can introduce extra degrees of freedom. It is challenging both technically and fundamentally to cascade multiple multispectral 3D polarization structures. Moreover, fuelled by system integration and miniaturization, there is considerable interest in developing compact optical devices capable of controlling polarization and color simultaneously on 3D structures.

II. Methods

To tackle these challenges, we propose a metasurface approach to generating multiple 3D polarization structures along the light propagation direction. Each polarization structure features different colors and an engineered 3D polarization profile. Our metalens design includes off-axis design, geometric phase realization, linear polarization rotation, multiple 3D structure design, introduction of color information, longitudinal control, and phase multiplexing. Different multi-colored 3D polarization knots and polarization cages are observed by changing the observation region along the longitudinal direction. We further showcase the application of the developed metalenses in realizing multiple 3D color images hidden in multiple 3D color images.

III. Results and Discussion

The light intensity distributions of the 3D polarization knots are modulated with a rotating analyzer, generating unusual features (e.g., dark gaps). Such a characteristic opens an avenue for image steganography—a technique which can hide a secret image inside a cover image. A polarization knot with the same light intensity profile can have many 3D polarization distributions and colors.

IV. Conclusion

Our approach has tackled the typical challenges of creating multiple multispectral 3D polarization structures: 3D polarization generation, multiple colors, and cascading control. The compact, flexible, and lightweight design of the metasurface provides numerous advantages over traditional polarization optics, making it highly suitable for applications across various research fields, including complex vector beam generation and optical encryption.

Abstract— **Kirchhoff's law of thermal radiation fundamentally limits the efficiency of photonic systems. We report the demonstration of spatiotemporally modulated nonreciprocal mid-infrared metasurfaces enabling the violation of the Kirchhoff's law at room temperature. We develop a theoretical framework to relate nonreciprocal scattering under spatiotemporal modulation with unequal absorptivity and emissivity.**

***Keywords*— metamaterials, nonreciprocity, Kirchhoff's law of thermal radiation, mid-infrared**

I. Introduction

The Lorentz reciprocity theorem states that a source and a detector of light can swap positions without changing the outcome of the measurement by the detector. Reciprocity assumes that light propagates in a linear, time-invariant medium with symmetric permittivity, permeability, and conductivity tensors. Metamaterials have revolutionized electromagnetic wave control. Reciprocity can have undesirable effects as well. Examples include solar cells re-emitting absorbed solar energy, radiative coolers absorbing thermal radiation, and antennas hearing their own echoes.

Here, we briefly report the to demonstration of nonreciprocal scattering in free space using a spatiotemporally modulated metasurface operating at mid-IR wavelength. We describe in detail he theory that related nonreciprocal scattering from a space-time graphene-based metasurface with the breakdown of Kirchhoff's law of thermal radiation (Fig. 1).

II. Methods

Our methodology integrates theory, simulation, nanofabrication and optical experiments.

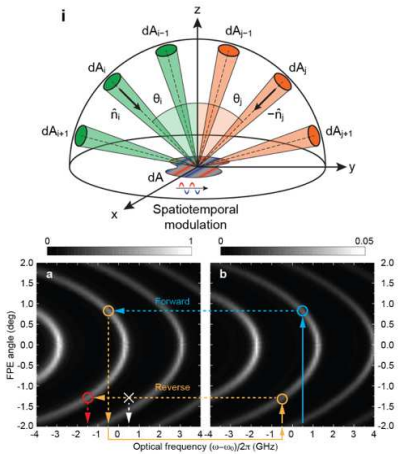

Fig. 1. (Top) Travelling-wave modulation of a metasurface; (Bottom) Frequency nonreciprocity via travelling-wave

III. Results and Discussion

We report the first demonstration of free-space non-reciprocal scattering at thermal wavelengths and connect it to the breakdown of Kirchhoff's law of thermal radiation.

IV. Conclusion

Together, our experiment and theory imply effective decoupling of absorption and emission channels by breaking time-reversal symmetry at thermal wavelengths.

***Abstract*— We study the scattering of waves at an interface whose properties vary in time, characterized by Lorentzian dispersion and an abrupt change in its parameters. Our work uncovers an unconventional mechanism in which novel frequency components are generated at the eigenmodes of the system. This phenomenon enables coupling between propagating and evanescent waves, allowing surface-wave modes to be directly excited from the far field without relying on spatially structured media. In addition, space-time interfaces can support unexpected optical spin effects induced by phase conjugation.**

***Keywords*— metamaterials, space-time interfaces, time-varying, linear frequency generation.**

I. Introduction

Time-modulated metasurfaces represent compact platforms capable of producing new frequencies without relying on traditional nonlinear phenomena. A representative example is a temporally modulated thin film [1], which operates through extended periodic modulation of an impedance surface. Under these conditions, the film generates additional frequencies and allows surface-wave modes to be directly excited from the far field, without requiring any supplementary spatial structuring.

In this work, we examine a temporally modulated dispersive interface characterized by Lorentz-type dispersion, whose material parameters switch abruptly in time. The system displays an unconventional linear generation of frequencies at its resonant response and, crucially, allows interaction between propagating and evanescent waves.

Our results point to a new route toward compact, high-speed photonic devices that bypasses the need for spatial patterning or prolonged temporal modulation.

II. Methods

We analyze a temporally modulated interface consisting of a dispersive dielectric slab of thickness L (with $L \ll \lambda$, where λ represents a characteristic wavelength) placed between two homogeneous, stationary, and non-dispersive half-spaces with relative permittivities ε_L and ε_R. The conceptual configuration is illustrated in Fig.1(a), which qualitatively shows the system's behavior following the temporal modulation, in the most general case of oblique incidence.

We focus both on transverse-electric (TE) and transverse megnetic (TM) modes of the form $\mathrm{Re}[E(z,t)e^{ik_x x}]\hat{\boldsymbol{e}}_y$ and $\mathrm{Re}\{e^{ik_x x}[E_x(z,t)\hat{\boldsymbol{e}}_x + E_z(z,t)\hat{\boldsymbol{e}}_z]\}$, respectively. Here k_x denotes the conserved transverse wavenumber, $\hat{\boldsymbol{e}}_\alpha$ is the unit vector oriented along the α direction, and i represents the imaginary unit. The interface is located at the plane $z = 0$, and its electromagnetic response can be described by appropriate sheet-transition conditions [2].

The dynamics of the surface polarization $\mathrm{Re}[\boldsymbol{P}(t)e^{ik_x x}]$ can be described by

$$\frac{\mathrm{d}^2\,\mathbf{P}}{\mathrm{dt}^2} + \gamma\frac{\mathrm{d}\mathbf{P}}{\mathrm{dt}} + \omega_0^2\,\mathbf{P} = \varepsilon_0\,\mathrm{L}\,\omega_\mathrm{p}^2\overline{\mathbf{E}}\,, \qquad (1)$$

where ε_0 is the vacuum permittivity, ω_0 and γ are the resonance frequency and damping parameter, respectively (constant over time), $\omega_p(t)$ is the time-varying plasma frequency, and $\overline{\mathbf{E}}(t) = \frac{1}{L}\int_{-L/2}^{L/2} dz\,\boldsymbol{E}(z,t)$.

Considering both sheet-transitions, Equation (1), one can obtain a semi-analytical theory in the case where the system features a temporal boundary (i.e., the plasma frequency experiences an abrupt change). In the stationary regime, where the plasma frequency remains constant, the interface supports both radiative and bound modes, as illustrated in Fig. 1(a). However, these modes cannot be directly excited by an incident propagating wave with a detuned frequency. Surprisingly, the temporal boundary can generate the system's eigenwaves even when the frequency of the incident field is far from the eigenfrequencies [3]. Moreover, this mechanism can be used to achieve unconventional spin/polarization conversion without the need for bi-anisotropy, chirality, or nonlinear effects [4].

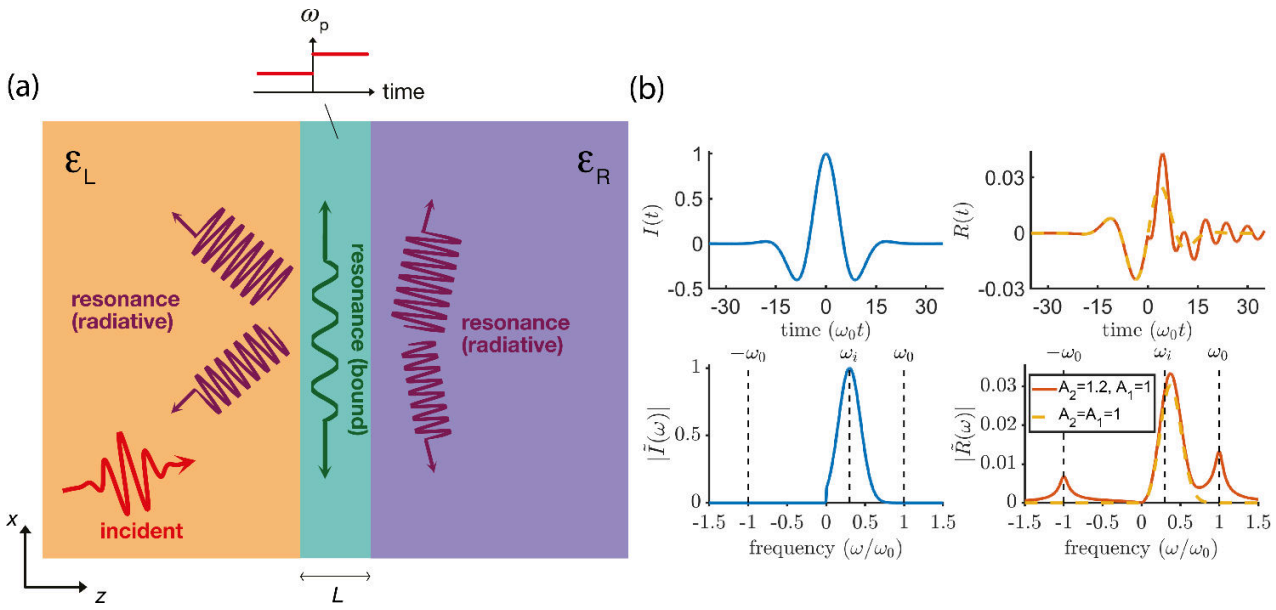

Fig. 1 (a) Schematic of the considered system: a time-varying dispersive interface implemented as a thin dielectric layer embedded between two homogeneous, stationary half-spaces with relative permittivities ε_L and ε_R. (b) Representative results for TE case, $k_x = 0$, with $\varepsilon_L = \varepsilon_R = 1$, $L = 0.16c/\omega_0$, and $\gamma = 5 \cdot 10^{-3}\omega_0$. The first row shows the temporal profiles of the incident $[I(t) = E_i(0^-, t)/E_0]$ and reflected $[R(t) = E_r(0^-, t)/E_0]$ wave packets, while the second row reports the corresponding spectra. Dashed vertical lines mark the carrier and resonance frequencies. Results obtained in the presence ($A_1 = 1$, $A_2 = 1.2$) and absence ($A_1 = A_2 = 1$) of the temporal boundary are compared. All spectra are normalized to the peak value of the incident spectrum.

III. Results and Discussion

As an illustrative example, we consider a temporally modulated Gaussian TE wave packet normally incident on the time-varying interface (i.e., $k_x = 0$), with electric – field profile $E_i(0^-, t) = E_0 e^{-t^2/\sigma^2 - i\omega_i t}$. Throughout this work, E_0 denotes a constant amplitude, ω_i the carrier angular frequency, and σ sets the temporal width of the wave packet. The temporal alignment is chosen such that the wave-packet peak reaches the metasurface exactly when the time switch occurs.

Figure 1(b) presents the system response in terms of the reflected field, for $\omega_i = 0.3\ \omega_0$, $\sigma = 10/\omega_0$, $\varepsilon_L = \varepsilon_R = 1$, $L = 0.16\ c/\omega_0$, and $\gamma = 5 \cdot 10^{-3}\ \omega_0$, where c is the speed of light in vacuum. In particular, the two panels in the first column display the temporal waveform and spectrum of the incident field, respectively, while the two in the second column show the reflected signal in the presence ($A_1 = 1$, $A_2 = 1.2$, orange solid curve) and absence ($A_2 = A_1 = 1$, yellow dashed curve) of the temporal boundary.

Notably, despite the incident wave packet not having spectral content at the resonant angular frequency ω_0, the reflected field exhibits pronounced components at $\pm\omega_0$ when a temporal boundary is introduced. As expected, this effect does not occur in the stationary case, where the plasma frequency remains constant.

IV. Conclusion

In conclusion, we introduce a semi-analytical framework for the scattering theory of dispersive space–time interfaces. These interfaces enable the generation of the system's eigenmodes, mediate the coupling between propagating and evanescent waves, exhibit unusual phase-conjugation, and spin/polarization effects. We also analyze the TM case dominated by epsilon-near-zero (ENZ) waves, with full details to be presented at the conference.

***Abstract*— We investigate exciton polaron formation in 2D semiconductors. By solving the Dyson equation, we obtain polaron energies and identify the regime were polaronic effects, such as renormalized group velocity, effective masses and transport, become significant. Our work provides a systematic microscopy and material specific theory to investigate polaron physics.**

***Keywords*— excitons, phonons, polarons, two-dimensional materials, semiconductors.**

I. Introduction

Electron–phonon interactions in semiconductors can lead to the formation of new quasiparticles known as electron polarons. These quasiparticles emerge when an electron induces a local distortion, and thus, a polarization in the ionic lattice of the crystal [1]. This can be conceptually described as the electron being dressed by a surrounding cloud of phonons that accompanies its motion through the crystal. As a consequence of this dressing, the electron properties are modified (renormalized), including a reduced group velocity and an enhanced effective mass of the polaron compared to that of a free electron with the same crystal momentum. Although electron polaron effects have been deeply investigated in a wide range of materials [1], polaronic effects have not been extensively studied in semiconductors where electron-hole quasiparticles (excitons) dominate the optical response of the material. Semiconducting monolayers of transition metal dichalcogenides (TMDs) are of particular interest due to their ability to form excitons with large binding energies and simultaneously exhibit strong exciton–phonon coupling [2], making them a favorable platform for exploring exciton polaron physics. In this work, we present a microscopic description of exciton polarons in TMDs and show a systematic methodology to obtain their dispersion, group velocity and effective mass.

II. Methods

We consider MoS_2 monolayer as a representative two-dimensional semiconductor and compute in this material exciton polaron energies by iteratively determining the poles of Dyson equation [3]. Within this formalism, we described the self-energy of the exciton polaron using the Fan Migdal function. We further provide a systematic comparison of the contributions of optical and acoustic phonons to exciton polaron formation, considering both intra- and intervalley excitons.

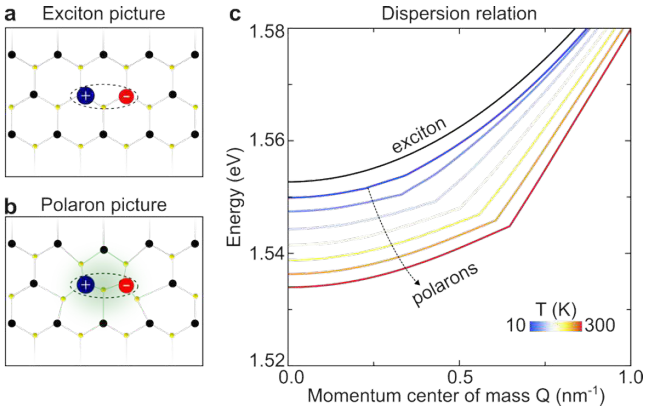

Fig. 1. **a** Schematic representation of an exciton in the hexagonal lattice of MoS_2. **b** Same as panel **a** but the lattice is distorted by the exciton. **c** Dispersion relations of 1*s* exciton (black line) in MoS_2 and acoustic exciton polarons at different temperatures (color lines).

III. Results and Discussion

Considering a single *s*-state exciton interacting with both acoustic and optical phonons in MoS_2 and WSe_2, we show that these interactions lead to the formation of exciton polarons in both materials. In particular, we find that the dispersion obtained from the Dyson equation exhibits a distinct kink at a characteristic momentum. This feature serves as a hallmark of polaron formation and emphasizes the crossover between a regime of bound exciton-polaron states and a regime dominated by exciton-phonon scattering. Below this characteristic momentum, well-defined bound polarons are formed, characterized by an energy redshift on the order of tens of meV and a mass enhancement of approximately 20% compared to that of 1*s* excitons with the same center-of-mass momentum (Fig. 1). We further show that these effects become increasingly pronounced with increasing temperature. Finally, we extend our methodology to include higher exciton states and incorporate momentum-dark excitons, thus providing a more comprehensive description of polaron formation in TMD monolayers.

IV. Conclusion

We develop a microscopic theoretical framework to investigate exciton polaron formation in two-dimensional semiconductors. Applying this framework to atomically thin semiconductors (MoS_2, WSe_2), we demonstrate that exciton-phonon interactions lead to the emergence of exciton polarons with modified group velocities, effective masses, and transport

below a specific critical momentum within the crystal. Our results provide a systematic analysis of polaronic effects in TMDs and establish a versatile methodology that can be extended to other excitonic materials, including perovskites and related TMD heterostructures.

***Abstract*— We demonstrate a Janus vortex meta-laser, which enables simultaneous asymmetric and full 2π phase modulation of two counter-propagating beams, owing to the asymmetric–symmetric hybrid configuration of the intracavity Janus metasurface.**

***Keywords*— vortex fiber laser; Janus metasurface; bidirectional light field control.**

I. Introduction

Metasurfaces (MSs), as a potent platform for light-field modulation, have been demonstrated to integrate compactly within laser cavities, allowing intracavity spatiotemporal light-field engineering with unprecedented precision[1]. Here, we demonstrate the Janus vortex meta-laser (JVML). By integrating a Janus metasurface (JMS), which is composed of merely a single-layer metasurface and a half-wave plate (HWP), this compact system with a streamlined design enables the asymmetric generation of vortex beams in two counter-propagating directions.

II. Methods

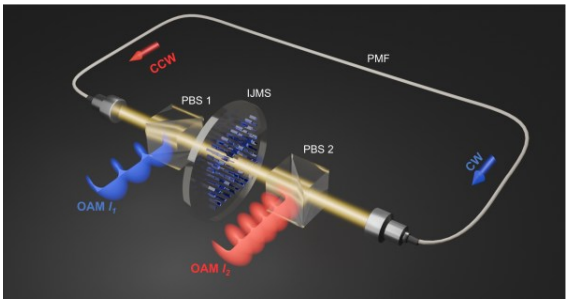

Fig. 1. The design of the Janus vortex meta-laser and the Janus metasurface. CW, clockwise; CCW, counterclockwise; PBS, polarization beam splitter; OAM, orbital angular momentum; PMF, polarization-maintaining fiber; IJMS, intracavity Janus metasurface.

The intracavity light field can be divided into two distinct categories based on its symmetry properties with respect to the wavevector (k) direction. For clockwise (CW) propagation light, the transmission matrix is given by $J_{CW} = \begin{bmatrix} a & b \\ c & a \end{bmatrix}$, while for light propagating in counterclockwise (CCW) direction, the corresponding matrix becomes $J_{CCW} = \begin{bmatrix} a & -c \\ -b & a \end{bmatrix}$. In this regime, the intracavity co-polarized component exhibits direction-independent symmetry, remaining invariant to the propagation direction. The cross-polarized component, however, displays a direction-dependent asymmetry, as it is interchanged when the k-vector direction is reversed. By harnessing this principle, our vortex laser design facilitates asymmetric structure-light emission while still fulfilling the self-consistency criterion for intracavity resonance [Fig. 1].

III. Results and Discussion

The results in Fig. 2 demonstrate that the JVML uniquely enables in-cavity, bidirectional generation of counter-propagating vortex beams (with topological charges $l_1 = -2$ and $l_2 = 8$), with different configurations achieving both high mode purity (>93%) and exceptionally large topological charges separation ($|\Delta\ell|$ up to 10).

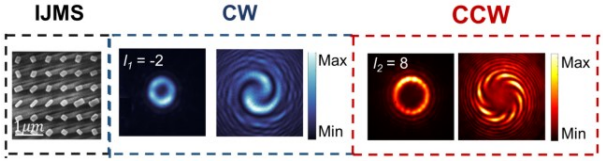

Fig. 2. Intracavity asymmetric bidirectional light-field manipulation in experiment.

IV. Conclusion

In summary, we demonstrate the first JVML, a novel architecture that enables direct intracavity generation of paired, counter-propagating vortex beams with, in principle, arbitrarily configurable topological charge separation, thereby introducing a novel degree of freedom for structured-light laser and opening up promising avenues in super-resolution microscopy, optical tweezers, precision measurement, optical communications, among others.

***Abstract*—We experimentally show a new mechanism for directly generating and tuning polarization entanglement for spontaneous parametric down-conversion (SPDC) in thin-film lithium niobate (TFLN), which relies on its three-fold rotational crystal symmetry. Furthermore, we demonstrate a nonlocal LN metasurface that supports frequency-tunable, degenerate and non-degenerate SPDC with doubly-resonant enhancement.**

***Keywords*— SPDC, thin-film lithium niobate, polarization-entanglement, frequency-tuning, nonlocal metasurface.**

I. Introduction

Entangled photon pairs play a pivotal role in many emerging applications including quantum communication, computing and sensing. While conventional photon-pair sources are based on spontaneous parametric down-conversion (SPDC) in bulk crystals or integrated photonic circuits, subwavelength-scale nonlinear crystals and resonant metasurfaces have emerged as a very versatile alternative [1], [2]. Here we show that leaving the track of phase-matched nonlinear bulk optics also allows the use of established nonlinear materials, such as lithium niobate (LN), in an unconventional way. We experimentally demonstrate that z-cut thin-film LN (TFLN) can directly generate photon pairs with continuously tunable polarization states. Interestingly, this does not require any specially engineered optical properties, but relies solely on LNs crystal symmetry. In the second part we demonstrate that a nonlocal metasurface consisting of TFLN combined with a nanostructured layer supports doubly-resonant and continuously frequency tunable photon-pair generation.

II. Results and Discussion

Implementations of (quasi-)phasematched SPDC in nonlinear TFLN almost exclusively relies on nonlinear interactions where pump, signal and idler wave propagate within the xy-crystal plane [3]. While this gives access to the largest nonlinear tensor component $\chi^{(2)}_{zzz}$, generation of polarization-entangled signal and idler photons is nontrivial and usually requires careful post-processing in additional optical circuitry. However, LN can actually *directly* generate polarization-entangled pairs when excited with a pump photon propagating along the z-axis – to our knowledge an approach not discussed in literature so far. The threefold rotational crystal symmetry around the z-axis enforces nonlinear tensors with equal magnitudes for polarization within the xy-plane, which can be exploited for generating polarization entanglement [4]. We experimentally demonstrate via quantum-state tomography that this tensor structure of LN enables direct generation of maximally entangled polarization Bell states for linearly polarized pump photons as well as continuous tuning of the degree of entanglement for elliptically polarized pump waves.

Next to polarization control we also demonstrate engineering of the SPDC spectrum in TFLN. For this we employ a nonlinear metasurface based on TFLN combined with a grating structure, effectively creating nonlocal guided-mode resonances in the LN layer. Momentum matching within one or multiple resonance bands provides resonant enhancement for both, signal and idler photon for any combination of energy degenerate or non-degenerate SPDC in the telecom band. Experimentally, we show SPDC with continuous tuning of the signal and idler wavelength from the degenerate case $\lambda_s = \lambda_i$ up to a wavelength difference $\Delta\lambda = 30$ nm. Both photons are always generated on resonance while their wavelength can be controlled via the incidence angle of the pump.

III. Conclusion

We demonstrate a new mechanism for generating and tuning polarization entanglement in TFLN and show doubly-resonant, spectrally tunable photon-pair generation in a nonlocal LN metasurface. These two examples highlight that LN thin films and metasurfaces offer very flexible engineering of the polarization and frequency properties of photon pairs while maintaining an extremely compact form factor.

***Abstract*—We develop an exact theory of photonic modes in 'open photonic time crystals', radiative nanoresonators with periodically time-modulated material properties. Our framework allows deriving analytical conditions for realizing parametric amplification in systems of arbitrary shape and size. We leverage our insights to design micro- and nanoscale parametric amplifiers.**

***Keywords*— metamaterials, dielectric nanophotonics, time-varying media, quasinormal modes, resonant states, non-Hermitian physics.**

I. Introduction

Over the past decades, advances in nanofabrication and materials science have enabled engineered composites with tailored electromagnetic responses, including metamaterials, metasurfaces, and photonic crystals made from dielectric or plasmonic nanoparticles [1], [2], [3]. Their unique optical behavior arises from nanoscale resonances that confine light and control its propagation, enabling functionalities beyond natural materials. Extending this concept to the temporal domain, materials with properties modulated in time open new opportunities for manipulating light [4], [5], [6], [7], [8]. Periodic modulation gives rise to photonic time crystals, where momentum bandgaps can lead to light amplification [5], [9], [10]. Implementing PTCs in finite, radiative nanostructures introduces new challenges, as resonances and radiation dominate their dynamics. To distinguish these systems from uniform, time-modulated media, we refer to the latter as 'bulk PTCs' and the former as 'open PTCs', emphasizing their ability to exchange energy with the environment. While most theoretical work has focused on bulk PTCs [11], [12], [13], understanding the interplay of radiation and temporal modulation in open PTCs is crucial for designing these devices at the nanoscale.

We have recently developed a general formalism to describe the photonic modes of open PTCs of arbitrary shape and size [14]. Here, we present this first-principles theory, highlighting how it predicts the conditions for parametric amplification of a photonic mode in a nanoresonator of complex shape.

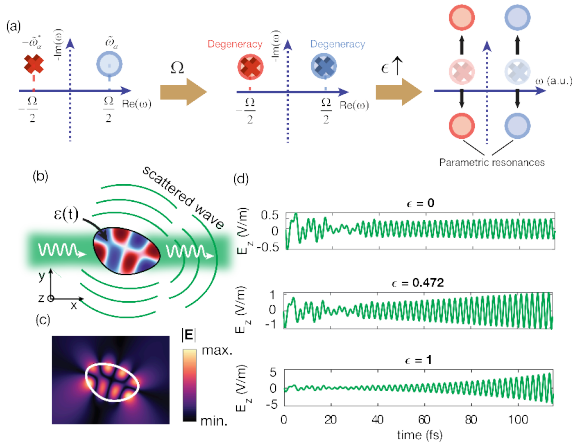

Fig. 1. (a) Sketch of the mechanism responsible for the formation of parametric resonances. Leftmost panel displays a static resonant state and its negative twin. Central panel shows the replicas from the two modes upon introducing a modulation Ω, such that $\Omega = 2\omega_\alpha$. Rightmost panel displays the modulated eigenfrequencies of the resonant states upon increasing the modulation amplitude. (b) Conceptual sketch depicting scattering of a plane wave (white arrows) by a complex-shaped cavity with periodically modulated permittivity. The static permittivity is fixed to $\varepsilon_u = 16$, emulating a high-index dielectric. (c) out-of-plane electric field of the considered unmodulated resonant state of the cavity. The resonant state has a quality factor $Q_\alpha \approx 52$. (d) Time domain simulations of the scattering by a plane wave with angular frequency $\omega = \mathrm{Re}(\tilde{\omega}_\alpha)$, when the permittivity is modulated at $\Omega = 2\mathrm{Re}(\tilde{\omega}_\alpha)$ at different modulation amplitudes ϵ. The plots show the z-component of the electric field at a point away from the scatterer along the direction of propagation of the incident plane wave.

II. Results and Discussion

We consider a sinusoidal modulation of the permittivity of an arbitrary resonator, with the following form

$$\varepsilon(t) = \varepsilon_u + \epsilon \sin(\Omega t). \tag{1}$$

As shown in our work [14], a photonic mode can amplify light when the modulation hybridizes it to a frequency-shifted replica of its negative twin. Consider a photonic mode α, whose eigenfrequency is given by $\tilde{\omega}_\alpha = \omega_\alpha - i\gamma$, where ω_α is the resonance frequency, and γ is the mode loss rate. As

sketched in Fig. 1(a), when $\Omega = 2\omega_\alpha$ a replica of the negative twin becomes degenerate with mode α.

Our theory then leads to a simple eigenvalue problem between the unmodulated photonic modes, given by

$$\begin{pmatrix} \frac{\Omega}{2} - i\gamma & 0 \\ -\Omega V & \frac{\Omega}{2} - i\gamma \end{pmatrix} \mathbf{c} = \tilde{\omega} \begin{pmatrix} 1 & V \\ -V & 1 \end{pmatrix} \mathbf{c}. \tag{2}$$

Here, the top component of $\mathbf{c}$ corresponds to the static photonic mode $\tilde{\omega}_\alpha$, while the bottom component represents the replica of its negative twin. The coupling coefficient V is obtained from the mode overlap:

$$V = \frac{\epsilon}{2i} \int |\mathbf{E}_\alpha(\mathbf{r})|^2 d\mathbf{r} \equiv \frac{\epsilon}{2i} I_\alpha. \tag{3}$$

For sinusoidal modulation, the integral is purely real since the negative twin is simply the complex conjugate of the positive-frequency mode [14].

Equation (2) can be solved exactly, but more insight is gained in the limit $V \ll 1$. With this approximation, the hybrid eigenfrequencies are:

$$\tilde{\omega}_\pm \approx \frac{\Omega}{2} - i\gamma \mp i I_\alpha \frac{\epsilon}{4} \sqrt{\Omega^2 + 4\gamma^2}. \tag{4}$$

The real parts remain $\mathrm{Re}(\tilde{\omega}_\pm) = \Omega/2$, while one of the imaginary parts increases with ϵ and the other decreases. A parametric resonance occurs when the modulation amplitude compensates the losses, bringing one eigenmode to the real axis. Beyond this threshold, further increase of ϵ can flip the sign of the imaginary part, effectively converting the mode into a lasing state, as illustrated in Fig. 1(a).

From Eq. (4), the modulation threshold ϵ_{thr} for any resonant state to become a parametric resonance can be easily found by setting the imaginary part to zero, giving:

$$\epsilon_{\text{thr}} \approx \frac{4\gamma}{I_\alpha \sqrt{\Omega^2 + 4\gamma^2}} = \frac{2\gamma}{I_\alpha |\tilde{\omega}_\alpha|}. \tag{5}$$

Equation (5) is a novel result allowing, without any fitting parameters, to estimate the required modulation amplitude to realize a parametric resonance for arbitrary open PTCs. It can be seen that the larger the imaginary part of the eigenfrequency is (the larger the decay rate), the larger will ϵ_{thr} need to be to bring it to the real axis. Therefore, it becomes clear that eigenmodes with small γ (large quality factors) can be more easily driven to the parametric regime. When $\gamma \ll |\omega_\alpha|$ and for small ϵ_{thr}, Eq. (5) simplifies to $\epsilon_{\text{thr}} \approx (Q_\alpha I_\alpha)^{-1}$, where Q_α is the quality factor of the unmodulated mode. This provides an accurate estimate of the threshold using only the mode's field and quality factor.

To illustrate that resonances govern amplification in open PTCs independent of size or geometry, we consider a complex two-dimensional high-index dielectric cavity shown in Fig. 1(b). We focus on a resonant mode in the visible range [Fig. 1(c)], which has a complex spatial profile and moderate quality factor $Q_\alpha \approx 52$, indicating significant radiation loss. Using Eq. (5), the parametric threshold is $\epsilon_{\text{thr}} \approx 0.48$.

To confirm our predictions, we perform time-domain simulations of a plane wave exciting the nanoresonator at $\omega = \omega_\alpha$ with the cavity modulated at twice the frequency. The initial time $t = 0$ is set at the start of the simulation, when the incident plane wave is turned on. We track the electric field 200 nm away from the resonator, shown in Fig. 1(d). In the unmodulated case, the field oscillates steadily at the frequency of the incident plane wave. Near the threshold, amplification emerges, and for $\epsilon > \epsilon_{\text{thr}}$, the field grows exponentially, signaling a lasing state [14], [15].

III. Conclusion

We have derived analytical conditions for parametric amplification and shown that they hold for open photonic time crystals of arbitrary shape and size. This generality confirms that our theory applies to a broad range of resonant systems, paving the way toward the rational design of time modulated nanophotonic devices, which are the natural next step in the control of light at the nanoscale.

Cavity-Enhanced Superfluorescence and Lasing Transitions in Two-Dimensional Single-Crystal Perovskite Superlattices

Jae Yong Suh[1,*]

[1]Department of Physics, Michigan Technological University, USA
*Corresponding author: jsuh@mtu.edu

***Abstract*—We report cavity-enhanced superfluorescence in pure two-dimensional (2D) perovskite single crystals. Unlike disordered thin films, these superlattices enable clean collective emission. Using Maxwell Bloch equations, we analyze the superfluorescence lasing phase transition and Burnham Chiao ringing within a microcavity, providing a framework for room temperature quantum optoelectronic devices.**

***Keywords*—superfluorescence, perovskites, microcavity, Maxwell-Bloch, phase transition.**

I. Introduction

Superfluorescence (SF) represents a hallmark of cooperative light-matter interaction. While typically observed at cryogenic temperatures, recent advancements in quasi-two-dimensional (2D) metal halide perovskites have enabled room-temperature observations [1-2]. However, standard quasi-2D thin films often exhibit ambiguous SF signatures due to phase impurities and structural disorder. In this work, we demonstrate that single-crystal microplatelets composed of a pure 2D superlattice—free of bulk phases—enable the observation of exceptionally clean SF characteristics. By integrating these crystals into 1D distributed Bragg reflector (DBR) microcavities, we investigate the cavity-enhanced SF regime and the transition into stimulated lasing.

II. Methods

Our High-quality Ruddlesden-Popper (RP) perovskite single crystals were synthesized via a solution-growth crystallization technique, producing $(PEA)_2PbX_4$ (X=Br,I) microplatelets with a strictly periodic 2D superlattice structure [3]. These crystals were subsequently integrated into 1D DBR microcavity structures. To capture the ultrafast dynamical emergence of SF, we employed Kerr-gated time-resolved spectroscopy. This technique utilizes a femtosecond gate pulse to induce transient birefringence in a Kerr medium, allowing for sub-picosecond temporal resolution of the collective emission pulses.

To model the dynamical emergence of SF, the system Hamiltonian is reduced to a semiclassical form by deriving equations of motion for the expectation values of the collective polarization (ρ_{ab}), inverse population (w), and cavity field amplitude (E). The governing Maxwell-Bloch equations are expressed as:

$$\frac{dE}{dt} = -\kappa E + ig\rho_{ab}$$

$$\frac{d\rho_{ab}}{dt} = -(\gamma_\perp + i\Delta)\rho_{ab} + igE_w$$

$$\frac{dw}{dt} = -\gamma_\parallel(w - w_0) + 4g\mathrm{Im}(E^*)\rho_{ab}$$

where κ is the cavity decay rate, g is the coupling strength, and γ represents the respective relaxation rates.

III. Results and Discussion

The experimental results reveal distinct SF signatures in the pure 2D superlattices, including a characteristic emission delay and a quadratic dependence of intensity on excitation power. Unlike thin-film counterparts, the single crystals exhibit clear Burnham–Chiao ringing near the excitation threshold.

Key findings include:

- **SF-Lasing Transition:** We identify a clear phase transition from collective SF to stimulated lasing governed by the cavity feedback strength.
- **Superlattice Role:** Analyses indicate that the ordered superlattice structure significantly lowers the SF threshold by facilitating long-range transition dipole alignment.
- **Ringing Conditions:** Theoretical modeling provides the boundary conditions for Burnham–Chiao ringing as a function of the collective pulse area.

IV. Conclusion

We have demonstrated that pure 2D perovskite superlattices serve as an ideal platform for cavity-enhanced superfluorescence. The transition between SF and lasing regimes is well-described by our Maxwell-Bloch framework, offering a predictive tool for designing next-generation

quantum light sources that operate at ambient temperatures

***Abstract*—We present an alternative approach based on the scattering-current multipole expansion to describe anapole excitations in photonic nanostructures. Using the method, we derive the exact anapole condition, opening the way towards design and realization of perfect anapoles.**

***Keywords*— anapoles, toroidal dipoles, multipole expansion.**

I. Introduction

Optical anapoles are localized excitations of electromagnetic fields that do not radiate, leading to nanoscale concentration of light energy. A popular example is an anapole originating from the destructive far-field interference of an electric dipole moment ($\mathbf{p}$) and a toroidal electric dipole moment ($\mathbf{T}$), which happens at the anapole condition ($\mathbf{p} + ik\mathbf{T} = 0$) [1]. Typically, the moments $\mathbf{p}$ and $\mathbf{T}$ are calculated using multipole expansion within the small-scatterer approximation [2]. Here, we demonstrate that this common description is often not accurate, and propose an alternative method based on the exact scattering-current multipole expansion [3]. The resulting anapole condition is valid for scatterers of arbitrary size and can be used to design perfectly nonradiating anapoles.

II. Methods

The commonly used approximate expressions for the electric dipole and electric toroidal dipole moments are

$$\mathbf{p} = \frac{i}{\omega}\int_{-\infty}^{\infty}\mathbf{J}d^3\mathbf{r}, \tag{1}$$

$$\mathbf{T} = \frac{k}{10\omega}\int_{-\infty}^{\infty}[(\mathbf{r}\cdot\mathbf{J})\mathbf{r} - 2r^2\mathbf{J}]d^3\mathbf{r}, \tag{2}$$

where $\mathbf{J}(\mathbf{r}) = -i\omega\epsilon_0[\epsilon_r(\mathbf{r}) - 1]\mathbf{E}(\mathbf{r})$ is the scattering current density (for a scatterer in vacuum), and $\epsilon_r(\mathbf{r})$ is the relative electric permittivity that depends on the coordinate $\mathbf{r}$. Outside the scatterer, ϵ_r = 1 and $\mathbf{J}$ = 0. The normalized scattering cross section due to $\mathbf{p}$ and $\mathbf{T}$ is given by

$$\sigma(\mathbf{p},\mathbf{T}) = \frac{k^4}{6\pi\epsilon_0^2E_0^2S}\left|\mathbf{p} + ik\mathbf{T}\right|^2, \tag{3}$$

where E_0 is the incident field amplitude and S is the geometric cross section of the scatterer. The conventional anapole condition is derived by setting $\sigma(\mathbf{p},\mathbf{T})$ to zero.

Alternatively to Eq. (3), the total electric-dipole scattering cross section can be calculated using the exact multipole expansion [4], which is valid for scatterers of arbitrary size. Considering only the dipole moment along z, this cross section can be written as

$$\sigma(a^E_{l=1}) = \frac{3\pi}{k^2S}\left|a^E_{l=1,m=0}\right|^2, \tag{4}$$

where l and m are the spherical harmonics' indices corresponding to the subsequent multipole expansion terms. We have recently derived the expressions for $a_{l,m}$ (both electric $a^E_{l,m}$ and magnetic $a^M_{l,m}$) in terms of the scattering-current multipole moments [3]. Specifically, we have obtained

$$a^E_{l=1,m=0} = \sqrt{2}C_1p_z^{\text{exact}} + \frac{7\sqrt{2}}{3}C_3O^{\text{exact}}, \tag{5}$$

where $C_1 = -ik^3/(6\pi\epsilon_0E_0)$, $C_3 = -ik^5/(210\pi\epsilon_0E_0)$, and

$$O^{\text{exact}} = 3O_{xxz} + 3O_{yyz} + 2O_{zzz} - O_{zxx} - O_{zyy}. \tag{6}$$

Here, the superscript "exact" in the $O_{\alpha\beta\gamma}$ terms is omitted for clarity. The scattering-current dipole and octupole moments p_z^{exact} and $O_{\alpha\beta\gamma}$ are defined as

$$p_z^{\text{exact}} = \frac{i}{\omega}\int_{-\infty}^{\infty} j_0(kr)\,J_z\,d^3\mathbf{r}, \tag{7}$$

$$O_{\alpha\beta\gamma} = \frac{15i}{2\omega k^2}\int_{-\infty}^{\infty}\frac{1}{r^2}j_2(kr)\,J_\alpha r_\beta r_\gamma d^3\mathbf{r}. \tag{8}$$

Equations (4)-(8) yield correct values of the scattering cross sections for scatterers of an arbitrary size. Based on these expressions, the exact anapole condition is written as

$$p_z^{\text{exact}} + \frac{k^2}{15}O^{\text{exact}} = 0. \tag{9}$$

The above equation shows that, in fact, the anapole originates from destructive interference between the far-field radiation contributions of scattering-current dipoles and octupoles.

III. Results and Discussion

Let us consider a silicon nanodisk of radius 300 nm and thickness 60 nm in vacuum. The nanodisk's orientation with respect to the incident light is shown in Fig. 1(a). The scattering is modeled numerically using COMSOL Multiphysics. The spectral dependences of the calculated scattering cross sections are shown in Fig. 1(b). The dependences show a clear scattering dip at a frequency of 308 THz (wavelength ~974 nm). The electric field distribution at this dip, shown in Fig. 1(a), is typical for an anapole excitation.

Fulfilling the anapole condition based on the approximate expressions [Eqs. (1)-(3)] is demonstrated in Fig. 1(c) and (d). In this figure, p_z and $-ikT_z$ are plotted together, intersecting at almost the same frequency in both amplitude and phase. This near-perfect coincidence leads to an almost complete suppression of $\sigma(\mathbf{p},\mathbf{T})$, with the cross section magnitude falling down to 0.064, as can be seen in Fig. 1(b). However, Fig. 1(b) also shows that the exact electric-dipole scattering

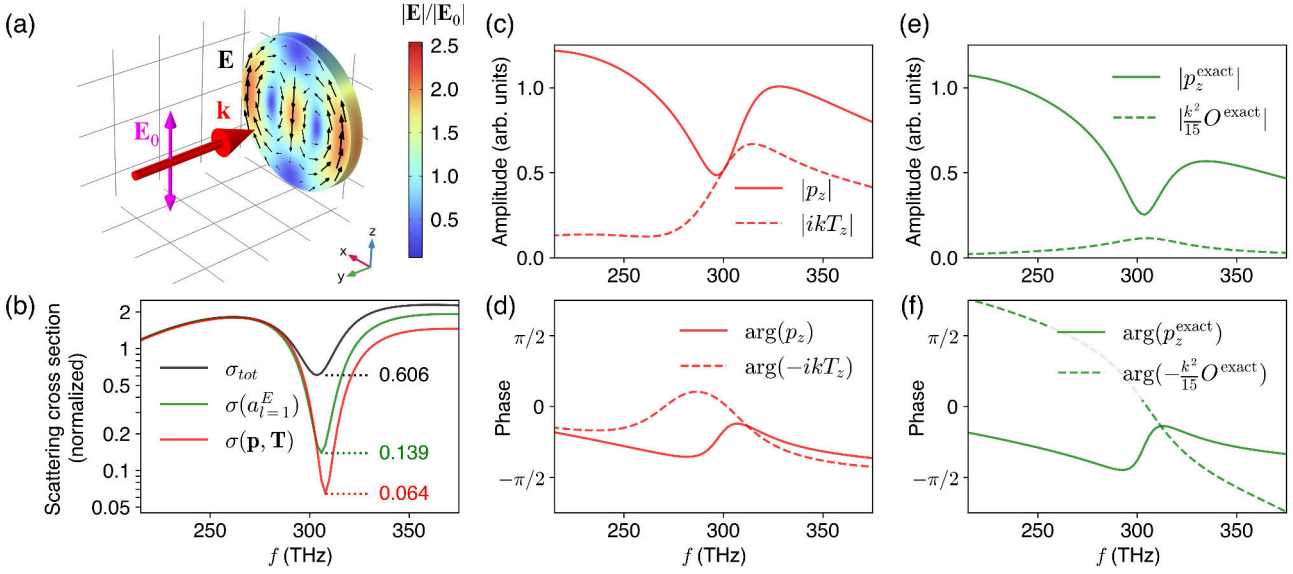

Fig. 1. (a) Excitation configuration ($\mathbf{E}_0$ and $\mathbf{k}$ - incident electric field and wave vector, respectively) and simulated electric field distribution (vector $\mathbf{E}$ and amplitude enhancement $|\mathbf{E}|/|\mathbf{E}_0|$) at the surface of a silicon nanodisk (thickness 60 nm, diameter 600 nm) at frequency 308 THz, corresponding to the anapole excitation. (b) Total scattering cross section (σ_{tot}, black curve), scattering cross section associated with the electric dipole and electric toroidal dipole moments $\sigma(\mathbf{p}, \mathbf{T})$, as defined in Eqs. (1)-(3) (red curve), and total electric-dipole scattering cross section $\sigma(a^E_{l=1})$ (green curve) obtained from the exact multipole expansion. The values at the scattering minima are shown for $\sigma(\mathbf{p}, \mathbf{T})$ and $\sigma(a^E_{l=1})$ by the corresponding red and green numbers. (c) and (d): Amplitude and phase of the electric dipole and electric toroidal dipole moments along z, calculated using Eqs. (1)-(2) (p_z and T_z, solid and dashed red curves, respectively). (e) and (f): Amplitude and phase of the exact scattering-current dipole moment p_z^{exact}, as defined in Eq. (7) (solid green curves), and the exact scattering-current octupole moments combined into $\frac{k^2}{15}O^{\text{exact}}$, i.e., the second term in Eq. (9), as defined in Eqs. (6) and (8) (dashed green curves).

$\sigma(a^E_{l=1})$ that includes scattering-current octupoles is associated with nearly twice as large a cross section at this point (0.139).

The reason for this imperfect scattering cancelation becomes clear after investigating the exact anapole condition defined by Eq. (9). Although the scattering-current dipole moment p_z^{exact} is perfectly out-of-phase with respect to the contributing octupole moments O^{exact} [see Fig. 1(f)], their amplitudes are far from identical [see Fig. 1(e)]. This reveals a room for improvement that would have been overlooked by using the approximate expressions. We also note that the total scattering cross section (σ_{tot}) is about 0.6 at the minimum due to a non-negligible contribution from unaddressed multipole moments.

IV. Conclusion and Outlook

The commonly used Eqs. (1)-(2) are valid only for deep-subwavelength scatterers, which makes them imprecise in designing nanostructures supporting anapoles, typically requiring dimensions on the order of $\lambda/2$ and larger. We present an alternative approach using a scattering-current multipole expansion, which is exact and valid for scatterers of arbitrary size. This approach opens the way to accurately design and realize perfect anapoles. For example, by using this approach, the nanodisk geometry considered here could be redesigned to enhance the octupole moments, matching the amplitudes of $\frac{k^2}{15}O^{\text{exact}}$ and p_z^{exact}. We believe that our method may unlock new capabilities of nanoscale light confinement by anapoles, which then could compete with, and possibly outperform, the recently widely explored quasi-bound states in the continuum. Experimental realization of such ideal anapole excitations on the III-V semiconductor platform is part of our ongoing work.

***Abstract*—We introduce our research on the development of infrared devices with high wavelength-selectivity. The strategy for selecting appropriate materials as well as optimizing device geometries are presented based on electronic band structure calculation and electromagnetic simulations. The devices can be applied to narrowband photothermal converters and ultrahigh Q value biosensors.**

***Keywords*—metasurfaces, Ni-based superalloy, quasi-bound state in continuum (qBIC), silicon.**

I. Introduction

Wavelength-selective light absorbers and emitters, or spectroscopic energy transducers for light, are expected to provide wide variety of applications in energy harvesting, remote and perceptive sensors for IoT devices. Especially, narrowband perfect absorption and emission in the infrared (IR) region are critical prerequisites for modern spectroscopy and energy applications such as non-dispersive infrared (NDIR) gas sensors, IR radiative heaters, and thermo photovoltaics. In this talk, we demonstrate our methodology to achieve narrowband IR absorption and thermal emission based on 2D and 3D nano architectures combined with IR plasmonic materials[1,2].

II. Results and Discussion

We investigated Ni–Al intermetallic compounds as thermally stable plasmonic building blocks for IR photothermal applications. Ni- or Al-based superalloys are thermally stable, heat-resistant materials that have been widely employed in automobile and aviation technologies. DFT calculations were employed to investigate the chemical compositions, crystal structures, and optical properties of the Ni–Al compounds. The candidates that exhibited the best optical properties were chosen for experimental characterization, including dielectric function measurements. Second, electromagnetic microdevice optimization was performed to determine the design of IR microdevices. We also examined the "material–device relationship" of the Ni–Al intermetallic compounds by benchmarking the microdevice performance and selected NiAl as the best material. Additionally, we benchmarked both the optical properties of NiAl and the performance of its microdevices against other well-known metals to highlight the potential of NiAl[1].

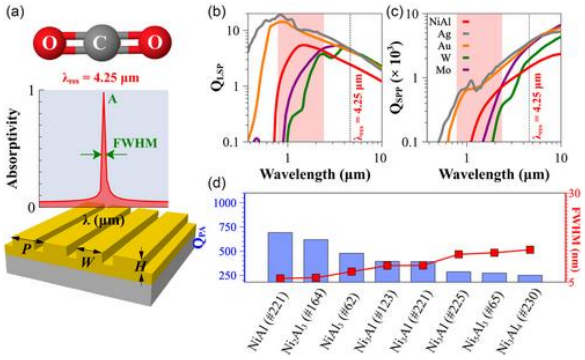

Fig. 1 a) Narrowband absorber with grating configuration. Comparison of two FOMs: b) Q_{LSP} and c) Q_{SPP} for NiAl and conventional plasmonic materials (Ag, Au, W, and Mo). The red area represents the near-IR region (0.78–2.5 μm). d) Quality factors (Q_{PA}) (blue bar plot) and FWHMs (red line plot) of all Ni–Al compounds-based grating devices constructed using the optimal structural parameters.

We have also explored the possibility of adopting low-loss semiconducting Si for ultrahigh quality (Q) factor infrared sensing applications. Quasi-bound states in the continuum (qBICs) have attracted great attention owing to their ultrahigh Q factors and strong electric field enhancement. The resulting enhancement of light–matter interactions has become among the key subjects of interest and stimulated particular interest in sensing applications in the IR region. In this study, we optimized the geometry of qBIC metasurfaces to realize resonant absorption with ultrahigh Q value for the sensing application down to single nanoparticles, or to monolayer regime[2]. Our proposed device offers promising opportunities for simple, cost-effective, and highly sensitive detection of virions and other pathogenic nanoparticles or molecules. We will also discuss the designs and possibilities of ultrahigh Q IR emitters based on our qBIC architecture.

***Abstract*—We demonstrate broadband infrared imaging enabled by nonlinear wave mixing in a resonant dielectric metasurface. A pump beam at the resonant wavelength can enhance infrared-to-visible conversion, allowing detection with a conventional visible camera. Dynamic phase modulation of the pump via a spatial light modulator enables programmable, multifunctional, and reconfigurable imaging.**

***Keywords*— metasurfaces, nonlinear optics, infrared imaging.**

I. Introduction

Conventional infrared imaging techniques rely on infrared cameras that are costly, offer limited spatial resolution, lack colour information, and often require active cooling. Recent advances in metasurfaces have introduced a new pathway for infrared-to-visible conversion via nonlinear wave mixing with significantly relaxed phase-matching conditions, enabling direct visualisation of infrared images using standard visible cameras [1], [2]. However, efficient upconversion typically relies on resonant enhancement at the signal or emission wavelength, restricting the operational bandwidth to narrow resonant windows and thereby limiting practical applicability.

Here, we overcome this limitation by introducing a nonlinear imaging platform in which a pump beam, rather than the signal or generated harmonic, is tuned to couple to the metasurface resonance for enhancing wave mixing processes [3]. This strategy decouples the imaging bandwidth from the intrinsic resonance linewidth and enables broadband nonlinear imaging of arbitrary objects using a single metasurface. Furthermore, by incorporating a spatial light modulator (SLM) to engineer the phase profile of the pump beam, we realise multifunctional and programmable infrared imaging. Combined with evolutionary optimisation, the platform enables dynamic image control and tunable nonlinear focusing, establishing a reconfigurable framework for computational and multifunctional infrared imaging [4], [5].

II. Results

We first design and fabricate a Si metasurface consisting of a Si film with Si nanodisks arranged periodically on top of the film, supporting a guided-mode resonance around 1130 nm (Fig. 1(b)). A pump beam tuned to this resonance wavelength is employed to enhance the four-wave mixing (FWM) process via resonant field confinement within the nanostructures. By tuning the signal wavelength from 1350 to 4700 nm, resonantly enhanced and high-efficiency FWM emission is consistently observed across the entire spectral range, as shown in Fig. 1(c). This pump-resonant configuration establishes the foundation for broadband infrared-to-visible upconversion imaging using a metasurface and a conventional visible silicon camera. As a result, we demonstrate broadband infrared imaging spanning wavelengths over 1000 to 4000 nm for arbitrary objects, with the upconverted images directly captured by a CMOS visible camera, as illustrated in Fig. 1(a).

Furthermore, we integrate a SLM into the nonlinear imaging system to enable real-time programmable nonlinear wavefront shaping using a single silicon metasurface composed of nanodisk arrays. The SLM and CMOS camera are connected through a genetic algorithm (GA), which iteratively optimises the phase distribution imposed on the pump beam based on the captured nonlinear images. The optimisation proceeds generation by generation until the nonlinear emission pattern converges to the target image as demonstrated in Fig. 2(a). By designing a metasurface resonance at 1510 nm, efficient third-harmonic generation (THG) is achieved, allowing infrared illumination to be converted into visible light after SLM modulation. Owing to the cubic intensity dependence of the THG process, the metasurface inherently suppresses weak background fluctuations, effectively performing a nonlinear denoising operation on the wavefront. These results demonstrate a dynamically reconfigurable nonlinear metasurface platform with strong potential for real-time optical computation, adaptive information processing, and multifunctional infrared imaging as exhibited in Fig. 2(b).

Finally, we further exploit SLM-based pump phase modulation to realise multifunctional infrared imaging (Fig. 2(c)). Specifically, we utilise sum-frequency generation to convert infrared light into the visible, where the pump beam modulated by SLM constructs an optically reconfigurable virtual lens. This approach enables precise control over the phase of the generated nonlinear optical field, resulting in programmable focusing of the upconverted emission. Both theoretical and experimental results demonstrate a tunable nonlinear focusing mechanism, in which the effective focal length can be continuously adjusted by varying the pump and signal wavelengths, as well as the phase distribution. Importantly, since the focal length depends on the input signal wavelength, the imaging plane position varies accordingly, indicating a promising po-

tential for multispectral infrared imaging applications.

III. Conclusion

Overall, we demonstrate a pump-resonant nonlinear metasurface platform that enables broadband infrared-to-visible upconversion imaging. By decoupling the conversion efficiency from the signal bandwidth, infrared images across a wide spectral range can be directly captured using a conventional silicon camera. Through SLM-based pump phase modulation, programmable nonlinear wavefront shaping and tunable multispectral focusing are achieved within a single static metasurface. This work establishes a dynamically reconfigurable nonlinear imaging architecture, offering a versatile framework for computational and multifunctional infrared photonics.

***Abstract*—Ultrafast resonant orbital excitation of transition-metal (TM) ions offers a powerful approach to drive spin dynamics in two-dimensional (2D) van der Waals (vdW) materials. In this work, we investigate mixed 2D systems containing different TM ions. Our findings demonstrate the mixing of TM species as a versatile strategy for engineering photomagnetism.**

***Keywords*— photoengineering, van der Waals materials, 2D antiferromagnetism, ultrafast magnetism, magnonics.**

I. Introduction

Ultrafast optical control of antiferromagnetic order is a key goal in spintronics and magnonics [1]. Resonant excitation of local orbital degrees of freedom, such as d–d transitions in transition-metal ions, offers a direct route to modify magnetic exchange and anisotropy on femtosecond timescales [2], [3], [4]. However, orbitally driven photomagnetism has been demonstrated in only a few materials, and the factors governing its efficiency remain unclear.

In this work, we study ultrafast spin dynamics induced by resonant pumping of d–d transitions in layered antiferromagnetic thiophosphates $Mn_{1-x}Ni_xPS_3$. First, we establish the photomagnetic response in single–magnetic-ion compounds [3], [4], where local orbital excitation triggers coherent spin precession via ultrafast anisotropy modulation. Then, we extend this approach to mixed compounds containing two distinct transition-metal ions, demonstrating that selective excitation of specific orbital resonances strongly enhances the efficiency and controllability of magnon generation.

II. Methods

Our methodology is based on the use of the ultrafast pump-probe method, where the first pulse (pump) triggers spin dynamics, which can be captured by the second pulse (probe) with time delay [5]. The pump photon energy $h\nu$ was tuned across different $d-d$ transitions of Ni and Mn ions. As a probe, we measured magnetic second harmonic generation (mSHG) and magnetic linear birefringence (mLB). These probes allow us to distinguish the antiferromagnetic order and to detect the spin dynamics.

III. Results and discussion

The main and very important observation is that $d-d$ transitions from Ni have a significantly larger photomagnetic response than from Mn, such that even at a 9:1 substitution of Mn:Ni, the spin-waves generated by photoexcitation of Ni $d-d$ transitions are nearly 15× larger than that generated by Mn. Surprisingly, the transition most effective for driving spin dynamics – one particular $d-d$ transition of Ni – is low optically active; however, it surpasses all Mn and the more optically active Ni *d-d* transitions.

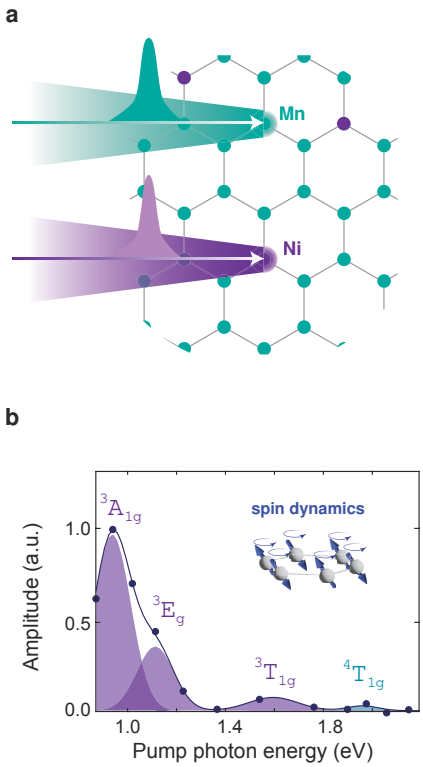

Fig. 1. (a) Schematics of the experiment. Mn (turquoise) and Ni (purple) ions form a hexagonal lattice and are randomly distributed; this image shows the fraction 9:1 of Mn:Ni. Pump photon energy was tuned across different $d-d$ transitions. (b) The amplitude of the excited spin dynamics as a function of pump photon energy. Dots are experimental data-points: solid line is a fit with four Gaussian peaks (shaded) corresponding to three Ni resonances (purple) and one Mn resonance (turquoise).

IV. Conclusions

Altogether, our results identify general design principles for orbitally driven photomagnetism in collinear antiferromagnets and establish transition-metal substitution as a powerful strategy for achieving efficient ultrafast control of antiferromagnetic spin dynamics.

***Abstract*—Valley coherence encodes quantum information in the relative phase of inequivalent momentum valleys, yet controlled intervalley coupling at room temperature remains challenging in monolayer semiconductors. We demonstrate that chiral liquid crystals enable near-field coupling between K and K' excitons via helicity-selective Bragg reflection accompanied by spin-flip, offering a scalable route toward valleytronic functionalities.**

***Keywords*— Valleytronics, chiral liquid crystal, monolayer semiconducting transition-metal dichalcogenides**

I. Introduction

Valley coherence in transition-metal dichalcogenide (TMD) monolayers relies on the coherent superposition of excitons residing in inequivalent K and K' valleys. However, at room temperature, rapid intervalley decoherence typically suppresses any steady-state linear polarization of the emitted photoluminescence. Here, we demonstrate that a properly engineered chiral photonic environment can instead mediate and stabilize intervalley coherence under ambient conditions.

II. Results and Discussion

By placing a WSe_2 monolayer on a chiral nematic liquid crystal supporting circular Bragg reflection, we exploit helicity-selective spin-flip reflection to induce an intrinsically unidirectional optical feedback between inequivalent valleys (Fig. 1). The optical response was investigated by polarization-resolved photoluminescence measurements, enabling both circular and linear polarization analysis of the emitted signal.

Experimentally, we observe a strong circular dichroism within the photonic band gap (Fig. 2a), associated with the emergence of a pronounced linear polarization component (Fig. 2b) revealing the existence of a coupling process responsible for the intervalley coherence. Within a Maxwell–Bloch framework, this process is captured by a coupling rate, which we estimate to exceed the excitonic decoherence rate. Numerical simulations support this picture by showing that circular Bragg reflection provides an efficient near-field feedback mechanism, consistent with a photonic spin-flip process capable of mediating intervalley coupling.

Fig. 1. Schematic representation of the coupling process for a monolayer deposited on a left-handed CLC. The emission of A ↻ and A ↺ excitons, associated with the K and K' valleys, is depicted.

Fig. 2. **a**) Photoluminescence spectra for right- (σ^-) and left-handed (σ^+) circular components. (**b**) Polar plots of the linear polarization-resolved emitted PL.

III. Conclusion

Our results establish chiral photonic spin-flip reflection as a scalable and room-temperature mechanism to mediate intervalley coupling.

Optical Properties Tuning of Quantum Emitters in WSe_2 Monolayers

Javier Martín-Sánchez[1,2]

[1]University of Oviedo, Spain
[2]Nanomaterials and Nanotechnology Research Center CINN CSIC, Spain

Abstract— We demonstrate strain control of quantum emitters in WSe_2 monolayers using piezoelectric actuators. Applied voltage enables reversible tuning of emission energy and brightness while preserving single photon purity. Strain modifies the excitonic potential landscape, enabling exciton redistribution. These results establish strain engineering as a tool for tunable photonic devices.

Keywords— quantum emitters, two dimensional materials, strain engineering, excitons, piezoelectric devices

I. Introduction

Quantum emitters in transition metal dichalcogenide monolayers, particularly WSe_2, have emerged as promising single photon sources due to their atomically thin nature, strong excitonic effects, and compatibility with nanophotonic integration [1]. Localized excitons formed by strain gradients generate discrete emission lines with single photon characteristics [2]. However, in most strain engineering approaches, the strain configuration is static, limiting the ability to dynamically control emission energy, brightness, and spectral uniformity among emitters. Achieving active and reversible control of these properties is essential for scalable quantum photonic technologies. In this work, we introduce a hybrid piezoelectric semiconductor platform that enables voltage controlled strain engineering [3]. This approach allows continuous and reversible tuning of the emission energy and intensity of individual quantum emitters by modifying the excitonic potential landscape, enabling dynamic control of single photon sources in two dimensional materials [4,5].

II. Methods

Monolayer WSe_2 flakes were mechanically exfoliated and transferred onto piezoelectric PMN-PT substrates patterned with micropillars. These pillars generate localized strain gradients that induce the formation of quantum emitters. By applying an external voltage across the piezoelectric actuator, controllable in-plane and out-of-plane strain fields were introduced, enabling dynamic modulation of the excitonic confinement potential. Optical characterization was performed using low temperature micro photoluminescence spectroscopy, allowing spatial and spectral resolution of individual emitters. Finite element simulations were used to model the strain distribution and bandgap modulation induced by the applied voltage. Additionally, drift diffusion modeling was employed to simulate exciton transport and redistribution under strain, providing insight into the mechanisms governing the observed optical modulation.

III. Results and Discussion

The application of voltage to the piezoelectric actuator induces controllable strain fields in the WSe_2 monolayer, enabling precise modulation of the optical emission of quantum emitters. We observe reversible spectral shifts of the emission lines reaching values up to several meV, and up to 18 meV in optimized configurations, demonstrating a wide tuning range without introducing degradation in the optical quality of the emitters. Time correlation measurements confirm that the single photon nature of the emission is preserved under strain, indicating that mechanical deformation does not affect photon purity or recombination dynamics.

In addition to energy tuning, strain also produces significant changes in the emission intensity of individual emitters. Some emitters become brighter while others are suppressed, indicating a redistribution of excitons across localized potential wells. Importantly, the total integrated emission remains nearly constant, demonstrating that strain does not significantly alter the total exciton population but rather modifies their spatial distribution. This behavior can be explained by strain induced changes in the band structure, which reshape the local potential landscape and influence exciton diffusion and capture processes.

Finite element simulations reveal that the strain distribution is highly non-uniform at the nanoscale, particularly near wrinkles or pillar edges, leading to both tensile and compressive strain regions. As a result, different emitters exhibit distinct spectral responses, including shifts with opposite sign depending on their position within the wrinkled monolayer. These findings demonstrate that strain engineering enables not only spectral tuning but also control of exciton localization and emission intensity, providing a versatile method for manipulating quantum emitters in two dimensional semiconductors.

IV. Conclusion

We have demonstrated a versatile piezoelectric strain engineering platform enabling dynamic control of quantum emitters in WSe_2 monolayers. Strain allows reversible tuning of emission energy over a wide spectral range while preserving single photon emission quality. Furthermore, strain induced modifications of the excitonic potential landscape enable controlled redistribution of excitons, resulting in tunable emission intensity. These combined capabilities provide a comprehensive method for controlling both spectral and intensity properties of quantum emitters. This approach represents a key step toward the realization of tunable, scalable, and integrated quantum photonic devices based on two dimensional materials.

Abstract—**We implement differentiable electromagnetic solvers for gradient-based inverse design of various optical systems. The differentiable eigenmode expansion solver is applied to photonic integrated circuits, and the differentiable RCWA solver to metasurfaces for mobile image sensors. Analytic derivatives combined with automatic differentiation enable fast and accurate large-scale optimization.**

***Keywords*— inverse design, metasurface, photonic integrated circuit, image sensor.**

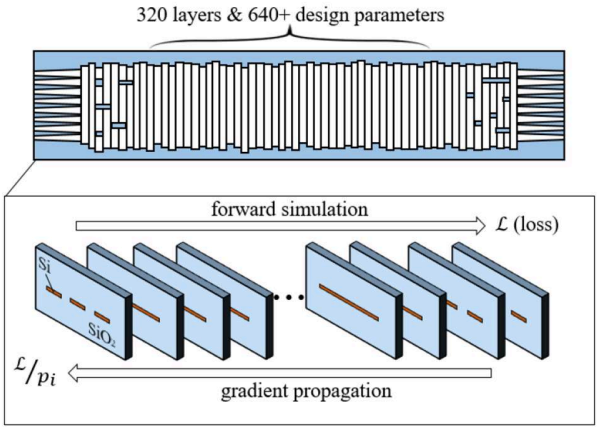

Fig. 1 Design procedure using the differentiable eigenmode expansion method (DEME).

I. Introduction

Gradient-based inverse design of large photonic structures requires efficient derivative evaluation. We implement eigenmode expansion and RCWA solvers within a framework combining analytic derivatives[1] and automatic differentiation, supporting scalable optimization of guided-wave and plane-wave devices.

II. Methods

The eigenmode expansion solver includes analytic derivatives of modal propagation and coupling operators. The RCWA solver provides analytic gradients of scattering responses. Both are embedded in an automatic differentiation pipeline to compute gradients with respect to design parameters for gradient-based optimization.

III. Results and Discussion

The mode-based solvers reduce computational cost by leveraging their scattering matrix formalism with reduced-dimensional modal representations. Matrix operations are performed in compact subspaces, and intermediate results are reused across optimization steps. This enables faster forward simulations and gradient evaluations compared to time-domain solvers such as FDTD. Large photonic structures are optimized efficiently while maintaining numerical accuracy and stable convergence.

IV. Conclusion

Differentiable eigenmode expansion and RCWA provide practical tools for large-scale photonic inverse design. The integration of analytic derivatives with automatic differentiation enables fast and accurate optimization of integrated photonic structures and metasurfaces relevant to mobile image sensors.

***Abstract*— By combining passive backbones with active materials, hybrid photonic crystal (PhC) platforms facilitate devices with superior performance and novel functionalities. Planar resonant cavities provide similar physical effects but offer a simpler alternative in terms of design and manufacturing.**

***Keywords*— hybrid photonic platforms, photonic crystals, resonant cavity, colloidal quantum dots, phosphors, nanolasers.**

Photonic crystals (PhCs) play a pivotal role in exploring intriguing scientific phenomena and developing highly efficient nanophotonic devices. Our research focuses on hybrid PhC platforms that integrate passive photonic backbones—engineered to induce specific nanophotonic effects—with optically active materials capable of photon absorption and emission. These hybrid architectures enable the high efficiency, low cost, and ease of fabrication required for next-generation photonic applications. The nanophotonic structures in our platforms typically utilize two-dimensional (2D) PhCs formed on planar backbones of high-refractive-index materials such as TiO_2 or Si_3N_4.

By leveraging photonic band-edges at the Γ-point, we utilize localized electric field enhancements at periodic "hot spots" commensurate with the underlying PhC structure. Strategically placing active materials at these hot spots maximizes light-matter interaction, leading to superior device performance. When the Γ-point resonance is tuned to the emission of the active material, it facilitates vertical lasing; specifically, by employing symmetry-protected bound-states-in-the-continuum (BIC) modes, we can exploit nearly infinite quality factors to reduce lasing thresholds by orders of magnitude [1]. Conversely, when the band-edge mode is tuned to the absorption band, the platform serves as an efficient PhC phosphor, significantly improving color conversion through the enhanced absorption of excitation photons [2].

Another vital hybrid platform in our research is the resonant cavity (RC) structure, which consists of a half-wavelength-thick cavity layer sandwiched between two distributed Bragg reflectors. By incorporating optically active materials within the cavity, we can achieve enhanced emission or absorption depending on the specific resonance conditions. While vertical-cavity surface-emitting lasers represent the standard application for emission-tuned resonances, absorption-tuned cavities serve as efficient color-conversion devices. Our group has successfully demonstrated this potential by developing an RC-based phosphor platform for full-color displays [3]. Moving forward, we expect hybrid PhC platforms to continue diversifying in structure and material composition, expanding their utility across a broad spectrum of future photonic applications.

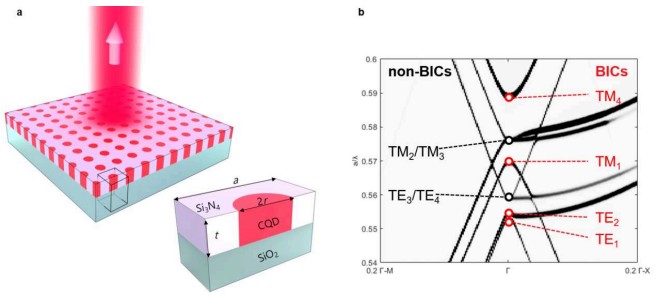

Fig. 1 Schematic of 2D PhC BIC laser platform and associated photonic band structure near Γ-point.

***Abstract*— We show that the sole knowledge of an object's limited size allows to achieve far-field label-free resolution beyond the Abbe-Rayleigh diffraction limit: higher resolution is achieved for smaller objects. We experimentally image subwavelength-size nanoparticles with λ/8 resolution. Furthermore, by adopting a physics consistent learning model we can increase resolution to λ/13.**

***Keywords*— diffraction limit, superresolution microscopy, machine learning.**

I. Introduction

Label-free far-field super-resolution optical imaging is achievable by allowing sufficient prior knowledge of the object such as its sparsity or accumulated through a posteriori examination of a similar class of object. Here, we show that the sole knowledge that the object is located in a field of view of limited size is sufficient to achieve super-resolution beyond the Abbe-Rayleigh diffraction limit: a higher resolution can be achieved with smaller objects.

To prove this, we developed an imaging method that is reciprocal to generating superoscillatory fields. We first quantify the fundamental trade-off between resolution and object size and identify a photon budget for the targeted resolution using a quantum Fisher information analysis. For the experiment, we measure coefficients of the field scattered from the object based on orthonormal field-of-view-limited Slepian-Pollak functions using a variable mask. We quantify the required photon numbers for the tomographic measurement considering the distortion of the optical setup using a Fisher information analysis. We experimentally achieve λ/7 and λ/8 resolution for the two-dimensional and one-dimensional imaging of subwavelength objects. The imaging resolutions are confirmed by various quantitative criteria such as effective bandwidth, point spread function, and Siemens star test.

Furthermore, we extend the method using a learning model trained on physics-consistent examples that can exploit correlations between accurately measured low-order Slepian-Pollak modes and noise-sensitive high-order modes. This enables robust recovery of deep sub-diffraction geometric features in our nanostructures and allow us to achieve imaging resolution of λ/13.

Our limited size object microscopy (LSOM) is a far-field imaging method that requires no assumption of the shape and complexity of the object and its labelling, thus allowing a wide range of applications in nanotechnology and biological studies of nanoparticles and isolated microorganisms.

Subwavelength metamaterials for modal and thermo-optic control in silicon interferometers

***Abstract*— Subwavelength metamaterials are becoming essential building blocks for the next generation of photonic integrated circuits. In this work, we explore their potential for loss reduction and thermo-optic control in advanced interferometers for the silicon-on-insulator platform.**

***Keywords*— Integrated optics, silicon photonics, subwavelength metamaterials.**

I. Introduction

Silicon-on-insulator (SOI) microspectrometers have gathered a great interest for diverse on-chip applications such as biological analysis, environmental monitoring, and remote sensing. Spatial heterodyne Fourier-transform (SHFT) microspectrometers, implemented through arrays of linearly-increasing Mach-Zehnder interferometers (MZIs), provide high resolution and optical throughput in compact footprints [1]. However, as greater spectrometer resolutions are targeted, insertion losses and thermal dependence of the constituent MZIs become increasingly critical. In this work, we tackle both challenges through the use of subwavelength grating (SWG) metamaterials [2], providing novel SWG building blocks for modal and thermo-optic control in SOI interferometers.

II. Power Management

Firstly, we introduce a new achromatic splitter architecture [3] that uses a Y-junction with a customized SWG transition at the junction tip, achieving the broadest bandwidth reported to date for a nanophotonic silicon power splitter. The device was simultaneously optimized for the TE_0 and TE_1 modes and also showed excellent performance for the fundamental TM_0 mode. In 3D FDTD simulations, the splitter demonstrated exceptionally low excess loss—below 0.2 dB for both TE_0 and TE_1 modes—across a 700 nm wavelength span (1300–2000 nm). For the TM_0 mode, excess loss remained under 0.3 dB over a 500 nm range (1300–1800 nm). Experimental measurements, though constrained by the available setup, closely matched the simulated results and verified low excess losses for all three modes within the 1430–1680 nm window. The device also exhibited strong resilience to fabrication variations, maintaining high performance under dimensional deviations of up to ±10 nm.

III. Thermal Management

Secondly, we explore the potential of SWG metamaterials for thermo-optic control in integrated silicon-on-insulator interferometers. We previously presented a MZI incorporating a SWG section in one of the arms to compensate thermally-induced drifts [4]. We build upon this earlier work by providing both an updated interferometer architecture, and advanced SWG metamaterials with a further tailored for thermo-optic response. As a result, reduced thermal sensitivity in an extended bandwidth is achieved.

IV. Conclusions

The devices reported in this work highlight the benefits of subwavelength grating metamaterials for the development of high-performance interferometers for the silicon-on-insulator platform. The reduced losses and enhanced resilience to thermal deviations achieved through subwavelength nanotechnology offer promising prospects for SHFT microspectrometry applications.

Competing Lattice and Defect Dynamics Govern Terahertz-Driven Ferroelectricity in Quantum Paraelectric $SrTiO_3$

Abstract: Our work resolves controversies in light-induced phase transitions by revealing that intense terahertz pulses can drive transient ferroelectricity in quantum paraelectric $SrTiO_3$, but the outcome is governed by a previously unrecognized competition between lattice distortions, defect pinning, and dipolar ordering. Spatially resolved measurements reveal that coherent antiferrodistortive modes suppress symmetry breaking on picosecond scales, while defects frustrate long-range order, allowing ferroelectricity only in pristine regions. This reconciles divergent interpretations and establishes defects as key regulators of light-induced quantum phase transitions.

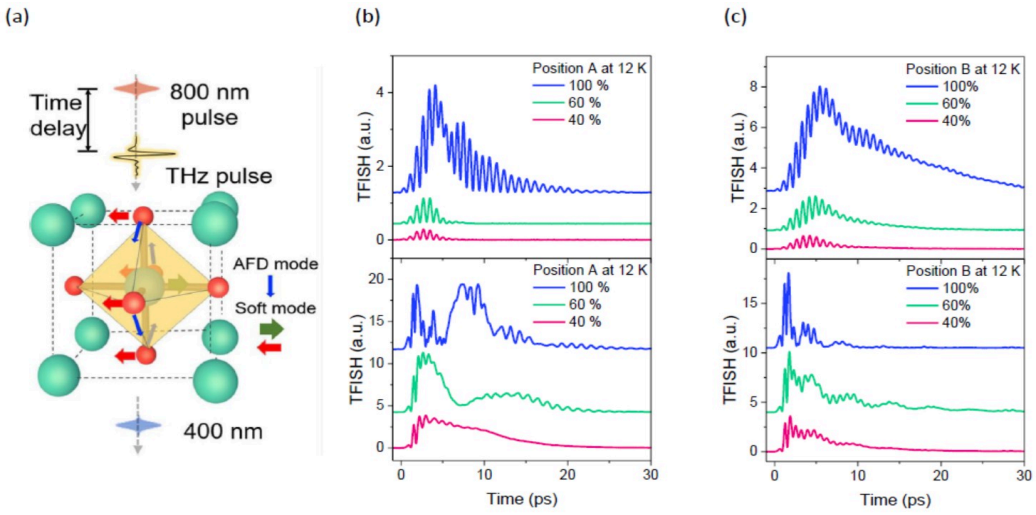

Figure1. (a) Schematic of time-resolved THz-driven SHG. Atomic displacements of soft and AFD modes are also sketched. (b-c) SHG traces at positions A (low oxygen-vacancy density) and B (high oxygen-vacancy density) at 12 K under multi-cycle resonant (center frequency of ~0.65 THz and bandwidth of 0.25~THz) and single-cycle excitation for different field strengths (100%, 60%, 40% of peak fields ~220 kV/cm (multi-cycle) and ~1.1 MV/cm (single-cycle)). Striking position dependence highlights the pivotal role of defects.

Intense terahertz (THz) pulses induce transient inversion-symmetry breaking in quantum paraelectric $SrTiO_3$, yet the underlying mechanism remains controversial [1-6]. Using fields up to ~1.1 MV/cm, we reveal spatially inhomogeneous THz-driven second harmonic generation (SHG) governed by competing lattice and defect

dynamics. Short-lived coherent antiferrodistortive (AFD) modes suppress dipole correlations within ~5 ps, while heavily damped soft/AFD modes and a defect-induced low-frequency mode (~0.1-0.3 THz) jointly prevent long-range ferroelectric coherence in oxygen-vacancy-rich regions. Collective modes manifested by oscillatory SHG components exhibit softening followed by hardening below a critical temperature $T^* \approx 28$ K, confirming transient ferroelectric order where defects are sparse. These results reconcile conflicting interpretations, establish defect-mediated competition as a central regulator of light-induced ferroelectricity, and open routes to ultrafast control of quantum materials.

***Abstract*— This work highlights CNR-IPCF group's contribution in contactless particle manipulation using optical and acoustic tweezers.**

***Keywords*— Optical tweezers, Acoustic manipulation, Nanoparticles, Raman spectroscopy, Force calibration.**

The contactless manipulation of matter at the micro- and nanoscale has emerged as a cornerstone of modern nanoscience, biophysics, and materials characterization. This abstract reviews the fundamental advancements in optical forces and optical tweezers (OT), highlighting the pioneering contributions of the CNR-IPCF group (Donato et al.) in capturing, spinning, and sensing complex nanostructures. Key developments include the spatial positioning and high-resolution structural characterization of liquid-phase exfoliated two-dimensional (2D) nanosheets [1], such as hexagonal boron nitride, where thermal fluctuation analysis allows the precise assessment of size scaling and optical trapping constants. Furthermore, by exploiting tailored polarization configurations and counter-propagating beam geometries, optical binding and the transfer of angular momentum (spin and orbital) can be effectively demonstrated in highly anisotropic systems like silicon nanowires [2] and chiral birefringent microparticles [3], inducing rich rotational and localization dynamics. Additionally, the integration of plasmon-enhanced optical trapping with surface-enhanced Raman spectroscopy (SERS) provides a robust platform for ultra-sensitive molecular detection and single-particle force transduction down to the femtonewton regime [4]. While conventional optical trapping excels at manipulating sub-micron dielectric particles and probing forces down to the femtonewton regime, it faces intrinsic limitations when scaling up to larger macroscopic volumes, or when dealing with highly absorbing, light-sensitive materials. To overcome these constraints, recent research has successfully expanded into the realm of acoustic manipulation. By transferring well-established optical tracking protocols and Brownian motion analysis frameworks to holographic acoustic tweezers, a consistent methodology for the precise force calibration of ultrasonic fields has been developed [5]. This synergistic integration bridges the gap between optical and acoustic trapping communities, enabling the stable levitation of diverse samples—ranging from cometary analogs [6] and microplastics to biological matter—far from substrate contamination. Ultimately, combining the high spatial resolution of optical forces with the extended force ranges of acoustic fields paves the way for advanced hybrid acousto-optical architectures, unlocking novel capabilities in container-less material processing, multi-scale sorting, and ultra-sensitive in-situ spectroscopy.

***Abstract*—Within optical thermodynamics, weakly nonlinear multimode optical systems evolve toward a Rayleigh Jeans distribution. We show that identical conserved power and internal energy do not uniquely determine thermalization. Initial states with the same equilibrium distribution can thermalize at very different distances, in correlation to their short-distance chaotic response.**

***Keywords*— nonlinear optics, optical thermodynamics, thermalization, optical lattices.**

I. Introduction

In recent years, a lot of attention in nonlinear optics has been given to heavily multimode optical systems, such as a highly multimode optical fiber [1], [2], where the modes are allowed to interact though nonlinearity. Although direct numerical simulations can yield accurate results for these systems, they are often prohibitively time-consuming due to the high number of modes. Moreover, such simulations fall short in offering profound physical insights or contributing to a general theoretical framework, which has been absent. Addressing this gap, an axiomatic thermodynamic theory of light, known as *Optical Thermodynamics*, has been formulated [3], [4], [5], [6], [7]. This approach enables the prediction of the statistical behavior of weakly nonlinear multimode systems by applying principles from thermodynamics [3], [4] and classical statistical mechanics [5], [7]. Through this framework, key thermodynamic quantities such as the equation of state, entropy, and the Rayleigh-Jeans distribution for modal occupancies can be derived analytically. Importantly, apart from numerically verified, the predictions of this thermodynamic theory have been recently experimentally validated in multimode fibers and optical lattices [8], [9], offering a pathway toward innovative applications in the realm of multimode nonlinear optics.

II. Methods

We investigate the dynamics in a one-dimensional discrete waveguide lattice consisting of M waveguide channels. For such a lattice, the normalized paraxial discrete nonlinear Schrödinger equation (DNLSE) reads

$$i\frac{du_n}{dz} + u_{n+1} + u_{n-1} + |u_n|^2 u_n = 0, \tag{1}$$

where z is the propagation distance and u_n is the amplitude of the electric-field envelope at the n^{th} waveguide. The two conserved quantities, the power $\mathcal{P}$ and the internal energy U, can be expressed in terms of the projection modal coefficients c_j and the finite spectrum $\{\epsilon_j\}_{j=1}^{M}$ of the linear lattice, namely $\mathcal{P} = \sum_{j=1}^{M} |c_j|^2 \equiv \sum_{j=1}^{M} p_j$ and $U = -\sum_{j=1}^{M} \epsilon_j |c_j|^2$, from which the equilibrium temperature T and chemical potential μ can be uniquely determined [3].

Within this framework, the system can explore all accessible microstates while conserving U and $\mathcal{P}$ until it reaches thermal equilibrium, where its optical entropy $S = \sum_{j=1}^{M} \ln \overline{|c_j|^2}$ is maximized. At equilibrium, the ensemble-averaged modal occupancies follow the Rayleigh-Jeans (RJ) distribution,

$$p_j^{\text{RJ}} \equiv \overline{|c_j|^2} = -\frac{T}{\epsilon_j + \mu}. \tag{2}$$

Although any initial distribution of modal occupancies $f(\epsilon_j) = |c_{j,0}|^2$ corresponds to a unique optical temperature T and chemical potential μ, the distribution $f(\epsilon_j)$ associated with a given (T, μ) is not unique. Consequently, the propagation distance z required for thermalization—where the averaged modal occupancies converge to the RJ distribution—depends not only on T and μ, but also on the initial distribution $f(\epsilon_j)$.

To quantify the deviation of the modal occupancy distribution from thermal equilibrium, we introduce the normalized distance from the RJ distribution,

$$D_{\text{RJ}}(z) = \frac{1}{2\mathcal{P}} \sum_{j=1}^{M} \left| p_j(z) - p_j^{\text{RJ}} \right|. \tag{3}$$

This metric is bounded as $D_{\text{RJ}} \in [0, 1]$ and represents the fraction of total power that must be redistributed among eigenmodes to reach thermalization. We conventionally define the thermalization distance z_{th} as the propagation distance at which D_{RJ} falls below a prescribed threshold, $D_{\text{RJ}} < 0.03$.

III. Results and Discussion

In Fig. 1 we show that the thermalization distance is not uniquely determined by the conserved quantities $(\mathcal{P}, U)$ but

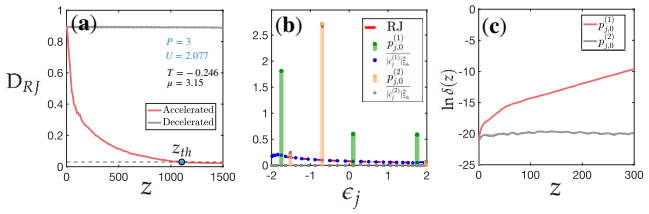

Fig. 1. (a) Evolution of $D_{\mathrm{RJ}}(z)$ for initial conditions leading to fast (red curves) and slow (gray curves) thermalization. (b) Modal occupancies $\overline{|c_j|^2}$ at z_{th} for the fast case (blue points), compared with the RJ prediction (red dashed line) and the slow case (gray square markers). Initial modal occupancies $p_{j,0} = \overline{|c_{j,0}|^2}$ are shown with green points (fast) and orange square markers (slow). (c) Short-z evolution of the occupancy-separation distance $\delta(z)$

depends sensitively on the specific initial modal distribution. For a target RJ equilibrium distribution with $T = -0.246$ and $\mu = 3.15$, we generate large ensembles of distinct initial conditions sharing identical values of (P, U) and propagate them under Eq. (1). Crucially, to isolate genuine dynamical effects from trivial proximity-to-equilibrium conditions, we restrict our analysis to initial conditions that all have the same initial distance from equilibrium. Despite this constraint, the resulting thermalization distances z_{th} exhibit pronounced variability.

In Fig. 1(b), we compare the modal occupancies at the propagation distance $z = z_{th}$ of a representative fast-thermalizing case ($z_{\mathrm{th}} \sim 10^3$) (blue points) with the corresponding theoretically predicted RJ distribution (red dashed line), while the initial modal occupancies are indicated by green points. For comparison, we also include alternative initial conditions (orange square markers) that lead to significantly slower thermalization ($z_{\mathrm{th}} \sim 10^5$), despite starting from the same initial value of $D_{\mathrm{RJ}}(z = 0)$. The latter case remains far from equilibrium at the propagation distance where the fast case have already thermalized, as reflected both in their larger values of D_{RJ} (gray curves in Fig. 1(a)) and in their modal occupancies at $z = z_{th}$, shown by gray square markers in Fig. 1(b), which exhibit significant deviations from the expected RJ distribution.

To quantify the sensitivity of the thermalization dynamics to the initial modal occupancies, we introduce a modal-occupancy-based chaos indicator defined within the manifold of fixed invariants $(\mathcal{P}, U)$. Starting from a set of modal occupancies $\{p_j^{(A)}(0)\}$ with $\mathcal{P} = \sum_j p_j^{(A)}$ and $U = \sum_j \epsilon_j p_j^{(A)}$, we construct a nearby modal-occupancy set $p_j^{(B)}(0) = p_j^{(A)}(0) + \alpha\,\delta p_j$, where α is a small fraction of $\mathcal{P}$. The perturbations δp_j are chosen to satisfy $\sum_j \delta p_j = 0$ and $\sum_j \epsilon_j\,\delta p_j = 0$, ensuring $\delta\mathcal{P} = \delta U = 0$. We then evolve both initial conditions under Eq. (1) and compute the corresponding modal occupancies $p_j^{(A)}(z)$ and $p_j^{(B)}(z)$. The occupancy-separation distance is defined as

$$\delta(z) \equiv \frac{1}{2\mathcal{P}} \sum_{j=1}^{M} \overline{\left| p_j^{(B)}(z) - p_j^{(A)}(z) \right|}, \tag{4}$$

where the overline denotes ensemble averaging over multiple random-phase realizations, taken to be common between $p_j^{(A)}(0)$ and $p_j^{(B)}(0)$. This quantity quantifies how rapidly two initially adjacent $(\mathcal{P}, U)$-conserving initial conditions develop distinct modal-occupancy trajectories.

As shown in Fig. 1(c), the short-z values of the logarithm of the occupancy-separation distance $\ln\delta(z)$ are consistently larger for the fast-thermalization initial conditions $p_{j,0}^{(1)}$ (red lines) than for the slow-thermalization initial conditions $p_{j,0}^{(2)}$. The short-z behavior of $\delta(z)$ thus provides a quantitative measure of the chaotic character of the underlying initial conditions.

IV. Conclusion

In conclusion, we have shown that thermalization distances in multimode nonlinear lattices are not uniquely determined by the conserved thermodynamic invariants but depend sensitively on the initial modal distributions. We show that fast or slow thermalization is associated with stronger or weaker short-z chaotic responses of the corresponding initial conditions, quantified through a modal-occupancy separation measure.

***Index Terms*—silicon nitride, integrated photonics, quantum optics, V grooves, heterogeneous integration, nanofabrication**

I. Introduction

Silicon nitride (SiN) has emerged as a leading material platform for integrated quantum photonics because it combines a wide optical transparency window, CMOS-compatible processing, and the potential for low propagation loss waveguides. These properties make SiN attractive for quantum communication, sensing, and photonic quantum information processing, where optical loss directly limits system performance and scaling.

However, a useful quantum photonic platform cannot consist only of low loss waveguides. Large scale systems also require passive fiber a lignment, r obust c hip p ackaging, a ccess to selected waveguide regions, and compatibility with hybrid or heterogeneous device integration. The key fabrication problem is therefore not merely to pattern SiN waveguides, but to add structural functionality while preserving the optical quality of the buried waveguide layer.

Here we report a fabrication approach that combines low loss stoichiometric LPCVD SiN waveguides with lithographically defined V g rooves a nd l ocalized o xide o penings above selected waveguide regions. The process is designed to maintain the integrity of the optical layer while enabling packaging and integration functions required for scalable quantum photonic circuits.

II. Fabrication Process

The process begins with a high quality silicon wafer. A 5 μm thermal oxide layer is grown to provide the lower optical cladding. Since stoichiometric LPCVD silicon nitride is intrinsically tensile stressed, a stress control step is introduced before nitride deposition. The thermal oxide is patterned using ultraviolet lithography in a damascene-like configuration to suppress crack propagation from wafer edges and within the wafer during deposition of the high stress SiN film [1].

A 400 nm stoichiometric LPCVD SiN layer is then deposited. Waveguides and photonic devices are defined using electron beam lithography with HSQ resist. A 5 μm PECVD oxide layer is deposited as the upper cladding, producing a symmetric buried-waveguide environment suitable for low scattering loss.

To define the V grooves and oxide-access windows, a thick aluminum hard mask is deposited and patterned using ultraviolet lithography. The first lithography step opens the V groove regions. The aluminum is etched using chlorine and argon plasma chemistry, followed by oxide etching using fluorocarbon inductively coupled plasma etching. This removes most of the oxide stack in the V groove openings.

A second lithography step patterns both the V groove openings and the local windows above selected waveguide sections. The exposed oxide is partially etched, leaving approximately 1.5 μm of oxide above the waveguides in the window regions while fully clearing the V groove regions down to the silicon substrate. A third lithography step protects the wafer during a timed buffered oxide etch, which removes the remaining oxide in the windows and exposes the SiN waveguide surface. Finally, anisotropic TMAH etching at 80 °C forms the silicon V grooves.

III. Results and Discussion

Figure 1 shows representative scanning electron microscope images of the fabricated structures. The local oxide windows expose selected buried waveguide regions while keeping the surrounding cladding intact. This is important for applications requiring direct access to the waveguide surface, including heterogeneous integration, sensing, post-processing, local actuation, or coupling to additional materials.

The V grooves provide passive alignment structures for fiber coupling and packaging. Their definition in the same lithographic process flow as the photonic structures improves compatibility between the optical circuit and the external fiber interface. This is critical for moving SiN quantum photonic chips from isolated test structures toward packaged, fiber-compatible modules.

The main practical advantage of this process is that the added mechanical and integration features are introduced after the low loss waveguide stack is formed. In this way, the optical layer can be optimized for propagation loss while the later processing creates the packaging and integration structures needed for deployable systems. This approach extends the fabrication-to-benchtop pathway previously developed for SiN-based quantum devices [2].

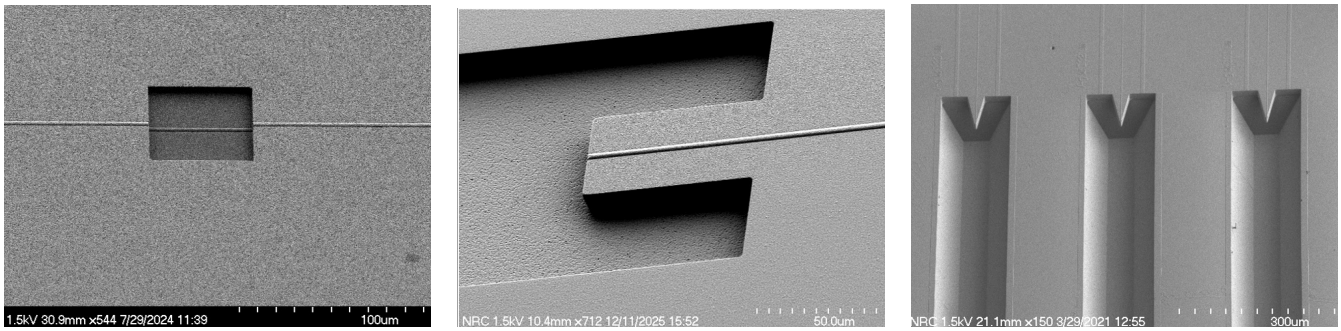

Fig. 1. Scanning electron microscope images of fabricated SiN platform features. Left: localized oxide window above a buried waveguide region. Center: window and V groove structure showing local access to the waveguide and etched alignment geometry. Right: array of anisotropically etched V grooves for passive fiber alignment.

IV. Conclusion

We have demonstrated a fabrication flow for a sovereign SiN integrated photonics platform that combines low loss stoichiometric LPCVD waveguides with structural features needed for packaging and hybrid integration. Lithographically defined V grooves enable passive fiber alignment, while localized oxide windows provide access to selected waveguide regions without removing the full cladding elsewhere on the chip. The result is a practical platform architecture for quantum integrated optics in which optical performance, fiber interfacing, and heterogeneous integration are addressed within a single process strategy.

Electrostatic Repulsion as a Governing Mechanism in Near- and Far-Field Optical Binding of Gold Nanoparticles

Manuel I. Marqués[1,*]

[1]Departamento de Física de Materiales, IFIMAC and INC, Universidad Autónoma de Madrid, Spain

*Corresponding author: manuel.marques@uam.es

***Abstract*—. This work shows that electrostatic interactions play a key role in optically bound particle configurations in fluids. Combining experiments and modeling, it reveals that weaker electrostatic repulsion favors near-field alignment with the light polarization, while stronger repulsion leads to far-field perpendicular arrangements. Simulations quantitatively match the experimental observations.**

***Keywords*—Optical Binding, Electrostatic Repulsion, Molecular Dynamics.**

I. Introduction

The dynamics and equilibrium configurations of optically bound particles immersed in a fluid arise from the interplay of multiple physical mechanisms, including optical forces, electrostatic interactions, and hydrodynamic effects [1].

From a theoretical perspective, a key challenge lies in disentangling the relative contribution of these interactions across different length scales. In this work, we combine experiments with a theoretical and numerical framework to demonstrate that short-range electrostatic forces play a central role in determining the observed optical binding configurations.

Within our model, electrostatic repulsion between gold nanoparticles is explicitly incorporated and systematically tuned to mimic variations in salt concentration. The theoretical analysis reveals that reducing the strength of the electrostatic interaction favors near-field optical binding, leading to particle arrangements aligned along the polarization direction of the incident field. Conversely, when electrostatic repulsion is dominant, the balance of forces shifts toward far-field optical binding, resulting in equilibrium configurations oriented perpendicular to the polarization direction.

Numerical simulations based on this model quantitatively reproduce the experimentally observed particle configurations across the explored parameter space [2] (Figure 1) These results underscore the decisive influence of electrostatic interactions in shaping the energy landscape of optically bound systems, particularly in the regime of far-field optical binding, where repulsive forces critically determine both stability and orientation of the particle assemblies

***Abstract*— We present multilayer aperiodic structures based on Weyl semimetals that maximize the nonreciprocal contrast over broad spectral and angular ranges. The strong broadband and wide-angle nonreciprocal response of the proposed structures highlights their potential in thermal photonic applications, including directional thermal emission, radiative energy control, thermophotovoltaics, and thermal management.**

***Keywords*— nonreciprocal thermal emitters, Weyl semimetals, optimization algorithms, temporal coupled-mode theory.**

I. SUMMARY

Nonreciprocal thermal emitters are photonic structures that violate Kirchhoff's law of thermal radiation, enabling asymmetric absorptivity and emissivity for waves incident from opposite directions or at symmetric angles, thereby allowing independent control of thermal absorption and emission across angles and wavelengths. This violation is achieved by breaking Lorentz reciprocity using materials such as Weyl semimetals or magneto-optical media with asymmetric permittivity tensors to decouple the rates at which thermal photons couple in and out of specific photonic channels. Weyl semimetals exhibit a large gyrotropic response in the mid-infrared, where their off-diagonal permittivity tensor components are comparable in magnitude to their diagonal elements. This allows them to achieve a near-complete violation of Kirchhoff's law, providing a level of control over thermal radiation that far exceeds the nonreciprocal effects typically observed in traditional magneto-optical materials. By strategically coupling distinct resonances, such as Fabry–Pérot, Brewster, or guided-mode resonances, the sign, magnitude, and spectral bandwidth of the contrast between emissivity and absorptivity can be precisely tuned. Such unprecedented control enables the creation of one-way thermal flows and the development of energy-harvesting technologies capable of approaching the Landsberg efficiency limit, which is impossible in conventional reciprocal systems.

However, most previously reported nonreciprocal thermal emitters achieve strong contrast between absorptivity and emissivity only under restricted conditions, such as narrow spectral windows or limited angular ranges, and are unable to maintain strong nonreciprocal contrast of opposite signs at different wavelengths over a wide angular range. Here, we present a systematic optimization framework for multilayer aperiodic structures based on Weyl semimetals that maximizes the nonreciprocal contrast over broad spectral and angular ranges. The proposed structures consist of planar thin-film stacks deposited on a semi-infinite metallic substrate, avoiding the need for complex lithographic patterning, while the use of Weyl semimetals enables strong intrinsic nonreciprocity without an external magnetic field. We use a memetic optimization algorithm combined with the transfer-matrix method to optimize both the material composition and the layer thicknesses of the structures to achieve robust wide-angle performance. We also develop a temporal coupled-mode theory formulation for the absorptivity and emissivity of the proposed structures and show that its predictions are in good agreement with the numerical results. The strong broadband and wide-angle nonreciprocal response of the proposed planar easy-to-fabricate structures highlights their potential in thermal photonic applications, including directional thermal emission, radiative energy control, thermophotovoltaics, and thermal management.

Compact High-Q Photonic Crystal Cavities with Improved Robustness to Disorder

***Abstract*— Compact photonic crystal cavities enable dense integration but typically require large footprints to achieve high Q-factors, increasing sensitivity to fabrication disorder. We present high-Q, small-footprint cavities optimized through a non-Hermitian perturbation theory framework, where periodicity breaking enhances resilience to fabrication-induced disorder as demonstrated by the near-field scanning optical microscopy experiment.**

***Keywords*— photonic-crystals, optical nanocavities, near-field scanning optical microscopy, non-Hermitian photonics.**

I. Introduction

Periodic nanostructures are widely used in photonics to engineer light–matter interaction [1-4]; however, their optical response is often strongly affected by fabrication imperfections, motivating increasing interest in design strategies that enhance robustness and reproducibility in real nanofabricated systems. Among those, photonic crystal (PhC) slab cavities [1] enabling strong light confinement within ultra small volumes, are widely used in integrated photonics and quantum optical platforms. Achieving high quality (Q) factors in these systems typically requires extended periodic mirrors surrounding the cavity defect, leading to large device footprints and enhanced sensitivity to fabrication induced disorder. Nanofabrication imperfections such as hole size variations, sidewall roughness, and positional errors introduce scattering losses and resonance detuning, limiting device reproducibility. This issue is particularly critical for applications requiring spectral alignment across multiple devices.

In this work, PhC slab cavities as small as 4 × 4 μm^2, achieving relatively high Q comparable to conventional large L3 cavities, despite occupying only a fraction of their footprint, are numerically and experimentally demonstrated. These structures are obtained through an optimization process that introduces an aperiodic, yet highly controlled, pattern of holes surrounding the cavity [4,5].

II. Methods

The investigated structures are based on L3 PhC slab cavities defined within a footprint of approximately 4 × 4 μm^2 (corresponding to 6 lattice periods). Starting from the unoptimized periodic design (R6), a gradient-based optimization framework based on non-Hermitian perturbation theory for quasinormal modes [4,6] is employed to maximize the cavity Q-factor of the fundamental L3 mode (Fig. 1a) by

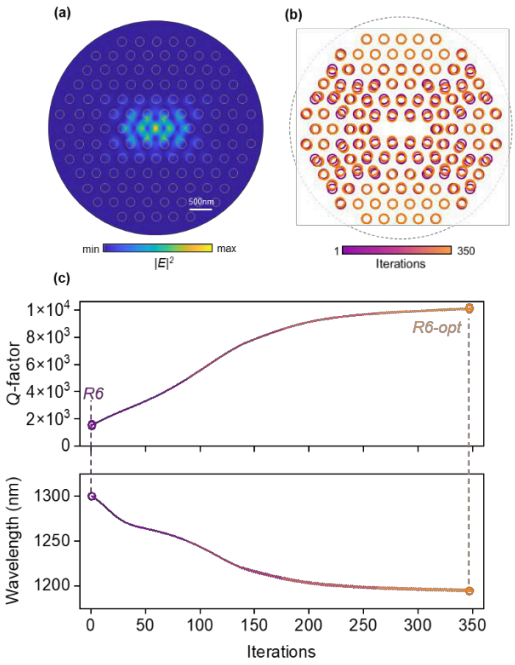

Fig. 1 (a) Simulated near-field electric field intensity maps for the fundamental mode of the original L3 cavity (R6). (b) Evolution of hole positions during the optimization process from the unperturbed reference cavity (R6, purple) to the fully optimized configuration (R6--opt, orange). (c) Simulated Q-factor (top panel) and resonant wavelength (bottom panel) as a function of optimization iteration for an L3 with lattice constant a=330nm and holes radius = 0.79a.

iteratively displacing the air holes surrounding the defect region. The optimization introduces in the final optimized design (labelled as R6-opt) correlated hole displacements that progressively break the original lattice periodicity while preserving the overall cavity symmetry [5]. Fig. 1(b) illustrates the displacement pattern of the air holes introduced during the optimization, while Fig. 1(c) summarizes the evolution of the cavity Q-factor (top panel) and resonant wavelength (bottom panel) along the optimization trajectory from R6 to R6-opt. The fabricated samples are based on GaAs heterostructures incorporating a dense layer of InAs quantum dots (QDs) emitting at 1300 nm. Optical characterization is achieved at room temperature using scanning near-field optical microscopy (SNOM).

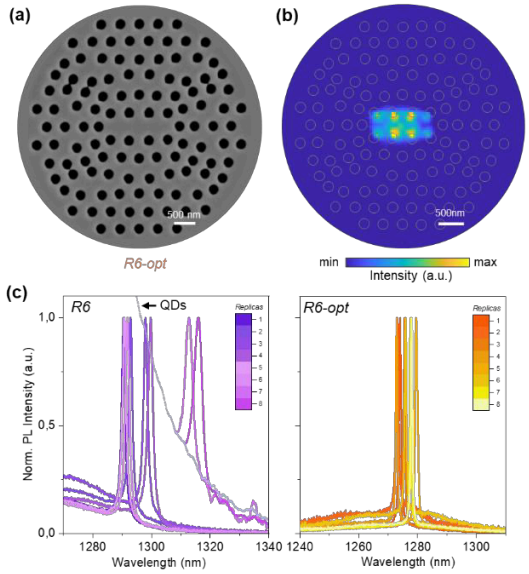

Fig. 2 (a) SEM image of the fabricated optimized R6-II cavity. (b) SNOM map of the optimized fundamental mode in the R6-II cavity. (c) Normalized SNOM PL spectra acquired at the location of maximum emission of eight nominally identical replica of R6 with a=320nm (left) and R6 II with a=350nm (right) and nominal radii. In the left graph the QD PL emission (light blue) is overlapped to the spectra.

III. Results and Discussion

In Fig. 2a we report the Scanning Electron Microscopy (SEM) image of the fabricated L3 cavity with optimized design (R6-opt), characterized by a final Q of $\sim 10^4$, that is comparable to the Q of a standard L3 cavity with 12 lattice periods (therefore extending up to $8 \times 8\ \mu m^2$ for the same lattice constant). A rigorous experimental characterization performed on R6-opt cavities with different lattice constants confirm that Q-factors follow the trend predicted by simulations, with a systematic increase from the unoptimized R6 design to the fully optimized design [4,5]. Moreover, the SNOM map acquired on the R6-opt cavity, shown in Fig. 1 (b), further demonstrates that the cavity mode remains well confined and spatially stable despite the periodicity breaking.

Beyond quality factor optimization, spectral reproducibility represents a critical and often overlooked limitation, largely arising from fabrication-induced disorder. Quantifying spectral stability provides a stringent metric to evaluate the applicability of the proposed cavities. In particular, for cavity–emitter coupling, performance is governed by the spectral alignment between the cavity mode and the emitter ensemble. Imperfections inherent to electron-beam lithography and etching processes are known to induce substantial device-to-device variations in photonic crystal cavity resonances. Here, we approach this issue by systematically investigating the spectral stability of optimized small-footprint cavities through a statistical analysis performed on multiple nominally identical replicas, directly linking engineered periodicity breaking to enhanced robustness against fabrication-induced disorder. Figure 2 (c) compares the SNOM photoluminescence (PL) spectra measured on multiple nominally identical replicas, revealing a significantly reduced spread of resonance wavelengths for the optimized cavities (right panel) with respect to the standard L3 R6 (left panel). This behavior indicates a reduced sensitivity to fabrication-induced imperfections, attributed to the correlated nature of the periodicity breaking introduced by the optimization [5].

IV. Conclusion

We have demonstrated that controlled periodicity breaking enables compact photonic crystal slab cavities combining high Q-factors with enhanced robustness to fabrication-induced disorder. By applying mode-driven optimization to small-footprint L3 cavities, we achieve improved optical performance together with significantly enhanced spectral reproducibility. In contrast to strictly periodic or fully disordered designs, PhC cavities based on engineered aperiodicity simultaneously achieve compact footprints, high optical performance, and improved reproducibility, making them suitable for dense on-chip integration.

***Abstract*—Conventional mode converters fully exchange optical power between two orthogonal modes, limiting multimode systems that require engineered modal power distributions. We present a passive silicon mode converter that enables geometrically defined conversion ratios using graded-index subwavelength metamaterials. Fifteen distinct and well-controlled conversion levels are demonstrated across the 1500–1600 nm bandwidth.**

***Keywords*—Silicon photonics, multimode operation, customizable mode conversion, subwavelength graded-index metamaterials.**

I. Introduction

Silicon-on-insulator (SOI) integrated photonics is increasingly leveraging multiple spatial modes to expand capacity and functionality, extending multimode platforms beyond optical communications into nonlinear, quantum, and programmable photonics[1-3]. These applications demand precise on-chip control of modal power, positioning mode converters as fundamental components in advanced multimode architectures. Customizable conversion ratios are particularly valuable for balancing modal amplitudes and compensating higher-order mode-dependent loss in intermodal four-wave mixing[1]. Moreover, spatial modes provide a high-dimensional encoding basis for integrated quantum photonics, where reproducible modal superpositions are essential for transverse mode-encoded gates and high-visibility quantum interference[3]. However, to the best of our knowledge, no fully passive structure has demonstrated geometry-defined control of the modal conversion ratio.

Here, we exploit subwavelength gratings (SWGs) and graded-index (GRIN) metamaterials to engineer modal propagation and realize broadband control of power conversion between transverse-electric (TE) modes with the same parity[4-6]. We propose a fully passive silicon mode converter comprising two back-to-back Y-junctions implemented with SWG metamaterials. The conversion ratio is set by inserting a controlled number of GRIN subwavelength (GRINS) segments between the junctions, yielding discrete, design-defined conversion levels while preserving broadband operation. Experiments demonstrate 15 TE_0–TE_2 conversion levels. The conversion fraction $CF = P_{TE2}/(P_{TE0} + P_{TE2})$ exhibits a quasi-linear dependence on the number of GRIN segments (N_{SWG}), with an average slope of (7.7 ± 0.4) % per N_{SWG} across the 1500–1600 nm wavelength range. The device occupies an ultracompact footprint of only 9.3 µm × 2.6 µm in the largest design configuration. 3D FDTD simulations indicate that the same approach can be extended to other mode pairs, such as fundamental and fourth-order TE modes, while maintaining broadband performance and compactness[7].

II. Principle of Operation and Device Design

The device implements design-customizable mode conversion by splitting and recombining the modal field using two SWG Y-junctions, as shown in Fig. 1.

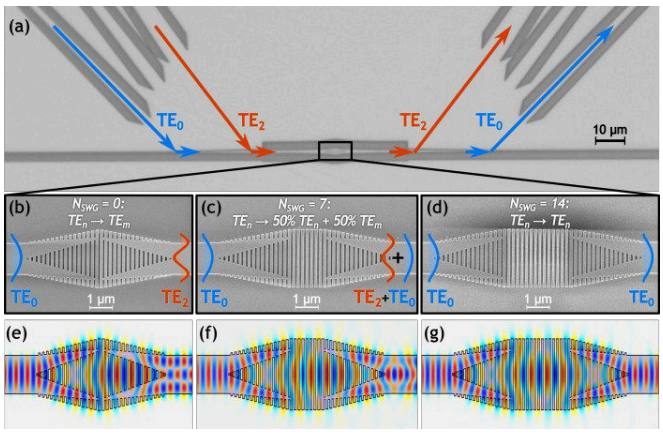

Fig. 1 (a) Optical microscope image of the characterization structure. (b–d) Scanning electron microscope images of the fabricated mode converter for N_{SWG} = 0, 7 and 14. (e-g) 3D FDTD simulations of the electric field ($\Re\{Ey\}$) propagating through the device under TE_0 mode excitation for N_{SWG} = 0, 7 and 14.

The first Y-junction excites a superposition of the two target modes. A subsequent GRINS region sets their relative optical phase and acts as a compact, broadband phase shifter. When the fields are recombined in the second Y-junction, the modal phase difference determines the interference condition and therefore the output modal distribution, enabling discrete conversion ratios between the TE_0 and TE_2 modes set by the number of GRINS segments.

The GRINS segments implement a parabolic transverse index profile through a laterally varying duty cycle. The resulting graded effective index produces mode-order-dependent propagation constants, enabling controlled TE_0–TE_2 phase accumulation with minimal dispersion by tuning the profile curvature. For $N_{SWG} = 0$ (Fig. 1(b,e)), the device operates near the full-conversion regime: injecting TE_0 (TE_2) results in in TE_2 (TE_0) at the output. For $N_{SWG} = 7$ (Fig. 1(c,f)), the converter is near the balanced point, producing an approximately equal TE_0/TE_2 power distribution at the output for either TE_0 or TE_2 excitation. Increasing N_{SWG} to 14 (Fig. 1(d,g)) suppresses mode conversion, and the injected mode remains predominantly at the output.

III. Results and Discussion

Beyond mode conversion, the proposed device enables design-defined modal weighting as a building block for multimode silicon photonics. Experimental measurements resolve 15 distinct levels of TE_0–TE_2 power conversion, as shown in Fig. 2. The conversion fraction shows an average local slope step of (7.7 ± 0.4) % per GRINS period in the entire measured wavelength range covering from 1500 nm to 1600 nm. These measurements agree closely with full three-dimensional simulations, supporting the robustness of the design for precise, broadband mode conversion in an ultracompact footprint. We further show that the same design methodology extends to higher-order mode pairs by demonstrating a second device that provides design-defined conversion ratios between fundamental and fourth-order TE modes while maintaining broadband performance and compact size.

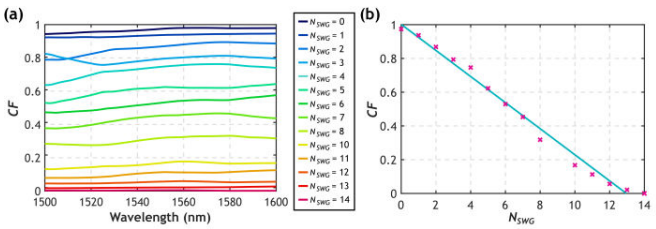

Fig. 2 (a) Measured conversion fraction for all device configurations (N_{SWG} = 0–14). (b) Linear regression of the conversion fraction at λ = 1550 nm. Results for N_{SWG} = 9 are omitted because the corresponding device was damaged during fabrication.

Abstract - **Dendritic plasmonic catalysts enable light-driven CO_2 reduction by co-localising optical hot-spots and active surface sites. This invited contribution presents a guided strategy progressing from model systems to scalable Au and Cu dendrites. Wavelength-resolved studies reveal how optical modes and near-fields control charge transfer, enabling wavelength- and material-selective multi-electron CO_2 reduction.**

INTRODUCTION

Dendritic metal electrodes are promising platforms for plasmon-assisted CO_2 reduction because their hierarchical morphology combines high surface area, dense catalytic sites, and nanoscale optical hot-spots within a single architecture. Abundant tips and junctions naturally concentrate electromagnetic fields under illumination, making dendrites well suited to reactions requiring repeated electron transfer and stabilization of surface-bound intermediates.

Selective conversion of CO_2 into multi-carbon (C_2^+) products, however, requires more than structural complexity[1] Efficient C–C coupling demands both localized delivery of multiple electrons and catalyst surfaces that intrinsically favour bond formation. This motivates a design strategy in which plasmonic excitation and catalyst material are treated jointly: optical excitation governs energy and charge localization, while the metal defines accessible reaction pathways[2].

Our group addresses this challenge by developing mechanistic understanding of plasmon-mediated excitation and translating it into dendritic catalyst design. Controlled plasmonic structures are first used to identify how optical mode structure, near-field localization, and excitation wavelength govern interfacial charge-transfer activity, allowing wavelength to be treated as an independent control parameter[3]. These insights are mapped onto dendritic architectures, where local geometry rather than global morphology dictates optical response. Gold dendrites serve as an optically stable reference system, enabling direct correlation between plasmonic hot-spot localization and photo-assisted reaction behaviour[2].

While gold dendrites provide a platform for establishing optical design principles, copper is uniquely active for carbon-carbon coupling in CO_2 reduction[4]. Extending plasmonic concepts from gold to copper dendritic catalysts enables the integration of wavelength-guided optical excitation with material-specific chemistry. In this contribution, we present a unified framework linking wavelength-selective plasmonic excitation, dendritic architecture, and catalyst material selection, outlining a pathway toward scalable, light-driven CO_2 reduction with combined wavelength and material control.

I. Methods and Results

To connect mechanistic plasmonic insight with practical catalyst design, we employ a hierarchical approach that links simplified plasmonic model systems to complex dendritic architectures. Our methodology combines electromagnetic simulations (BEM, FEM), nanoscale optical characterization, cathodoluminescence (CL) spectroscopy, surface-enhanced Raman spectroscopy (SERS), and photo-assisted catalytic measurements[5].

Wavelength-dependent excitation behaviour is first established using well-defined plasmonic model systems, including Au nanotriangle arrays and nanoparticles. These structures support tunable optical modes, enabling systematic investigation of

how excitation wavelength, near-field localisation, and absorption influence plasmon-mediated charge-transfer activity. Electromagnetic simulations correlate geometric parameters with resonance shifts and field enhancement, while wavelength-resolved SERS using molecular probe systems provides an experimental readout of interfacial plasmonic excitation without directly probing CO_2 intermediates.

Insights from these mechanistic proof-of-concept studies are translated to self-assembled Au nano-dendrites fabricated via controlled electrodeposition. CL mapping reveals that plasmonic emission is strongly localized at high-curvature tips and branch junctions and exhibits wavelength-dependent spatial distributions, confirming that local geometry dominates optical response rather than overall morphology. Photo-assisted catalytic and electrochemical measurements demonstrate that Au dendrites provide a robust platform for plasmon-enhanced CO_2 reduction, with broadband optical modes supporting repeated interfacial electron-transfer events.

While deterministic wavelength selectivity is readily established in simplified plasmonic systems, extending precise wavelength control to dendritic architectures remains an active area of investigation due to their multi-mode optical response. Ongoing work focuses on correlating wavelength-resolved excitation with changes in reaction rate and product distribution in dendritic electrodes.

Building on this foundation, the framework is extended toward copper dendritic catalysts. Copper is intrinsically active for carbon–carbon coupling in CO_2 reduction, and coupling plasmonic excitation with Cu dendritic architectures enables the integration of wavelength-guided optical control with material-specific reaction pathways. In this context, Au dendrites serve as an optically well-defined reference, while Cu dendrites represent the chemically selective target system.

II. Conclusion

We present a mechanistically guided approach to designing plasmonic dendritic catalysts for light-driven CO_2 reduction. Wavelength-resolved studies in model plasmonic systems reveal how optical mode structure and near-field localisation govern charge-transfer activity, which is translated to scalable Au dendrites where local geometry dominates optical response. Extending these principles to Cu dendritic catalysts couples plasmonic excitation with intrinsically C–C-coupling-active surfaces, outlining a pathway toward wavelength- and material-selective CO_2 reduction

Perovskite Superfluorescence and High Temperature Macroscopic Quantum Effects

Kenan Gundogdu

Department of Physics, NC State University
corresponding author: kgundog@ncsu.edu

Abstract— Macroscopic quantum coherence is typically associated with low temperatures, where thermal fluctuations do not rapidly destroy phase correlations. In solids, however, electronic coherence is strongly influenced by lattice dynamics, making it unclear how collective quantum states can persist at elevated temperatures. In this talk, I will show how studies of superfluorescence provide a powerful window into the emergence of macroscopic coherence in condensed matter systems. By tracking the buildup of collective emission in lead-halide perovskites[1,2,3], we find that superfluorescence does not originate from simple radiative synchronization of independent dipoles. Instead, it reflects the formation of an underlying many-body excitonic state, shaped by strong exciton–lattice interactions.

Our results reveal a general mechanism in which lattice dynamics actively reorganize the electronic landscape, enabling the emergence of coherent excitonic order at high temperatures. This perspective establishes superfluorescence as a diagnostic of nonequilibrium phase transitions and points to a broader principle for achieving macroscopic quantum coherence in strongly interacting systems.

Reversible metal electrodeposition for high-contrast active optical and metamaterials

Po-Chun Hsu[1,*]

[1] Pritzker School of Molecular Engineering, University of Chicago, USA
*Corresponding author: pochunhsu@uchicago.edu

***Abstract*— Reversible metal electrodeposition (RME) can switch between plasmonic and dielectric behavior with a substantial change in refractive index, which implies a small required volume of active materials and switching energy. While conventional thin-film RME has shown great promise as color-neutral, high-efficiency smart windows, it holds even greater potential as a versatile tuning knob for accomplishing exotic functionalities when combined with nanophotonics designs and molecular engineering. In this talk, I will demonstrate these new concepts by introducing our recent RME-based active optical devices: (i) Adaptive solar heater and sub-ambient radiative cooler. We demonstrated that the RME-based solar heater can achieve high solar absorptivity via localized surface plasmon resonance (LSPR) due to temporally modulated electrodeposition and amorphous bimetallic alloy with extremely high extinction coefficient. Reversing the bias will switch the device to the radiative cooling mode, which has high solar reflectivity (for true sub-ambient cooling) due to the extreme thin device thickness. (ii) Bandwidth-optimized multispectral dynamic thermal emitter. We performed Fresnel phase-shift analysis and Bayesian optimization on a Fabry-Perot cavity to design the thermal emitter with a selective emissivity band, which can be switched by reversible metal electrodeposition and other metal-to-insulator (MIT) materials. Low-to-intermediate loss of the MIT layer and high refractive index in the dielectric layer are shown to be key to band selectivity and tunable range. (iii) High-efficiency active beam-steering metasurface. Incorporating nanoantenna with RME allows us to control the phase front and achieve active beam steering at very high signal-to-noise ratio (i.e., diffraction efficiency), thanks to the high index contrast. These RME-enabled research can bring transformative impact on active optics and thermoregulation, such as smart building envelopes, spacecraft thermal engineering, radiative cooling, and reconfigurable antenna.**

*Corresponding author: rpestourie3[at]gatech.edu

***Abstract*—The integration of artificial intelligence with computational electromagnetics is shifting design from simulation-driven iteration toward knowledge-driven discovery. This summary categorizes AI-Solvers that accelerate physics simulation and AI-Optimizers that reduce design complexity through learned geometric representations, enabling trustworthy, scalable, and transferable electromagnetic device optimization across emerging engineering applications.**

***Keywords*— artificial intelligence, optimization, metasurfaces, approximate solvers**

I. Introduction

Electromagnetic device design increasingly requires simultaneous optimization across performance, robustness, and manufacturability constraints. Traditional workflows rely on iterative simulation-driven optimization, such as gradient-based topology optimization. Although these approaches coupled with fullwave solvers have enabled major advances in photonics and microwave engineering, they remain a computational bottleneck for many state-of-the-art electromagnetic applciations. Scientific machine learning is emerging as a transformative framework to reduce design cost while extracting transferable design knowledge across device families. We highlight how artificial intelligence can enhance both solvers and optimizers for design [1].

II. AI-Solvers: Synergistic Acceleration of Physical Simulation

A global trend in inverse design is to accelerate optimization by accelerating the underlying physical solver. Physics-informed machine learning has proposed replacing numerical solvers with neural network approximations that directly learn physical operators from data or governing equations [2]. While such approaches can significantly reduce simulation cost, they introduce approximate models in which the governing physics is implicitly relearned from data. Although this strategy appears redundant when physics is already known, the primary limitation lies in verification and generalization: these approximate models are called uncontrolled. When surrogate solvers are deployed within optimization loops, there is generally no guarantee that the resulting optimal design lies within regions where the learned model remains accurate.

An alternative paradigm consists of developing fast approximate solvers with controllable error, where approximation accuracy improves as physically meaningful parameters converge toward asymptotic limits. Data-driven approximate solvers for electromagnetics demonstrate this concept by combining physical approximation with decomposition numerical methods that preserve some theoretical guarantees asymptotically [3]. For instance, in the locally periodic approximation for metasurfaces, fast solvers become arbitrarily accurate as the rate of variation of the structure approaches zero. When the data-driven components rely on approximations with bounded error, such as Chebyshev polynomial expansions, approximation accuracy can be characterized theoretically and controllable.

However, approximate solvers face a controllability versus complexity tradeoff. Increasing geometric richness often requires introducing additional subdomain parameterizations, reintroducing the curse of dimensionality despite potential benefits from the blessing of dimensionality in high-dimensional modeling [4]. This limitation is particularly evident in parameter-intensive approximate solvers such as the overlapping-domain decomposition [5].

Hybrid approaches such as Physics-Enhanced Deep Surrogates (PEDS) provide an intermediate strategy by combining neural networks with low-fidelity solvers for interpretable machine learning models [6]. Rather than learning field responses directly, these models learn physically meaningful inputs to low-fidelity solvers, preserving interpretability while enabling accelerated evaluation. This formulation opens the black box of neural surrogates and allows direct verification of learned interpretable quantities during optimization. Recent applications to transport phenomena further demonstrate how physics-enhanced surrogates can maintain physical interpretability while achieving substantial acceleration [7].

III. AI-Optimizers: Learning Design Manifolds

The concept of learning solver inputs rather than outputs naturally leads to a second paradigm shift: accelerating design by learning a representation of high-performance solutions. Instead of attempting to reproduce physical simulations, AI-Optimizers aim to learn low-dimensional manifolds of feasible and high-performing designs. In this formulation, acceleration is achieved by reducing the number of optimization iterations rather than reducing the cost per iteration.

This paradigm fundamentally changes the relationship between machine learning and physics-based optimization. By operating in the design space rather than the physics space,

AI-Optimizers remain compatible with high-fidelity solvers embedded within optimization loops, thereby preserving reliability and addressing long-standing concerns regarding generalization in PDE-constrained optimization.

This approach raises an apparent chicken-and-egg problem: *if high-quality designs are required to learn design representations, why is optimization still necessary?* Transfer learning provides a resolution. Pretrained representation models, particularly those developed for computer vision, enable learning geometric priors from relatively limited physics-driven datasets. Because geometries resemble structured visual data they benefit from advances in generative modeling and representation learning.

Hybrid inverse-design frameworks illustrate this paradigm shift by combining representation learning with physics-based optimization [8]. These approaches demonstrate substantial reductions in simulation cost while improving state-of-the-art device performance of polychromatic beam deflectors. By leveraging latent representations and pretrained models, AI-enhanced optimizers overcome two major redundancies of traditional gradient-based topology optimization: each optimization run traditionally fails to reuse knowledge from prior solutions, and the informational return from simulation evaluations diminishes near local optima. By learning transferable design priors, AI-Optimizers enable optimization strategies that become increasingly efficient across problem instances.

IV. Conclusion

The synergy between AI-Solvers and AI-Optimizers is transforming electromagnetic design workflows into closed-loop discovery pipelines linking simulation, optimization, fabrication, and validation. Design opportunities lie both at the output and the input of electromagnetic solvers.

Acknowledgments

RP thanks Steven Johnson for fruitful discussion about controlled versus uncontrolled approximations.

Topology Optimized High-Q Photonic Crystal Resonators for the THz Band

Stephen M. Hanham[1,*]

[1]Department of Materials, Imperial College London, U. K.
*Corresponding author: s.hanham@imperial.ac.uk

***Abstract*—This work presents a topology optimization framework for designing two-dimensional slab photonic crystal resonators for the terahertz band. The method generates manufacturable resonators with high Purcell factors and sub-diffraction-limited modal volumes, while explicitly enforcing fabrication constraints through minimum feature size control and geometric filtering.**

***Keywords*— photonic crystals, terahertz, topology optimization.**

I. Introduction

Photonic crystal resonators (PCRs) have demonstrated a remarkable ability to simultaneously achieve ultra-high quality (Q) factors and extremely small modal volumes in the optical region of the electromagnetic spectrum [1]. More recently, these concepts have been successfully extended to the terahertz (THz) frequency range, where both microbeam [2], [3] and two-dimensional slab [4], [5] PCRs have been experimentally demonstrated using high-resistivity silicon and low-loss polymer platforms [6]. PCRs have also recently been employed as frequency-selective elements to stabilize low phase-noise oscillators, highlighting their growing relevance for practical millimeter-wave and THz systems [7].

Despite the high level of maturity of PCRs, the problem of systematically designing cavities that maximize the Q-factor to modal volume ratio (Q/V_m) remains an open and largely unresolved challenge. In this work, we describe an automated approach for the design of 2D silicon slab THz PCRs that attempts to maximize Q/V_m while respecting fabrication constraints.

II. Topology Optimization

Topology optimization (TO) is a computational technique that allows for the optimization of electromagnetic structures defined by free-form dielectric geometries [8]. In the present work, we apply gradient-based TO to determine the dielectric distribution ϵ_r of the silicon slab defining a THz PCR to maximize Q/V_m.

For the optimization step, a continuous density design variable $\boldsymbol{x} \in [0,1]^N$ is introduced which defines the relative permittivity according to $\epsilon_r(\boldsymbol{x}) = 1 + (\epsilon_{si} - 1)\boldsymbol{x}$ over the slab design region $D \subset \Re^2$, where $\epsilon_{si} = 11.68$ is the relative permittivity of high-resistivity silicon. The use of a continuous design variable allows for the straightforward computation of the sensitivities $\partial g(\boldsymbol{x})/\partial \boldsymbol{x}$, where $g(\boldsymbol{x})$ is the objective function defined as $g(x) = -|\psi|^2$ and ψ is the relevant field component to maximize at the center of the cavity $(x, y) = (0, 0)$. This can be set to either the electric or magnetic field depending upon the intended application of the cavity.

To encourage the optimizer to converge to a binary distribution for the relative permittivity (i.e. $\boldsymbol{x} = 0$ for air and $\boldsymbol{x} = 1$ for silicon), a projection operator is used to project $\boldsymbol{x}$ into a binary space with a gradually increasing sharpness as described in [8]. A density filter is also applied to $\boldsymbol{x}$ to impose a minimum feature size on the optimized dielectric distribution to ensure fabricability. The gradient-based optimization is performed using the Method of Moving Asymptotes (MMA) [9]. The finite element method is used to evaluate the PCR's performance at each epoch.

III. Results and Discussion

The slab area defining the PCR cavity was chosen to be $2\lambda_0$ by $2\lambda_0$. A dielectric slab waveguide was defined for exciting the cavity with its fundamental TE_0 mode.

Fig. 1(a) shows an example of an optimized cavity produced using the TO algorithm after ~400 epochs. A periodic Bragg-like structure can be observed around the central region of the cavity. The modal volume calculated was found to be significantly below the diffraction limited volume of $(0.5\lambda_0)^3$ in air.

In contrast to previous studies, TO was additionally employed to maximize the magnetic field confinement, targeting applications in which light–matter coupling is governed by the magnetic-field Purcell factor and magnetic dipole interactions. Interestingly, the optimized structures lacked the characteristic bow-tie structure demonstrated in previous works where the electric-field Purcell factor is maximized [10].

IV. Conclusion

An automated approach based on TO has been developed for the design of THz 2D slab PCRs with high Purcell factors (Q/V_m) and sub-diffraction modal volumes. Future work is to

fabricate the structures for applications in terahertz and millimeter-wave sensing and oscillators.

Intelligent Nanofabrication for Nanophotonics: Quantifying and Understanding Process Variability

Wenhan Zhang[1,*], Ben Mills[1], and Kevin F. MacDonald[1]

[1]Optoelectronics Research Centre, University of Southampton, UK
*Corresponding author: wz2e25@soton.ac.uk

***Abstract*— Fabrication variability is an inherent challenge in nano-manufacturing. We present a bi-directional variational autoencoder – a graphical generative model – that simulates a realistic distribution of process outcomes for a given input design, enabling quantitative analysis of principal deviation modes, and thus well-informed design and process parameter optimisation.**

***Keywords*— nanofabrication, deep learning**

I. Introduction

Nanofabrication techniques underpin the development of photonic and electronic materials and devices, the performance of which is highly sensitive to nanoscale geometry. Such techniques inherently exhibit stochastic variations that lead to discrepancies between designed and realised structures. Conventional process simulation methods typically assume ideal outcomes or provide single deterministic predictions, offering little or no insight into realistic fabrication uncertainties. Here, we introduced a bi-directional conditional variational autoencoder (Bi-CVAE) neural network that models a realistic distribution of likely process outcomes for a given input mask design, generating a set of statistically plausible output sample scanning electron microscope (SEM) images that reflecting observed experimental fluctuations. In conjunction with principal component analysis, this 'one-to-many' capability enables quantitative comparisons of manufacturing variations and their occurrence probabilities. It can inform process control, material/device (inverse) design, and design tolerance and risk mitigation strategies, ultimately improving performance and yield.

II. Methods, Results, and Discussion

We consider focused ion beam (FIB) milling – a vital manufacturing and rapid prototyping technique in plasmonics, nanophotonics and metamaterials research – as a test case. The Bi-CVAE network encodes a training set of binary design masks and corresponding electron microscope (SEM) images of fabricated samples (several iterations of each design) into a latent space. By sampling this latent space, a set of plausible SEM images for new, previously unseen masks can subsequently be generated (Fig. 1a). Importantly, the bi-directional architecture of the network introduces cycle-consistency between mask-to-SEM and SEM-to-mask transformations, which is critical for stable training, and enforces physical correspondence between input and output.

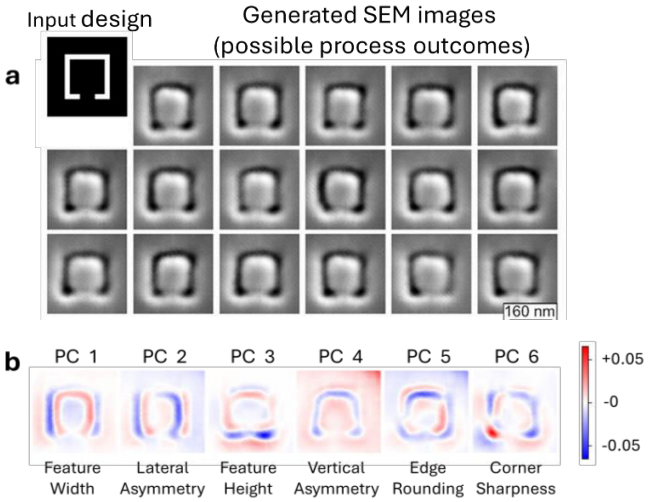

Fig. 1: Quantifying FIB milling variability for a plasmonic split-ring metamolecule: (a) Design mask [top left] and a sample set of possible SEM images for this design [milled into a gold film], generated by a trained Bi-CVAE neural network. (b) Leading principal component eigenmodes from a set of 1000 generated SEM images. Red and blue colours correspond to under- and over-milling, respectively [quantified in terms of pixel intensity].

A principal component analysis performed on the generated image set reveals the dominant modes of fabrication deviations from the intended design (Fig. 1b) and their relative statistical importance. For the plasmonic split-ring resonator case shown in Fig. 1, we find that the first three eigenmodes, corresponding to feature width, left/right asymmetry and height, together describe ~50% of variations, and 10 modes cover ~85%.

This probabilistic characterisation of fabrication variability provides a foundation for informed design adaptation and process control, enabling optimisation guided by realistic uncertainty rather than idealised assumption or trial-and-error.

Manipulating matter with vector twisted light

M. Babiker*,

School of Physics, Engineering and Technology, University of York, YO10 5DD, England
*Corresponding author: m.babiker@york.ac.uk

***Abstract*—Recent work on the influence of higher order (vector) twisted light on matter immersed in such light has led to a variety of novel effects involving dielectric and magnetic particles. This presentation describes the principles, the methodology and the results that have recently emerged in a number of interesting scenarios.**

***Keywords*— Poincaré modes, magneto-optics, optical forces.**

I. Introduction

Optical manipulation stems from the mechanical effects which laser light imparts on matter, both in the form of atoms and molecules or matter as small particles. This currently active area of research continues to be a subject of great interest, both from a fundamental point of view and for useful applications.

II. Methods

An established general framework for the description of twisted light is in terms of higher order Poincareé modes [1]. This accounts for the polarisation states of all forms of optical vortex modes, both scalar and vector and is such that any optical mode is represented by a specific point on the surface of a unit Poincaré sphere of order m. The Poincare higher order modes can possess orbital angular momentum (OAM), Spin Angular Momentum (SAM), as well as helicity and chirality.

We focus on our recent investigations on a number of topics involving twisted light and matter, namely: magneto-optic media [2]; coupling of matter to optical fiber evanescent modes [3], OAM transfer; spin-orbit coupling; dipole and quadrupole interactions optical, vortex mode mixing, atom trapping, optical forces and torques and dynamics in twisted light.

III. Results and Discussion

The interaction leads to trapping, or to matter motion in the vortex fields due to forces and torques [4]. For example, we can evaluate the trajectory and final steady state rotation of an ionic particle in the focal plane of two counter-propagating doughnut beams. In the steady state, this rotation amounts to a steady electric current and there is a corresponding magnetic field, which can be used, for instance, for switching the direction of a localized electron spin or a magnetic particle. Another example shows how the Faraday Effect can be made to change the magnitude and direction of the local polarization of an optical vortex as the beam propagates in a magneto-optic medium [2], which modifies the forces. As and example, Fig. 1 displays the distribution of the gradient torque on a particle due to reactive helicity [4].

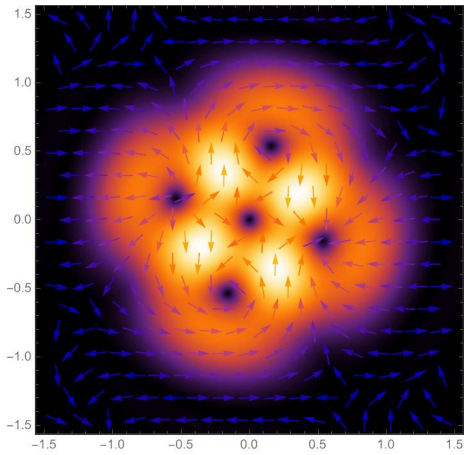

Fig. 1. Vector plot showing the (texture) distribution of the gradient torque due to the gradient of the real part of the optical helicity density for a second order ($m = 2$) radially-polarised Poincaré mode. Lengths are in units of beam waist w_0. This is one of the figures in a current article (in progress) [4]

IV. Conclusion

We have highlighted how vector twisted light leads to new different and versatile forms of matter manipulation. The versatility is enabled by the choice of any twisted light of any chosen form of wave polarizations and any of order. The useful outcomes are new types of optical forces and torques that can be used flexibly in the dynamics and trapping of matter and its use [5,6].

Programmable Nanophotonics with the Plasmonic Phase-Change Material In_3SbTe_2

Lukas Conrads[1,*], Matthias Wuttig[1], Thomas Taubner[1]

[1]Institute of Physics (IA), RWTH Aachen University, Germany
*Corresponding author: conrads@physik.rwth-aachen.de

***Abstract*— We summarize our current research in active nanophotonics using the plasmonic phase-change material In_3SbTe_2 (IST) which exhibits a non-volatile insulator-to-metal transition upon crystallization. We highlight optical programming of functional metasurfaces for emissivity-shaping and infrared beam-shaping including holography, as well as tailoring polaritons on polar crystals and doped semiconductors.**

***Keywords*— phase-change material, metasurface, polaritons, reconfigurable.**

I. Introduction

Metasurfaces have evolved as versatile platforms for tailoring light-matter interactions. Combining metasurfaces with active materials such as phase-change materials (PCMs) [1] promises reconfigurable modifications of the metasurface functionalities. Conventional PCMs enable non-volatile resonance tuning based on a change in refractive index due to positive permittivity values in the amorphous and crystalline phases. The recently introduced plasmonic PCM In_3SbTe_2 (IST) features a plasmonic crystalline phase with negative permittivity in the entire infrared spectral range. [2,3] In contrast to conventional antenna resonance tuning based on a change in refractive index, IST allows for directly reconfiguring the shapes and sizes of the antennas to modify electromagnetic resonances accordingly.

II. Results and Discussion

Here, we now demonstrate rapid prototyping of large area metasurfaces for controlling thermal emissivity, beam steering, lensing and holography. Using a commercial direct laser writing setup, we locally switch the IST from an amorphous dielectric to a crystalline metallic phase. First, we show flexible encoding of different absorption/emission properties within a metasurface by patterning an adaptable grating absorber metasurface. [4] Moreover, we design a lithography-free narrowband and diffuse emitter based on a Fabry-Perot resonance with a switchable IST layer on top to turn on and off the emissivity of the device. [5]

Next, we exploit the geometric phase of rotated crystalline IST rod antennas in combination with circularly polarized light for designing and programming arbitrary phase profiles within the metasurface to realize a multitude of applications such as beam-steering, lensing, optical vortex beams and holography. [6] The fast writing procedure speeds up workflows and paves the way towards mass production of reconfigurable metasurfaces without cumbersome and time-consuming fabrication methods such as electron beam lithography.

Finally, we employ IST on top of the polar crystal SiC and the doped semiconductor CdO to launch and confine surface phonon polaritons and surface plasmon polaritons into laser-written resonators with the ability to modify the resonator shapes to tune the observable polariton modes. [7,8]

III. Conclusion

We have established the plasmonic PCM IST as a versatile platform in nanophotonics for direct programming and reconfiguring functional metasurfaces as well as polariton launching structures. The ability to directly program arbitrary shapes boosts fabrication of nanophotonic devices which conventionally require cumbersome and time-consuming techniques.

***Abstract*— Phase-change metasurfaces are applied to manipulate light-driven reactions, enabling tunability using a Sb_2S_3 cavity. Plasmonic resonance supported by a Au nanodisk array determines the excited-electron population, and, when coupled with the tunable cavity, results in a 2.4-fold modulation of product yield, which illustrates the potential for reversible catalytic control.**

***Keywords*— Phase-changing material, tunable metasurface, light driven reactions, localized surface plasmonic resonance.**

I. Introduction

Phase-change materials (PCMs) provide a promising platform for tunable metasurfaces in energy applications[1]. In light-driven reactions, localized surface plasmonic resonance can govern reactivity by modulating the population of excited electrons in lowest unoccupied molecular orbitals[2], thereby selectively suppressing or enhancing specific products[3].

II. Methods and Results

Tunable metasurfaces exploit the phase-dependent refractive index of PCMs, which switch between amorphous and crystalline states under varying thermal conditions. Antimony sulfide (Sb_2S_3) is a promising PCM, owing to its suitable bandgap (~1.2 eV) and strong visible-light absorption. Fig. 1A illustrates the reversible phase-switching mechanism: crystallization occurs when amorphous Sb_2S_3 (a-Sb_2S_3) is heated above the activation energy, whereas amorphization is achieved by heating crystalline Sb_2S_3 (c-Sb_2S_3) above its melting point followed by rapid quenching[4].

Figure 1B shows a PCM-based tunable metasurface where the cavity material supports constructive interference in the amorphous phase. The cavity resonance hybridizes with the plasmonic resonance of a Au nanodisk array on top, enhancing plasmonic coupling and thereby increasing near-field strength and hot-electron populations[5]. In contrast, crystallization of Sb_2S_3 alters the refractive index to support destructive interference, weakening coupling to the plasmonic resonance.

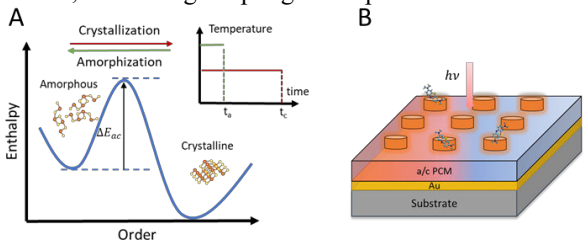

Fig. 1 A. Enthalpy–structure order diagram of Sb_2S_3. B. configuration of Au ND coupled PCM cavity.

The metasurface absorption is measured by a micro-spectrophotometer. At the effective wavelength of 633 nm of the targeted reaction, a 40% absorption difference is observed between a/c-Sb_2S_3 states. Consequently, the tailored resonance enables catalytic control, as demonstrated using methylene blue (MB) degradation as a model reaction. Surface-enhanced Raman spectroscopy reveals a 2.4-fold enhancement in reactivity upon phase switching.

III. Conclusion

A tunable PCM metasurface enables reversible control of the plasmonic resonance strength via phase transitions. Phase-induced refractive index changes drive mode hybridization with cavity resonances, allowing precise modulation of catalytic yield under identical illumination.

***Abstract*— Self-assembled, broadband absorbing nanoparticle films with ~1 nm plasmonic nanogaps reveal wavelength-dependent hot carrier generation. Carriers are tracked at steady-state timescales using electrochemical photovoltage spectroscopy. Molecular control over carrier extraction is demonstrated through chemical functionalisation of nanogaps. Plasmon-enhanced hot electron generation extends from visible to near-infrared wavelengths (>800 nm).**

***Keywords*— plasmonic nanogaps; hot carrier dynamics; self-assembly; electrochemical spectroscopy; solar energy conversion**

I. Introduction

Hot carrier generation in plasmonic nanostructures offers a route to extend solar-driven photocatalysis across the visible spectrum and even into the near-infrared. Extreme optical field enhancement in ~1 nm nanogaps facilitates the efficient generation and harvesting of hot carriers for photochemistry. Resolving carrier behaviour remains challenging due to their short lifetimes, but steady state analysis under extreme plasmonic confinement unveils important mechanistic insights.

II. Methods

Mono-/Multi-layer aggregate films (MLAggs) of Au nanoparticles are formed through self-assembly. Using rigid redox-active or redox-inert linker molecules, billions of highly reproducible nanogaps are formed in our large-area samples (~1 cm^2). We introduce *electrochemical photovoltage spectroscopy* (EC-PVS), a novel use of electrochemical open cell potential monitoring under monochromatic VIS-NIR illumination, to spectrally resolve plasmonic charge carrier generation and extraction on steady-state timescales.

III. Results and Discussion

Experimental results show:

- Strong, broadband absorption in ~20 nm thick MLAggs
- Distinct interband and intraband hot carrier mechanisms
- Hot carrier extraction by redox-functionalised nanogaps
- Plasmon-enhanced hot carrier generation and extraction from 450-850 nm

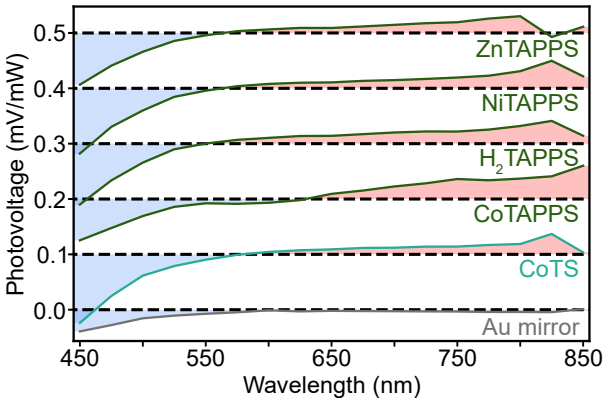

Fig. 1: Photovoltage spectra of chemically distinct MLAggs

IV. Conclusion

This work demonstrates that molecularly functionalised self-assembled plasmonic aggregates exhibit enhanced, broadband hot carrier generation and extraction, and introduces electrochemical photovoltage spectroscopy as a facile technique for tracking wavelength-dependent carrier behaviour, advancing the tools for molecular catalysis and nanoscale optical energy utilisation for full solar spectrum photocatalysis.

***Abstract*— By synthetically controlling colloidal semiconductor nanocrystal heterostructure we have made significant progress toward an ideal quantum emitter – on-demand (blinking- and bleaching-free), high-purity, room-temperature, spectrally tunable (blue-visible to telecommunications wavelengths) single-photon sources. More recently, we have engineered brightness (emission speed and directionality), chirality, polarization and photon indistinguishability through advanced nanointegration.**

***Keywords*— quantum dots, nanoantennas, single-photon source.**

I. Introduction

We synthetically control nanocrystal heterostructure to advance colloidal quantum dots (QDs) as functional, nearly ideal quantum emitters. We have further aimed to influence brightness (speed and directionality), chirality, polarization and photon indistinguishability using external environmental effects, a strategy generally outside the control of the chemist.

II. Methods

Our methodology combines precision synthesis with scanning-probe nanointegration to realize novel properties. We establish and utilize synthesis-structure-function correlations to design next-generation QD building blocks, characterized using advanced single-nanostructure optical spectroscopy and microscopy, as well as a suite of structural and chemical techniques that combine single-nanostructure and ensemble methods for a rigorous, systematic analysis of key correlations "from the inside-out" (Figure 1).[1] Lastly, we advance additive,[1] subtractive[2] and "one-pot"[3] shell-growth strategies as required by material system.

III. Results and Discussion

Through synthesis alone, we have achieved photons-on-demand. Our "giant" or thick-shell core/shell QDs (gQDs) are non-blinking and non-photobleaching.[1,2] With collaborators we take advantage of this unusual stability to construct highly directional, radially polarized and/or fiber-coupled single-photon sources by placing single gQDs into bullseye antennas using scanning probe direct-write nanolithography.[4,5] Alternatively, in a separate collaboration, we have realized ultrafast (to 65 ps) and ultrabright (to ~12.6 MHz) room-temperature single-photon emission in the O and C telecommunications bands via coupling stable PbS/CdS QDs to solution-processed plasmonic nanocavities.[6]

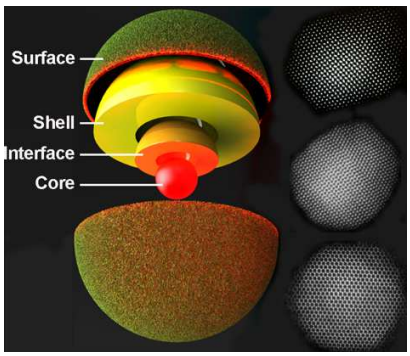

Fig. 1 Schematic illustration of the components of the core/shell QD "from the inside out." Aberration-corrected HAADF-STEM images of QDs used to study synthesis-structure-function correlations.

IV. Conclusion

Using synthesis and nanointegration, we have demonstrated new single-photon sources that provide photons-on-demand, record collection efficiencies and ultrafast photon generation.

***Abstract*— This paper presents a self-powered, chip-scale near-infrared spectroscopic device with broadband, filter-free detection with high responsivity, spectral selectivity, and proportional intensity scaling. Broadband detection covering the NIR spectrum, surpassing conventional Si-bandgap limitations, operating at room temperature and zero bias, with high correlation when benchmarked against commercial FTIR measurements.**

***Keywords*— Surface plasmon resonance (SPR), NIR photodetector, Miniaturized spectrometer.**

I. Introduction

The study builds on previous efforts in NIR plasmonic photodetection, particularly the embedded grating structures [1]. Our earlier reports [2] established a solid foundation for NIR detection; however, the responsivity was limited to a few tens of μA/W, and spectroscopy beyond 1400 nm remained unproven. Additionally, device lifetime was constrained due to unstable interface properties, plasmonic shifts, and reliability concerns. This work advances these results by extending detection across a broader portion of the NIR spectrum—nearly covering the entire range—using a single tunable device. Interface modifications improved long-term stability, enabling reliable operation for over two years. Moreover, the device achieves high sensitivity and accurate spectral reconstruction at room temperature, providing a scalable, CMOS-compatible platform. These improvements represent a significant step forward, promoting device applications in gas detection and elemental identification based on absorption signatures beyond NIR-II, which are hardly achieved using conventional Si-based detectors.

II. Methods

Device geometry was optimized through extensive modeling and experimental validation to achieve wavelength-specific plasmonic photodetection, ensuring high selectivity. The diffraction grating was patterned onto the Si surface through electron beam lithography and dry etching processes. Sequential depositions of Ti/Mo interlayer and top gold (plasmonic) metals were performed using an EB evaporation system. The device is then established on a vibrating cantilever structure as shown in Fig. 1, where the device angle (incidence angle) is changed through an acoustic vibration, and a photocurrent signal is captured.

III. Results and Discussion

Combining Ti/Mo interlayer in the plasmonic structure broadened the device operation range, owing to modifying the barrier height and interface properties. This facilitates the transport of low-energy photogenerated carriers (less than 25 μW at 1900 nm), while maintaining high linearity and sensitivity as shown in Fig. 2. It further demonstrates clear SPR peaks even with parallel exposure to visible light. It maintained higher stability with neither hysteresis nor deterioration in photocurrent measurements over 700 days. The sharp and selective SPR peaks facilitated the expansion of the spectral range for reconstructive spectroscopy to longer wavelengths (Fig. 3(a)). Since the degree of surface sensitivity can be controlled by collecting photoelectrons emitted at different emission angles to the surface plane, the reconstruction of multiple parallel incident wavelengths could be successfully demonstrated (Fig. 3(b)). Making it a powerful technique for investigating the electronic and chemical structures. High sensitivity and stable responsivity even at low light intensity (Fig 4(a, b)), with fast switching capabilities of 25μs (Fig. 4 (c)), are demonstrated. Filter-free quantitative spectroscopy closely matched the performance of a commercial spectrometer (Fig. 4(d)), with long-term stability and durability testing demonstrating less than a 5% decline in responsivity with no observable plasmonic shift. Meanwhile, conventional devices exhibited a plasmonic shift in SPR peaks of 1.5° per SPR peak and a responsivity reduction exceeding 30%. This research represents a significant leap in NIR photodetection and spectroscopy, with far-reaching implications across applications for various scenarios such as gas sensing and environmental monitoring.

IV. Conclusion

We demonstrated a compact Schottky-based photodetector for reconstructive spectroscopy. The system accurately reconstructed incident spectra with high robustness, achieving over 90% correlation with a commercial FTIR spectrometer, while eliminating optical filters and multiple detectors to significantly reduce system footprint. The angle-tuning scheme is inherently compatible with MEMS actuation, providing a clear pathway toward fully miniaturized, high-precision SPR-based spectroscopic systems.

***Abstract*—We experimentally demonstrate bound-state-in-the-continuum lasing modes in deformed honeycomb-lattice nanowire photonic crystals. From the spatial distribution of local polarization, we extract and identify the associated topological charges of the lasing modes.**

***Keywords*— BIC modes, photonic crystal surface emitting lasers, photonic topological insulators.**

I. Introduction

Topological photonics allows for new designs for topological edge mode lasing, e.g., valley-Hall photonic crystal lasers [1]. Alternatively, these new designs can be used for vertically emitting lasers based on semiconductor nanowires, e.g., a deformed honeycomb lattices. Bound-states-in-the-continuum (BICs) can be used for enhancing non-linear effects with enhanced Q factors [2]. These BIC modes appear as a singular point with a topological charge in the far-field radiation pattern showing extremely high Q factors [3].

In this work, we experimentally demonstrate BIC lasing modes in epitaxially grown InGaAs nanowires. By characterizing the far-field emission patterns, we successfully identify a topological charge of -2.

II. Methods

We design the nanowire lasers by deforming the hexagons in honeycomb lattices of InGaAs nanowires. The undeformed honeycomb lattice has the periodicity a = 640 nm and the centre-to-centre distance $R = a/3$ = 213 nm. For extended honeycomb structures, we set R = 230 nm and R = 190 nm respectively. To fabricate the laser, we use the selective area epitaxy method which employs a 20 nm SiN mask with an array of air holes with the diameter of 30 to 50 nm to define the location of the InGaAs nanowires.

As reported in Ref. [4], the two band edges have different symmetries where p-orbital (d-orbital)-like are at the top (bottom) band edge. The doubly degenerate d-orbital like band edge mode is a quadrupolar mode and, importantly, is a BIC mode with a high Q factor. The radiation pattern was measured using the back-focal plane measurement.

III. Results and Discussion

As shown in Fig.1, the optically pumped lasing from the extended honeycomb lattice exhibits a characterisitic doughnut-shaped radiation pattern. Upon rotating the polarizer counterclockwise by 90°, the emission pattern of the quadrupolar modes is observed to rotate clockwise by 45°. This confirms the topological charges of the lasing modes is -2, which is consistent with the theoretical prediction in Ref. [5].

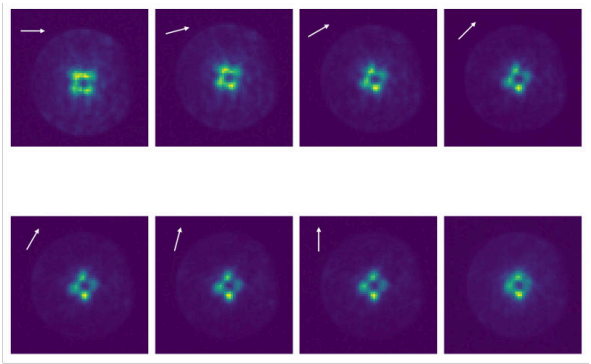

Fig. 1. Far field lasing pattern polarization dependence for an expanded lattice.

IV. Conclusion

We have demonstrated BIC lasing modes using epitaxially grown InGaAs nanowire photonic crystals. The topological charge -2 of the quadrupoloar modes has been confirmed using far-field measurement.

***Abstract*— We use polarization-resolved Raman scattering to probe optical spin in silicon metasurfaces under circular excitation. By tuning disk size and wavelength, we observe strong Raman enhancement with far field polarization losses. Simulations show that quadrupolar resonances spatially varying near fields that depolarize the emitted Raman signal.**

***Keywords*— high-index dielectric metasurfaces, Raman scattering, circular polarization, Mie resonances.**

Nanostructured dielectric metasurfaces provide a powerful platform for tailoring polarization in light–matter interactions for advanced photonic functionalities [1]. However, experimentally accessing the polarization state of optical evanescent fields remains challenging. Raman scattering in silicon, with a well-known polarization response in bulk [2], is an attractive way to address this issue. Despite Raman signal enhancements have been widely demonstrated in nanophotonic structures with strong electromagnetic confinements, its polarization response in such situations remains unexplored [3].

Here, we experimentally explore Silicon on Sapphire disk metasurfaces with polarization-resolved Raman spectroscopy (Fig. 1a). Using circularly polarized light for illumination, we relate the measured Raman enhancement and its Degree of Circular Polarization (DOCP) to Mie resonances in the metasurface, and we link these to the internal field optical spin with numerical simulations.

Our experimental results show, in different metasurfaces:
- Strong Raman enhancement with high DOCP.
- Strong Raman enhancement with strong DOCP losses.

Simulations, together with multipolar analysis, show:
- A good agreement between simulation and experiment.
- DOCP drops connected to angled collection in moderate NA objectives.
- Intrinsic loss of DOCP related to quadrupolar resonances in the metasurface (Fig. 1b).

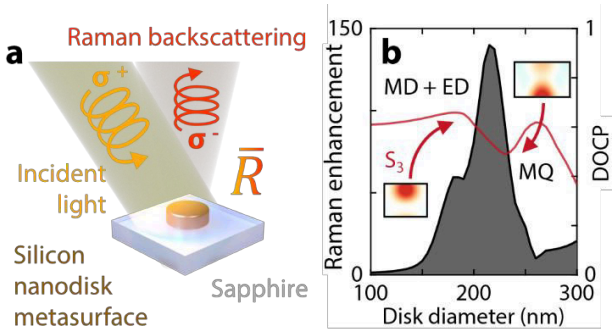

Fig 1. a) Concept art of the studied metasurface. b) Correlation of Raman enhancing resonances with DOCP in simulations.

In conclusion, quadrupolar modes produce complex near-field distributions with spatially varying optical spin, leading to polarization loss in the Raman emission. Polarization-resolved Raman scattering is a useful probe of near-field polarization and optical spin in dielectric nanophotonic systems.

***Abstract*—We present a experimental and theoretical study of plasmon-assisted harmonic generation in the visible and ultraviolet ranges. Our results are supported by a microscopic hydrodynamic model describing the nonlinear interaction at metal surfaces. This work is part of an ongoing effort to explore frequency conversion in metallic metastructures, with emphasis on efficiency, tunability and applications.**

***Keywords*— nonlinear optics, gold metasurfaces, plasmonics, harmonic generation.**

I. Introduction

Nonlinear (NL) frequency conversion in metals has been a cornerstone of nonlinear optics research since the field's inception, driven by the large third-order susceptibilities of plasmonic materials despite their inherent absorption in the visible (VIS) and near-infrared (NIR) spectral ranges. Rapid advances in nanofabrication techniques have enabled the precise design of subwavelength resonant optical metamaterials. Under resonant conditions, plasmonic nanostructures induce strong spatial confinement of the electromagnetic field in the vicinity of the metal surface, that significantly enhances light–matter interactions, leading to large surface nonlinearities and increased frequency conversion efficiencies. The resonant response is governed by both geometrical parameters and intrinsic material properties, including the dielectric functions of the metal and surrounding media at the operating wavelength [1]. Despite this fabrication progress, a comprehensive understanding of how the materials commonly used in photonic nanostructures respond to linear and nonlinear excitation by ultrashort laser pulses across different spectral ranges remains incomplete.

Recently, we have conducted systematic experimental and theoretical studies of the NL optical behavior of metals, achieving a deeper understanding of the fundamental physical mechanisms governing their response [2]. In particular, measurements of second harmonic (SH) and third-harmonic (TH) generation from 20nm and 70nm thick gold nanolayers have enabled the extraction of intrinsic material properties [3]. Studies performed on layers only a few nanometers thick eliminate common simplifying approximations and reveal additional interaction mechanisms that must be incorporated into accurate theoretical models. These insights provide a solid foundation for interpreting NL optical effects in more complex nanostructured structures.

The NL conversion efficiency of a simple metallic nanolayer is typically very low, but it can be significantly enhanced in carefully designed metasurfaces by exploiting plasmonic resonances. Under resonant conditions, plasmonic nanostructures can induce strong spatial confinement of the electromagnetic field near the metal surface. Strong plasmonic interactions substantially enhance light–matter coupling and can excite large surface nonlinearities, giving rise to efficient harmonic generation.

II. Results and Discussions

We first investigated 2D Au nanogratings exhibiting reflection resonance tunable from 700 nm to 1100 nm. We measured the SH and TH generation as a function of the input wavelength, tuned around the resonance at 800 nm. The generated SH (400 nm) and TH (266 nm) signals are shown in Fig.1. The total SH efficiency of the grating is approximately 1400 times larger than that of a planar gold nanolayer. Likewise, the total TH efficiency exhibits an enhancement factor of nearly 4000. Reflected SH efficiencies were also measured around 1000 nm and 1100 nm, yielding comparable enhancement factors. Extensive numerical simulations were performed using our theoretical model, yielding SH and TH enhancement factors in excellent agreement with the experimental results. The simulations accurately reproduce the spectral shape, bandwidth, and peak amplitude of the measured NL response, demonstrating near-perfect correspondence between theory and experiment. [4]

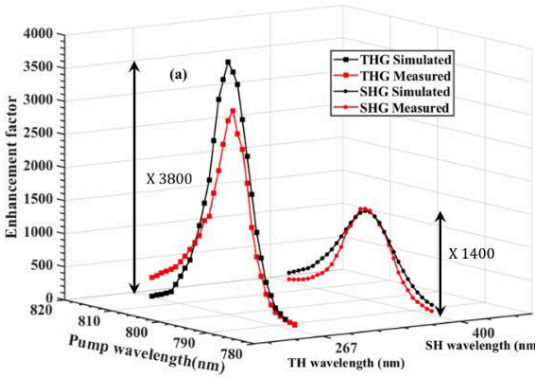

Fig. 1. SH and TH harmonic generation enhancement from a 2D gold grating.

We extend our investigation to a more sophisticated quasi-3D metasurface consisting of nanoholes patterned in gold nanolayers deposited on a structured polymer substrate (Figs. 2a and 2b). While this architecture offers increased flexibility in tuning and shaping the plasmonic resonance, our results indicate that it yields a lower NL enhancement compared to the simpler nanograting structures. Figure 2c shows a narrow plasmonic resonance cantered around 790 nm. The resonance depth and spectral position depend sensitively on the geometrical parameters of the system and the thickness of the gold layer deposited on top.

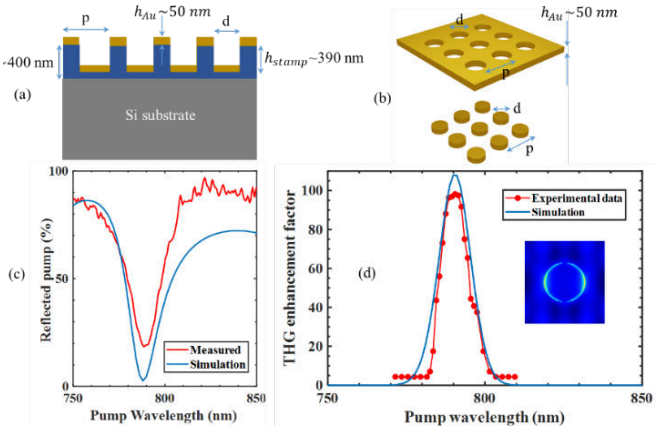

Fig. 2 (a) 2D side schematic of the crystal; (b) 3D view of the two Au layers; (c) the plasmonic resonance at normal incidence (d) Simulated and experimentally detected enhancement profile of the THG around the wavelength of resonance.

We detect and quantify the THG efficiency, and corroborate our theoretical and experimental observations of shape, spectral width, and maximum amplitude of the spectral response. The total efficiency, when scaled to the TH reference signal originating from the unpatterned portion of the gold sample, measured exactly in the same experimental conditions, gives us an enhancement factor of 100 (Fig.2(d)). [5]

III. CONCLUSIONS

We demonstrate two and three orders of magnitude enhancement of the SH and TH generation in different gold metasurface in the visible and deep-UV regime, despite their inherent absorption in these ranges. Precise engineering of metasurface and modern fabrication methods promise very well-tailored plasmonic structures and is the way to produce compact UV light sources embedded with nonlinear components, which represent a crucial step toward the realization of coherent and efficient nanoscale deep-UV light sources.

Advancements in Chiral Nanophotonics via Block Copolymer Supramolecular Assembly and Plasmonic Antenna-Reactor Catalysis

Dong Ha Kim*

Department of Chemistry and Nanoscience, Ewha Womans University, Seoul 03760, Korea
*Corresponding author: dhkim@ewha.ac.kr

***Abstract*— We report chiral supramolecular assemblies from star-shaped block copolymers and chiral molecules enabling stable, full-color circularly polarized luminescence with tunable directionality for advanced optical devices. We further develop chiral plasmonic nanomaterials for optically controlled catalytic cancer therapy and spin-polarized electrocatalysts for efficient, durable acidic water electrolysis toward sustainable hydrogen production.**

***Keywords*— chirality, block copolymer, supramolecular self-assembly, plasmonic antenna-reactor, water splitting.**

I. Introduction

Chirality has emerged as a powerful design principle for controlling light–matter interactions, charge transport, and catalytic reactivity at the nanoscale. By integrating structural asymmetry with functional nanomaterials, it becomes possible to manipulate circularly polarized photons, spin-polarized electrons, and plasmon-enhanced electromagnetic fields within a unified platform.

Beyond optical functionality, chiral plasmonic nanostructures enable dynamic regulation of catalytic processes under circularly polarized light. These developments establish chirality-guided nanomaterials as a versatile framework bridging advanced optoelectronics, precision nanomedicine, and clean energy catalysis.

II. Methods

Chiral supramolecular assemblies were constructed via controlled self-assembly of star-shaped block copolymers with chiral small molecules, followed by structural and CPL characterization. Chiral plasmonic nanoparticles were synthesized through ligand-directed growth and circularly polarized light modulation, then integrated with catalytic or single-atom sites. Optical, electrochemical, and biological assays evaluated performance.

III. Results and Discussion

Hierarchical self-assembly produced well-defined chiral nanostructures exhibiting strong, tunable circularly polarized luminescence across the visible spectrum with enhanced stability, overcoming prior red-emission limitations. Under circularly polarized light, chiral plasmonic nanoparticles showed handedness-dependent field enhancement, enabling selective amplification of enzyme-mimetic catalytic cascades and significantly improved tumor cell inhibition. In electrochemical systems, integrating chiral Au nanostructures with single-atom iridium centers induced spin-polarized charge transfer, lowering overpotentials and accelerating reaction kinetics in acidic water electrolysis.

IV. Conclusion

These studies establish chirality as a unifying strategy to control photons, plasmons, and spin-polarized electrons at the nanoscale. Hierarchical supramolecular and plasmonic architectures enable advanced circularly polarized emission, optically programmable cancer therapy, and efficient acidic water electrolysis, demonstrating broad potential across photonics, biomedicine, and sustainable hydrogen energy technologies.

***Abstract*— Coherent coupling between light and high-frequency sound waves in integrated photonic circuits enables unique signal processing functionalities. This effect, known as Brillouin scattering, allows for frequency-selective amplification and phase shifts that are widely exploited in microwave photonics and optical signal processing applications, sensing, and the generation of low-noise microwave and optical signals. In this invited talk, I will present several approaches for tailoring Brillouin interactions on a photonic chip. On the one hand, engineering of the waveguide cross-section and the waveguide material determines both the Brillouin frequency shift and the interaction linewidth. In particular, tailoring the waveguide dimensions, especially its height, strongly influences the opto-acoustic overlap and for appropriately designed thin waveguides, Brillouin interactions can couple light to surface acoustic waves (SAWs). Exposing the acoustic wave at the surface of the waveguide provides new opportunities to manipulate light-sound interactions and to develop novel sensing schemes. On the other hand, engineering the photonic density of states in on-chip waveguides and resonators offers an additional degree of freedom for controlling Brillouin interactions. The density of states can be tailored by introducing one-dimensional photonic bandgaps into the waveguide. These bandgap structures can either enhance or inhibit the Brillouin interaction. In particular, suppressing cascaded higher-order Brillouin scattering in resonators presents a promising pathway toward improving Brillouin laser performance.**

***Abstract*—An indium-arsenide quantum dot is embedded in a circular-Bragg grating microcavity to create a bright single-photon source emitting at 1.5 µm wavelength. Periodic excitation of a confined hole spin in the presence of an external magnetic field enables the sequential generation of photons entangled in a linear cluster state.**

***Keywords*— telecom wavelength, quantum dot, CBG microcavity, entanglement, photonic cluster states**

I. Introduction

Photonic cluster states are a key resource for quantum information processing. In particular, their generation at the telecom wavelength around 1.5 um enables optimal use in existing silica-fiber networks due to low photon loss. By using a semiconductor quantum dot as a matter–light interface, we generate these states deterministically, paving the way toward future scalability.

II. Methods

Emission at the telecom wavelength is achieved by growing InAs quantum dots in an InAlGaAs matrix. Compared to the traditional GaAs environment, this matrix enables the quantum dots to grow larger, relaxing the confining energies of trapped excitonic complexes. A hole-trion optical transition is then driven by externally applied laser pulses to produce photons entangled in a cluster state [1].

Harvesting the quantum dot emission is achieved by embedding it in a circular-Bragg grating ('bullseye') microcavity [2]. Its cavity mode outcouples from the material surface with a directional Gaussian profile that is efficiently collected by an optical objective. In addition, the cavity mode induces a Purcell effect of $F_p \approx 4.3$, reducing the hole-trion lifetime to $\tau_L = 240 \pm 5$ ns. This enables coherent mapping between the matter spin and the emitted photons without substantial dephasing.

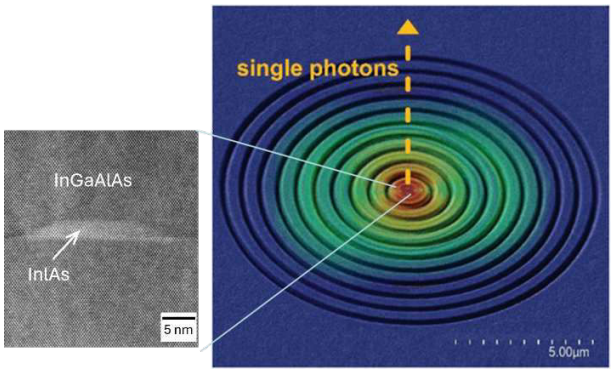

Fig. 1. A quantum dot is embedded in a circular-Bragg grating microcavity.

III. Results and Discussion

We implemented a cluster state generation protocol using a pulsed laser with a repetition rate of 80 MHz. The output spin–photon entanglement is characterized using three-photon correlation tomography.

Experimental results show:

- Hole coherence time of $T_2^* = 15.9 \pm 1.7$ ns [3]
- Spin–photon polarization entanglement with negativity $\mathcal{N} = 0.27 \pm 0.02$.
- Cluster state generation with process map fidelity of $\mathcal{F} = 0.71 \pm 0.01$ compared to the ideal case.

IV. Conclusion

We have demonstrated spin–photon-photon cluster state generation directly at the telecom C-band.

***Abstract*— Active, micro-scale photonic systems have been demonstrated by combining liquid crystalline polymers and 3D micro-structuration. Liquid crystalline polymers are characterized by their ability to undergo significant, reversible changes when triggered by light, enabling an all-optical reconfiguration of 3D responsive nanostructures for tunable linear and nonlinear photonics.**

***Keywords*— Liquid crystalline polymers, two-photon lithography, nonlinearity, physical unclonable function, all-optical modulation**

Polymer-based photonic platforms provide a cost-effective and versatile framework for engineering controllable optical functionalities across the micro- and nanoscale. Recent progress in advanced lithographic and additive manufacturing techniques have enabled the fabrication of complex three-dimensional architectures in functional materials, opening new opportunities for integrating stimuli-responsive systems into photonic devices.

Liquid crystalline polymers offer a unique mechanism for dynamic control, exhibiting large, reversible, and anisotropic changes under thermal or optical excitation. This responsiveness allows for the simultaneous reconfiguration of device geometry and refractive index, transforming light from a mere information carrier into a tool for the active modulation of tunable linear and nonlinear photonic components. In this way, we achieve remote and reversible modulation of optical functionalities in photonic structures, including micro-lasers, beam steering devices, microcavities, and photonic crystals [1-2]. While these structures operate in the linear regime, we are investigating nonlinear optical responses at low light intensities by thermo-optical nonlinearity of polymer-stabilized liquid crystals [3]. Furthermore, we show that the spatiotemporal control of optical responses in complex photonic materials can enhance the security of all-optical physical unclonable functions [4-5]. These photo-responsive systems can enlarge the potential of integrated polymer photonics and cybersecurity by enabling a dynamic control of light by light at low-power.

Abstract— **This presentation examines the formation of a lateral *pn* junction in graphene integrated with an ordered array of Au nanocylinders on a SiC substrate (fig.1a). Spatially resolved Raman spectroscopy reveals a coupled interplay between mechanical strain, plasmon-enhanced Raman response, and charge redistribution across the graphene/Au interface. The ordered nanocylinder architecture provides well-defined mechanical boundary conditions that enable separation between regions dominated by structural disorder and regions characterized by spatially correlated strain, allowing the evolution of lattice symmetry, carrier redistribution, and phonon behavior to be followed spectroscopically. A spectroscopic marker of the structural interface is provided by the appearance of a SiC-related Raman feature near 2100 cm⁻¹, observed only in the Au-covered region due to plasmon-enhanced scattering. This feature enables localization of the graphene/Au boundary independently of optical contrast. Hydrogen-intercalated graphene on SiC exhibits intrinsic *p*-type doping far from the nanocylinders, reflected in the positions of the G and 2D Raman modes and consistent with quasi-free-standing graphene formed by hydrogen intercalation [1,2]. Approaching the nanocylinder array introduces strong but spatially non-uniform strain, manifested by peak shifts and broadening of the G, G′, and 2D modes, indicating coexistence of locally distinct strain and doping environments. Deeper inside the ordered array, stabilization of Raman peak positions and intensities coincides with the emergence of a more spatially coherent strain field. Three complementary Raman signatures contribute to the physical interpretation of the graphene/Au interface. The evolution of the D band reflects enhanced Raman sensitivity to locally broken lattice symmetry and associated intervalley scattering activated by strain inhomogeneity and interfacial perturbations. The subsequent reduction of D-band intensity within the spatially ordered region indicates that the observed signal is consistent with amplification of pre-existing lattice perturbations rather than the formation of permanent structural defects. The G-band response provides an additional probe of lattice perturbation and symmetry breaking. Close to the interface, reduced G-band intensity together with increased separation of its Raman shift from the G′ mode is consistent with structural inhomogeneity and non-uniform strain. Within the ordered nanocylinder array, recovery of G-band intensity and stabilization of its spectral position coincide with the transition toward a more spatially coherent strain field and reduced disorder. In contrast, the spectral evolution of the 2D band (fig.1b) reveals lifting of phonon degeneracy in regions where strain becomes spatially correlated. The appearance of 2D-band splitting coincides with the development of coherent strain rather than with regions of strongly non-uniform strain. Simultaneously, the position of the 2D mode exhibits a maximum followed by a decrease, consistent with a gradual transition from intrinsic *p*-type to effective *n*-type carrier behavior. The lateral *pn* junction therefore forms in the region where correlated strain and plasmon-modified charge redistribution spatially overlap and is displaced from the structural interface identified by the SiC Raman feature. Finite-element simulations identify three flexural mechanical resonances of the Au nanopillars at 1.89, 2.30, and 2.32 GHz for a geometry defined by 100 nm diameter, 200 nm height, and 192 nm period. These GHz frequencies are consistent with locally resonant bending modes of the nanopillars rather than Bragg-type surface acoustic waves of the substrate. Under optical illumination, localized surface plasmons at the Au pillars generate near-field enhancement and thermo-elastic stress that provide a plausible pathway for acousto-plasmonic interaction between plasmonic excitations and GHz flexural phonons. Strain-induced modulation of graphene carrier density and screening in this regime is conceptually consistent with previously reported plasmon–phonon coupling mechanisms in graphene [3-5]. Recent experiments further demonstrate GHz acoustic modulation of plasmonic resonances in Au nanostructures [6] and describe such interactions within the framework of tunable acoustoplasmonic metasurfaces [7]. The interaction may be described phenomenologically by a strain-mediated coupling Hamiltonian :**

$$H_{int} = g\varepsilon(r,t)n(r,t)$$

where ε denotes the flexural strain field of the nanopillar resonance, n the graphene carrier density modulated within plasmonic hot spots, and g an effective strain–charge coupling constant describing energy exchange between phononic and plasmonic subsystems. Within this framework, plasmon-induced local screening can progressively compensate intrinsic *p*-type doping in hydrogen-intercalated graphene, consistent with the carrier-polarity evolution inferred from Raman spectroscopy.

Overall, the results establish a spectroscopically resolved mechanism for lateral *pn*-junction formation governed by the interplay of strain coherence, plasmon-enhanced Raman response, and charge redistribution in graphene coupled to a locally resonant metallic nanostructure. This coupled strain–plasmon–flexural-phonon behavior defines a physical platform relevant to META-scale nano-optoelectronics, where mechanical, electronic, and photonic degrees of freedom can become intrinsically linked within two-dimensional material systems.

Abstract — Here we will provide an integrated overview of our recent advances in colloidal quantum well (CQW) materials and devices, spanning their heterostructure designs and integration into metadevices. We will present examples of CQW-based photonic structures and devices for classical and quantum light generation.

Keywords — Semiconductor nanocrystals, colloidal quantum wells, optoelectronics, quantum optics

Colloidal semiconductor quantum wells (CQWs), also known as nanoplatelets, have emerged as a versatile materials platform for next-generation optoelectronics and nanophotonics owing to their atomically precise thickness control, narrow emission linewidths, giant oscillator strength, and strongly anisotropic transition dipoles. These attributes enable strong and highly tunable light–matter interactions in solution-processable media.

In this talk, we will present an integrated overview of our recent advances in CQW materials and devices, spanning heterostructure engineering, optical gain engineering, photonic integration, and quantum light generation. In particular, we will discuss atomically flat and tightly confined CQWs designed for color conversion and light-emitting applications [1–9]. By engineering advanced CQW heterostructures, we will show record-high efficiencies from CQW-based LEDs [10-12], together with record-high optical gain coefficients and ultralow lasing thresholds in colloidal laser platforms [13,14]. We will also discuss the integration of these nanocrystals with carefully designed dielectric and photonic structures to realize colloidal metadevices [15]. Finally, we will present highly engineered CQW heterostructures for room-temperature single-photon emission and high-purity quantum light generation [16].

Given their accelerating progress, these solution-processed nanocrystals offer great promise to challenge their epitaxial thin-film counterparts in semiconductor optoelectronics.

***Abstract*—III-nitrides, including AlN and GaN epitaxially grown on sapphire, are an attractive platform for integrated nonlinear photonics. We present our recent work on nonlinear optics in AlN/GaN microresonators and waveguides, including Kerr comb generation, optical parametric oscillation (OPO), stimulated Raman scattering (SRS), and supercontinuum generation (SCG).**

***Keywords*— AlN, GaN, microcombs, optical parametric oscillation, stimulated Raman scattering, supercontinuum.**

I. Introduction

Aluminum nitride (AlN) and gallium nitride (GaN) are wide bandgap semiconductors with both intrinsic $\chi^{(2)}$ and $\chi^{(3)}$ optical nonlinearities. AlN/GaN epitaxially grown on sapphire exhibit large refractive index contrast, making such III-nitrides on insulators an attractive platform for integrated nonlinear photonics [1,2]. In this talk, we present our recent work on nonlinear optics in AlN/GaN high-Q microrings and straight waveguides, including Kerr comb generation, optical parametric oscillation (OPO), stimulated Raman scattering (SRS), and supercontinuum generation (SCG).

II. Broadband Kerr Comb Generation

By optimizing the inductively coupled plasma dry-etching process [2,3], AlN/GaN microrings with intrinsic quality factor (Q) around 2×10^6 can be fabricated. Broadband Kerr comb generation is demonstrated at the near-infrared (NIR) regime in both AlN and GaN high-Q mircorings.

Thanks to the large nonlinear refractive index of GaN ($n_2 \sim 1.4\times10^{-18}$ m^2W^{-1}), which is several times larger than that of Si_3N_4 or $LiNbO_3$, parametric oscillation threshold power as low as 6.2 mW is demonstrated in GaN microring with an intrinsic Q factor of 1.8×10^6 [2]. In addition, single soliton comb generation in GaN microrings is implemented by an auxiliary laser pumping scheme, as shown in Fig. 1.

Being non-centrosymmetric, III-nitrides harbor intrinsic $\chi^{(2)}$ nonlinearity, which allows up-conversion of the NIR Kerr comb lines into the near-visible regime via second-harmonic (SH) and sum-frequency (SF) processes. As shown in Fig. 2, simultaneous generation of broadband NIR and near-visible combs are recorded in a 60-μm-radius AlN microring [4].

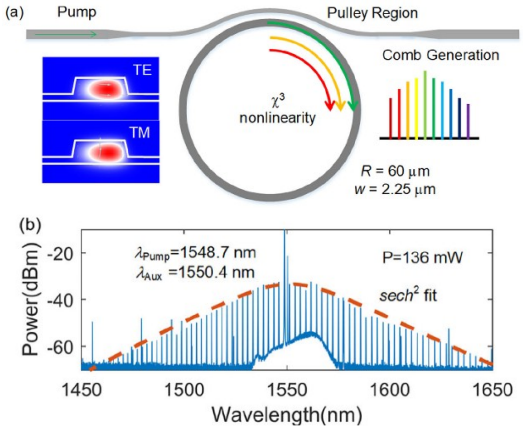

Fig. 1 Single soliton comb generation in a GaN microring.

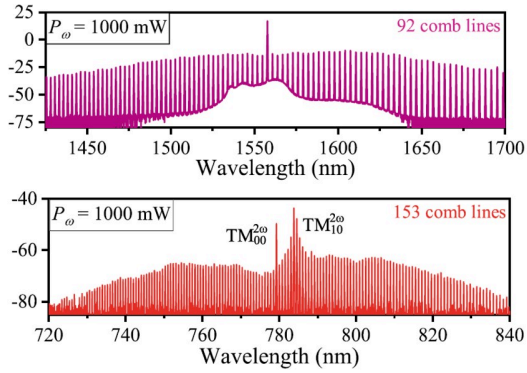

Fig. 2 Simultaneous generation of broadband NIR and near-visible combs in an AlN microring.

III. OPO in III-Nitride Microresonators

Light ranging from visible to mid-infrared wavelengths can be generated with low threshold and wide tunability via OPO based on $\chi^{(3)}$ nonlinear process. Widely separated tunable OPO is demonstrated in GaN microresonators [5]. Special care is paid to the dispersion engineering of the microring, so as to ensure phase-matching as well as to achieve normal dispersion to inhibit FWM.

As shown in Fig. 3, OPO frequency separation up to 96.6 THz is recorded in a 150-μm-radius and 2.7-μm-width GaN microring. The signal (idler) sideband can be shifted by 26.7 (21.3) THz, as the pump is tuned by 2.7 THz into different resonances.

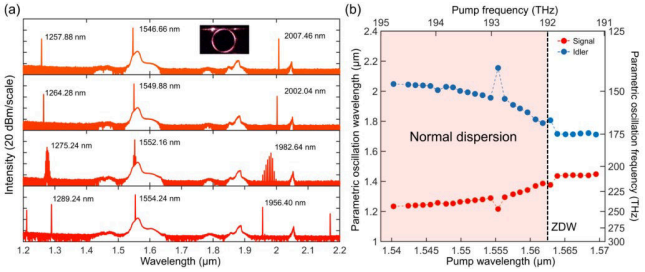

Fig. 3 Tunable OPO sidebands in a GaN microring.

IV. Microcavity Raman Lasers

Wurtzite III-nitrides boast six Raman-active optic phonons, making them appealing for Raman lasing [6,7]. As shown in Fig. 4, single-mode Raman lasing is recorded in an 80-μm-radius AlN microring with an intrinsic Q factor of 2.3×10^6. The threshold power for TM-polarized pump is as low as 8 mW. The Stokes shift is ~612 cm^{-1}, corresponding to excitation of the A_1 (TO) phonon. Furthermore, single mode Raman lasing with Stokes shift of ~657 cm^{-1} is recorded with TE pump, corresponding to the E_2 (high) phonon mode.

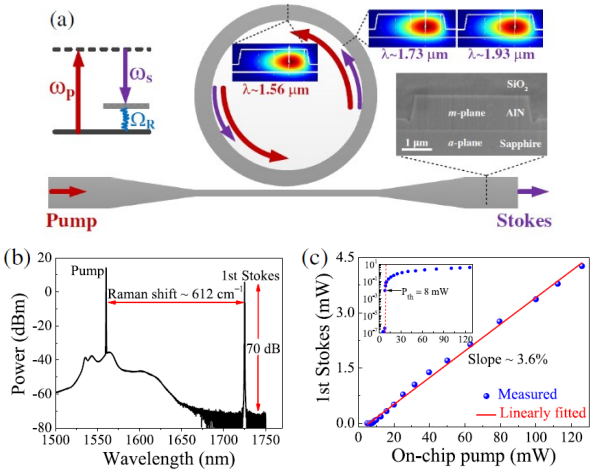

Fig. 4 Integrated AlN Raman laser with TM-polarized pump.

V. Supercontinuum Generation

Octave-spanning SCG in both AlN and GaN waveguides have been demonstrated, thanks to their wide transparency window and simultaneous $\chi^{(2)}$ and $\chi^{(3)}$ nonlinearities. The large nonlinear refractive index n_2 of GaN makes it particularly attractive for broadband SCG. As shown in Fig. 5, when pumped by erbium doped fiber laser with a pulse duration of 70 fs and a repetition rate of 100 MHz, two-octave-spanning SCG generation is obtained in a 2-mm-long dispersion engineered GaN waveguide, covering the spectral range from 600 nm to 2400 nm. Second- and third-harmonic generation are recorded simultaneously, further extending the spectral coverage [8].

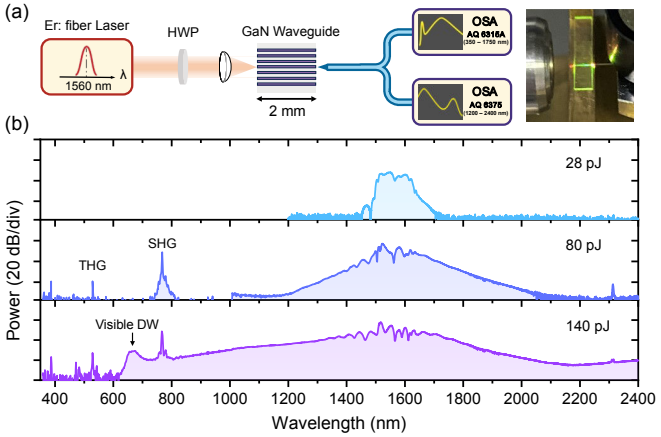

Fig. 5 Experimental setup and recorded spectra of SCG in GaN waveguides.

VI. Conclusion

A series of nonlinear optics have been implemented with AlN/GaN microresonators and waveguides, including broadband Kerr comb generation, widely separated tunable OPO, high efficiency Raman lasers, and octave-spanning SCG, confirming AlN/GaN on sapphire as an attractive platform for on-chip nonlinear photonics.

***Abstract*—We present optical measurements on inverse opals with controlled second-harmonic generation within a fabrication-tunable photonic stopband. We create scalable, 3D, second-order photonic crystals with unprecedented domain sizes (over 100 unit cells), overcoming previous limitations by combining colloidal self-assembly of polystyrene opals for templating and sol-gel barium titanate chemistry for replication.**

***Keywords*— second harmonic generation, colloidal self-assembly, 3D photonic crystals, photonic crystals, USAXS.**

I. Introduction

Three-dimensional nonlinear (second-harmonic) photonic crystals can simultaneously generate different nonlinear processes, such as second-harmonic generation, optical parametric amplification, and other sum- and difference-frequency processes, along different photonic-crystalline directions.[1] Laser-poling and laser-erasing have been utilised in materials such as lithium niobate and barium-calcium titanate.[2] With the first bottom-up fabricated 3D second-harmonic woodpile photonic crystal, we introduced the later used sol-gel chemistry in combination with soft-nanoimprint lithography.[3] However, creating large crystals in all three dimensions, mainly in the z-direction, presents a considerable challenge, primarily due to the chemical inertness of metal oxides.[4]

II. Methods

We selectively synthesised monodisperse polystyrene colloidal nanospheres with tunable unit sizes to self-assemble opal photonic crystals with different stopband wavelengths. These serve as templates for infiltration with barium titanate sol-gel. During calcination and annealing, the organic host matrix is burnt away, leaving an inverse fcc network of tetragonal barium titanate. The tetragonal phase was verified by the pumping power dependence of the higher-harmonic signal (Figure 2 a). We fabricate samples with unprecedented sizes for single domains: > 3000 unit cells in x, y directions and > 100 in the z direction (Figure 1 a, b). Due to their size, we were able to isolate individual single domains. We verified their intact internal photonic crystal structure, together with their initial growth direction normal to the substrate along the (111)-direction of the fcc crystal, using ultra-small-angle x-ray spectroscopy. One single individual domain was mounted on a rotation stage normal to the incident beam, and the resulting 2D diffraction patterns were recorded angle-dependent (Figure 1 c, d). The achieved optical reflectivity values are above 80% relative to a DBR mirror throughout all the fabrication. We can engineer the final photonic band gap over the entire optical range, matching it to both material and setup requirements.

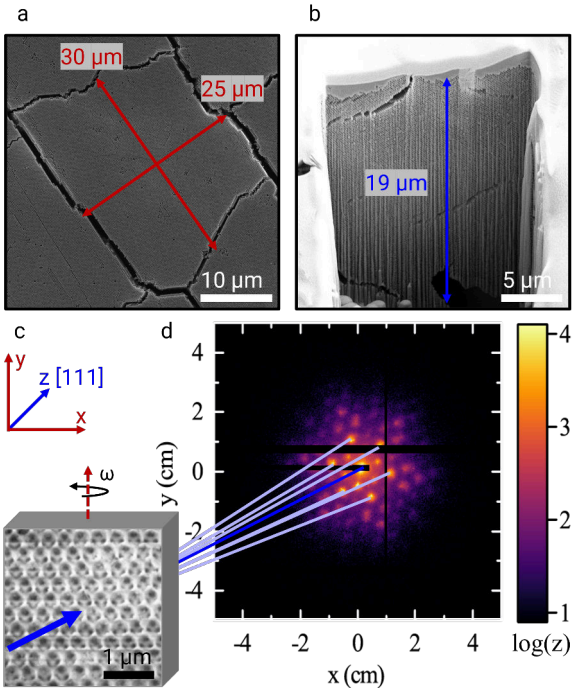

Fig. 1. Inverse barium titanate photonic crystals; Scanning electron microscopy images with domain dimensions: (a) In the (111)-plane and (b) normal to it. (c) Free-standing single domain with its rotation axis for ultra-small angle X-ray spectroscopy; (d) The corresponding 2D diffraction pattern for the (111)-direction.

III. Results and Discussion

With our approach, we overcame previous limitations, especially stacking in the z-direction, while maintaining full tunability of the initial unit cell and, consequently, the final dimensions. By reverse-engineering the final stopband centre wavelength, we can both avoid the materials' absorption regime and match the available laser setups. This allowed us to measure the SHG signal as a wavelength sweep over the stopband, where we observed band-edge enhancement,

a stopband dip, and field-localisation asymmetry. A detailed discussion on the interpretation of these experimental findings is still ongoing, but they mark important steps towards experimentally targeting inhibited spontaneous emission. [5] For this, we are taking steps to replace the colloidal fcc template with a photonically superior, larger bandgap colloidal diamond structure.[7] Configurations to investigate inhibited excitation can be fabricated using the same technique with our controlled size tunability.[6]

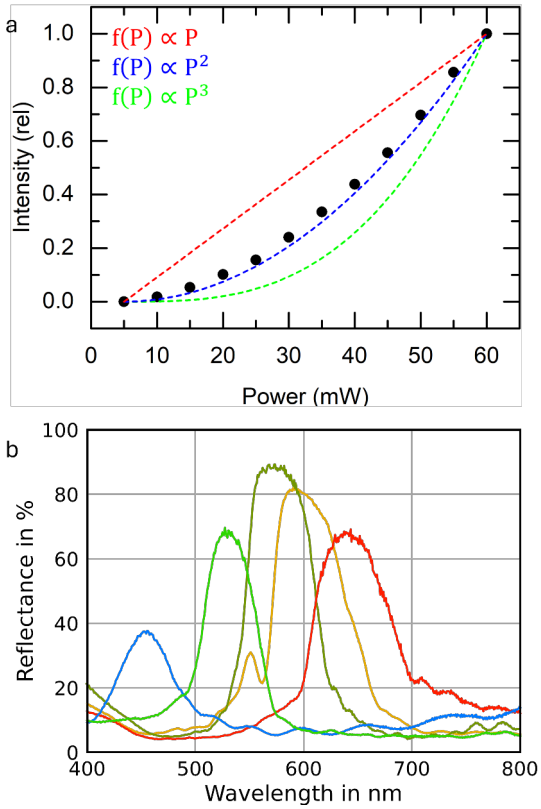

Fig. 2. Barium titanate inverse opal photonic crystals: (a) Pumping-power dependent signal intensity series showing the second-harmonic scaling; (b) Reflectance spectra for different inclinations with optical range colour coding with its most pronounced stopband in (111) direction.

IV. Conclusion

In this study, we demonstrated the use of colloidal-crystal templating for a second-order optical material. We successfully replicated the photonic network into a second-order material and demonstrated, for the first time, a stopband (linear photonic bandgap) from a fully scalable three-dimensional photonic crystal (Figure 2 b) made of a $\chi^{(2)}$ optical material (Figure 2 a).

***Abstract* — We present a numerical study showing the reconstruction of SPP dispersion diagram of a metal–dielectric interface from extraordinary optical transmission resonances in gratings with subwavelength Fabry–Pérot apertures. By varying periodicity, each device probes distinct momentum states, enabling reconstruction of the SPP dispersion in close agreement with eigenmode solutions.**

***Keywords* — Plasmonic Metagrating, Non-Hermitian Photonics, Quasinormal Mode Analysis, Dispersion Diagrams.**

I. Introduction

Plasmonic materials enable strong optical confinement and field enhancement, but their response is highly sensitive to the dielectric function, fabrication conditions, oxidation, and microstructure [1–3]. Consequently, small variations in optical constants can significantly alter device performance [4]. Among the most informative descriptors are the dispersion relation and plasmonic efficiency, which link frequency to momentum and determine propagation, confinement, and loss [5,6]. For periodic plasmonic lattices, dispersion diagrams are typically obtained from angle-resolved reflection measurements [7,8]. These methods probe SPP Bloch modes of the patterned interface, but the intrinsic flat-interface SPP continuum is folded into the Brillouin zone and may be obscured by Wood anomalies and geometry-dependent artifacts. As a result, extracting material-related dispersion from periodic structures remains nontrivial.

Here, we investigate an alternative approach based on extraordinary optical transmission through plasmonic gratings with subwavelength apertures acting as Fabry–Pérot (FP) resonators. Instead of scanning the incidence angle, the grating period is varied to probe different optical momenta, where each device acts as a discrete momentum probe. Because the resonances arise from hybridization between cavity-like FP modes and surface-bound plasmons, their spectral shifts encode both geometric and material dispersion. Numerical results show that, after separating these contributions, the corrected resonances reconstruct the SPP dispersion of the metal–dielectric interface.

II. Methods

The system considered is a one-dimensional plasmonic grating containing periodic subwavelength apertures. The metallic blocks are embedded in the same dielectric on both sides (Fig. 1.a). The unit-cell period and thickness are set equal (H = L). The structure is excited at normal incidence with TM polarization, so that transmission is dominated by slit-supported TM modes. Dispersion diagrams are evaluated using modal analysis based on a non-Hermitian quasi-normal mode (QNM) formulation [9,10]. Momentum-space sampling is achieved by sweeping the grating periodicity H, with each structure probing a discrete in-plane wavevector $k = 2\pi/H$.

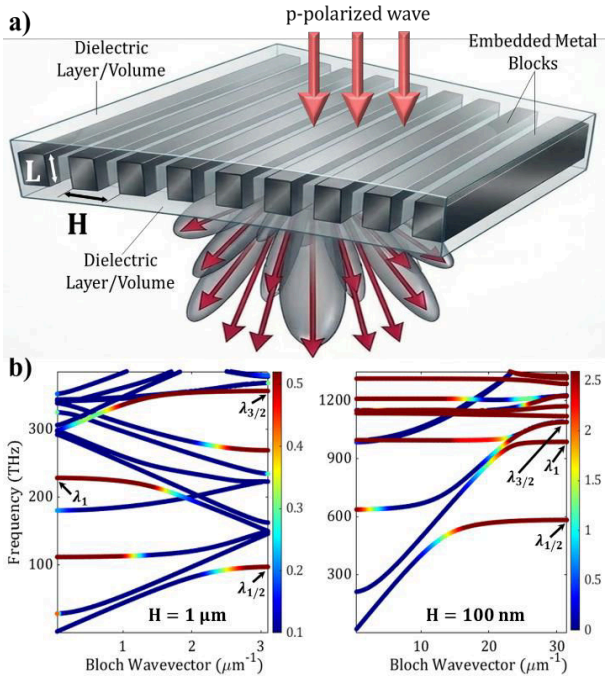

Fig. 1.a) Schematics of the structure consisting of a plasmonic slab embedded in a dielectric matrix (air). H and L are parameters of the unit cell. b) QNM-derived photonic dispersion diagrams for the plasmonic system at two sizes 1 µm and 100 nm. The colormap encodes energy leakage into the metal blocks. FP resonances at $\lambda_{1/2}, \lambda_1, \lambda_{3/2}$ are depicted.

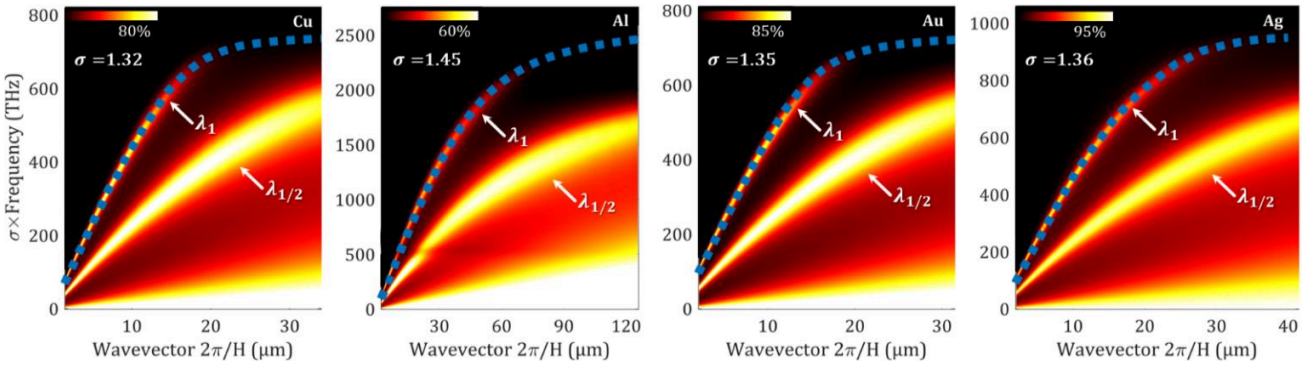

Fig. 2 Optical transmission maps through plasmonic grating composed of different materials (Cu, Al, Au, Ag) as function of the corrected frequency $\sigma(r,\varepsilon) \times f$ against the wavevector. FP resonant bands are highlighted. The colormap reflects the plasmonic efficiency. The true SPP signature, evaluated using eigenmode studies, is shown in blue.

The FP resonance frequencies extracted from transmission spectra should be corrected by a factor $\sigma(r,\varepsilon) = \sigma_{geo}(r) + \sigma_{mat}(\varepsilon)$ to recover the SPP signature. The geometric factor $\sigma_{geo}(r)$ accounts for aperture-induced field leakage and inter-cavity coupling deviating from ideal FP behavior [11]. The material factor $\sigma_{mat}(\varepsilon)$ encapsulates additional phase shifts introduced by dispersive permittivity. The total correction $\sigma(r,\varepsilon)$ is calibrated by aligning the low-frequency branch to the free-space light line, where dispersive effects are negligible [12].

III. Results and Discussion

A. Modal Hybridization and Photonic Dispersion

Fig 1.b compares the photonic dispersion diagrams obtained by QNM-FEM for two grating periodicities. The colormap encodes energy leakage into the metal blocks and reveals significant energy penetration for $H = 100$ nm. For $H = 1$ µm, the diagram exhibits classical grating-coupled SPP behavior with Bloch bands folded at the Brillouin zone boundary, modulated by FP-like resonances at half-wavelength multiples: half-wave, fundamental, and three-half-wave FP modes ($\lambda_{1/2}$, λ_1, $\lambda_{3/2}$) [13]. Above $\lambda_{3/2}$, diffraction dominated high-order modes suppress coherent optical transmission.

At H = 100 nm, the larger reciprocal lattice vector drives modes into the evanescent zone before Brillouin zone folding, producing flat bands, anti-crossings, and strong FP–SPP hybridization. The energy localization colormap clearly distinguishes delocalized photonic states from tightly bound plasmonic cavity modes, which leak optical energy into the metallic boundaries, confirming substantial field penetration into the metallic blocks at high frequencies. Above the SPP frequency (~1160 THz), additional localized modes emerge as flat bands due to hybridization between Bloch-SPP modes and aperture waveguide modes. These near-zero–group-velocity bands are a signature of strong photonic hybridization.

B. SPP Dispersion Reconstruction via FP Resonances

Fig. 2 illustrates the FP–SPP hybridization mechanism responsible for the frequency shifts as a function of the period-derived wavevector. The plasmonic response naturally appears over different frequency ranges for different metals, reflecting their distinct dielectric dispersions and plasmonic efficiencies. Overlaid in blue are the reference SPP dispersion curves obtained from eigenvalue analysis of the corresponding flat metal–air interfaces. The dispersion maps are reconstructed by tracking the second-harmonic FP resonance (λ_1) while sweeping the grating periodicity for four metals: copper (Cu), aluminum (Al), silver (Ag), and gold (Au) [14].

As shown in Fig. 2, the FP resonance bands red-shift markedly, particularly at small periods (large wavevectors), where stronger field confinement enhances interaction with the metal and dispersive effects become more pronounced in the near field. The transmission amplitude decreases accordingly, governed by the intrinsic ohmic losses of each material. These trends enable dispersion mapping, demonstrating that the second-harmonic FP modes faithfully trace the independently calculated SPP dispersion of the flat metal–air interface. Furthermore, the transmission intensity in Fig. 2 simultaneously encodes plasmonic efficiency: sharp, high-transmission resonances indicate low-loss plasmonic coupling, whereas broadened or suppressed features reflect increased ohmic dissipation and mode degradation.

***Abstract*: Optical anisotropy plays a crucial role in the manipulation of light. Transition metal dichalcogenides possess both high refractive index and high birefringence, opening opportunities to tailor Mie resonances. Here, we investigate optical resonances in MoS_2 nanoplatelets with both geometrical and refractive index anisotropies to control light scattering.**

***Keywords*: high-refractive index, high birefringence, Mie resonances.**

Anisotropy plays a crucial role in manipulating light, underpinning optical components such as polarizers, waveplates, and modulators, as well as phenomena like phase-matching in nonlinear optics. The functionality of these devices hinges primarily on the retardance between two orthogonal linear polarizations, which is proportional to both the thickness and the birefringence (Δn) of the material. A large birefringence is thus beneficial for the performance and compactness of such components. Birefringence is also a tunability degree of freedom for nanophotonics, for example, in electro-optic modulators, waveguides with reduced cross-talk, and electro-optic polarization conversion. Beyond natural materials, metasurfaces and metamaterials can be constructed to achieve high anisotropy but suffer from losses and fabrication challenges. As a result, natural materials with higher anisotropy than conventional dielectrics or metals are in demand.

Transition metal dichalcogenides are promising birefringent materials due to their layered van der Waals structure, which naturally yields a large intrinsic birefringence exceeding unity. In particular, molybdenum disulfide (MoS_2) possesses one of the highest birefringence of all natural materials in the near infrared. Such a high birefringence is possible thanks to the presence of strong excitons. They endow MoS_2 with a high in-plane refractive index above 4, enabling a higher out-of-plane index contrast than lower-index dielectrics. A high refractive index also enables the presence of Mie-type resonances in MoS_2 nanostructures, thereby enhancing and controlling light-matter interactions.

Here, we study the optical resonances sustained by MoS_2 nanoplatelets made of high refractive index material with high optical anisotropy. These nanoplatelets have both geometrical and refractive index anisotropies. Their high refractive index

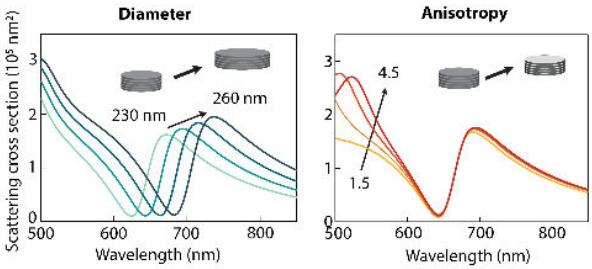

Fig. 1 - Different dependence of electric and magnetic dipole resonances on geometrical and optical anisotropy.

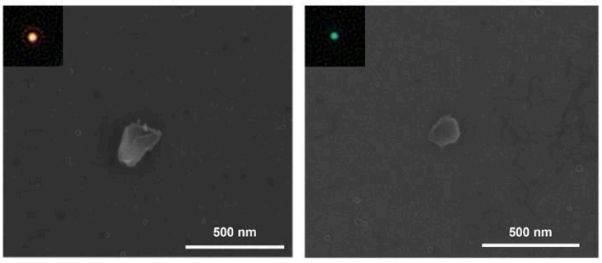

Fig. 2 - Single MoS_2 nanoplatelets: scanning electron microscopy and dark-field scattering microscopy images showing a tunable optical response.

enables them to sustain electric and magnetic resonances. We find a distinct impact of changes in geometry and birefringence on the tunability of the electric and magnetic resonances, which we explain using multipolar expansions.

Our experimental results characterize the optical response at the single MoS_2 nanoplatelet level using dark-field spectroscopy, including a variety of color changes in the visible on different substrates. We also reveal polarization-dependent resonances arising from their geometrical anisotropy. By employing chemical etching, we change the size of individual

nanoplatelets, thereby enabling controllable resonance tuning as evidenced by color changes observed in dark-field images of individual nanoplatelets.

In summary, high-refractive-index nanoplatelets with intrinsic out-of-plane anisotropy and large birefringence exhibit a wealth of electric and magnetic multipolar resonances that are sensitive to geometry and anisotropy in distinct manners. We demonstrate the diversity of optical responses of these individual MoS_2 nanoplatelets. We envision that these nanoplatelets could be used to enhance and direct light scattering and light emission, with applications in light-emitting devices and lasers.

***Abstract*—Improvement of nanostructured infrared photodetectors based on increasingly complex semiconductors epitaxies requires feedback on the optical parameters of each layer. Here, SNOM imaging and spectroscopy on a cleaved facet is used to characterize the cut-off frequency of type II superlattice, the doping level of heavily doped semiconductors and surface plasmons.**

***Keywords*— epitaxy, photodetectors, near-field, plasmons.**

I. Introduction

Sectors such as defense, medical science and chemical and bio-sensing need mid and long-wave infrared room temperature photodetectors. Commercially available technologies, as HgCdTe photodetectors, quantum well infrared detectors and more recently III-V superlattices [1], [2], face challenges to reach high sensibility at room temperature. To improve the detectivity and increase the working temperature of these photodetectors, the complexity of the epitaxy increases through the use of specific junction design or the use of nanophotonique with structured electrodes.[3], [4]. This leads to the development of complex stacking of III-V semiconductors, with the use of heavily doped semiconductor to replace traditional metals. Due to the increase in epitaxy complexity, the direct characterization of the junction function is no longer enough to answer the need of technological feedback. Moreover, classical retrieving of geometrical and composition of the layers by transmission electronic microscopy (TEM) on cross section lamella prepared by focus ion beam (FIB), is not suitable to retrieve the optical characteristics of the material in the infrared, and can be tricky to implement on some materials [5], [6].

In this context, the scattering near field optical microscope (SNOM) can be a useful tool to characterized such complex stacking. This technic can indeed be used to probe the dielectric constant of materials [7], [8] or to image plasmons and phonons in materials [9]. It has already been used to probe the doping level of thin layers [10], [11], [12], and the plasma wavelength and the dielectric constant[13], but only on bulk layer. We proposed here to investigate the use of s-SNOM characterization to analyze the layers parameters of a cleaved complex epitaxial heterostructure composed of highly doped semiconductor and type II superlattice (T2SL), design to be a long-wave infrared photodetector.

II. Methods

The sample is first cleaved with a diamond tip to characterize the sample on the lateral facets. The stacking parameters and the general optical properties of the layers are first retrieved through SNOM imaging at several infrared wavelength. The mechanical image and the optical amplitude of the stack at different wavelength are presented in Figure 1. The main layers are visible both in AFM and in optical amplitude: the heavily doped semiconductors have a mirror behavior in the infrared, and therefore the scattered optical amplitude is higher for these layers than for the other layers of the stack.

III. Results and Discussion

Combining near-field measurement and simulation, we determine the dielectric function of the T2SL heterostructure, and the plasma frequency of the heavily doped semiconductor layers. The SNOM analysis allow therefore a precise characterization of the optical properties of the layers, needed for simulation of the properties of the whole stack.

Fig. 1. A : AFM image of the stack with the mechanical phase contrast, B: Optical near field images of the stack at several wavelengths in amplitude referenced with the GaSb substrate amplitude

Finally, three bulk surface plasmon polaritons (BSPP) are studied. This phenomenon occurs at the interface of the highly

doped layer and was studied through near field and hyperspectral imaging. The nearfield imaging allows to determine the characteristic distance of the phenomenon, which are less than 100 nm, and the near field spectroscopic studied allow to precise the wavelength at which the BSPPs occurs for each interface.

IV. Conclusion

This work illustrates a new way of creating technological feedback on a more fundamental basis than the functional feedback usually available. This work paves the way to other heterostructures analysis such as T2SL bariodes, quantum well or quantum cascade photodetectors. Moreover, it paves the way to new studies of plamsons.

***Abstract*— We demonstrate a sub-millimetre all-solid multicore fibre probe for Raman Spectroscopy. By utilising a multicore fibre design and a differential dopant approach, we were able to suppress inter-core crosstalk and therefore reduce the generation of Silica Raman background. The monolithic all-fibre probe achieves 98 percent collection efficiency relative to direct coupling and enables fluorescence-free Raman spectra reconstruction of highly fluorescence samples.**

***Keywords*— Raman Spectroscopy, Raman Fibre Probe**

I. Introduction

Raman spectroscopy is a label-free and non-destructive optical technique capable of examining the intrinsic biochemical signatures of biological tissue. It holds strong potential for minimally invasive optical biopsy and, therefore, real-time cancer diagnostics [1]. Nevertheless, the use of Raman spectroscopy as a clinical in-vivo tool has not yet been fully realised due to various technical challenges. One such challenge is the silica background generated from the optical fibres used to remotely examine otherwise unreachable tissue regions [2]. Another significant drawback is the autofluorescence background generated from these tissue regions [3], [4].

Previous approaches have relied on hollow-core fibres and complex distal optics to suppress silica background, including negative curvature fibres such as those demonstrated in [5], [6]. While effective, such solutions require advanced fabrication and complex probe assembly, limiting scalability and disposable clinical use.

Here, we present a fully monolithic all-solid sub-millimetre single-fibre Raman probe. By engineering the refractive index contrast and dopant composition between the excitation and collection cores, we demonstrate low crosstalk, improved collection efficiency, and background suppression in a robust and manufacturable design.

II. Multicore Fibre & Fan-In/Fan-Out Design

The multicore fibre was fabricated using the stack-and-draw technique and comprises a seven-core all-solid structure: one single-mode excitation core surrounded by six graded-index multimode collection cores (Fig. 1). The excitation core consists of undoped silica with a fluorine-doped cladding, while the collection cores are germanium-doped with undoped silica cladding.

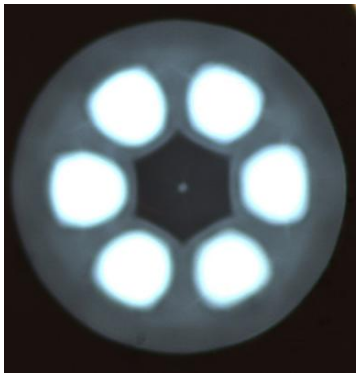

Fig. 1. Optical micrograph of our multicore fibre, which consists of a single-mode central excitation core surrounded by six multimode collection cores.

The difference in dopant composition introduces a refractive index contrast between the excitation and collection cores, resulting in distinct effective indices for the supported modes. This index difference reduces modal overlap and suppresses inter-core cross-talk, limiting the transfer of pump light from

the excitation core into the collection channels. As a result, the excitation and collection cores can be positioned in close proximity without significant optical coupling, enabling a compact probe geometry while maintaining modal isolation. The fibre has an outer diameter of 390 µm, and the complete probe diameter remains below 1 mm when enclosed in polyimide tubing, making it suitable for endoscopic use.

The probe is interfaced with the experimental system via an all-fibre fan-in/fan-out reformatter device (Fig. 2), designed to independently address each core. A single-mode fibre is aligned to the central excitation core for delivery of 785 nm pump light, while six multimode fibres are coupled to the surrounding collection cores for Raman signal retrieval. The collected signals are subsequently rearranged and directed to the spectrometer.

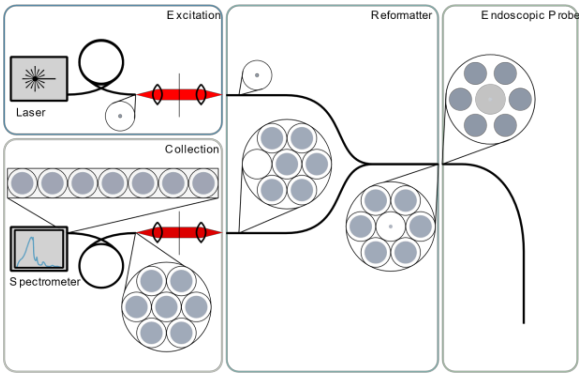

Fig. 2. Experimental setup. The central single-mode core of our probe is coupled to a 785 nm tunable single-frequency laser, and the six multimode collection cores are bundled together and fed into a portable Raman spectrometer. The central core is used to excite the distal sample, while the surrounding cores collect the Raman signal from the sample.

This fully fibre-integrated configuration eliminates the need for free-space coupling optics between the disposable probe and the benchtop system. Consequently, the assembly offers improved mechanical stability, reduced alignment sensitivity, and straightforward plug-and-play operation, which are important considerations for practical and clinical implementation.

III. Results and Discussion

To evaluate the background suppression and collection capabilities of the designed fibre probe, initial baseline measurements were conducted using ethanol. The probe's response was first recorded in air to capture any residual silica background, then submerged in ethanol to acquire the backscattered Raman spectrum of the sample. The resulting spectra, shown in Figure 3, clearly display distinct peaks within the spectral region of interest that correspond to ethanol's characteristic vibrational modes [6]. Although some residual silica background noise remains, the intrinsic response of our fibre is substantially lower than that of a conventional solid-core fibre, performing comparably to, or better than, alternative approaches such as hollow-core fibre probes.

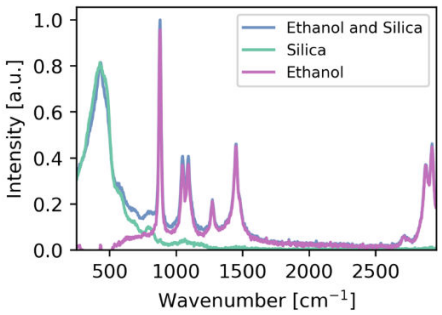

Fig. 3. The collected Raman signal when the pump light is coupled to the central single-mode core before (in air) and after the distal tip of the fibre probe was immersed in ethanol. Signal from ethanol obtained by subtracting the two plots.

We further validated the probe using sesame oil, a challenging sample for Raman spectroscopy due to being high fluorescent. Its fluorescence level is comparable to that of human lung tissue, making it a relevant benchmark for biological applications

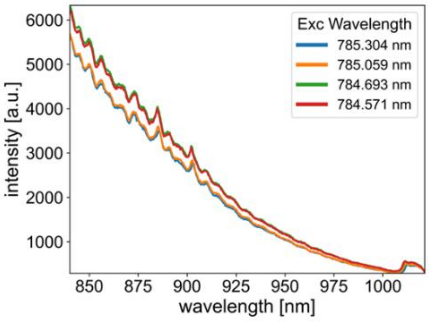

Fig. 4 Raw Raman spectra of sesame oil for four slightly shifted excitation wavelengths.

To remove background fluorescence, we applied Multi-Spectral Estimation of Regularized Spectra (MSERS) [3]. This technique exploits the fact that while fluorescence background is insensitive to small shifts in excitation wavelength, Raman peaks shift predictably with the source wavelength. MSERS uses a statistical model to simultaneously separate Raman and fluorescence contributions from a series of spectra collected at slightly shifted excitation wavelengths. To implement this, we used a temperature-tunable source (DBR-785) to acquire the shifted spectra shown in Fig. 4, from which a background-free Raman spectrum was reconstructed. The resulting fluorescence-free sesame oil spectrum is shown in Fig 5.

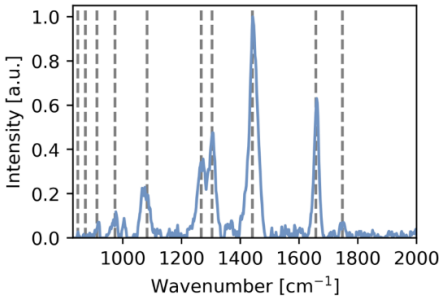

Fig. 5. Reconstructed background- and fluorescence-free spectrum of sesame oil when using the MRES technique.

IV. Conclusion

We have presented a fully monolithic all-solid sub-millimetre multicore fibre Raman probe capable of simultaneous excitation and collection through a single fibre. By engineering the refractive index contrast between cores of a multicore fibre, the probe achieves low inter-core crosstalk and effective silica background suppression without the need for complex distal optics. Validation measurements using ethanol and sesame oil demonstrate the probe's ability to recover clean Raman spectra even in highly fluorescent samples comparable to human tissue. Combined with its compact sub-millimetre diameter and plug-and-play fibre interface, this probe represents a practical and scalable step toward real-time, in-vivo Raman Endoscopy.

***Abstract*— We exploit phase-change materials such as GST and Sb_2S_3 to propose and demonstrate original programmable and multilevel functionalities in integrated photonic devices such as photonic circuits and metasurfaces.**

***Keywords*— Nanophotonics, phase-change materials, programmable devices.**

I. Introduction

Phase change materials (PCMs) are currently revolutionizing nanophotonics by providing ways to reconfigure optical functionalities without any moving parts. Building on this phenomenon, the last decade has witnessed many exciting reports of novel devices exploiting PCMs such as for example beam-steering, tunable light emission, reflection and absorption, programmable metasurfaces and reconfigurable neural networks [1-3]. A large majority of the first studies were using standard PCMs such as GeSbTe as simple binary on-off switches. However, PCMs present another degree of freedom for tunability: multilevel non-volatile states encoded into partial change of phase. Furthermore, recently a new class of low-loss PCMs emerged (e.g. Sb_2S_3 and Sb_2Se_3), with negligible optical absorption in the near-infrared [4,6].

II. Results and Discussion

We first present a method to electrically set multilevel states of crystallization in GST and exploit it to continuously program the free-space reflection of a pixel, spanning a three-orders of magnitude modulation [7].

In a second part, we will present the concept of spatially-controlled planar crystal growth in PCMs, a novel method for programming the growth of optically homogeneous low-loss PCM, leveraging the seeded directional and progressive crystallization within confined channels. We have demonstrated the applicability of guided crystallization on the emerging PCM Sb_2S_3 in two different devices: a programmable optical phase shifter and a reconfigurable metasurface. By patterning a Sb_2S_3 patch onto a Mach-Zehnder interferometer, we successfully programmed ten distinct phase shifts. Next, the ability to precisely control the phase transition of Sb_2S_3 between amorphous and optically homogeneous states was leveraged in reconfigurable metasurfaces, enabling a 100 nm spectral modulation of a bound state in the continuum mode, while preserving the metasurface functionalities. We then conclude on the perspectives for this technology.

III. Conclusion

We have demonstrated methods to go beyond conventional phase-change modulation, by electrically-programming multilevel states in GST and by spatially programming the in-plane guided growth of optically homogeneous Sb_2S_3 crystals.

***Abstract*— A topological Dirac semimetal/semiconductor eutectic lamellar heterostructure is introduced to a grating-gate planar transistor as a new 'striped' channel material to configure a two-dimensional active plasmonic metasurface. It effectively suppresses the oblique plasmon modes, killers for instability-driven terahertz lasing and amplification. Its novel concept, physics, and device implementation are addressed.**

***Keywords*— Dirac plasmon, topological insulator, eutectic lamellar heterostructure, instability, terahertz, metasurface.**

I. Introduction

The fundamental bottleneck to industrializing 6G and 7G terahertz (THz) communication systems is the THz technological gap [1]. We have been studying novel physics and advanced materials to overcome this challenge [2]. This paper proposes a unique laser transistor amplifier planar device structure consisting of (i) a "striped" metasurface channel that uses a topological Dirac semimetal/semiconductor eutectic lamellar heterostructure and (ii) dual- or triple grating-gate electrodes that actively control the electromagnetic responses of the metasurfaces [3]. This paper discusses the novel concept, the underlying physics, and strategy for device implementation, as well as their impact on science and technology.

II. Methods

The proposed approach integrates advanced material synthesis, theoretical modeling of plasmon instability, and device-level implementation. The conceptual framework combines Topological insulator (TI)/semiconductor eutectic lamellar heterostructures (TI-EuHetero) materials, Coulomb-drag instability, and a striped-channel transistor architecture.

A. Material synthesis and characterization [4]

The TI-EuHetero, particularly Bi_2Te_3/Te, were fabricated using controlled directional solidification. The growth process enables self-organized lamellar architectures with tunable periodicity ranging from sub-micrometer to tens of micrometers. Bi_2Te_3 is a three-dimensional topological insulator whose surface-state dispersion and hybridization gap depend on film thickness: ultrathin films exhibit a gap due to inter-surface coupling, while thicker films recover gapless Dirac surface states [5]. In bulk-like or heterostructured configurations relevant to THz device operation, however, the electrical response is predominantly governed by bulk semiconducting or semimetallic carriers, with the topological surface states contributing only weakly. Under these conditions, the material effectively behaves as a narrow-gap semimetal for high-frequency transport, while its topological surface states remain spectroscopically present but play a secondary role.

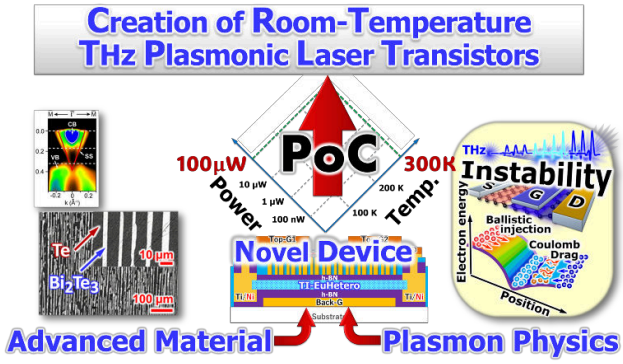

Fig. 1 Conceptual image of the proposed material/physics/devices.

B. Theoretical framework: Coulomb-drag instability [6,7]

The physical mechanism underlying THz amplification is based on the Coulomb-drag instability of Dirac plasmons, where ballistic carriers injected under drain bias interact with confined carriers in the gated channel. This interaction leads to backflow currents and negative differential conductance (NDC), enabling plasmon gain in the THz regime. Theoretical modeling incorporates carrier transport asymmetry, many-body Coulomb interactions, and hydrodynamic plasma effects, predicting instability-driven amplification even at room temperature.

C. Device architecture and metasurface design [3]

A 2.5D striped-channel plasmonic transistor is implemented by integrating TI-EuHetero into a grating-gate field-effect transistor (FET) (Figs. 2 and 3). The lamellar structure inherently forms a periodic striped channel, eliminating the need for nanoscale etching while suppressing oblique plasmon modes. Dual- or asymmetric dual-grating-gate (ADGG) electrodes are employed to:

1) electrostatically define plasmon cavities,
2) induce p–i–n junctions, and
3) enhance plasmon confinement and resonance.

Device fabrication follows a scalable top-down process including gate stack formation, heterostructure transfer, lithographic patterning, and dielectric encapsulation.

D. Simulation and experimental validation

A multiscale modeling framework combining first-principles calculations, electron–phonon-plasmon-polariton interactions, and carrier transport ensemble Monte Carlo simulations and electromagnetic simulations are used to optimize plasmon resonance conditions, effective permittivity, and damping factors, while experimental validation includes THz emission and absorption measurements under current injection. The combined methodology ensures consistency between theoretical predictions and device performance.

III. Results and Discussion

A. Material performance and electronic properties

Structural and electronic properties were characterized using micro-Raman spectroscopy, atomic force microscopy (AFM), and angle-resolved photoemission spectroscopy (ARPES), confirming high crystallinity and atomically sharp interfaces. The fabricated Bi_2Te_3/Te eutectic heterostructures exhibit excellent and tunable lamellar periodicity together with asymmetric Dirac dispersion and favorable band alignment, enabling p–i–n junction formation [4]. These properties support high carrier mobility and low plasmon damping, which are essential for efficient THz plasmonic operation.

B. Evidence of plasmonic gain and instability

Previous graphene-based devices demonstrated THz amplification up to ~9% at room temperature, confirming the feasibility of current-driven plasmon gain [8]. However, the gain remains insufficient for lasing. The proposed TI-EuHetero platform enhances this mechanism through stronger Coulomb interactions and reduced damping, enabling significantly higher instability-driven gain.

C. Suppression of plasmon damping

A critical limitation in conventional planar devices is overdamping caused by oblique plasmon modes [9]. The intrinsic lamellar “striped” geometry of TI-EuHetero channels effectively suppresses these modes, leading to improved quality factors and stronger resonant plasmon oscillations (Figs. 2 and 3). This represents a key breakthrough toward achieving coherent THz emission at room temperature.

D. Device-level performance and metasurface response

The integration of TI-EuHetero into grating-gate transistor architectures enables the realization of an active plasmonic metasurface. Experimental and simulated results demonstrate:

- strong THz absorption approaching unity at resonance,
- broadband response with significantly enhanced bandwidth compared to conventional THz absorbers, and
- good agreement between theoretical models and measured spectra.

Furthermore, cascading Coulomb-drag instability in ADGG structures enables resonant amplification and self-oscillation in the THz range. Analytical evaluation indicates an overall performance improvement exceeding two orders of magnitude compared to conventional graphene-based devices.

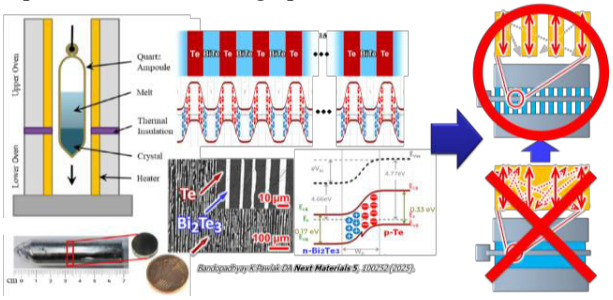

Fig. 2 Conceptual image of the TI-EuHetero lamellar structure and properties.

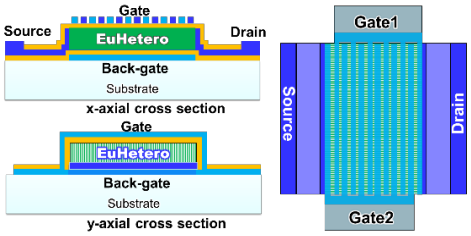

Fig. 3 Conceptual image of the striped-channel transistor architecture.

E. Implications for THz technology

The results demonstrate a viable pathway to overcome the “THz gap” by combining new materials, new physics, and novel device architectures. The proposed approach enables scalable, electrically driven, room-temperature THz sources suitable for next-generation communication systems.

IV. Conclusion

We demonstrated a pathway to room-temperature THz plasmonic laser transistors by combining advanced materials, novel physics, and scalable device architectures.

***Abstract*—We demonstrate strong collective emission from a cavity-mediated steady-state subradiant state. In a tailored photonic environment with balanced cavity dissipation ns emitter-field coupling strength, As a key signature of steady-state subradiance, we observe strong photon bunching with elongated decay. Our approach paves the way for generating and harnessing quantum correlations .**

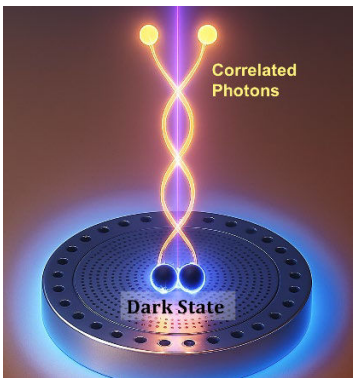
***Keywords*— Collective interaction, Subradiance, quantum dots, nanophotonics.**

I. Introduction

Cooperative effects such as super(or sub)radiance in quantum systems arise from the interplay among quantum emitters. While bright superradiant states have been extensively studied and have yielded important insights into cooperative phenomena, subradiant states remain less explored due to their inherently dark state nature. However, subradiance holds significant potential as a valuable quantum resource exploiting long-lived and large-scale entanglement, which is a key for advancing quantum information technologies.

II. RESULT

We experimentally demonstrate cavity-mediated steady-state subradiance in two quantum dots (QDs) coupled to a low-Q nanophotonic cavity. The engineered cavity environment balances emitter–cavity coupling and dissipation, enabling a dominant steady-state population in a subradiant collective state.



Photon correlation measurements reveal strong photon bunching, with $g^{(2)}(0)>8$ exceeding the classical limit when the QDs are spectrally coupled to the cavity.

The collective state suppresses single-photon decay while enabling a cascade two-photon emission process, resulting in an extended antibunching decay time of ~36 ns. Numerical simulations based on a Tavis–Cummings model with dissipative dynamics confirm that steady-state subradiance emerges when incoherent pumping, cavity dissipation, and emitter–cavity coupling are properly balanced.

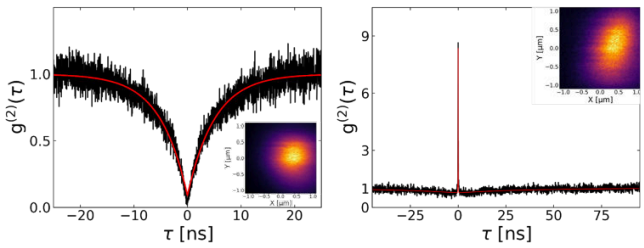


Fig. 1 Comparison of $g^{(2)}(t)$ curve with cavity-coupled single dot and two quantum dots

III. Conclusion

These results provide the first experimental demonstration of steady-state subradiance in cavity-coupled quantum dots under incoherent pumping, revealing controllable collective quantum correlations in solid-state emitters. The work establishes a platform for engineering multi-emitter cooperative phenomena and generating strongly correlated photons for quantum photonics applications.

Abstract **Laser micropatterning enables aluminum surfaces to achieve high infrared emissivity and superhydrophilic wetting for passive radiative cooling and autonomous dew harvesting. Laser-textured samples reach emissivity up to 0.95, promote stable filmwise condensation, and enhance capillary drainage. Outdoor experiments show up to 70 percent higher dew yield than state-of-the-art commercial condensers.**

Keywords**— laser texturing, radiative cooling, dew harvesting, infrared emissivity, superhydrophilic surfaces.**

I. Introduction

Atmospheric water harvesting through dew condensation is a promising strategy for decentralized freshwater production. Passive radiative cooling enables autonomous operation by allowing surfaces with high emissivity in the 8–13 μm atmospheric window to cool below ambient temperature and reach the dew point. However, conventional metallic surfaces suffer from low emissivity and unfavorable condensation dynamics, limiting water collection efficiency. Surface engineering via laser micro/nanofabrication provides a scalable route to tailor emissivity, wettability, and fluid transport behavior for improved dew harvesting performance.

II. Methods

Aluminum substrates were processed using nanosecond pulsed laser scanning to generate parallel microgrooves and multiscale roughness. The treatment increases surface oxidation and effective area, producing broadband infrared absorption and superhydrophilic wetting. Surface morphology was characterized by SEM and optical profilometry. Wettability was evaluated through contact angle and capillary wicking measurements. Infrared emissivity was measured by FTIR reflectivity in the atmospheric window. Condensation and water collection behavior were assessed in laboratory climatic chambers and in a one-year outdoor dew harvesting installation.

III. Results and Discussion

Laser-textured aluminum exhibits emissivity values up to 0.95 in the 8–13 μm range and transitions from moderate hydrophilicity to superhydrophilicity. The grooved topography promotes rapid capillary wicking and stable filmwise condensation, reducing retained liquid volume by approximately threefold compared with untreated dropwise-condensing surfaces. Radiative cooling experiments show temperature reductions of up to 5 °C below ambient under radiative deficit conditions. Outdoor testing demonstrates a consistent improvement of approximately 70 percent in collected dew water relative to a high-emissivity painted reference condenser [1]. The enhanced performance is attributed to earlier onset of water collection and more efficient drainage enabled by capillary-guided flow.

IV. Conclusion

Laser micropatterning transforms reflective metallic surfaces into robust radiative cooling emitters and efficient dew harvesting platforms. The combination of high infrared emissivity, superhydrophilic wetting, and capillary-driven drainage enables scalable, passive, and durable atmospheric water harvesting suitable for real-world needs.

***Abstract*— This study presents a scheme of using flat optics composed of geometric-phase metasurfaces to cool neutral atoms and assembly them into arrays of individually trapped atoms. We exploit the ability of metastructures in controlling the phase, amplitude, and polarization of light with sub-wavelength resolution to generate tailored wavefronts for cooling and optical dipole trapping of atoms.**

***Keywords*— cold atoms array, dielectric metasurfaces, magneto-optical trapping (MOT), optical dipole trapping (ODT).**

I. Introduction

Cold-atom arrays prepared by laser cooling and trapping play a central role in precision measurements and quantum technologies, enabling advances in quantum metrology, sensing, quantum computing, and quantum simulation. In conventional experiments, alkali or alkaline-earth atoms confined in an ultrahigh-vacuum chamber are first cooled near the Doppler limit using a magneto-optical trap (MOT), and then the cooled atoms are trapped and arranged into lattice configurations using optitraps (ODTs). However, these MOT and ODT implementations typically rely on complex and bulky optical assemblies, leading to large experimental footprints and high sensitivity to optical misalignment. Here, we propose and experimentally demonstrate a metasurface-based platform that enables laser cooling and optical trapping within a compact, planar architecture, by exploiting the capability of dielectric metastructures in controlling the phase, amplitude, and polarization of light at sub-wavelength resolution.

II. Methods

Our proposed metasurface-based MOT employs a metasurfaces composed of the Pancharatnam–Berry phase structures to generate the diffracted and transmitted wavefronts with tailored polarization states. Figure 1 schematically illustrates the MOT configuration employing a diffraction-engineered metasurface. The metasurface is designed such that, under normal incidence of a circularly polarized beam of a given handedness, it generates multiple diffracted beams with the opposite handedness, along with a central transmitted beam that preserves the incident polarization. The diffracted beams are directed toward the optical axis at a fixed angle θ. A second collimated circularly polarized beam is introduced from the counter-propagating direction, with the optical axes of both beams aligned along the axial direction of the quadrupole magnetic field. The transmitted axial beam and the corresponding oblique diffracted components overlap spatially, forming a region in which atoms interact with all beams. When the magnetic-field zero is adjusted to position within this overlap region, atoms are trapped and cooled.

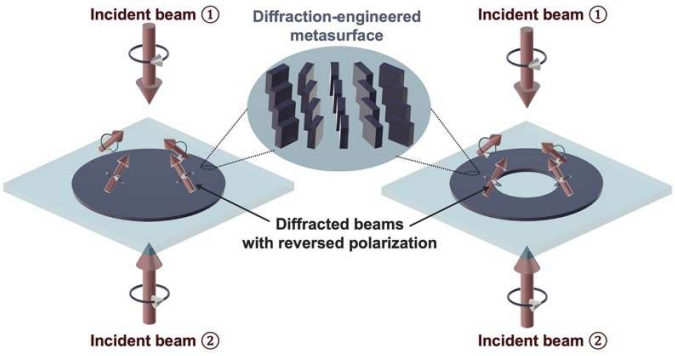

Fig.1 Schematic illustration of a magneto-optical trap (MOT) configuration employing a diffraction-engineered metasurface that enables atomic cooling under single-direction illumination.

III. Results and Discussion

In the metasurface-based MOT, the transverse restoring forces are primarily generated by the diffracted beams generated by the metasurface, whereas the axial restoring forces arise mainly from the counter-propagating axial light fields, which are essential for balancing the trapping forces along the longitudinal axis. Moreover, the independently tunable intensities of the incident and diffracted beams provide precise control over both axial and transverse restoring forces. We experimentally demonstrate successful trapping and cooling of cesium atoms, and support the trapping mechanism with numerical calculations of optical radiation forces.

After cooling in the MOT, atom ensembles are assembled into arrays of individual atoms using optical dipole trapping based on the optical tweezer principle. High-fidelity atom arrays require optical tweezers with sufficiently deep trapping

potentials, well-defined geometric configurations, and high intensity uniformity across individual traps. In this study, we demonstrate a metasurface hologram that simultaneously generates and focuses light into arrays of focal spots under collimated-beam illumination, thereby forming optical tweezer arrays. Owing to the subwavelength-scale phase modulation offered by the metastructures, which is approximately 20 times finer than that achievable with conventional spatial light modulators, the fabricated meta-hologram produces trapping potentials comparable to those of a high–numerical-aperture lens with *NA* values of up to 0.9. Furthermore, it enables the formation of dual-spot arrays with inter-spot separations approaching the diffraction limit.

IV. Conclusion

In conclusion, we have demonstrated and verified the performance of metasurfaces in magneto-optical trapping and optical dipole trapping of alkali-metal atoms. The cooling and trapping of atoms with metasurfaces, without the need for extra optical components, demonstrates high optical efficiency, and scalability potential. These characteristics highlights the potential of metasurfaces in realization of compact and lower-power quantum systems, with broad applications in quantum metrology, quantum information processing, and atomic physics.

***Abstract*— Polymer based passive radiative coolers incorporating silica microspheres are investigated to enhance infrared emissivity. Films are fabricated and characterized by infrared spectroscopy. Thermal performance is evaluated through temperature dynamics measurements under controlled conditions. Compared to the pure polymer, microsphere filled samples exhibit enhanced emissivity and improved radiative cooling performance.**

Keywords - radiative cooling, polymer films, infrared emissivity, thermal characterization

I. Introduction

Passive Daytime Radiative Cooling (PDRC) has emerged as an effective strategy for reducing thermal loads without energy consumption, by exploiting selective radiative heat exchange with the cold outer space. An efficient radiative cooler must simultaneously exhibit high reflectance across the solar spectrum to minimize solar absorption and strong thermal emissivity within the mid-infrared atmospheric transparency window [1].

Polymer-based materials have recently attracted significant attention for PDRC applications due to their intrinsic infrared emissive properties [2]. In this work silica microspheres were embedded within polymer films in order to improve the emissivity and to customize the optical properties of polymer matrices [3]. The polymer-based radiative cooling films were developed and characterized to investigate the relationship between infrared emissivity and thermal cooling performance.

II. Methods

Polymer based radiative cooling films incorporating silica microspheres of different diameters are fabricated by hot pressing and laminated onto stainless steel substrates coated with an optically thick silver layer. Optical properties are characterized by infrared spectroscopic ellipsometry to assess emissivity and optical response. Thermal performance is evaluated by temperature-dynamics measurements under radiative loads in highly controlled and reproducible conditions.

III. Results and Discussion

Infrared spectroscopic measurements reveal that the incorporation of silica microspheres enhances the emissivity of the polymer films within the mid infrared atmospheric window. This is due to both the intrinsic absorbance/emissivity of silica in the mid-IR, and to the occurrence of finite-size dielectric resonances in few-micron-sized dielectric spheres.

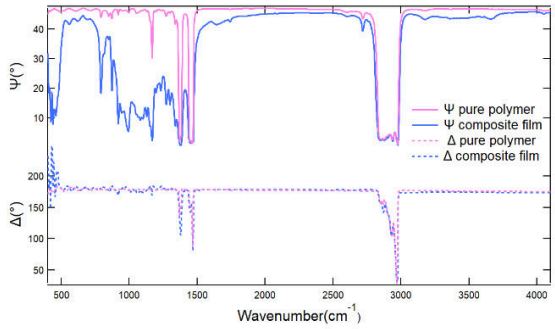

Fig. 1 Infrared spectroscopic ellipsometry response for pure polymer and silica microsphere filled composite films.

Thermal measurements were performed in a custom-built vacuum chamber, where the radiative cooler systems were exposed to a cold heat sink (liquid nitrogen source), while at the same time minimizing spurious heat losses by convection and conduction.

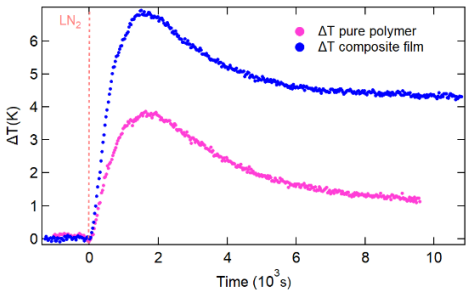

Fig. 2 Temperature difference between the radiative cooling film and a dummy reference under vacuum conditions, showing enhanced cooling for the composite sample.

The results demonstrate that polymer composite films containing silica microspheres exhibit a larger temperature reduction compared to the pure polymer reference. This enhanced cooling behavior is consistent with the increased infrared emissivity observed in the optical characterization.

IV. Conclusion

Polymer-based radiative cooling films incorporating silica microspheres demonstrate enhanced passive cooling performance compared to pure polymer samples. Infrared optical characterization and vacuum chamber thermal measurements confirm the role of increased emissivity in promoting radiative heat dissipation. These results highlight polymer composites as materials for passive thermal management.

Electromagnetic Wave Localisation in Aperiodic and Correlated Disorder Photonic Structures

Marian Florescu, Alex Meek and Kriss Stokkereit

Optoelectronics Research Centre, University of Southampton, United Kingdom
*Corresponding author: m.florescu@soton.ac.uk

***Abstract*— We study electromagnetic wave transport and localisation in aperiodic and correlated disordered structures in one and two dimensions. Ensemble simulations show that correlated disorder tunes transparency, localisation, and band gap formation. A minimum spacing constraint stabilises short range structure and enables controlled localisation.**

***Keywords*— hyperuniform disorder, correlated disorder, photonic structures, wave localisation.**

I. Introduction

Quasicrystalline photonic structures constitute a prime example of aperiodic structures, while hyperuniform disordered photonic systems suppress large scale density fluctuations while retaining tunable short and intermediate range correlations [1]. The one- and two-dimensional cases exhibit distinct structural behaviour compared with higher dimensions, with unusually persistent short-range correlations that strongly influence wave transport and localisation. In this context, aperiodicity and correlated disorder provides a powerful route to control light localisation, bridging regimes of extended transport and Anderson localised states without relying on perturbed periodic order or complete randomness [2-6].

II. Methods

We generate 5-fold symmetric quasicrystalline structures and stealthy hyperuniform point patterns with controlled disorder strength, optionally enforcing a minimum spacing between neighbouring points. Photonic microstructures are constructed by arranging high index scatterers along the unit cell. We compute eigenmodes and localisation metrics using band structure simulations and validate transport trends using a scattering matrix approach across ensembles and system sizes. Statistical averaging over large ensembles is used to suppress sample-specific fluctuations and isolate the role of structural correlations in governing localisation and transport behaviour.

III. Results and Discussion

Results and Discussion

• The results reveal a clear separation between distinct transport regimes governed by the degree of hyperuniformity. At low frequencies, correlated disorder gives rise to extended transparency regimes in which wave propagation is robust despite the absence of periodic order. As frequency increases, modes progressively localise, with localisation strength and spectral extent strongly modulated by the underlying structural correlations.

• Analysis of inverse participation ratios, density of states, and level spacing statistics shows that hyperuniform systems support both single parameter scaling and non-scaling transport regimes. The boundaries between these regimes shift systematically with disorder strength, reflecting the competition between long range hyperuniform correlations and short-range structural fluctuations.

• Introducing a minimum spacing between scattering elements suppresses pathological short-range clustering while preserving hyperuniformity. This modification enables the emergence of photonic band gap behaviour and produces a more controlled localisation landscape. Disorder resolved analysis demonstrates that the observed transport properties remain stable under additional perturbations, highlighting the resilience of correlated disorder engineered photonic media.

IV. Conclusion

Aperiodicity and correlated disorder provide a compact route to engineer transparency and localisation through structural correlations rather than periodicity alone. These findings establish aperiodicity and correlated disorder as a practical and robust design parameter for photonic and metamaterial systems.

***Abstract*- Phase nanoengineering enables direct local control of the physical properties of complex oxide thin films. We create stable magnetic landscapes that define spin-wave waveguides, magnonic crystals and networks, in YIG. Such devices allow long distance spin-wave propagation and cascading, opening the way to RF signal processing using spin waves.**

***Keywords*- phase nanoengineering, yttrium iron garnet, magnonics, direct laser writing, spin waves.**

I. Introduction

Magnonics seeks to transport and process microwave information on-chip using spin waves rather than charge currents. YIG is the reference complex oxide because its exceptionally low damping supports long coherent propagation, yet conventional nanopatterning damages crystalline garnets preventing long-distance spin-wave propagation, and mostly offers two dimensional geometries. Here, we show that phase nanoengineering via direct laser writing overcomes this limitation by locally tuning the material properties after growth.

II. Methods

Phase nanoengineering [1] uses a localized energy source to write stable, grayscale property landscapes directly into a film. In particular, direct laser writing focuses ultraviolet light, producing highly localized transformations to the crystalline phase of the material, which in turn leads to changes in its magnetic properties. In crystalline YIG, a 405 nm laser is used to either recrystallize the material in a strained high anisotropy three-dimensional volume in 1 micron thick films [2], or to amorphize selected regions in 100 nanometer films [3].

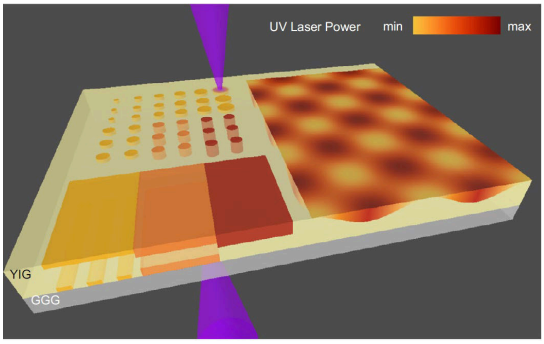

Fig. 1 Phase nanoengineering writes stable magnetic and structural landscapes that manipulate spin waves in YIG.

III. Results and Discussion

We use UV laser writing to create three-dimensional anisotropy profiles in single crystal YIG. We show that the perpendicular magnetic anisotropy rises by about thirty times, with approximately 100 nanometer-wide lateral features, continuous depth control, and the possibility to realize buried patterns written through the transparent GGG substrate. These profiles tune the spin-wave dispersion, localization and nonreciprocity, enabling direct write magnonic crystals [2].

In this second case, laser amorphization turns exposed YIG nonmagnetic while preserving crystalline channels (i.e. waveguides) for low loss propagation. The devices show spin-wave transport with low magnetic losses for hundreds of wavelengths. Using this methodology we demonstrate coherent power transfer in coupled waveguides, low-loss directional couplers, phase shifters, splitters, demultiplexers and phase controlled routers. Cascading these primitives, we realize programmable interferometric meshes with up to nineteen couplers and phase shifters in seven cascaded stages, operating without intermediate amplification [3].

IV. Conclusion

Together, these results demonstrate phase nanoengineering as a monolithic route to realize integrated low-losses magnonic platforms, overcoming the long-standing issue of scalability and cascading in magnonic platforms for classical and quantum processing.

***Abstract*—We present a theoretical framework for compact photon pair generation in periodically poled layered semiconductors. The model predicts enhanced brightness, polarization tunability, and compatibility with integrated quantum photonics.**

***Keywords*– spontaneous parametric down conversion, transition metal dichalcogenides, periodic poling, entangled photons, integrated quantum photonics.**

I. Introduction

Spontaneous parametric down-conversion (SPDC) is one of the most established mechanisms for generating entangled photon pairs for quantum communication, sensing, and photonic quantum information processing. Standard SPDC sources are usually based on millimetre- or centimetre-scale bulk nonlinear crystals, because the probability of pair creation is small and must be accumulated over a long propagation length. This requirement is difficult to reconcile with integrated quantum photonics, where the desired sources should be thin, bright, stable, and directly compatible with miniaturised optical circuits.

Layered transition metal dichalcogenides (TMDs) provide an attractive alternative. In particular, the non-centrosymmetric 3R polytype of MoS_2 possesses a large second-order nonlinear response while allowing multilayer assembly at the micron scale. The central difficulty is that a short sample does not automatically guarantee efficient SPDC: the signal and idler fields must remain phase matched with the pump, and the finite stack produces reflections that cannot be ignored. The work summarised here addresses these issues by developing a full theoretical description of SPDC in periodically poled 3R-TMD slabs, with emphasis on brightness scaling, emission geometry, and polarization entanglement.

II. Methods

The proposed device is a stack of nonlinear 3R-TMD slabs in which neighbouring slabs are rotated by π around the optical axis. This rotation leaves the linear optical response essentially unchanged in the isotropic approximation, but it flips the sign of the relevant in-plane components of the second-order susceptibility tensor. The stack therefore implements quasi-phase matching, in direct analogy with periodically poled bulk crystals, but using geometric rotation of van der Waals layers rather than ferroelectric domain inversion [1], [3].

The calculation is organised in three steps. First, the linear scattering problem is solved for the finite TMD structure. In the telecom region, where absorption and dispersion are weak, the electromagnetic field can be quantized canonically in a homogeneous effective medium. Signal and idler modes are labelled by transverse momentum, propagation direction, and polarization, and the corresponding creation and annihilation operators form the basis for the perturbative treatment [2].

Second, the nonlinear interaction Hamiltonian is derived from the second-order polarization. Periodic poling is represented by a spatially alternating tensor, or equivalently by a Fourier series whose odd harmonics supply the missing longitudinal momentum. This gives an analytic coupling amplitude between pump, signal, and idler modes. In the degenerate case considered in the numerical analysis, a 780 nm pump generates signal and idler photons at 1560 nm. The phase mismatch depends on the propagation directions of the two generated photons; consequently, the model naturally includes forward-forward, backward-backward, and forward-backward pair emission.

Third, the finite-size character of the stack is retained by a transfer-matrix treatment. This step is essential because the micron-scale sample is not simply a short piece of bulk nonlinear material. Multiple reflections at the interfaces dress the quantum modes and introduce low-quality cavity resonances. The final biphoton wavefunction is obtained after rewriting the nonlinear Hamiltonian in terms of outgoing vacuum modes, allowing direct calculation of the photon-pair flux collected within a chosen numerical aperture.

The same formalism also provides direct access to the quantum state rather than only to the conversion rate. For a fixed emission direction, the biphoton state is a coherent superposition of the four polarization amplitudes HH, HV, VH, and VV. Its degree of entanglement is evaluated through the reduced-state purity, concurrence, and fidelity with respect to the target Bell state. For realistic detection, the polarization density matrix is reconstructed by integrating over the angular modes accepted by the collection numerical aperture. This step traces out spatial information and captures the dephasing that appears when photons emitted at different angles acquire different phases before being measured.

III. Results and discussion

For the parameters analysed, the optimal single-slab thickness is close to 580 nm. At this thickness, periodic poling creates a quasi-phase-matched emission cone and strongly enhances the number of detected photon pairs. The efficiency grows faster than the usual quadratic dependence on the number of coherently phased slabs. This super-quadratic behaviour is not a violation of phase-matching intuition; it arises from the combination of quasi-phase matching and finite-stack resonances.

The theory predicts that photon pairs are produced not only in the transmitted forward-forward channel, but also in backward-backward and mixed forward-backward channels. These additional channels are weaker than the forward emission, yet they are physically important because they result from the cavity-like nature of the layered system and would not be expected in the same way from a conventional long bulk crystal.

The polarization state is controlled mainly by crystal symmetry and pump polarization. Periodic poling changes brightness and angular distribution, while leaving the intrinsic entanglement structure largely intact. A linearly polarized pump can select Bell states or coherent superpositions of them, whereas circular pump polarization suppresses the polarization entanglement. This behaviour is consistent with recent demonstrations of entangled photon-pair generation in 3R-TMD materials [4], [5].

The collection aperture is a relevant design parameter. A larger aperture collects more photon pairs, increasing the useful brightness, but it also mixes angular components with different phases. The resulting polarization density matrix can therefore become less pure even when each individual emission direction is nearly maximally entangled. This trade-off is familiar from high-brightness bulk SPDC sources, but here it appears in a much thinner platform and is coupled to the finite-stack resonances. The model therefore gives a practical route for choosing the slab number, poling period, and collection geometry together, rather than optimising the pair-generation rate alone.

IV. Conclusions

The study identifies periodically poled 3R-TMDs as a promising platform for ultrathin, integrated, and polarization-programmable entangled photon sources. The next theoretical developments should include absorption near excitonic resonances, anisotropy at large emission angles, finite lateral dimensions, and realistic collection optics. Experimentally, the main challenge is precise multilayer fabrication with controlled rotation, thickness, and optical quality.

***Abstract*— Hyperbolic polaritons provide a powerful platform for subwavelength directional light manipulation, yet most existing systems are limited to Mid-infrared frequencies and lack rigorous analytical dispersion descriptions. Here, we realize visible-light hyperbolic polaritons in anisotropic hyperbolic metamaterial films with engineered in-plane hyperbolic anisotropy. The supported surface modes exhibit pronounced photonic spin Hall effect, which were then used to realize a multichannel spin-dependent photonic circuit based on a twinning hyperbolic metamaterial. More importantly, we derive the first closed-form analytical iso-frequency contour (IFC) for these polaritons, explicitly revealing their strict hyperbolic topology and quantitatively predicting propagation asymptotes and energy-flow directions. Near-field optical experiments and full-wave simulations show excellent agreement with the analytical model. This work establishes both a versatile visible-near infrared frequency hyperbolic polariton platform and a universal analytical framework for deterministic planar nanophotonic design.**

***Abstract*—Optically levitated nanoparticle in vacuum is an ideal optomechanical platform for precision measurements, particularly enabling the detection of ultraweak forces. Nevertheless, quantum backaction and inherent instabilities induced by the trapping laser fundamentally restrict further improvements in force sensitivity and resolution. To circumvent these bottlenecks, we actively drive the levitated nanoparticle's mechanical motion in a phase-locked phonon laser mode and integrate a carrier-modulation measurement architecture to enhance force sensing capabilities. The stable and high-amplitude oscillation of the phonon laser allows for the robust trapping under 1 mW-level laser power, which in turn reduces the force noise to $4.0(3) \times 10^{-22}$ N/Hz$^{1/2}$. Furthermore, by using phase-locked phonon laser, the measurement system achieves active stabilization and extended coherence time with the measured signal to 12, 500 seconds, realizing a measurement resolution of $8(4) \times 10^{-24}$ N with a sensitivity of $9.3(7) \times 10^{-22}$N/Hz$^{1/2}$ under a loaded force. These results establish the phonon laser as a low-noise, long-coherence-time, self-stabilizing platform for precision measurements, as well as in quantum and fundamental physics tests.**

***Abstract*— We demonstrate an ultra-compact InP triplexer for combo-PON using boundary adjoint optimization. The 92-μm device achieves <0.8 dB insertion loss across three bands, overcoming weak confinement limitations. Simulations confirm high fabrication tolerance, enabling high-density monolithic integration.**

***Keywords*– integrated photonics, inverse design, topology optimization, adjoint method.**

I. Introduction

The coexistence of GPON, 10G-PON, and 50G-PON in next-generation optical networks demands compact wavelength multiplexers [1][2]. Conventional InP-based multiplexers, however, suffer from large footprints due to weak optical confinement and material dispersion over broad bandwidths. We propose an inverse-designed triplexer using boundary adjoint optimization. The device achieves an ultra-compact length of 92 μm and maintains insertion losses below 0.8 dB across all three bands, with numerical simulations further confirming its high fabrication tolerance.

II. Methods

In this study, we utilize a custom-developed adjoint-based gradient descent boundary optimization algorithm, integrated with FDTD simulation software to enable boundary topology optimization for large-scale photonic devices. The gradient calculation process is formulated as follows:

$$\left.\frac{dF(\vec{E})}{d\varepsilon}\right|_{\vec{r}} = Re\left[\frac{dF(\vec{E})}{d\vec{E}(\vec{r}_0)}\frac{d\vec{E}(\vec{r}_0)}{d\varepsilon}\right] \propto \mathrm{Re}\left[\vec{E}_{adj}(\vec{r})\cdot\vec{E}_{old}(\vec{r})\right]$$

where F denotes the objective function and ε represents the dielectric permittivity. The optimization process is illustrated in Fig. 1; the device performance is iteratively enhanced by deforming the waveguide boundaries based on the computed gradient information.

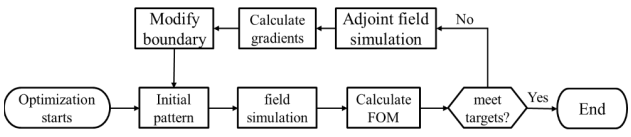

Fig. 1 Optimization algorithm process.

III. Results and Discussion

The final device model designed in this study is illustrated in Fig. 2, with the corresponding performance results shown in Fig. 3. The insertion losses at the center wavelengths of the three bands are 0.76 dB (1342 nm), 0.55 dB (1490 nm), and 0.61 dB (1577 nm), respectively. The total footprint of the device is remarkably compact, with a core length of only 92 μm.

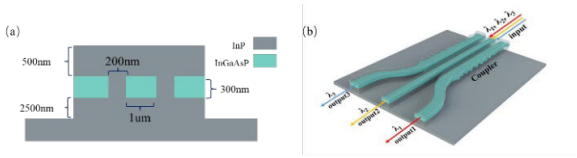

Fig. 2 (a) Device Cross-Section;(b) Device Model.

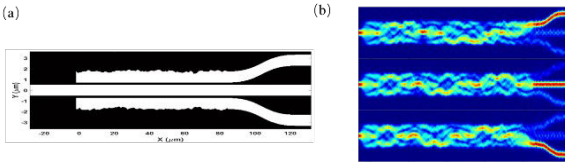

Fig. 3 (a) Structural geometry; (b) Simulated electric field distributions for the three operational wavelengths.

IV. Conclusion

In conclusion, an ultra-compact InP-based triple-wavelength multiplexer is demonstrated using boundary topology optimization. The device achieves a core length of only 92 μm, with insertion losses maintained below 0.8 dB across all three target bands. The design exhibits excellent fabrication robustness.

***Abstract*— 3D printed micro potentials in a dye-filled micro cavity allow to study Bose Einstein condensation of photons in almost arbitrary potential landscapes. We exemplary demonstrate the influence of dimensionality on the thermodynamic properties as well as topologically protected states for these driven-dissipative quantum systems.**

***Keywords*— 3D micro printing, photonic quantum gases, dimensional cross-over, topological protection.**

I. Introduction

Photonic quantum gases explore the physics of open driven-dissipative quantum systems under ambient conditions and thus open access to thermodynamics and transport phenomena in quantum gases in the weakly interacting regime. The technology of 3D micro-printing [1], which predominantly was developed to fabricate structures for nanophotonics (e.g. photonic crystals, metamaterials) allows to create potential landscapes for photonic quantum gases in dye-filled micro cavities (see Fig. 1), which surpass the current state of the art in terms of potential size and definition, potential depth, coupling strength, and number of coupled potentials by at least an order of magnitude. We realize as demonstration of the capabilities box potentials with rectangular side walls (see Fig. 1 b), anisotropic harmonic potentials, double-well potentials with dimensions on the scale of the wavelength of light as well as potential lattices with topological non-trivial properties (see Fig. 1 c and d). [2] The high fidelity of our approach allows us to study the dimensional crossover from 2D to 1D harmonic potentials and the resulting changes in the thermodynamic properties. [3]

II. Methods and Results

We use three-dimensional micro printing [1], also known as direct laser writing, to fabricate the potential landscapes on the cavity mirrors, which are covered with a high reflectance coating. The cavity is filled with Rhodamin 6G and pumped by a cw laser running at 532 nm. To prevent bleaching of the dye, the laser is pulsed using two acousto-optical modulators. Waveplates allow to choose any polarization state of the pump light on the Poincaré sphere to study the dependence of the polarization in the quantum gas from the one of the pump laser. For linear polarization the emitted light from the condensed quantum gas follows the pump polarization while the thermal cloud emits unpolarized light.

Adding the micro potentials allows for designing the potential landscape. For example, printing a Sue-Shriefer-Heger (SSH) chain (see Fig 1 c and d) of micro potentials clearly allows for the distinction between the topological trivial and topological non-trivial variant by studying the corresponding spectra of the quantum gas (see Fig. 2).

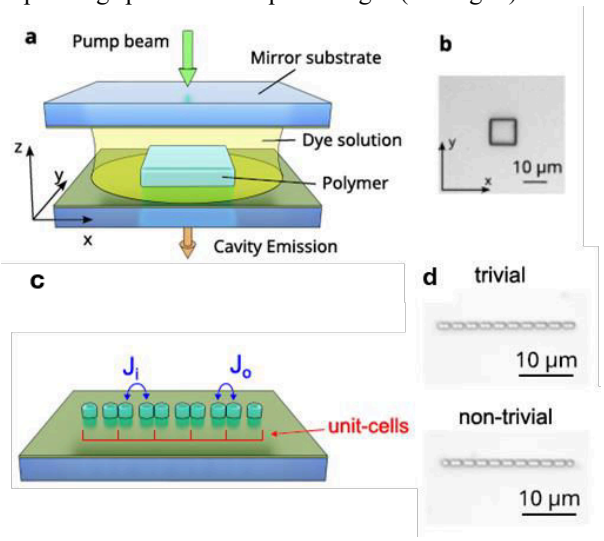

Fig. 1 a: Dye-filled micro cavity with a schematic of a printed box potential. b: light microscope image of the box potential on one of the highly reflective mirrors. c: Scheme of a non-trivial SSH chain with the two different couplings strength. d: light microscope images of a trivial and non-trivial realization of the SSH chain.

The spectra are measured by sending the light emitted from the cavity via grating onto a camera. Thus, it allows to either image the spectra over the spatial coordinate or by adding another lens into the beam path over the momentum coordinate. Plotting the spectra over the real space coordinate clearly demonstrates that the two edges states indeed appear at the two ends of the SSH chain, as expected (see Fig. 2 right hand side).

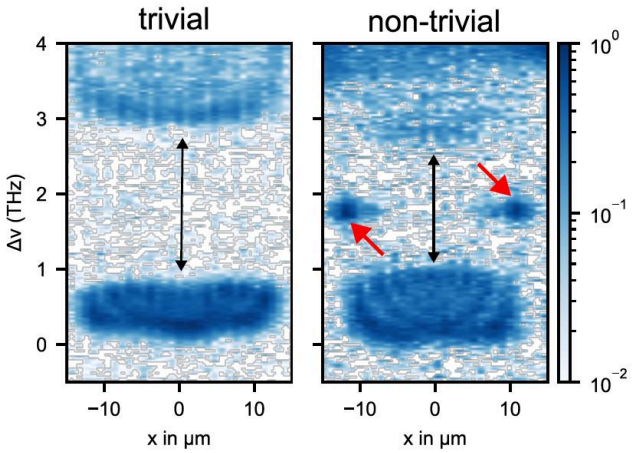

Figure 2: Spectra over the real space coordinate of the cavity. While for the trivial SSH chain only the opening of the gap can be seen (left hand side), the two characteristic edge states forming at the two ends of the chain energetically centered in the gap can be detected for the non-trivial chain (see red arrows).

III. Conclusions

We have demonstrated that combining technologies predominantly developed for the fabrication of nanopotonic structures with photonic quantum gases allows for novel investigations into the physics of open quantum systems. As proof of principle we fabricated and measure several different potential landscapes, starting from single micropotentials which we deform to study dimensional crossover, over coupled micropotentials to the topologically non-trivial SSH chain. Our approach allows in an unprecedented way defining potential landscape for photonic quantum gases and, thus, opening the way for novel studies in open driven-dissipative quantum systems.

***Abstract*— We discuss optical properties of twisted bilayer graphene (TBG) obtained from an atomistic tight-binding model including lattice relaxation. By including interaction effects within the Hartree-Fock approximation [1,2], we further accurately capture corrections to the renormalization of the Fermi velocity. Apart from the charge response, we will also calculate the magnetic and chiral response [3].**

***Keywords*— moiré materials, optical conductivity, Drude weight**

I. Introduction

There has been a lot of focus on the electronic properties of twisted bilayer graphene (TBG), but also the related optical response can be used to discuss basic phenomena. E.g., the observed superconductivity can be characterized via the Drude weight that can be measured, e.g., via scattering-type scanning near-field optical microscopy.

II. Methods

We employ a tight-binding model with Slater-Koster parametrization to model twisted bilayer graphene. Also, lattice relaxation is included, but more importantly, Coulomb interaction is approximated by a self-consistent Hartree-Fock scheme [1]. This is done using the package FORGE – Fock Optimization of Real-space Giant Environments [2]. By this, we are able to discuss the renormalization of optical properties such as the Drude weight and also the optical conductivity, shown in Fig. 1 for a twist-angle in the magic angle regime.

The interaction is parametrized by two parameters, the Hubbard interaction U and the dielectric constant ϵ respectively the related coupling constant $\alpha \sim 1/4\pi\epsilon_0\epsilon$ which is measured in units of eVa with a=0.246nm the lattice constant of graphene. Depending on the Hubbard interaction, the Hartree-Fock self-consistency procedure leads to either a valley polarized (VP) or a valley-coherent (VC) phase.

We will discuss the optical properties via the Kubo formula using the Hartree-Fock renormalized eigenfunctions and velocities/vertices. We will also discuss magnetic and chiral response as outlined in Ref. [3]. The flat-band regime is obtained for a slightly larger twist angle by increasing the interlayer hopping parameter as done in Ref. [4].

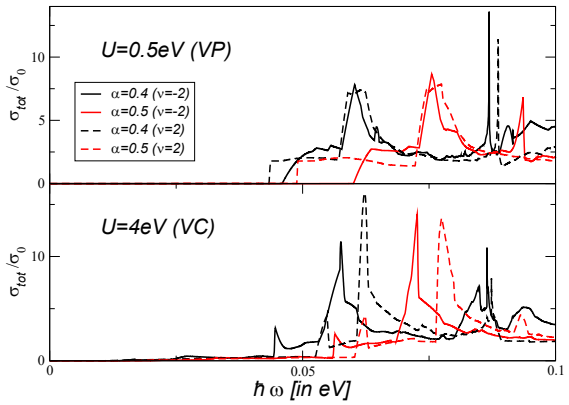

Fig. 1 The optical conductivity in units of the universal conductivity of graphene $\sigma_0 = e^2/4\hbar$ for electron ($\nu = 2$) and hole ($\nu = -2$) doping for different coupling constant α and Hubbard interaction U. Upper panel for U=0.5eV: the flat-band system is in the valley-polarized phase. Lower panel for U=4eV: the flat-band system is in the valley-coherent phase.

III. Results and Discussion

Our simulations show the following trends:

- VC bands are narrower than VP bands.
- VC Drude weights are smaller than VP Drude weights.
- VC optical gaps are soft; VP optical gaps are hard.
- VC magnetic response is 5 times smaller than VP magnetic response.
- For nematic phases, we find large in-plane magnetic dipole moments of the order of 8 Bohr magnetons.

IV. Conclusion

We have investigated the optical conductivity in twisted bilayer graphene including interactions that lead to either valley-polarized or valley-coherent phases. Our results should be relevant for future experiments in the THz-regime.

Artificial magnetism and passivity in plasmonic clusters with spatial dispersion

R. Dwivedi[1], K. Vynck[2], A. Baron[3], A.Aradian[3,*]

[1]Institut des Nanotechnologies de Lyon, INSA, CNRS, University Claude Bernard, France

***Abstract*— We show that the optical response of dense, random, spherical clusters made of plasmonic nanoparticles can be efficiently described as that of equivalent, homogeneous spheres of the same size, made of an effective, spatially dispersive medium displaying artificial magnetism. Passivity requirements for the obtained effective media will be discussed.**

***Keywords*— plasmonic nanoparticles, random clusters, effective medium, artificial magnetism, spatial dispersion, passivity.**

I. Introduction

We studied the optical properties of spherical clusters containing hundreds of 7 nm gold nanoparticles with varying volume fractions f, using high-precision T-matrix simulations. While these provide high accuracy for scattering and Mie coefficients, they are computationally expensive and lack physical intuition for dense clusters. To overcome this issue, we investigated to what extent these clusters can be equivalently described using more intuitive, effective parameters like permittivity and permeability.

II. Methods

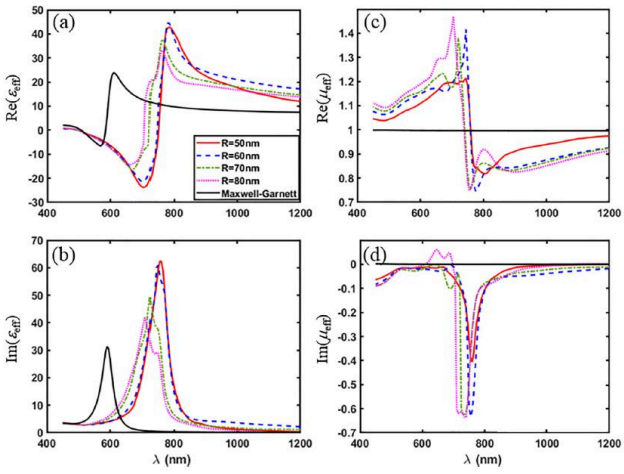
We therefore analyzed clusters (from 50 to 80 nm radius and f=5% to 44%) using T-matrix calculations to identify their multipolar scattering response. We then set to obtain electromagnetic equivalents, by fitting these results to the scattering response of fictitious homogeneous spheres, i.e. looking for spheres made of an effective material such that their multipolar coefficients matched those of the clusters over the whole spectrum of interest.

III. Results and Discussion

For low-density clusters (f<15%), we find that equivalent spheres made of a simple medium with an effective dielectric permittivity only are sufficient to match the properties of the clusters.

For high-density clusters (f>15%, up to 44%), this simple approach fails since interparticle couplings give rise to non-local effects: we find that homogeneous spheres filled with an effective material with three physical parameters efficiently reproduce the dense clusters' Mie coefficients. This three-parameter description derives from the theory of weak spatial dispersion, and comprises an effective permittivity ε_{eff}, an effective permeability μ_{eff} (i.e., artificial magnetism) and a parameter k_L describing the presence of longitudinal waves in the medium (in addition to standard transverse waves).

Figure 1 shows the plots for ε_{eff} and μ_{eff} obtained in the homogeneous spheres equivalent to dense clusters with radii ranging from 50 to 80 nm and a fixed volume fraction f=44%.



These results will be discussed during the talk, including the existence and localization of longitudinal waves in the homogeneous spheres and in the clusters. We will also discuss the fact that Im(μ_{eff}) comes out as negative, as shown in Fig.1, and whether this violates any passivity requirement.

DNA origami-based photonic crystals for visible light

Gregor Posnjak*, Tim Liedl

Department of Physics and CeNS, Ludwig-Maximilians-Universität München, Germany
*Corresponding author: gregor.posnjak@lmu.de

***Abstract*— We use DNA origami to design colloidal particles which controllably assemble into intricate lattices such as the diamond structure with periodicities on the order of hundreds of nanometers. Coating the structures with high-refractive index materials leads to complete 3D photonic band gaps in the visible.**

***Keywords*— 3D photonic crystals, self-assembly, DNA origami, visible light.**

I. Introduction

Manufacturing of 3D photonic crystals in the visible is a long-standing scientific challenge. To achieve a complete photonic band gap in the visible range several conditions have to be satisfied: appropriate lattice symmetry (e.g. diamond), periodicity of about half the wavelength, a high refractive index contrast, and a suitable volume fill fraction. With most approaches it is difficult or impossible to satisfy all conditions. Recent advances in DNA origami enable us to precisely control all the relevant parameters, leading to successful formation of rod-connected diamond cubic lattices[1].

II. Methods

DNA origami is a powerful nanotechnology method which allows us to design nanoscale particles of practically arbitrary shape. The selective binding of DNA sequences enables us to program the strength and relative orientation of binding between DNA origami particles, leading to intricate lattice geometries such as the diamond cubic structure, which are otherwise difficult to achieve through self-assembly. The assembled structures have low volume fill ratios, allowing for additive modification with sol-gel chemical reactions (SiO_2) and atomic layer deposition (TiO_2 and other oxides)[2]. The freedom over DNA origami design allows us to tune the periodicity and symmetry of the assembled structures[3].

III. Results and Discussion

Our experimental results show:

- Diamond lattices with 160 and 250 nm periodicity
- Clathrate lattices with 400 and 650 nm periodicity
- Orientation dependent reflections when coated with SiO_2
- Photonic band gaps when coated with TiO_2

The DNA origami structures are modifiable in an addressable fashion, enabling precise addition of plasmonic particles and dyes, serving as nanostructured breadboards for photonics.

IV. Conclusion

DNA origami offers the versatility of design, length scale and down-steam material processing needed for manufacturing of 3D photonic crystals. The self-assembly aspect removes the need for expensive machines and makes the process massively parallel, offering a viable platform for novel photonic materials.

Polarization control of photons with photonic crystal devices

Xiulai Xu[1,*]

[1]School of Physics, Peking University, China
*Corresponding author: xlxu@pku.edu.cn

Abstract: We present experimental demonstration in chiral and polarization-controlled quantum photonics based on topological photonic crystal waveguides and photonic molecules. By engineering cavity–waveguide interfaces and coupled-cavity supermodes, robust chiral light–matter interaction, directional single-photon routing, and enhanced emitter–photon coupling are achieved, offering scalable routes toward integrated quantum photonic circuits.

Introduction and Methods: Precise control of photon polarization, chirality, and emitter–photon coupling at the nanoscale is a central goal of integrated quantum photonics. However, conventional nanocavities and waveguides often suffer from fixed eigenpolarizations, limited interaction regions, and sensitivity to disorder. Topological photonic crystal waveguides and photonic molecules formed by coupled cavities provide complementary routes to engineer local density of states, modal symmetry, and polarization landscapes. We combine two strategies: (i) triangular-lattice topological photonic crystal waveguides supporting high-transmittance bends and large regions of circularly polarized fields for chiral coupling to quantum emitters, and (ii) photonic molecules composed of coupled nanocavities, where hybridized supermodes enable flexible spectral and spatial control of light–matter interaction. These platforms are integrated with semiconductor quantum dots for on-chip experiments.

Results and discussion: Topological waveguides enable spin-dependent, directional photon transport and robust chiral emission, while maintaining low-loss propagation through sharp bends. Photonic molecules provide tunable mode splitting, spatially delocalized fields, and polarization-selective coupling, allowing controlled redistribution of emission among hybridized modes. Together, these effects yield enhanced and programmable emitter–photon interactions, as well as stable single-photon routing on chip. Both of them establishes a versatile toolbox for controlling polarization, chirality, and coupling strength in quantum nanophotonics. Their scalability, design flexibility, and compatibility with solid-state emitters make them promising building blocks for large-scale quantum photonic networks, spin–photon interfaces, and reconfigurable quantum information processors.

Magnonic Waveguide Networks for Spin-wave Computing

Rudolf Bratschitsch[1,*]

[1]Insitute of Physics and Center for Nanotechnology (CeNTech), University of Münster, Germany

*Corresponding author: Rudolf.Bratschitsch@uni-muenster.de

***Abstract*—We demonstrate a maskless approach for fabricating spin-wave waveguides using focused silicon ion implantation. Using spatially resolved Faraday rotation microscopy, we directly image spin-wave propagation and extract dispersion relations, decay lengths, and mode profiles. To demonstrate scalability, we fabricate a large spin-wave network, paving the way for magnonic integrated circuits.**

***Keywords*— spin wave computing, waveguides, Faraday rotation, magnonic network.**

I. Introduction

The rapid growth of artificial intelligence and data-driven technologies has sparked an immense interest in alternative computing architectures, which go beyond conventional electronics. Spin waves (magnons) have emerged as a promising platform for next-generation physical computing. They are collective excitations of magnetization and offer several key advantages, such as excellent energy efficiency, broad operational frequency bandwidth and nanometer-scale wavelengths, rendering highly integrated devices possible [1]. The material of choice with the lowest known spin-wave damping is the magnetic insulator yttrium iron garnet (YIG). YIG has recently become available as high-quality single-crystal films on the wafer scale.

II. Results and Discussion

We demonstrate low-loss spin-wave waveguides in a thin YIG film using a maskless silicon ion implantation technique [2]. By using the focused ion beam, an amorphous cladding of the magnon waveguide is created, where the magnetization is drastically reduced. At the same time, the excellent magnetic properties in the YIG core of the waveguide are preserved. The spin-wave propagation is imaged via optical Faraday rotation microscopy, which enables spatially resolved measurements of spin-wave amplitude and phase throughout the engineered structures. We achieve spin-wave decay lengths exceeding 100 µm even in submicron waveguides, substantially outperforming current state-of-the-art etched devices. Furthermore, the dispersion relations of these waveguides are highly tuneable by adjusting both waveguide width and implantation dose, providing unique flexibility for integrated magnonic circuit design.

Using our new technique, we fabricate a large-scale spin-wave network, featuring 198 crossings with 34 input and output ports (Fig. 1).

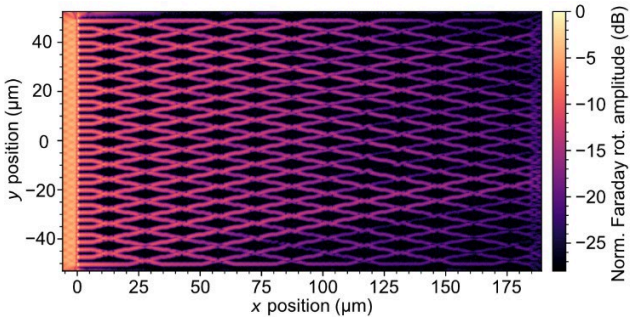

Fig. 1 Spin-wave network consisting of 198 crossings and 34 input and output ports [2].

III. Conclusion

Our etchless, scalable approach paves the way for wafer-scale, low-loss magnonic integrated circuits (MICs), enabling advanced, high-efficiency spin-wave-based computing and signal-processing architectures.

Machine Learning for Inverse Design

Philippe Tassin

Department of Physics, Chalmers University of Technology,
SE-412 96 Göteborg, Sweden

***Abstract*—I will present an overview of our work on using machine learning for inverse design in nanophotonics, with emphasis on free-form inverse design, the use of machine learning in inverse design, physics-informed neural networks, and adaptive metamaterials.**

***Keywords*—inverse design, machine learning, nanophotonics, photonic crystals, metamaterials.**

Inverse design, i.e., fully automated design by a computer without intervention of a human, is promising to revolutionize photonics. There are currently two major ways to achieve a fully automatic free-form design of a photonic device: (1) gradient-descent optimization with the adjoint method (sometimes called topology optimization) [1] and (2) machine-learning-driven inverse design where a neural network acts as a fast surrogate model for expensive simulations [2]. Both approaches require a large number of simulations, either in the iterative optimization process or as training data for a neural network. I will first compare the advantages and disadvantages of these two methods.

I will then show two examples of the free-form design of a metamaterial, where we train a neural network as a surrogate model: a metamaterial lens [3] and a Zernike phase mask [4]. While these examples demonstrate the possibility of this method, such a brute-force approach to training a neural network as a surrogate model requires an extreme amount of training data, often in the order of tens to hundreds of thousands of simulations. This is because the network has to learn the "physics," i.e., has to learn from data that the optical response has to obey Maxwell's equations and has to respect symmetries in the physics. I will show that this knowledge can be built in into a neural network by using QNM-Net (a network containing a physics layer) [5] and/or by using equivariant networks (which have symmetries built-in) [6], and that this substantially reduces the amount of data needed to an amount that is feasible to generate.

Finally, I will show how machine learning can help to build adaptive metamaterials that respond to changes in the environment.

Acknowledgments

We acknowledge financial support from Chalmers' area of advance Nano, from the Swedish Research Council under Grant No.~2020-05284, and from the Knut och Alice Wallenberg Stiftelse under Grant No. 2022.0090. The training data generation and neural network training were performed on resources provided by the Swedish National Infrastructure for Computing (NAISS), at the Chalmers/C3SE and KTH/PDC sites, partially funded by the Swedish Research Council under Grant No. 2022-06725. The work was performed in part within the framework of the Excellence Center META-PIX (Grant No. 2022-06575).

***Abstract*— We present a unified framework for optimising photonic reservoir computing, combining nonlinear substrates and engineered encoding layers. Using gain-controlled multimode fibres, we identify structural complexity as a task-independent design metric. Complementarily, we demonstrate that deliberate phase wrapping beyond [0, 2π) dramatically enhances expressivity via synthetic Fourier mode generation and mixing.**

***Keywords*— reservoir computing, optical computing, photonic scattering, erbium-doped fibres.**

Nonlinear wave propagation provides a powerful substrate for analogue information processing. Photonic Reservoir Computing (RC) exploits these dynamics by encoding input data into optical waves interacting in a complex photonic system, and performing machine learning tasks via linear regression of intensity measurements [1,2]. Wave-based photonic reservoirs offer inherent parallelism, high bandwidth, and favourable scaling. A key challenge, however, remains how to control the degree of nonlinearity expressed by the reservoir, as required to adapt the system operating regime to different machine learning tasks.

In this invited talk, we present recent results addressing two complementary aspects of photonic RC design: the optimisation of the nonlinear photonic substrate and the engineering of the optical encoding layer. In the first part [3], we investigate a feed-forward reservoir based on Erbium-Doped Multi-Mode Fibres (ED-MMF), where input data is encoded in the wavefront of a signal beam, and the nonlinear response is controlled by a structured pump beam within the gain medium. Due to the interplay of gain saturation, mode competition, and nonlinear coupling, the system implements a tunable nonlinear transformation controlled by global parameters (pump and signal powers). We benchmark performance on regression, classification, and chaotic time-series prediction tasks, demonstrating that an intermediate nonlinear regime near the gain threshold consistently yields optimal results. The system performance is directly connected to the degree of structured information carried by the optical waves as they propagate through the system, quantified by the measurement of the Kolmogorov Complexity of the reservoir outputs. This metric provides a task-independent criterion for tuning photonic reservoirs, analogous to the spectral radius in echo-state networks. In the second part [4], we address the encoding layer in scattering-assisted photonic reservoirs, where input data is encoded in the phase front (e.g., via an SLM), propagated through a random scattering medium and detected via intensity measurement. Conventionally, phase encoding is restricted to the $[0,2\pi)$ period to preserve bijectivity. We demonstrate that deliberately wrapping the phase domain beyond the natural period yields dramatic expressivity enhancements across regression and classification benchmarks that are unattainable within a single period. The mechanism arises from the interplay of phase encoding, random scattering, and intensity detection: the SLM constructs synthetic Fourier features whose bandwidth scales with the wrapping factor α, while the scatterer and quadratic detection induce frequency-difference mixing that generates additional nonlinear features. Formally, this connects photonic RC with Random Fourier Features (RFF) methods in machine learning and with Hamiltonian-encoded quantum extreme learning machines, where eigenvalue spacings determine accessible frequencies. The enhancement is robust to finite bit depth and shot noise, confirming its experimental feasibility.

Together, these results establish that optimal photonic RC requires the co-design of the nonlinear substrate and the encoding scheme. Structured complexity, whether measured by the KC of the reservoir's output features or by the bandwidth of synthetic Fourier modes generated at the encoding stage, emerges as a unifying principle for the design of next-generation wave-based analogue computing platforms.

***Abstract*— We present an optically programmable photonic platform that overcomes static geometric design limitations for exceptional points. Utilizing dynamic refractive index modulation via an external pump, we successfully steer eigenvalue and eigenvector coalescence. This approach offers a tunable set of exceptional point solutions, enabling deterministic control over device directionality**

***Keywords*— photonics, non-Hermitian optics, reconfigurability.**

I. Introduction

Non-Hermitian singularities known as Exceptional Points (EPs), where eigenvalues and eigenstates coalesce, enable unprecedented light control [1]. However, exploring these degeneracies on-chip has traditionally relied on static geometric tuning, requiring the fabrication of multiple devices with different scatterer positions or configurations to tune the losses [2]. To overcome this limitation, we present a platform featuring dynamic all-optical programmability on a single chip. By applying an external optical pump, the effective refractive index of the silicon core is nonlinearly modulated. This shifts the condition for the EP activation, and, as result, this non-Hermitian effect can be tuned optically.

II. Results and Discussion

The device consists of an all-pass silicon microring loaded with two fixed nanocylinders (SEM image, Fig. 1b). Their fixed angular separation sets the asymmetric coupling between CCW and CW modes. The transformation from this static response to an optically programmable topology is schematized in Fig. 1a. Adjusting the pump power under 10 mW, a small index modulation of 0.005 is induced in the ring resonator. This variation modifies the relative optical accumulated between the scatterers. This phase shift completely changes the balance between the complex scattering strengths inducing an asymmetric divergence in CCW to CW and reverse coupling. Consequently, the coalescence conditions are swept across the probe spectrum, tracing a curved EP trajectory as a function of the power of the optical pump, that is injected at a different wavelength that the probe, eliminating any intereference possibility. As diagrammed in Fig. 1, the pump routes the system from a directional chiral state to an inverse reflection

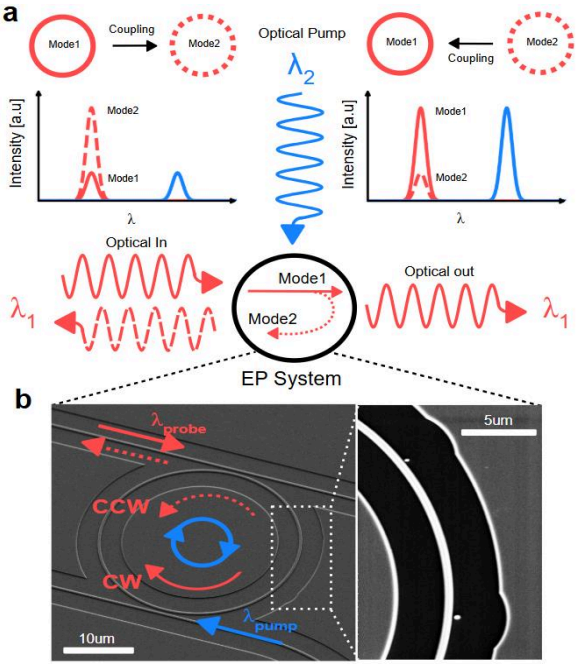

Figure 1. a) Scheme of the optical control of the EP and b) SEM image of the implementation

state, or any intermediate configuration, unlocking scalable control over the nonlinear enhancement.

III. Conclusion

We demonstrated full on-chip programmability of EPs in silicon microrings via all-optical control. Replacing physical reconfigurations with dynamic index modulation unlocks a continuous range of EP solutions on a single device, enabling reversible routing of chiral states and a scalable path to program non-Hermitian enhancements.

Non-Reciprocal Silicon Photonic Resonators with 2D $CuCrP_2S_6$

Mahmoud S. Rasras[1,*], Ghada Dushaq.[1]

[1]Department of Electrical and Computer Engineering, NYUAD, Abu Dhabi, UAE
[2]Center for Smart Engineering Materials, NYUAD, Abu Dhabi, UAE
*Corresponding author: mrasras@nyu.edu

***Abstract*— A compact non-reciprocal photonic device is demonstrated by integrating a two-dimensional magnetic material with silicon microring resonators. Magnetic ordering induces directional asymmetry with low loss and high isolation. The device operates in the transverse electric mode and supports broadband operation relevant to short-wavelength infrared photonic systems.**

***Keywords*— 2D materials, non-reciprocal Photonic, Silicon Photonics, photonic resonators.**

I. Introduction

Non-reciprocal photonic devices are essential for integrated optical systems, enabling signal isolation and directional control in applications spanning communications and quantum technologies. Achieving optical non-reciprocity on chip remains challenging due to material and integration constraints. Two-dimensional multiferroic materials, such as $CuCrP_2S_6$, offer a promising route toward compact, efficient, and CMOS-compatible non-reciprocal photonic devices.

II. Methods

Silicon microring resonators were fabricated on silicon-on-insulator wafers with a 220 nm device layer. Multilayer CuCrP2S6 flakes were mechanically exfoliated and deterministically transferred onto the waveguide. Optical transmission was measured in the transverse electric mode under an external magnetic field applied in Voigt geometry.

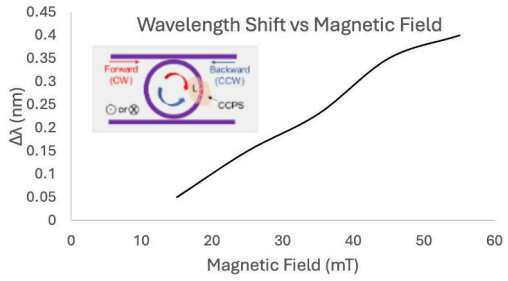

Fig. 1 Non-reciprocal transmission and resonance splitting in CCPS-integrated microring resonators.

Nonreciprocal behavior was evaluated through resonance splitting and phase shift, described by $\Delta\beta = \frac{2\pi\Delta\lambda}{FSR.L_{MO}}$ and $\Delta\lambda = \lambda\frac{\Delta n_{eff}}{n_g}$, where L_{MO} denotes the interaction length, FSR the resonator free spectral range, and n_g the group index.

III. Results and Discussion

The CCPS-integrated microring resonators exhibit clear non-reciprocal behavior under an applied magnetic field. Clockwise and counterclockwise resonances split by up to 0.4 nm, yielding isolation ratios up to 28 dB with low insertion loss. The devices operate in the transverse electric mode and maintain broadband performance across the C-band. (Fig. 1)

IV. Conclusion

We have demonstrated compact, low-loss non-reciprocal silicon photonic devices enabled by multilayer CCPS, achieving high isolation, broadband operation, and TE-mode compatibility, underscoring strong potential for short-wavelength infrared optical isolation and integrated photonic systems.

Light-Driven Order: Shift and Injection Raman Forces Driving Coherent Phonons

Habib Rostami[1*] and J. Luke Pimlott[1]

[1]Department of Physics, University of Bath, Bath BA2 7AY, United Kingdom
*Corresponding author: hr745@bath.ac.uk

***Abstract*—Ultrafast optical fields drive coherent lattice dynamics in quantum materials. We introduce shift and injection Raman forces as quantum-geometric mechanisms for coherent phonon generation. Arising from band geometry and interband electron-phonon asymmetry, these forces enable tunable, symmetry-selective lattice control beyond conventional Raman mechanisms.**

***Keywords*— quantum geometry, Raman forces, coherent phonons, ultrafast optics, two-dimensional materials, light-matter interaction.**

I. Introduction

Ultrafast optical excitation offers a route to control quantum materials beyond equilibrium by coupling electronic and lattice degrees of freedom on femtosecond-to-picosecond timescales. Light-induced responses can reveal hidden order, drive symmetry switching, and manipulate structural degrees of freedom in layered and low-dimensional materials. Examples include light-driven Kerr rotation in centrosymmetric bulk WSe2 [1], ultrafast symmetry switching in WTe2 [2] and MoTe2 [3], and light-induced Raman-force-driven shear motion in bilayer graphene [4]. These results motivate a microscopic theory of optical forces that goes beyond conventional descriptions of coherent phonon generation.

II. Shift and Injection Raman Forces

Coherent phonons are usually described through impulsive stimulated Raman scattering or displacive excitation. These mechanisms are commonly formulated in terms of equilibrium optical susceptibilities and do not fully expose the role of electronic band geometry, symmetry, and interband electron-phonon coupling.

Here we introduce shift and injection rectified Raman forces as generic mechanisms for coherent phonon generation [5]. These forces are phononic analogues of photogalvanic effects. They arise from quantum-geometric properties of electronic bands, including the quantum geometric tensor, a phononic shift vector, and interband asymmetries in electron-phonon coupling. The injection force produces a displacive lattice response associated with asymmetric carrier excitation, whereas the shift force generates an impulsive resonant drive that becomes prominent when time-reversal symmetry is broken.

III. Representative Example

As a prototypical platform, we consider a bilayer Haldane model and examine optically driven interlayer shear phonons. This example shows that the magnitude and direction of the Raman forces can be tuned by optical frequency and magnetic flux. The result demonstrates that coherent phonon generation can be controlled through band geometry and symmetry, rather than only through equilibrium Raman susceptibilities.

IV. Conclusion

Shift and injection Raman forces provide a quantum-geometric framework for ultrafast lattice control. The mechanism is generic and applies beyond the representative shear-phonon example. It opens a route toward symmetry-selective optical manipulation of coherent phonons and light-driven structural dynamics in layered quantum materials.

Infrared Silicon Metalenses through Deep-UV for Thermal Imaging

Kai Sun[1,*], Jordan Scott[1], Xingzhao Yan[2], Jun-Yu Ou[1], Otto L. Muskens[1]

[1]Physics and Astronomy, University of Southampton, UK
[2]Optoelectronics Research Centre, University of Southampton, UK
*Corresponding author: k.sun@soton.ac.uk

***Abstract*— This presentation will overview recent infrared silicon metalenses developed by our group for compact thermal imaging and telecommunications. It will cover metalenses across SWIR, MWIR and LWIR bands, scalable fabrication routes, integrated metasurface concepts and selected optical characterization results, with emphasis on practical opportunities for infrared metaoptics.**

***Keywords*— metaoptics, metalens, thermal imaging, deep-UV.**

I. Introduction

Metasurfaces consisting of subwavelength nanostructures allow for engineered optical response beyond bulk materials. Here, we demonstrate developed various silicon-based infrared metalenses for SWIR, MWIR and LWIR bands, manufactured through deep-UV lithography.

II. Methods

The metalenses were designed using Keysight RSoft Photonics Design Tools, MetaOptics Designer (MOD). The unit cell response was initially simulated through rigorous coupled wave analysis (RCWA) and then the full design was generated through multi-variable optimizations using MOD.

The designed metalenses were manufactured through Deep-UV lithography and plasma etching technique to form silicon pillars. Through our recently developed technique [1], double-sided metalenses could be manufactured in wafer-scale and on both sides of the substrates. In addition, through switching technique, metalens dimensions can be enlarged over the DUV reticle limits.

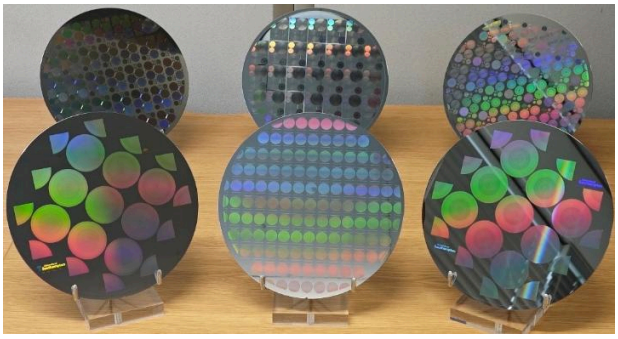

Fig. 1 Family photo 6 batches of infrared metalenses over 200 mm Si substrates.

III. Results and Discussion

Figure 1 shows the family photo of 6 metalens wafers (8-inch) using Deep UV lithography (200 nm minimal features) from serial batches, showing the progression of infrared metalens design, starting with a few millimeter diameter lenses and increasing in size to 40 mm diameter designs. These metalenses cover various infrared bands, short-wave infrared (SWIR), mid-wave infrared (MWIR) and long-wave infrared (LWIR). One set of metalenses was designed for MWIR thermal imaging with metalens and moth-eye structures on the two sides of the substrate, respectively, which is enabled by our novel manufacturing technique.

IV. Conclusion

We have demonstrated double-sided metalens with moth-eye anti-reflection coatings together with focal metalens. The fabricated metalenses were optically characterized in terms of focal performance, modulation transfer function (MTF) and thermal imaging performance. The moth-eye integrated metalens shows improved performance over single-sided metalens.

I. Introduction

Two-dimensional layered materials exhibit unique optical, excitonic, and nonlinear properties arising from reduced dimensionality and strong Coulomb interactions. Their van der Waals nature enables deterministic integration onto nanophotonic structures without lattice matching constraints, making them highly attractive for hybrid device architectures. By combining atomically thin semiconductors and insulators with high-Q optical cavities, it becomes possible to engineer light–matter interaction at the nanoscale with unprecedented flexibility.

Here present our recent advances in van der Waals hybrid photonic devices, where two-dimensional materials can be used to tune, define, and reconfigure optical resonators. Across multiple cavity platforms, including air-mode silicon nanobeam cavities [1,2], self-aligned two-dimensional photonic crystal (PhC) cavities [3,4], and ultrahigh-Q silica microspheres [5], we demonstrate how atomically controlled thickness, mechanical flexibility, and optical nonlinearity of layered materials provide new mechanisms for cavity modulation, quantized resonance control, and hybrid nonlinear functionalities.

II. Air-Mode Silicon Nanobeam Cavity

Air-mode silicon photonic crystal nanobeam cavities provide strong field localization in low-index regions, maximizing overlap between the optical mode and externally integrated materials. By transferring few-layer van der Waals flakes onto these cavities, we achieve efficient and controllable modification of cavity resonances (Fig. 1).

A key feature of this platform is the quantized resonance shift induced by atomically precise layer thickness [1]. Because each additional layer introduces a well-defined perturbation to the effective refractive index, discrete mode shifts are observed, directly reflecting thickness quantization at the atomic scale. Flexible and reversible tuning of cavity properties is further enabled by stacking and removing ultrathin flakes of two-dimensional materials.

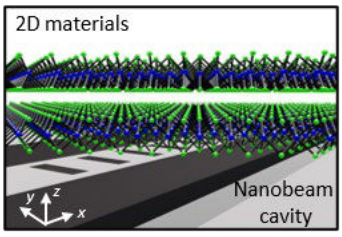

Fig. 1: A schematic of a 2D /cavity hybrid [1].

Extending this hybrid approach beyond static tuning, we have also implemented all-optical switching devices that leverage refractive index modulation in two-dimensional semiconductors integrated with air-mode silicon nanobeam cavities [2]. In these devices, a thin flake of a two-dimensional semiconductor such as molybdenum ditelluride is placed on top of the cavity and excited by an optical pump pulse. The photo-induced carriers in the flake cause a rapid shift in the cavity resonant wavelength, enabling switching operations on time scales of tens of picoseconds with low switching energies of a few hundred femtojoules.

Careful design of the nanobeam geometry ensures large mode overlap with the two-dimensional material while maintaining high cavity quality factors on the order of 10^4 even after integration. Measurements show that the quality factor remains sufficiently high for efficient low-energy switching despite modest reductions after material transfer, indicating that absorption and additional scattering introduced by the two-dimensional flake are small.

These results demonstrate that air-mode silicon nanobeam cavities not only serve as sensitive platforms for quantized mode control through van der Waals materials but also provide an efficient hybrid platform for ultrafast optical signal processing. Their performance highlights the advantages of

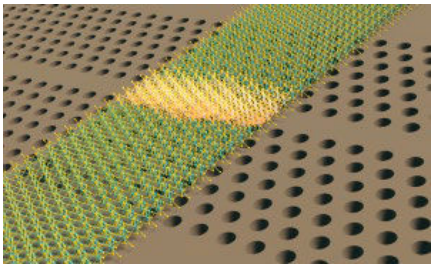

Fig. 2: A self-aligned cavity formed by an atomically thin flake [3].

integrating two-dimensional semiconductors with high-Q photonic structures for active photonic functionalities.

III. 2D Photonic Crystal Self-Aligned Cavity

Moving beyond tuning pre-fabricated nanocavities, we developed a self-aligned hybrid cavity concept in which the two-dimensional material itself locally defines the cavity within a photonic crystal waveguide (Fig. 2). When a flake is placed onto a PhC waveguide, its refractive index perturbation creates a confined defect mode at the flake position, effectively forming a cavity wherever the material is transferred [3,4].

This approach eliminates the need for lithographically predefined cavity defects and alignment steps. The cavity position and characteristics are instead determined by the geometry and thickness of the transferred flake, enabling post-fabrication cavity formation with high spatial flexibility. Arrays of hybrid cavities can therefore be realized through deterministic material placement.

Such self-aligned architectures illustrate a paradigm shift: van der Waals materials act not only as active media but also as structural elements that define photonic confinement. This concept provides a scalable route toward programmable photonic circuitry based on material placement.

IV. Ultrahigh-Q Silica Microsphere

The hybridization strategy extends beyond planar silicon photonics to three-dimensional ultrahigh-Q whispering-gallery-mode resonators [5]. Silica microspheres support extremely long photon lifetimes, providing a sensitive platform for investigating nonlinear and optomechanical effects.

By integrating two-dimensional materials onto ultrahigh-Q silica microspheres, we functionalize otherwise passive dielectric cavities. The mechanical flexibility of atomically thin layers allows conformal attachment to curved surfaces, while their strong optical nonlinearity and excitonic response introduce new interaction channels (Fig. 3). Hybrid microsphere devices demonstrate enhanced nonlinear effects and tunable optical responses without significantly degrading intrinsic cavity Q factors.

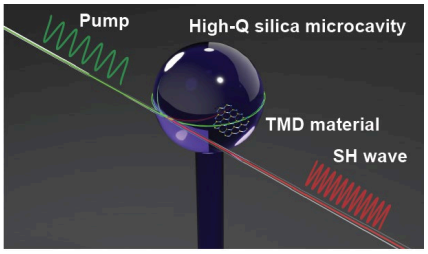

Fig. 3: Second harmonic generation with 2D-material/microsphere hybrid device.

V. Conclusion

Van der Waals hybridization offers a powerful and versatile strategy for next-generation nanophotonic devices. By integrating atomically thin materials with high-Q cavities, we demonstrate discrete and reversible resonance tuning, self-aligned cavity formation, and nonlinear functionalization across silicon nanobeams, photonic crystal waveguides, and silica microspheres.

These results highlight how layered materials transform passive photonic resonators into dynamically configurable and multifunctional devices. The convergence of ultrahigh-Q photonics and van der Waals materials opens new opportunities for hybrid nonlinear optics, reconfigurable photonic circuits, and quantum nanophotonics, establishing a flexible platform for nanoscale light–matter engineering.

***Abstract*— We demonstrate a spatio-temporal photonic metalattice formed by combining a static metagrating with a transient lattice written by two-beam interference in a low-index transparent conductor. The structure is revealed via internally generated third-harmonic diffraction.**

***Keywords*— time-varying metamaterials, nonlinear optics.**

I. Introduction

Ultrafast time-varying photonics is enabled by strong nonlinearities in low-index transparent conductors, where femtosecond excitation produces large transient refractive-index modulation and control of photon energy and momentum [1–3]. This allows functionality to be written in time rather than space (nanofabrication), complementing metasurface phase-gradient approaches [4] and enabling reconfigurable diffraction and temporal lattice formation on femtosecond timescales [5,6].

II. Methods

Our experiments make use of a subwavelength AZO film, patterned into a 1D metagrating. Two phase-coherent femtosecond NIR pumps interfere to write a transient grating. The film simultaneously generates third-harmonic radiation acting as an internal probe for direct diffraction mapping [7,8].

III. Results and Discussion

Combined dual-beam excitation on the metagrating reveals a full two-dimensional spatio-temporal lattice through orthogonal diffraction signatures. The transient lattice diffracts third-harmonic radiation with efficiency comparable to the physical grating, confirming time-written periodicity as an effective diffractive structure. Pump wavelength shifts structural diffraction but leaves temporal diffraction nearly invariant due to scaling of transient pitch and the corresponding generated harmonic wavelength. Incidence angle reshapes diffraction topology, while pump delay tunes harmonic spectra through ultrafast temporal modulation [1,6].

IV. Conclusion

Combining a fabricated metagrating with an optically written transient lattice enables a spatio-temporal photonic metalattice directly visualised through self-generated third-harmonic diffraction. This approach shifts diffractive photonic design from fixed geometry toward radiation engineering, enabling ultrafast reconfigurable diffraction and full programmable control of photon momentum and spectrum [1–4].

***Abstract*— We create disordered structures exhibiting specific spectral features, from stealthy hyperuniformity to completely new structures, "gyromorphs", that exhibit rotational order alongside translational disorder. We evaluate their optical properties using a coupled dipoles method and show how specific optical responses may be reached by optimizing for features in the structure factor.**

***Keywords*— metamaterials, disorder, bandgap, coupled dipoles, Fourier transform.**

I. Introduction

Periodic and quasiperiodic systems are characterized by extensive peaks in their structure factors. In finite two dimensional systems, the strongest of these peaks populate the vertices of a polygon - a square in a square lattice, a triangle in a triangular lattice, and higher order polygons in quasicrystals. In contrast, disordered structures commonly only exhibit broad, smooth features in their structure factors. However, we show that it is indeed possible to create disordered structures that exhibit a ring of regularly-spaced extensive peaks in the structure factor, unifying the two seemingly contradictory qualities. These "gyromorphs" exhibit higher and better-resolved peaks than quasicrystals of the same rotational order. This specific feature of a ring of high peaks on the structure factor makes gyromorphs ideal candidates for isotropic bandgap materials. Using a coupled dipoles approximation, we show that gyromorphs indeed exhibit complete, isotropic photonic bandgaps that are deeper and wider than those formed by stealthy hyperuniformity, high-order quasicrystals, and Vogel spirals for both scalar and vector waves in 2d and 3d.

II. Methods

Disordered structures are generated via an optimization algorithm FReSCo (Fast Reciprocal Space Correlator). We use a coupled dipoles approximation to calculate transmission spectra and density of states within our structures.

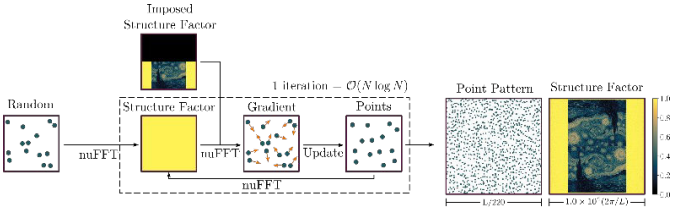

Fig. 1 Schematic diagram of the FReSCo algorithm.

Using two-photon lithography (NanoScribe), we fabricate network structures with similar structural features. We measure the transmission spectra of these networks with FTIR spectroscopy using an optical microscope with a Cassegrain objective.

III. Results and Discussion

FReSCo enables custom design of reciprocal space features in point patterns, including features that initially seem contradictory, as in the case of gyromorphs.

Using even a fairly naïve single-scattering argument, we can design spectral features (e.g. a ring of high peaks) with optical properties (e.g. an isotropic bandgap) that are preserved in the multiple scattering regime.

Network structures based on the point patterns can be shown to exhibit features of the predicted spectra.

IV. Conclusion

We have created and assembled tools to design disordered structures with specific spectral features. We are also able to utilize the relation between structure factor and single scattering to design metamaterials with specific optical properties. Future work will focus on the experimental verification of the optical properties of these structures.

Bulk-Radiation Correspondence in Radiative Photonic Lattices

Xinyi Yuan[1,*], Grazia Salerno [2,*]

***Abstract*—We develop a non-Hermitian model to describe the guided and leaky modes of photonic crystal slabs with non-local responses. Within this framework, we investigate the concept of bulk-radiation correspondence in the vicinity of the Γ-point of the square lattice and the K-point of the honeycomb lattice. The results show that the comparability is not universal and completely breaks down around bound states in the continuum.**

Keywords — photonic crystal slab, non-hermitian, bulk-radiation correspondence, bound states in the continuum.

I. Introduction

The concept of radiation topology generalizes the photonic Berry curvature to the far-field, resulting in a curvature term defined by the unit polarization vectors in momentum space:

$$B^f = -i\left(\langle\partial_\mu E|\partial_\nu E\rangle - \langle\partial_\nu E|\partial_\mu E\rangle\right). \tag{1}$$

For two-level systems, e.g., cavity polariton system, cavity lattices, one can map the two degrees of freedom onto Bloch sphere and relate wavefunctions with observables through polarimetry [1], [2], [3]:

$$B^b = \frac{1}{2} sin\theta(\partial_x\theta\cdot\partial_y\phi - \partial_x\phi\cdot\partial_y\theta). \tag{2}$$

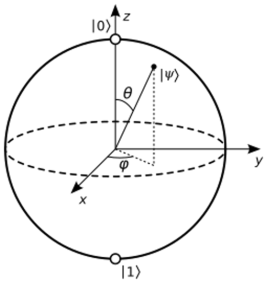

Fig. 1. A schematic showing how an effective two-level wave system is represented and mapped onto a Bloch sphere.

For photonic lattices, however, the multi-band nature makes it less legitimate to directly apply the two-level treatment. Further, the interplay between radiative modes in the far-field brings in new features, e.g., bound states in the continuum (BICs).

We develop a non-Hermitian Model to study the influence of non-locality and non-Hermiticity on the validity of the correspondence in radiative photonic lattices.

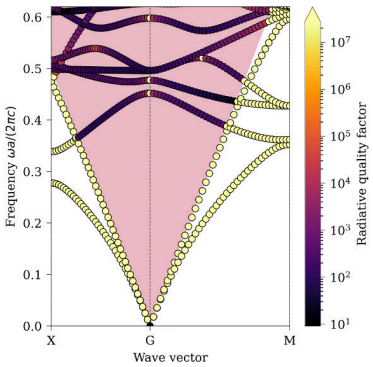

Fig. 2. Example of band structures in a PhC slab. The band structure was calculated using the Legume package [4], based on Guided Mode Expansion.

II. Modeling

Considering a photonic crystal slab made from isotropic, lossless, non-magnetic ($\mu = 1$), and nond-ispersive medium, treating the periodic change in the refractive index profile $\Delta\epsilon(\boldsymbol{r})$ as perturbation. For a time-harmonic field defined as $\boldsymbol{E}(\boldsymbol{r},t) = \boldsymbol{E}(\boldsymbol{r})e^{-i\omega t}$, the master equation for the TE mode is formulated as a *generalized eigenvalue problem*:

$$\nabla\times(\nabla\times\boldsymbol{E}) = \frac{\omega^2}{c^2}\varepsilon(\boldsymbol{r})\boldsymbol{E} \tag{3}$$

where the complex frequency $\omega = \omega_r - i\gamma$ accounts for the radiative loss through its imaginary component γ.

The band structure can be understood by considering guided modes folded at diffraction orders (m,n), where m, n are integers [4]. For a lattice with periodicity a_1 and a_2, the diffraction orders are located at multiples of the reciprocal lattice vector $\mathbf{G} = mG_1\hat{\mathbf{k}}_1 + nG_2\hat{\mathbf{k}}_2$, where $G_{1,2} = 2\pi/a_{1,2}$ defines the Brillouin zone. In the case of a rectangular lattice, for example, $a_{1,2} = a_{x,y}$, $\hat{\mathbf{k}}_{1,2} = \hat{\mathbf{k}}_{x,y}$ and $G_{1,2} = G_{x,y}$. We indicate the guided modes in the vicinity of $\mathbf{G}$ with in-plane wave vectors $(k_x,k_y) \in 1^{st}BZ$ as $|m,n\rangle$. These guided modes constitute the basis for the effective model. Here, we only consider a single "unfolded" guided mode - for instance, the fundamental TE guided mode propagating in the uncorrugated slab made of the average effective index. The thickness of the slab is chosen to ensure operation in

the single-mode regime, and all other guided TE modes lie at much higher energies.

The dispersion relation of the mode $|m,n\rangle$ in the vicinity of Γ-point corresponding to $\mathbf{G}$ with a group velocity v_g is:

$$\omega_{m,n} = \omega_0 + \frac{v_g}{\hbar}\left(|\mathbf{k_{m,n}}| - |\mathbf{G}|\right), \tag{4}$$

where ω_0 is the mode frequency at the first Γ-point. The guided modes are then coupled via a diffractive mechanism and the radiation continuum. The coefficients determining the coupling parameters can be obtained from a perturbative method based on the periodic potential profile acting on the photonic modes.

For TE modes, the unit polarization vector $\hat{\mathbf{p}}_{\mathbf{m,n}}$ associated with the guided mode $|m,n\rangle$ is perpendicular to the corresponding unit in-plane wavevector $\mathbf{k_{m,n}}$. We define the angle $\theta_{m,n}$ on the $k_x - k_y$ plane as

$$\theta_{m,n} = \arg\left[k_x + mG_x + i(k_y + nG_y)\right], \tag{5}$$

such that

$$\hat{\mathbf{k}}_{m,n} = \cos\theta_{m,n}\cdot\hat{\mathbf{k}}_x + \sin\theta_{m,n}\cdot\hat{\mathbf{k}}_y, \tag{6}$$

$$\hat{\mathbf{p}}_{m,n} = -\sin\theta_{m,n}\cdot\hat{\mathbf{k}}_x + \cos\theta_{m,n}\cdot\hat{\mathbf{k}}_y, \tag{7}$$

see Fig. **??**.

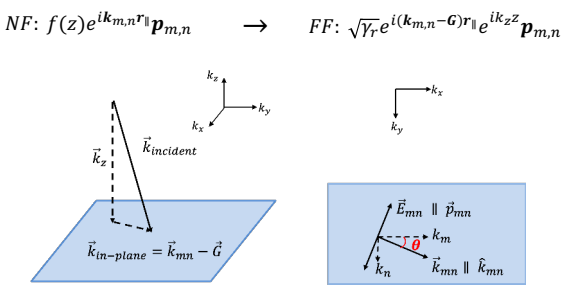

Fig. 3. The geometric representation of the basis sets $\mathbf{k_{m,n}}$ and $\mathbf{E_{m,n}}$.

The coupling via the radiation continuum is achieved through far-field interference, resulting in the loss of photons at a rate γ_r. The loss exchange depends on the product between the polarization components $\hat{\mathbf{p}}_{\mathbf{m,n}}$ and $\hat{\mathbf{p}}_{\mathbf{m',n'}}$ and the projection angle between two guided modes can be represented as

$$\varphi_{m,n,m',n'} = \theta_{m,n} - \theta_{m',n'}. \tag{8}$$

The effective Hamiltonian can thereby be written as

$$\hat{H}_{\text{rad}}(k_x,k_y) = \sum_{m,n}\left(\omega_{m,n} + i\gamma_r\right)|m,n\rangle\langle m,n| + \sum_{m,n,m',n'}\left[t_{m,n,m',n'} + i\gamma_r\cos(\varphi_{m,n,m',n'})\right]|m,n\rangle\langle m',n'|. \tag{9}$$

The unit vector that characterizes the corresponding far-field radiation can thus be written as

$$|E\rangle = \Sigma_{m,n}c_{m,n}(-\sin\theta_{m,n}\cdot\hat{\mathbf{k}}_x + \cos\theta_{m,n}\cdot\hat{\mathbf{k}}_y). \tag{10}$$

III. Results and Discussion

A. Analytical Results

Substituting Eq. (1) with Eq. (10), we get

$$\begin{aligned} B^f = &-i\sum_{j,l=1}^{N}\cos(\theta_j-\theta_l)\Big[\{\partial_\mu c_j^*\partial_\nu c_l - \partial_\nu c_j^*\partial_\mu c_l\}+ \\ &c_j^* c_l\left(\partial_\mu\theta_j\partial_\nu\theta_l - \partial_\nu\theta_j\partial_\mu\theta_l\right)\Big]+ \\ &-i\sum_{j,l=1}^{N}\sin(\theta_j-\theta_l)\Big[c_l\left(\partial_\mu c_j^*\partial_\nu\theta_l - \partial_\nu c_j^*\partial_\mu\theta_l\right)- \\ &c_j^*\left(\partial_\mu\theta_j\partial_\nu c_l - \partial_\nu\theta_j\partial_\mu c_l\right)\Big]. \end{aligned} \tag{11}$$

The term in curly brackets represents the bulk Berry curvature. Straightforwardly, the relation $B^f = B^b$ does not always hold. The establishment of the equation is subject to specific conditions, e.g., when the sum has only contributions from $j = l$. It might also hold roughly for the case where the redundant terms are sufficiently small. In real experiments, these conditions would correspond to particular choices of system settings, e.g., material properties, lattice prototypes, and site geometries. For completeness, one can analogously repeat the derivation with left eigenstates to obtain the biorthogonal curvatures B^b_{LR} and B^f_{LR}, which leads to an expression of the same form as the one in Eq. (11).

B. Numerical Results

The model is applied to the Γ-point of a square lattice and the K-point of a honeycomb lattice, respectively. Here, we present only the results for the honeycomb lattice, full numerical results can be found in [6].

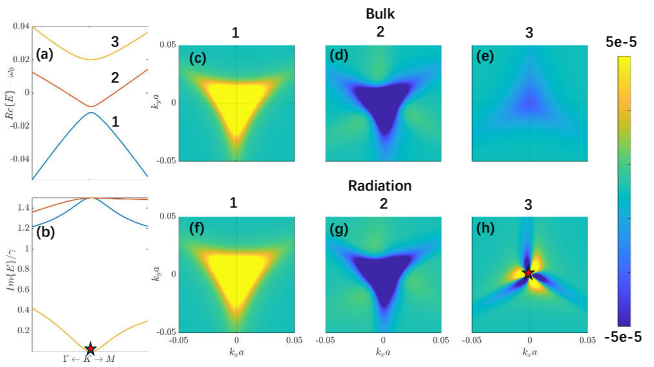

Fig. 4. Patterns showing bulk and radiation Berry curvatures around the valleys of the non-local honeycomb in a weakly asymmetric regime.

The results indicate that the concept of bulk-radiation correspondence is not universal in radiative photonic lattices. The correspondence completely breaks down in the presence of far-field singularities, while for non-BIC bands it can hold under special symmetry conditions, e.g., inversion symmetry. Besides, net Berry curvature concentration is captured at the K, K' of non-local honeycomb, corresponding to non-Hermitian AZ class A ($C_0, d = 2$) and topological invariant $\mathbb{Z}$ [7].

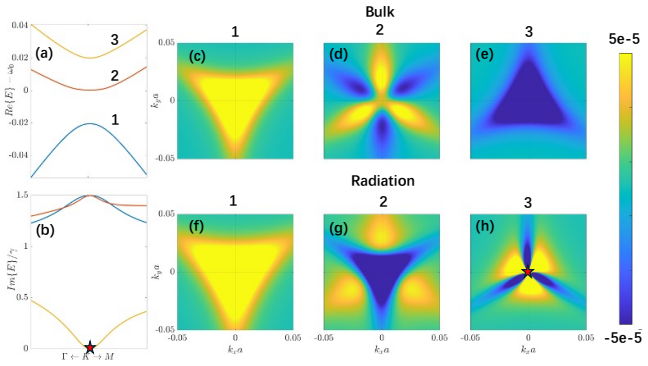

Fig. 5. Patterns showing bulk and radiation Berry curvatures around the valleys of the non-local honeycomb in a strongly asymmetric regime.

C. Discussion

The breakdown of bulk-radiation correspondence lies in two aspects: dimensional mismatch of the bulk-radiation projection and unavoidable leakage from guided resonances in the photonic crystal slab under consideration.

Firstly, it's not fully legitimate to ignore the multi-band nature of photonic lattices without any valid justification, especially for those with $a < \lambda$. The non-local nature of the photonic Hamiltonian, the vectorial aspect, and the inclusion of complex eigen-frequencies in the master equation give rise to an intrinsic dense eigenvalue problem. The full Hamiltonian is thus harder to separate into invariant subspaces with assigned dimensionality, even just locally. This results in more complicated connections between the states both within the band and among the bands, reflecting on the local geometric properties of the parameter space, e.g., the distorted Dirac cone with non-equal flattening processes as shown in Fig. 4 and Fig. 5.

Unlike the case discussed in ref.[1], the multi-band nature leads to dimensional mismatch upon projecting the bulk Hilbert space to the far-field synthetic parameter space. This dimensional mismatch results in loss, distortion, or blurring of local geometric features of the original manifolds. There are occasions when the projection is correctly done so the main features can be kept, but that's not guaranteed in general. These occasions could mostly relate to effective decoupling of the local Hamiltonian, e.g., those with block-diagonal structures accidentally formed from the wavefunction coupling, or those with inversion symmetry thus being more inherently sparse-like.

Besides, radiation loss is unavoidable in the photonic crystal slabs considered in the model built in Sec. II. The escaping photons from guided resonances interfere in the far field, and the energy redistribution resulting from far-field interference will reversely regulate the near-field photon behaviors. In our model, the far-field regulation manifests as coupling between spatially coherent modes via the radiative continuum. That is to say, the information of the bulk Bloch states carried by the leaky modes will be further deformed in the far field as a result of intensity modulation. One manifestation is that the highest degree of destructive interference happens at the BIC points, corresponding to a complete loss of all the information about the bulk Bloch states.

Thus, the bulk-radiation correspondence is not universal in radiative photonic lattices. The two-band regime is not complete, and far-field interference plays an essential role. This is consistent with the analytical results obtained in part A. Additionally, we infer that the bulk-radiation correspondence also fails in non-lattice planar photonic structures with more than two decoupled degrees of freedom, where effective two-level treatment no longer applies.

IV. Conclusion

By developing an effective model to describe the guided and leaky modes of non-local radiative photonic lattices, we construct the bulk and the radiation Berry curvatures. We analyze the comparability between bulk and radiation topology with both analytical and numerical methods. The analytical results straightforwardly convey that the bulk-radiation correspondence is not universal, and the validity depends on the particular bulk Bloch states. The numerical results further exemplify specific cases where the bulk-radiation correspondence holds and collapses.

Notably, the correspondence completely breaks down surrounding the field singularities on the BIC bands, while it can hold on non-BIC bands under special symmetry conditions, e.g., inversion symmetry. Besides, net Berry curvature concentration is captured at the valleys of the non-local honeycomb lattice, facilitating further exploration on generalized topological phases in photonic lattices beyond the regimes with localized couplings and Hermiticity.

***Abstract*—We introduce an imaging-based microfluidic sensor for continuous, time-resolved detection and sizing of rare microparticles in flow. Incoherent illumination and an imaging geometry ensuring full-volume focus yield sharp transit images. Automated subtraction, tracking and flow-normalized counting provide calibration-free concentrations and size distributions, enabling real-time monitoring of distribution tails dynamically.**

***Keywords*— time-resolved sensing, single-particle characterization, microfluidics, imaging**

I. Introduction

Precise characterization of particle populations in liquid dispersions is a central challenge in emerging continuous processing environments across nanotechnology, biotechnology, and advanced materials manufacturing [1,2]. While established techniques provide robust access to nanoscale fractions, the statistically rare but process-critical large-diameter tail of particle distributions remains difficult to quantify in a time-resolved and calibration-independent manner. Yet, these micron-scale outliers often dominate stability, safety, and functional performance of the respective liquid [3,4].

II. Methods

Our remedy to this situation is an imaging-based sensing approach, enabling continuous, time-resolved detection and sizing of microparticles in flow. The solution combines a microfluidic platform based on the OF2i®-technology [5,6,7] with incoherent illumination and a geometry guaranteeing that each particle above the detection threshold produces a sharply resolved image during transit, enabling deterministic detection of low-concentrated, micron-sized particles. Continuous video acquisition is combined with automated background subtraction, particle tracking, and extraction of the most contrast-rich frame to extract accurate particle diameters. By correlating particle counts with flow rates during measurement and acquisition time, the method directly yields absolute number concentrations and size distributions without external calibration standards.

III. Results and Discussion

The approach enables real-time monitoring of the temporal evolution of the large-diameter tail during dynamic process adjustments. Experimentally, we demonstrate robust operation under continuous-flow conditions (cf. Fig. 1).

IV. Conclusion

Our results illustrate how tailored optical imaging geometries combined with microfluidic control can provide reliable access to low-abundance microparticles, offering a scalable platform for continuous particle characterization in both laboratory and industrial environments.

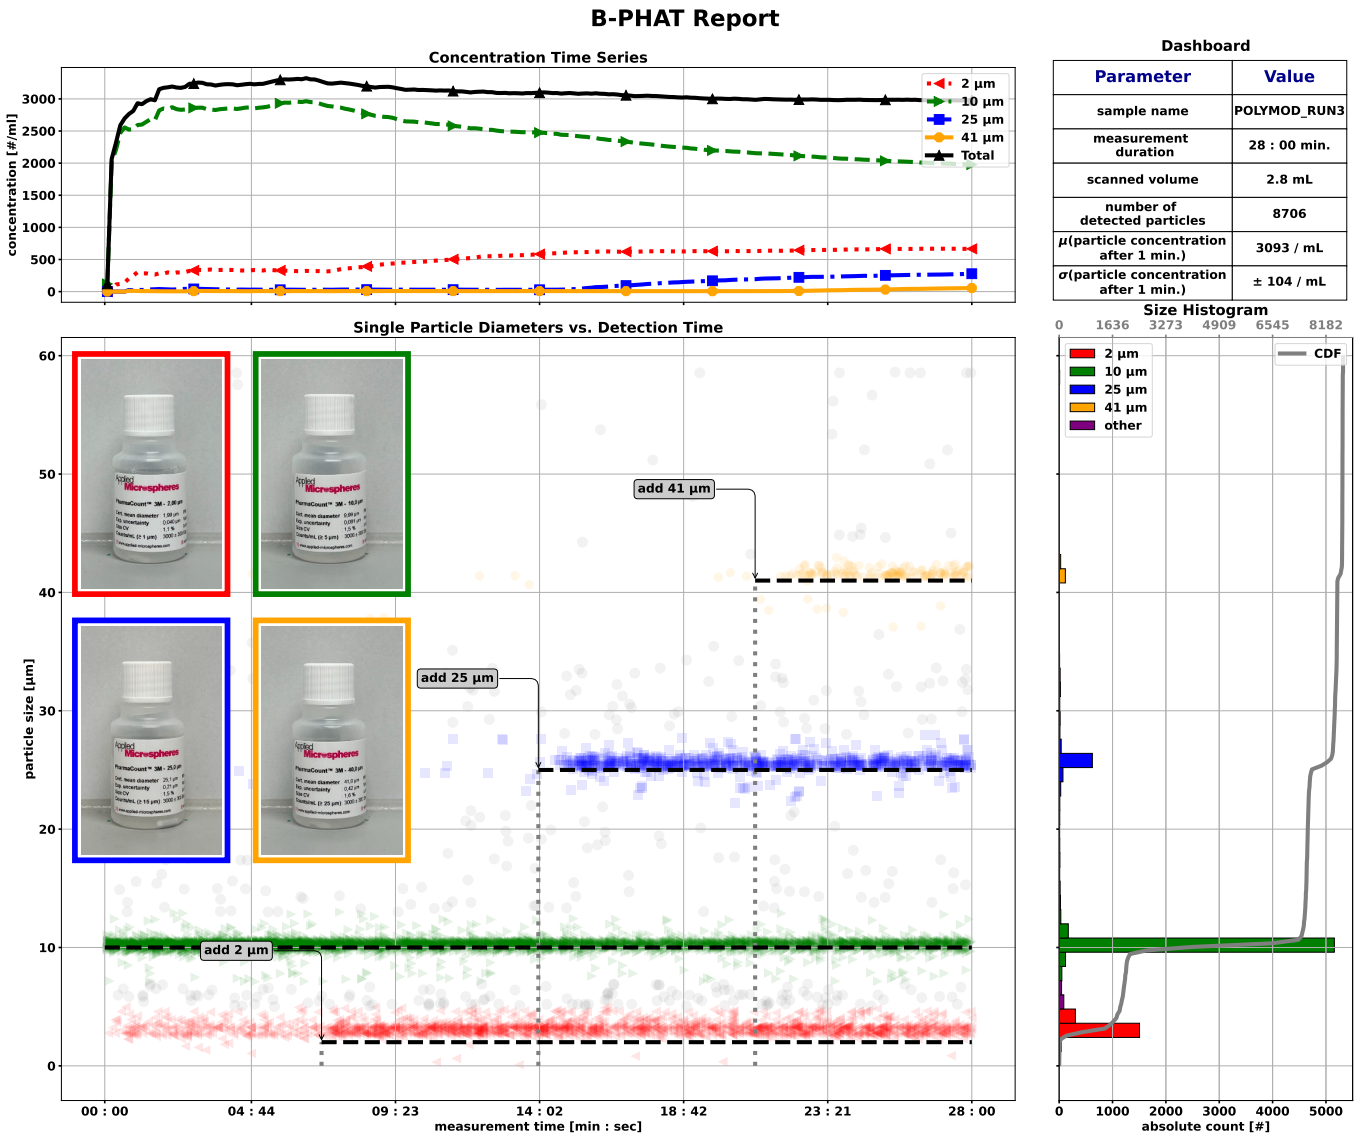

Fig. 1: Over a 28-min measurement, SI-traceable spherical polystyrene particle size and counting standards (nominal concentration: 3000 / ml each) were added sequentially to the feed reservoir supplying the device, ultimately producing a four-component mixture of 2, 10, 25, and 41 µm particles. The scatter plot shows the emergence of each population at the expected times (vertical dashed lines) and with diameters close to their nominal values (horizontal dashed lines). The concentration time series (top) demonstrates calibration-free absolute counting: the total mixture concentration (black) remains close to the expected 3000 / ml after each addition. The plot on the right gives the absolute particle size histogram over the entire measurement together with the corresponding cumulative distribution function (CDF).

Fundamental Passive Components for Topological Photonic Integrated Circuits

***Abstract*— We propose topological photonic integrated circuits (TPICs) based on topological edge states preserving spin and orbital angular momentum of light. Fundamental passive components, including topological converters, vertical couplers, and splitters, are developed for practical integration with silicon photonics. Their design principles and experimental demonstrations are presented.**

***Keywords*— topological photonic integrated circuits, silicon photonics, optical communication**

Tracing the topology of electronic systems such as topological insulators and Weyl semimetals into photonic platforms has led to the emergence of topological photonics [1]. In topological photonics, Z_2 topological phases can be realized using photonic crystal structures composed of honeycomb lattices with dielectric unit cells possessing C_{6v} symmetry [2][3]. Owing to the high degree of freedom in photonic structure design, these systems provide flexible control of photonic band structures and light propagation characteristics.

One of the most remarkable phenomena in topological photonic systems is the emergence of topological edge states at the interface between two structures with distinct topological phases. These edge states enable robust light propagation even in the presence of structural imperfections or sharp bends, while preserving the internal degrees of freedom of light, including spin angular momentum (i.e., circular polarization) and orbital angular momentum (i.e., optical vortex states). Circular polarization and optical vortices are regarded as key resources for next-generation high-capacity optical communications, and therefore topological photonic systems capable of maintaining these properties within integrated optical circuits have attracted significant attention.

Against this background, we have proposed a concept in which portions of conventional silicon photonic integrated circuits are replaced with topological photonic structures, referred to as topological photonic integrated circuits (TPICs). The objective of TPICs is not merely to introduce topological effects into optical circuits, but to establish a practical integrated photonic platform capable of leveraging the unique advantages of topological light transport while maintaining compatibility with existing silicon photonics technologies.

To realize practical TPICs, it is essential to develop a set of fundamental passive components that can efficiently interface topological photonic structures with conventional optical systems. In particular, at least the following three elements are indispensable. The first is a topological converter that enables highly efficient coupling between conventional silicon waveguides and topological photonic structures [4]. Such a converter is necessary because strong mode mismatch generally exists between ordinary waveguide modes and topological edge states. The second is a topological vertical coupler that enables efficient coupling between free-space optical beams and topological photonic systems [5][6]. This component is crucial for integrating external optical inputs with on-chip topological devices. The third is a topological splitter/switch capable of dividing optical signals into arbitrary intensity ratios while preserving the internal degrees of freedom of light, including polarization and orbital angular momentum [7][8]. Preservation of these properties during splitting operations is particularly important for advanced optical communication and information processing applications.

In conventional photonic integrated circuits, passive components for input/output coupling, routing, splitting, and signal transfer constitute the foundation of all optical functionalities. Similarly, in topological photonic systems, the realization of robust and practical integrated circuits requires a complete set of such passive building blocks. Establishing these components is therefore a key step toward the development of large-scale topological photonic integrated systems.

In this talk, we will discuss the design principles, physical mechanisms, and experimental demonstrations of these fundamental TPIC components in detail. Particular emphasis will be placed on how topological photonic structures can be utilized to preserve and manipulate the internal degrees of freedom of light within integrated optical circuits, as well as on their potential applications in future high-capacity and highly robust photonic systems.

***Abstract*— Hybrid plasmonic–molecular architectures were fabricated by depositing a self-assembled monolayer of gold nanocubes (AuNCs) onto a previously formed aminoporphyrin (NH_2TPPH_2) thin film. The photophysical behavior of the system was investigated before and after AuNC deposition using fluorescence spectroscopy, including absorption and emission measurements as well as fluorescence lifetime analysis. The molecular fluorophore exhibits a structured absorption profile in the visible region, while the Au nanocubes display a broad extinction band spanning from the visible to the near-infrared; this spectral complementarity was deliberately selected to ensure a significant overlap with the plasmon resonance, thereby fostering strong coupling between the fluorophore and the nanostructure. Such an arrangement allowed for a systematic study of the NH_2TPPH_2 photophysical response under controlled plasmonic excitation conditions, enabling, for the first time, an investigation of the relationship between excitation wavelength and plasmon band intensity within a single platform for plasmon-enhanced fluorescence (PEF). In addition, preliminary results on the PEF performance of an AuNC monolayer-based system are presented.**

A New Effective Medium Approximation for Nanostructure on a Layered Films

Kotaro Kajikawa[1]

[1]School of Engineering, Institute of Science Tokyo, Japan
*Corresponding author: kajikawa.k.1a5f@m.isct.ac.jp

***Abstract*— We present an effective medium approximation for calculating the optical response of nanostructures on layered films. Unlike conventional approaches based solely on numerical simulations such as FDTD, the proposed method enables analytical evaluation of the optical response. The calculated results show good agreement with both numerical simulations and experiments.**

***Keywords*— effective medium approximation, metal nanoparticle, LSPR**

It has been challenging to analytically evaluate the optical response of structures comprising metal nanostructures on layered films. Consequently, numerical methods such as FDTD and FEM have typically been employed; however, these approaches require substantial computational resources, and the physical interpretation of the obtained results remains limited. To address these issues, we propose a new method in which the layered film is approximated as an effective medium. This method is well-suited for use in combination with boundary value problems involving multipole expansions. Comparison with numerical simulations and experimental results demonstrates good agreement.

Harnessing Effective Medium Birefringence for Broadband Chirality Generation in Resonant Metasurfaces

***Abstract*—Optical metasurfaces are a versatile platform for controlling chirality and enhancing chiral light–matter interactions. Rather than creating resonators with chiral geometries, we show that advances in nanofabrication enable resonant chiral metasurfaces using effective medium anisotropies arising from deeply sub-wavelength patterning, creating new avenues for harnessing chirality in resonant systems. *Keywords*— metamaterials, chiral metasurfaces, chirality.**

With advances in nanofabrication over the past two decades, our ability to realize chiral metasurfaces has grown dramatically, with recent demonstrations of chiral lasing [1], improved sensing of chiral molecules [2], and enhanced chiral light–matter interactions [3]. As geometry is often the most accessible control parameter, demonstrations of chiral metasurfaces frequently rely on chiral resonator geometries. For a lossless dielectric resonator with $\mu' = 1$, chiral structuring leads to near-field chirality generation and destruction through Eq. 1 [4].

$$-\nabla\varepsilon' \cdot \frac{1}{8}\mathrm{Im}(\mathbf{E} \times \mathbf{E}^*) \tag{1}$$

Rather than relying on chiral geometries, metasurfaces can also create or destroy chirality through the use of optically anisotropic materials for which $\nabla\varepsilon' \neq 0$ (Fig. 1a). Comparing the optical birefringence of common optical materials with their maximum refractive indices (Fig. 1b) the birefringence values range from 4×10^{-3} to 1.62, with corresponding maximum refractive indices of 2.12 and 4.16. Instead of relying on natural optical anisotropy, artificial form birefringence can be introduced through structural patterning, as is commonly done in waveplate design [5]. With the experimental realization of new optical materials possessing very large refractive indices, such as iron pyrite with $n \approx 4.6$ [6], the maximum achievable form birefringence is beginning to approach that of the best anisotropic materials (Fig. 1c). However, maintaining optical resonances in such metasurfaces requires feature dimensions below 50 nm.

Here, we experimentally demonstrate an all-dielectric metasurface composed of two length scales, with deeply sub-wavelength features producing an anisotropic effective medium response and a larger-scale feature defining the optical

Fig. 1. (a) Schematic illustrating chirality generation using either chiral structuring or an anisotropic effective medium. (b) Comparison of birefringence and maximum refractive index for common bulk optical materials and multilayer two-dimensional material flakes (MF). (c) Theoretical and computational predictions, obtained using rigorous coupled-wave analysis (RCWA), of birefringence and maximum refractive index for a grating structure with 50 nm periodicity, 200 nm thickness, and 0.5 fill fraction.

Fig. 2. (a) Scanning electron micrograph of the fabricated TiO_2 resonator, with a top-down view shown in the inset. (b) Measured transmittance spectra showing three prominent resonances for linearly polarized light with polarization angles ranging from 0° to 90°. (c) Measured S_3 Stokes parameter showing broadband chirality generation.

resonator. Using these structures, we realize visible wavelength resonances with significant chirality generation, demonstrating a promising design pathway for chiral metasurfaces.

To fabricate the metasurfaces, we used a standard damascene process in which a high aspect ratio mold was patterned by electron beam lithography into resist (SML-2000) on a fused silica substrate. After development, a low-temperature, thermal atomic layer deposition process was used to conformally coat the metasurface with TiO_2, which was then etched by reactive ion etching to remove the overgrowth. After the remaining resist was removed, the freestanding structure was obtained (Fig. 2a). For the effective medium structuring, we patterned air gaps with a width of 30 nm and a periodicity of 90 nm, corresponding to an expected effective medium birefringence of 0.37. The larger resonator structure consisted of circles with a radius of 260 nm arranged in a square lattice with a periodicity of 600 nm. A top-down scanning electron micrograph shows that the resonator profiles (Fig. 2a) slightly break two-fold rotational symmetry since the periodicity of the small-scale features is slightly mismatched with the diameter of the circles.

After fabrication, we performed transmittance measurements (Fig. 2b) for linearly polarized light with the polarization axis oriented perpendicular (0°), diagonal (45°), and parallel (90°) to the grooves that produce birefringence. Across the three orientations, three clear resonances are observed at 683 nm, 748 nm, and 790 nm, showing that the structure is capable of supporting resonances in the visible. To measure the generated chirality, we recovered the Stokes parameters for linearly polarized incident light. The spectral profile of S_3 (Fig. 2c) shows broadband chirality generation with S_3 values reaching -0.65, with the influence of the 748 nm resonance being clearly visible.

In conclusion, we demonstrated a chiral metasurface comprised of resonators with effective medium birefringence. Although the transmitted beams are elliptically polarized, these results demonstrate the potential of tailoring optical anisotropy for controlling chirality in resonant metasurfaces.

On-chip Integrated Intelligent Photonic Computing

Kun Liao

Department of Physics, Peking University, China
Email: kunliao@pku.edu.cn

***Abstract*— We report advances in photonic neural networks that broaden functionality, increase computational complexity, and improve system-level integration for practical intelligent photonic computing, paving the way toward highly integrated and scalable next-generation intelligent photonic computing chips.**

***Keywords*— photonic neural networks, photonic computing chips, silicon photonics.**

I. Introduction

Integrated photonic chips, characterized by their high data throughput and low power consumption, have demonstrated broad application prospects in optical communications, computing, LiDAR, sensing, and imaging. Leveraging on-chip optical interconnects, integrated photonic neural networks have emerged as one of the most promising paradigms for optical computing. However, their further development remains constrained by several key challenges, including limited computational efficiency, insufficient nonlinear response, restricted network scalability, and system-level integration complexity.

II. Results and Discussion

We demonstrate a series of studies exploring new opportunities for the development of on-chip integrated photonic neural networks from multiple perspectives, including functionality expansion, computational efficiency improvement, system complexity enhancement, and high-level integration. First, we extend silicon-based integrated photonic neural networks beyond conventional inference tasks to perform complex mathematical operations, such as transcendental equation solving [1] and matrix eigenvalue solving [2]. We further design and implement a reconfigurable optical nonlinear activation layer based on a graphene/silicon heterojunction, enabling efficient and flexible on-chip nonlinear activation functions [3]. In addition, we develop an inverse-designed ultracompact photonic computing platform that supports diverse applications, including photonic simulations for topological insulator models with high measured fidelity and image classification tasks with on-chip training [4]. To enhance scalability and architectural flexibility, we propose a universal and reconfigurable on-chip neural network architecture that enables in situ switching and deployment of multiple network models within a unified photonic hardware framework, supporting both static and dynamic tasks [5]. Moreover, we demonstrate a monolithically hetero-integrated photonic computing system that integrates light sources, photonic processors, and photodetectors all on a single chip, and experimentally validate its capability in quantum simulation and computer vision tasks [6].

III. Conclusion

In summary, these studies collectively advance on-chip integrated photonic neural networks in terms of functionality, computational capability, architectural flexibility, and system-level integration. By enabling complex mathematical operations, efficient optical nonlinearity, compact inverse-designed platforms, scalable reconfigurable architectures, and monolithically integrated photonic computing systems, this body of work moves photonic neural networks closer to practical and general-purpose intelligent computing hardware. These developments not only improve the performance and versatility of photonic processors, but also highlight a viable path toward highly integrated, energy-efficient, and scalable next-generation intelligent photonic computing chips for scientific computing, artificial intelligence, and quantum technologies.

***Abstract*— We investigate a special class of disordered photonic heterostructures, hyperuniform disordered (HuD) photonic structures, that allows to deterministically tailor Anderson localization and diffusive transport.**

***Keywords*— Hyperuniformity, Scanning Near-field Microscopy.**

Disorder is traditionally regarded as a detrimental element in photonic systems, often associated with unwanted scattering losses, localization effects, and poor reproducibility. However, over the past two decades, this perspective has shifted significantly as it has become clear that disorder, when properly engineered, can serve as a powerful design parameter [1,2]. In particular, correlated disorder systems have emerged as a versatile platform for controlling light–matter interaction beyond the constraints of periodic photonic crystals and fully random media. By embedding structural correlations into otherwise disordered arrangements, it is possible to tailor optical transport, density of states, and scattering properties in ways that are inaccessible to either extreme [3].

Among correlated disordered systems, Hyperuniform Disordered (HuD) materials have attracted growing attention in photonics due to its unique statistical and physical properties. Hyperuniform structures are characterized by anomalously suppressed density fluctuations at large length scales, resulting in a vanishing structure factor in the long-wavelength limit [4]. This property places hyperuniform systems in an intermediate regime between crystalline order and complete randomness. Unlike periodic lattices, hyperuniform structures lack Bragg peaks and long-range translational symmetry, yet they retain a form of hidden order that strongly influences wave propagation. In photonic systems, disorder hyperuniformity has been shown to enable phenomena traditionally associated with periodic media, such as isotropic photonic band gaps [5,6], while preserving the robustness and fabrication tolerance of disordered architectures. This combination is particularly appealing for applications requiring omnidirectional light control, including waveguiding, light confinement, and enhanced emission control. Furthermore, the absence of long-range periodicity reduces sensitivity to defects and allows for greater flexibility in device geometry, which is advantageous for integrated photonics and three-dimensional photonic materials.

Here, Taking advantage of the combination of the HuD design in slab platforms, optically activated with embedded quantum dots, and near-field hyperspectral imaging with sub-wavelength resolution, we investigated light localization in HuD networks, and unveil different physical mechanism that lead to the formation of different kind of defects with different localization lengths and Q factors [7-10]. The possibility of detecting different regimes of light confinement in a system, whose structuring is at the junction between fully-ordered and completely random systems, open routes yet to be explored for addressing basic physics and practical applications of correlated disorder materials.

***Abstract*— Tapered fiber photometry can be exploited for depth-resolved deep-brain recording using fluorescent reporters and in label-free Raman approaches to probe the intrinsic molecular composition without exogenous markers. Combined with plasmonic enhancement, these approaches offer complementary strategies to investigate neural dynamics and tissue composition in vivo.**

***Keywords*— tapered fibers, fiber photometry, deep brain recording, Raman spectroscopy, SERS, label free sensing, fluorescent reporters, plasmonic enhancement, neural activity monitoring.**

I. Introduction

Understanding neural activity in deep brain regions is fundamental for decoding brain functions and studying diseases. Optical techniques have emerged as powerful tools for interrogating neural circuits with high temporal resolution and cell-type specificity. Among these, fiber photometry has become widely adopted due to its minimal invasiveness, compatibility with freely behaving animals, and ability to access deep brain structures through implanted optical fibers.

Traditionally, fiber photometry relies on genetically encoded fluorescent indicators to monitor cellular and sub-cellular processes such as calcium and neurotransmitter dynamics. These label-based approaches provide high sensitivity and molecular specificity, enabling real-time monitoring of defined neuronal populations during behavior.

II. Discussion

Recent technological advances have expanded the capabilities of fiber-based neural interrogation. Tapered optical fibers allow improved light delivery and collection efficiency across extended brain volumes, enabling depth-resolved recordings with reduced tissue damage [1]. At the same time, the development of novel fluorescent biosensors has increased sensitivity and multiplexing capabilities for simultaneous monitoring of multiple signals.

In parallel, label-free approaches are emerging as complementary strategies. Raman spectroscopy, implemented through minimally invasive tapered fiber probes, enables detection of intrinsic molecular vibrations without the need for exogenous reporters [2]. Although inherently limited by weak scattering signals and background noise, integration with plasmonic nanostructures and surface-enhanced Raman strategies significantly improves sensitivity. When decorated with plasmonic nanostructures, these probes further enable surface-enhanced Raman detection of neurotransmitters, enabling label-free measurements of neurotransmitters in vitro with a limit of detection down to 10^{-9} molar concentration [3,4].

III. Conclusion

Together, label-based and label-free fiber photometry approaches provide a broader framework for investigating neural activity, biochemical signaling, and tissue composition in vivo.

Bare and nano-machined tapered optical fibers provide a powerful and versatile platform for multimodal neural interrogation in deep brain regions, enabling depth-resolved fiber photometry of neural activity dynamics, vibrational Raman spectroscopy for in vivo brain cancer tissue identification, and surface-enhanced Raman detection of neurotransmitter concentration.

***Abstract*— We fabricate highly regular 2D perovskite microcrystals by recrystallization that function as optical cavities and sustain strong light-matter interaction. The cavity modes and polariton dispersion are governed by the non-linear wavelength dependence of the refractive index, leading to slow light propagation at the band edge.**

***Keywords*— polaritons, exciton, 2D perovskite, microcrystals.**

I. Introduction

Two-dimensional (2D) metal halide perovskites are emerging materials with bright and tunable emission that are highly attractive for light emission and lasing. Their hybrid organic-inorganic structure provides ample opportunities to tailor their optical properties and radiative recombination dynamics.[1, 2] Strong dielectric confinement results in high exciton binding energies, and their high refractive index favors strong-light matter interaction.[3, 4] In particular, highly homogeneous slabs of 2D perovskites can act themselves as optical cavities and lead to self-hybridization of the photonic cavity modes with the band edge exciton levels. One peculiar property of the architecture in which the semiconductor light emitting material itself forms the optical cavity, is the strong non-linearity of the complex refractive index. This has several interesting implications: a pronounced decrease in group velocity of the light, and an abnormal dispersion near the band edge that results in high damping and leaky optical modes.

II. Results and Discussion

We investigate the reflectance and photoluminescence of single 2D lead iodide microcrystals that act as highly efficient optical cavities. We observe an extremely large number of cavity modes in microcrystals with micrometer thickness. This allowed us to determine the complex refractive index using the interference fringes method combined with a Cauchy dispersion for the transparent low energy range of the cavity mode spectrum. We then use the obtained dispersion of the refractive index in the calculation of the exciton-polariton anticrossing based on a Lorentz oscillator model, and by fitting the experimentally obtained reflectance minima near the band gap we obtain the longitudinal optical (LO) and transversal optical (TO) exciton energies and the damping coefficient Γ.

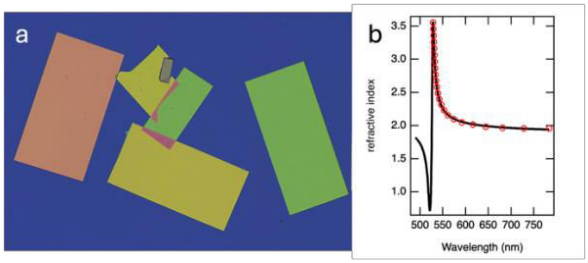

Fig.1. Optical image of 2D perovskite microcrystals (a) and the refractive index dispersion of PEA_2PbI_4 microcrystals (b).

III. Conclusion

2D perovskite microcrystals with highly regular shape and homogeneous thickness constitute a versatile platform for integrated and non-linear photonics.

Abstract: We present a compact flat-optics (metasurface) platform capable of generating and dynamically tuning multispectral grafted vortex beams together with azimuthally engineered multispectral orbital angular momentum (OAM) combs. By coherently superimposing multiple helical phase distributions, the system produces optical beams with tailored topological charges and controllable multispectral OAM spectra, creating new opportunities for applications in optical encryption, advanced communication systems, and particle manipulation.

In this work, we introduce a metasurface based strategy for the generation and manipulation of multispectral grafted vortex beams (GVBs) and azimuthally structured OAM combs, overcoming limitations of conventional bulk optical components. GVBs [1], formed through the superposition of multiple helical phase profiles, exhibit distinctive optical features and have attracted considerable interest in singular optics and quantum applications. Traditional generation techniques, however, typically require complicated and bulky optical setups. Our proposed approach employs a single metasurface to synthesize various GPVB superpositions with different topological charges, enabling asymmetric distributions of optical singularities. Moreover, the positions of these singularities can be tuned through the introduction of an initial phase offset, removing the need for complex optical alignments.

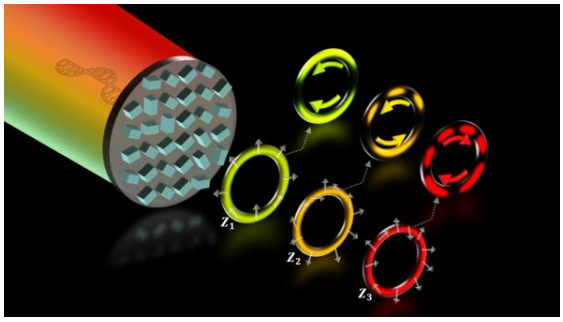

Fig. 1. Schematic of the metasurface for creating multiple longitudinally variable GPVVBs

We further demonstrate the generation of multispectral perfect vector vortex beams (GPVVBs) [2,3] using a multifunctional metasurface that combines several different colored GPVVBs (Fig. 1). These beams exhibit spatially varying polarization states and allow flexible control over multiple topological charge combinations. Dynamic modulation of these beams is achieved by incorporating a rotating half-wave plate, providing additional tunability and enabling potential applications in adaptive optical encryption and high-capacity data transmission.

Finally, the metasurface platform is extended to produce multispectral OAM combs with adjustable mode spacing, offering a compact and efficient method for generating structured OAM spectra across multiple spectral channels (Fig. 2). This capability significantly increases the information-carrying capacity of optical systems and supports emerging applications in next-generation optical communication and information processing technologies [4].

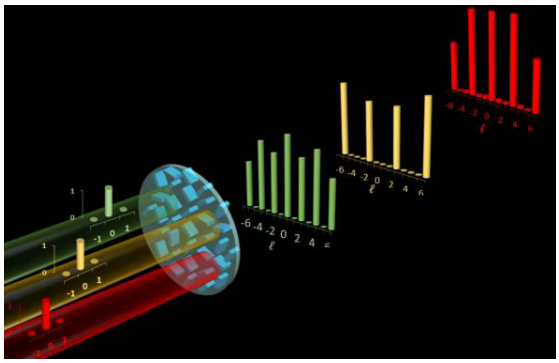

Fig. 2. Schematic of a metasurface for realizing multicolored OAM combs.

***Abstract*— The evolution from large language models (LLMs) to agentic systems has created a new frontier of scientific discovery, enabling the automation of complex research tasks that have traditionally required human expertise. We present an autonomous agentic framework that automates the complete end-to-end workflow of electromagnetic metamaterial inverse design, including the development of the forward surrogate model itself. When queried with a desired optical spectrum s^*, the agent autonomously reasons, plans, and utilizes external tools via APIs to propose a custom deep learning model and generate an optimized geometrical configuration g^* via a deep inverse method. This framework mimics the workflow of a human researcher through its ability to reason, adapt its strategy in real-time, and use internal reflection, representing a new paradigm for accelerating nanophotonic design.**

Coherent Thermal Wavefront Manipulation Using Hierarchical Metasurfaces

Yungui Ma

College of Optical Science and Engineering, Zhejiang University, Hangzhou 310058, China

Conventional coherent light-field manipulation approaches are inherently incompatible with the spatiotemporal incoherence of thermal radiation sources. Although recent progress in thermophotonics has enabled directional thermal emission, arbitrary control of thermal wavefronts— essential for applications such as focusing and holography— still represents an unresolved challenge. Here, we present a universal strategy for designing meta-emitters with lossy and lossless outer boundaries, which support thermal emission with arbitrarily engineered wavefronts. The lossy and lossless interfaces are synergistically coupled via a single-mode waveguide, converting incoherent thermal photons into coherent surface waves for wavefront shaping. The designer surface mode of the meta-emitter allows independent optimization of photon lifetime and propagation length, enabling scalable spatial coherence engineering. As proof of concept, we experimentally demonstrate near-diffraction-limited self-focusing emission, high-quality speckle-free quasi-two-dimensional thermal holography, and spatially multiplexed holography. Moreover, coupling optimization indicates that spatial coherence exceeding 1000λ0 can be achieved. The proposed meta-emitter platform establishes a transformative paradigm that bridges stochastic thermodynamic emission and precise photonic engineering, paving the way for high-information-content thermal radiation technologies.

***Abstract*— Quantum-dot semiconductor structures are emerging as promising materials for compact THz sources due to their broadband gain and ultrafast carrier dynamics. We demonstrate enhanced CW and pulsed THz emission using nanoantenna-integrated photoconductive antennas, enabling efficient room-temperature operation and positioning QD-based devices for next-generation THz applications.**

***Keywords*— Quantum-Dot, THz, nanoantenna.**

I. Introduction

Quantum-dot (QD) semiconductor structures, traditionally employed in laser development, have recently emerged as promising materials for compact terahertz (THz) sources. Their unique combination of broadband gain and absorption, alongside ultrafast carrier dynamics, enables novel approaches to THz radiation generation. In this work, we present recent advances in both continuous-wave (CW) and pulsed THz emission from QD-based photoconductive antennas enhanced with optical nanoantennae. The integration of nanoantennae within the antenna gap significantly boosts efficiency, enabling room-temperature operation in an ultra-compact footprint. Furthermore, the incorporation of bandgap-engineered semiconductor materials, quantum-confined structures, and interdigitated electrodes broadens the pump absorption range and improves carrier mobility, both critical for THz performance. These developments position QD-based architectures as a highly promising platform for next-generation ultra-compact THz sources, with potential applications in spectroscopy, imaging, and high-speed wireless communications.

***Abstract*— We introduce an optical microscopy approach capable of retrieving the complex vectorial electromagnetic field at the image plane (that is, intensity, phase, and polarization of light) in a single acquisition. The method combines a polarization-sensitive camera with a two-dimensional diffraction grating (cross-grating) placed in close proximity to the image sensor.**

***Keywords*— microscopy, polarization, plasmonics, nanoparticles, metasurfaces, Jones, Stokes.**

Nanophotonics and optical microscopy are now tightly intertwined in modern research, as high-resolution optical characterization is essential for studying nanomaterials, such as dielectric and plasmonic nanoparticles, metasurfaces, and 2D materials. Yet, existing microscopy techniques are often complex to implement or limited to measuring light intensity, overlooking spectral, phase, and polarization features. Here, we introduce an optical microscopy approach capable of retrieving the full complex vectorial electromagnetic field at the image plane (that is, intensity, phase, and polarization of light) in a single acquisition. The method combines a polarization-sensitive camera with a two-dimensional diffraction grating (cross-grating) placed in close proximity to the image sensor. Beyond light beam characterization, this configuration enables sample characterization, through Jones matrix imaging of métasurfaces, complex optical polarizability tensor measurements of nanoparticles.

Multifunctional Optical Metasurfaces and Their On-Chip Integration

Bo, Xiong[1,*] , Minjun, Xie[1,]

[1] College of Information Science and Electronic Engineering, Zhejiang University, China

***Abstract*— Using dielectric deflective metasurfaces, we propose a novel out-of-plane modulation scheme. The metasurface is used to deflect vertical incident light to an oblique angle. This deflection introduces a lateral wave vector component. Overall, the integration of the metasurface and subwavelength grating enables a new vertical coupling scheme with high efficiency.**

***Keywords*— Metasurface, Chip Integration.**

I. Introduction

Optical micro/nanostructures enable the manipulation of light–matter interactions at subwavelength scales and serve as a key approach for optical field sensing and high-resolution detection and imaging. As a typical silicon photonics device, vertical grating couplers (VGCs) function as optical I/O interfaces that convert vertically incident light into in-plane light. They offer the advantage of not requiring angled polishing of coupling fibers, making them advantageous in wafer-level testing and multicore fiber packaging. In this paper, we propose a novel out-of-plane modulation scheme to realize vertical coupling, which combines a dielectric metasurface with an apodized binary grating to achieve high-efficient vertical coupling on the 220 nm SOI platform.

II. Methods

The overall device consists of a deflected silicon metasurface and an apodized single-etched grating coupler. The process of receiving vertically incident light into the waveguide device can be understood in two steps. Initially, TE-polarized light enters from the air and interacts with the nanopillars comprising the metasurface, resulting in deflection through the SiO2 cladding (Fig. 1 (a)). Subsequently, the obliquely incident light is captured by the SEGC and efficiently coupled into the waveguide (Fig. 1 (b)). By introducing a lateral wave vector component, the deflection prevents the vertical coupling from bi-directional transmission. This new scheme enables the straightforward realization of vertical coupling designs based on binary grating structure.

For the metasurface design, we employed a square periodic boundary with each side measuring 640 nm, and α-Si nanopillar with a height of 900 nm as the fundamental unit, as illustrated in Fig. 1 (d). The parameter "a" and "b" denote the width and length of nanopillars, respectively.

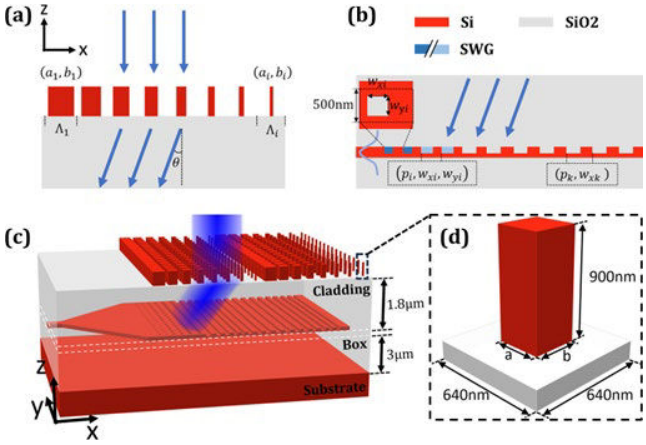

Fig. 1 (a) Operation of deflective metasurface. (b) Single-etched grating coupler. (c) Vertical grating coupler integrated with deflective metasurface. (d) Meta unit.

III. Results and Discussion

The manufacturing process of proposed VGC is illustrated in Fig.2. Fig.2 (a)-(d) shows the production process of the GC. The grating is fabricated on a 220 nm SOI wafer. After a standard Electron Beam Lithography (EBL) process a 100 nm shallow Si etch is performed. 1.8 μm SiO2 cladding and 900 nm α-Si film were grown by Plasma-Enhanced Chemical Vapor Deposition (PECVD) technology sequentially. We fixed the parabolic taper length to be 110 μm. A grating width of 12 μm were chosen for mode matching with the SMF. Fig.2 (e)-(h) show the production process of the deflective metasurface.

The sample size is adjusted to a size of 50 μm × 50 μm in order to fully cover the grating area. When the alignment error occurs, the metasurface corresponding to the grating region has a consistent phase gradient, resulting in an alignment-insensitive response. Fig. 3 (a) shows SEM images of the grating coupler while Fig. 3(b) provides more details of the SWG region. The fabricated metasurface are presented in Fig. 3 (c), from which we can clearly observe Si nanocolumns with nine different sizes. Fig.3 (d) and Fig.3 (e) show the optical images of whole VGC samples.

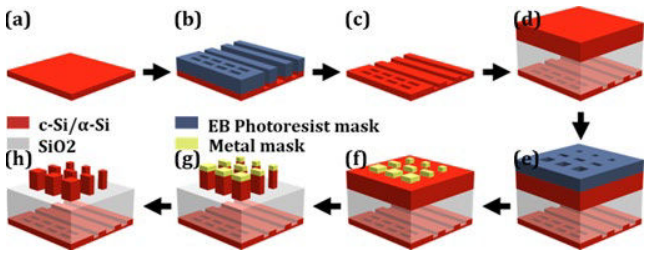

Fig. 2 Fabrication process of VGC. (a)–(c) Fabrication process of apodized single-etched grating. (d) Deposition of SiO2 and α-Si layer. (e)–(h) Fabrication process of deflective metasurface.

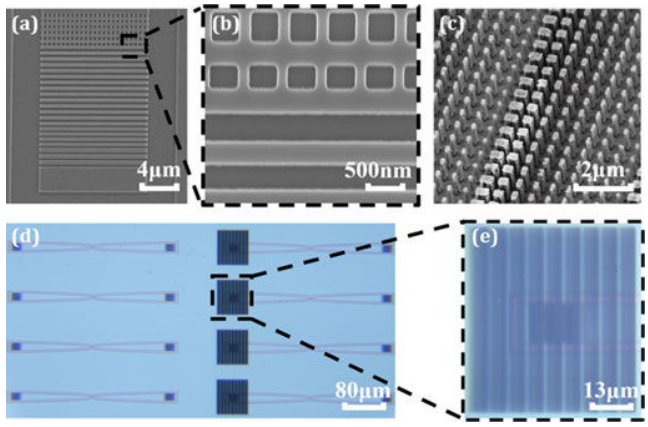

Fig. 3 (a) SEM image of single-etched GC. (b) Detailed view of the SWG area. (c) SEM image of metasurface nanopillars. (d) Mircoscopy view of VGC. (e) Detailed view of the VGC covered with metasurface.

For the measurement setup, a SANTEC TSL-550 tunable laser is utilized as the light source, and its polarization is restricted to TE mode through adjustment of the polarization controller. For the VGC sample test, the incident light is vertically coupled into the sample with the metasurface. The collected light was then measured by a YOKOGAWA AQ2200-221 optical power meter. A wavelength scan was performed from 1500 to 1600 nm with a 0.2 nm step. The grating samples with and without the metasurfaces were both evaluated under vertical incident. Compared to the reference sample without metasurface, Fig. 4 (a) shows a 45 dB significant enhancement in CE when metasurface is integrated. A more detailed test result in Fig.4 (b) shows that the VGC has a peak CE of -3.36 dB at 1549 nm with a 1-dB bandwidth of about 32 nm (blue solid line) under vertical incidence. And the reference grating under oblique incidence has a peak CE of -2.75 dB at 1550 nm with a 1-dB bandwidth of about 33 nm (orange solid line). Compared to their simulation results, the test results exhibit an extra loss of approximate 1dB, mainly owing to the fabrication error of the SEGC

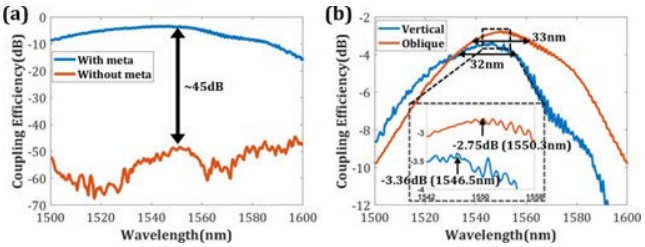

Fig. 4 (a) Experimental results of GCs with and without meta under vertical incidence. (b) Experimental results of our VGC under vertical incidence and the reference GC under oblique incident.

IV. Conclusion

In conclusion, a new vertical grating coupling scheme combined with deflective metasurfaces is experimentally demonstrated on the 220 nm SOI platform. Using dielectric metasurface, vertically incident light can be deflected to the target angle, which can be collected by the apodized single-etched grating coupler with high efficiency. The measured coupling efficiency is 3.36 dB at 1546.5 nm with a 1-dB bandwidth of 32 nm. Further characterization tests reveal the architecture's angular tolerance, with approximately 3° tolerance for angular deviations, and x-axis displacement tolerance of 6 μm. Subsequent research works will go deeper into the phase distribution and freedom of degrees of metasurface, which may develop additional functions and channels into the vertical coupler device, such as polarization splitting grating coupler and wavelength-division-multiplex receiver.

Direct Nanoimprint Lithography as an Additive Full-Wafer Manufacturing Platform for All-Inorganic Metaoptics and AR Waveguides

James J. Watkins

Polymer Science and Engineering, University of Massachusetts, USA
[2]Myrias Optics, Amherst, MA, USA
watkins@umass.edu, watkins@myriasoptics.edu

***Abstract*— We fabricate all-inorganic, high-efficiency, metalenses, metasurfaces, DOEs and waveguides on full-wafer platforms with cycle times of less than 5 minutes/wafer via additive nanoimprint lithography using TiO_2 nanoparticle dispersion inks for applications in the visible and near IR. With recent advances, we achieve refractive indices up to 2.6, which further enhance device performance.**

***Keywords*— metaoptics, nanoimprint, metasurface, augmented reality**

Overview

Full wafer-scale fabrication of high-efficiency, all-inorganic optical devices, including metalenses and metasurfaces operating in the UV, visible, and IR spectra, AR/VR waveguides, IR dot projectors, and polarization-controlled metasurfaces, is demonstrated using additive nanoimprint lithography (NIL) with nanoparticle dispersion-based inks. Approximately 1,000 visible-wavelength metalenses (4 mm diameter) were fabricated per 8-inch wafer, exhibiting high optical efficiency and excellent uniformity. The absolute and relative efficiencies of the metalenses exceed 80% and 90%, respectively, reaching approximately 95% of the maximum simulated efficiencies for this design. This close agreement indicates that performance is not limited by materials or processing, but in this case by the design itself.

The use of nanoparticle dispersion inks enables the fabrication of all-inorganic, high-MTF AR waveguides with imprint cycle times significantly shorter than those of polymer/nanoparticle composites. The refractive index of these structures can be increased up to 2.3 using a short post-imprint atomic layer deposition (ALD) process. With recent advances in materials systems, we can now achieve refractive indices up to 2.6 with very low waveguide losses. Combined, these attributes offer superior performance, including an expanded field of view (FOV) in AR waveguides and reduced manufacturing costs.

Furthermore, the fabrication of polarization-sensitive, phase/amplitude-controlled holograms demonstrates that this process can replicate asymmetric nanostructures with aspect ratios >10 via direct imprinting without etching. The resulting optics are organic-free due to a post-imprint calcination step and exhibit outstanding dimensional and optical stability, as confirmed by accelerated environmental testing and laser-induced damage testing (LIDT). This work establishes a viable path for true, full-scale additive manufacturing of meta-optics across the UV-to-IR spectrum.

Synthesis of Colloidal Nanoalloys by Ultrafast Laser Irradiation

Andrés Guerrero-Martínez[1,*] and Guillermo González Rubio[1]

[1] Departamento de Química Física, Universidad Complutense de Madrid, Spain
*Corresponding author: aguerrero@quim.ucm.es

***Abstract*— Colloidal nanoalloys synthesized by ultrafast laser irradiation offer tunable optical and catalytic properties driven by localized surface plasmon resonances. Femtosecond pulses enable controlled reshaping and alloying, avoiding fragmentation typical of longer pulses. This approach provides precise control over composition and structure, linking synthesis conditions with functional performance in advanced nanomaterials.**

***Keywords*— ultrafast laser irradiation, metal nanoparticle, LSPR, core-shell nanomaterial, colloidal nanoalloy**

I. Introduction

Over the past two decades, the rapid advancement of metal nanoparticles has been largely driven by their distinctive optical properties, particularly those linked to localized surface plasmon resonances (LSPRs) [1]. Significant effort has focused on the rational design and controlled assembly of these nanostructures to develop nanoplasmonic systems with tunable optical responses. A key factor in this progress has been the ability to probe light–matter interactions at the nanoscale, enabled by ultrafast laser techniques capable of resolving electron dynamics with high temporal resolution.

II. Methods

Femtosecond laser irradiation has emerged as a powerful tool for studying and tailoring plasmonic properties [2]. Following excitation, conduction electrons rapidly thermalize and transfer energy to the lattice and surrounding medium, often inducing controlled surface melting while preserving nanoparticle structure. In contrast, nanosecond pulses typically cause fragmentation or uncontrolled melting, as excitation and relaxation occur on similar timescales. These differences enable precise size tuning, including conversion of polydisperse colloids into monodisperse nanoparticles [3] and the generation of hollow nanostructures [4].

III. Results and Discussion

Applying these methodologies to multimetallic nanoparticles further expands their potential. Ultrafast laser processing enables the synthesis of nanoalloys with adjustable compositions and morphologies, leading to synergistic effects that surpass those of single-metal systems [5]. These nanoalloys exhibit improved plasmonic behavior, enhanced stability, and notable catalytic performance in areas such as sensing, energy conversion, and chemical reactions. In addition, the combination of ultrafast spectroscopy with controlled irradiation offers fundamental insight into their electronic and structural evolution, establishing a direct link between synthesis strategies and functional properties.

IV. Conclusion

The combination of pulsed laser techniques with nanoalloy engineering provides a versatile platform for both fundamental research and technological applications, opening new avenues for the development of advanced nanomaterials.

Polarization-Controlled Lattices of Sub-Wavelength Photonic Spin Skyrmions

Andrei Afanasev[1,*]

[1]Department of Physics, The George Washington University, USA
*Corresponding author: afanas@gwu.edu

***Abstract*— We theoretically analyze properties of topological spin textures of optical fields characterized by spin orientation in all three dimensions and described in terms of Bloch merons and skyrmions. Formation of isolated skyrmions, their lattices and their propagation in space are described.**

***Keywords*— photonic lattice, topological photonics, optical spin, optical skyrmions.**

We provide an account of newly observed three-dimensional (3D) spin skyrmions found near phase singularities of both optical and acoustic vortex beams. While beams' intensity profiles expand during propagation due to diffraction, certain polarization features near phase singularities maintain constant transverse spatial dimensions, the property noticed for optical vortices [1], and dark fringes in the interference patterns of light [2] or sound [3].

Defining a "spin alignment parameter" for the beam propagating in z-direction as

$$\chi_{TL}(\boldsymbol{s}) = |s_\perp|^2 - s_z^2,$$

where $\boldsymbol{s}$ is a unit vector along the spin direction, we analyze spin dynamics of the propagating beams, with predictions shown in Fig.1. These calculated spin textures can be identified as skyrmions of propagation-independent sub-wavelength transverse size. A detailed analysis reveals that these spin textures can be associated with Bloch-type merons (N_{sk}=1/2) and skyrmions. Such novel spin structures were recently discovered experimentally in optical [4-5] and acoustic vortices [6].

Next, we analyze formation of the lattices for the above-described topological spin textures in the intermediate field and show that in a hexagonal lattice of phase singularities formed by triplets of discrete circular polarized sources and characterized by alternating values of topological charges ($l = \pm 1$), 3D spin skyrmions form only at lattice sites which have opposite signs of circular polarization (σ) and the topological charge ($\sigma l < 0$). Flipping the sign of σ allows shifting between skyrmionics sublattices in a behavior resembling spin Hall effect of light.

Propagating of the photonic lattice into the far field, we observe that while the size of the lattice cells expands due to diffraction, the skyrmion textures remain constant in transverse size.

We present a theory of spin transfer of optical 3D spin skyrmions to the atomic matter.

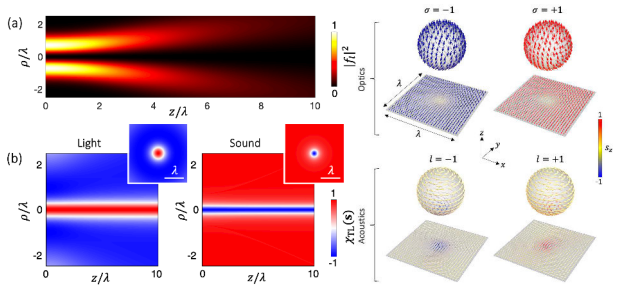

Fig. 1. (a) A diffracting intensity pattern of a vortex beam with OAM=1; (b) Calculated non-diffracting profiles of the spin alignment parameter χ_{TL} (s) for the light and sound in the longitudinal and transverse planes; (c) corresponding skyrmionic spin patterns [6].

***Abstract*—The generation of heat at the micro and nanoscale is growing research field due to their breakthrough application in nanochemistry, medical and life science. Here we investigate the photothermal conversion ability and applications of an optical nanocavity. A temperature increase higher than 550°C is obtained with an intensity of only 75 mW/mm^2.**

***Keywords*— photo-thermal conversion, ENZ metamaterials, optical nanocavity, Fano resonance.**

I. Introduction

High-efficiency photo-thermal conversion is emerging as a fundamental aspect for different applications such as nanomedicine, nanochemistry and chemical engineering. Conventional materials often struggle with spectral selectivity, but the engineering of the multilayer structure constituting the optical nanocavities provides a tunable framework for enhancing light-matter interaction. These structures localize electromagnetic energy at the nanoscale allowing to obtain high absorption at the selected wavelength. This work presents a multilayer design that maximizes heat localization, offering a scalable path for high-performance photo-thermal devices without the need for complex, high-cost nanopatterning.

II. Results and Discussion

The proposed photo-thermal converter, comprising an optimized metal-insulator multilayer architecture, was modeled using the Transfer Matrix Method (TMM) to target a resonance at $\lambda = 532$ nm. The optimized stack consists of an arrangement of metal and dielectric layers with a hundreads nanometer optical cavity between the metals. The proposed system presents a strong interaction between the metallic radiative channel and the Fabry-Perot cavity resonance producing a Fano optical response.

To elucidate the underlying physics, Finite Element Method (FEM) simulations were employed to analyze electric field localization and layer-specific absorption. The numerical results confirm the Fano behavior with an asymmetry factor of q $\approx$ -1.43. Notably, the structure maintains "flatband" absorption stability across incident angles of 20° to 40°.

Experimental validation was conducted by illuminating the structure with a 532 nm laser and monitoring the thermal response via an infrared camera. The multilayer stack demonstrated exceptional conversion efficiency, reaching temperatures exceeding 550°C at a low power intensity of only 75 mW/mm^2 within seconds.

This significant thermal enhancement was leveraged to develop a fiber-coupled optical scalpel for surgical applications. An optimized tip, designed via FEM and fabricated through 3D printing, was coated with the multilayer structure and integrated onto an optical fiber. The device achieved a localized, controlled temperature of 120°C, demonstrating high potential for precise, minimally invasive photothermal therapy.

III. Conclusion

Thermal properties of epsilon near zero(ENZ) nanocavity are experimentally and numerically demonstrated. Upon illumination at the resonance wavelength an increasing of local temperature more than 550°C is observed. The operational wavelength can be tuned by design to operate in the whole visible range. The proposed system opens the way to new applications in several field such as surgery, defrosting, nanoheaters and biotechnologies.

***Abstract*— Aluminum-doped ZnO (AZO) is a promising material for photonic applications because of its tunable plasmonic response and the low optical losses in the near-infrared (NIR). We have investigated the role of nanostructuration in the ultrafast optical response and in the dynamics of electron populations of engineered AZO metasurfaces.**

***Keywords*— focused ion beam, nanostructuration, transient absorption spectroscopy, transparent conducting oxide.**

I. Introduction

Transparent conducting oxides like AZO combine high transparency and high conductivity, exhibiting epsilon-near-zero behavior in the NIR–MIR range with low losses and ultrafast switching [1]. Their optical properties are tunable via growth conditions, post-growth treatments, or external stimuli, and can be further controlled through metasurface nanostructuring. Unlike noble metals, TCOs are better suited for NIR–MIR applications due to lower, tunable charge density. However, fabricating sub-100 nm structures is challenging, requiring uniform films and optimized lithography. Combining TCOs tunability with FIB nanostructuration enables further control over local electromagnetic fields and carrier dynamics, opening the way to engineering new types of photonic components and designing new photophysical properties by using subwavelength resonant nanostructures. For this purpose ultrafast spectroscopy has revealed a powerful tool to study hot-carrier dynamics and nonlinear responses, enabling control of plasmonic excitations and supporting advanced photonic, sensing, and all-optical modulation applications.

II. Methods

Electromagnetic simulations were carried out by using the commercial software COMSOL Multiphysics, solving Maxwell's equations in the frequency-domain, using the experimental permittivity spectra measured for an AZO thin film (Al 4 at.%). AZO films were deposited at room temperature on MgO(001) substrates by magnetron sputtering and the nanostructures were fabricated by means of focused ion beam (FIB). Transient optical spectroscopy experiments were performed pumping with 1600 and 3000 nm laser and probing with two setups for the UV-VIS and the NIR range.

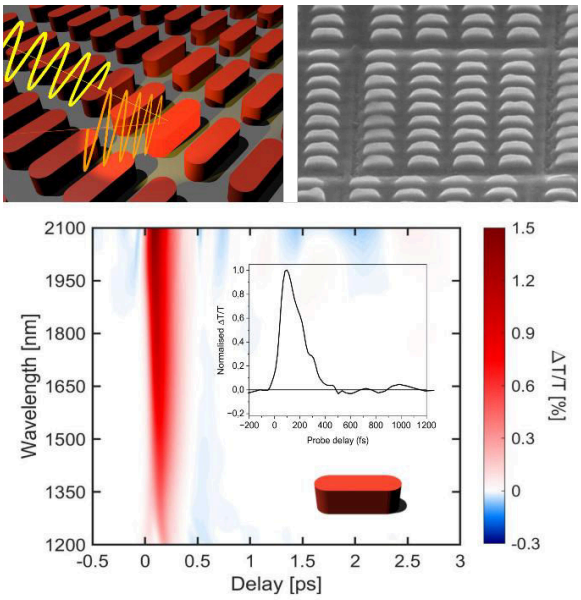

Fig. 1 AZO nanorods array by FIB (upper) and transient differential transmission map as a function of delay time and probe photon energy (lower panel).

III. Results and Discussion

We have simulated the optical static response of nanorods and nano-Ls as a function of geometrical parameters (height, lateral sizes, pitch) to maximize the absorption of the system in the NIR. We have realized the nanostructures by FIB with the parameters obtained from simulations, fabricating nanorods

with 150 nm length and 80 nm height, and nano-Ls with arm lengths of 200 and 300 nm.

We have then investigated the ultrafast response of the film and of the two arrays pumping at 1600 nm within the plasmon resonance band of the film and at 3000 nm, matching the resonance of the nanostructures, probing from 325 to 500 nm and from 1200 to 2100 nm. The transient differential transmission signal presents a negative band assigned to photoinduced absorption at time zero that decays in ∼1 ps. The NIR region is dominated by a positive band extending until 2000 nm, that after ∼ 100 fs becomes negative and then decays to zero. In the nanostructures after the excitation, a positive ΔT/T band is present in both nanostructure arrays, as for the AZO film. This bleaching signal demonstrates, as supported by our calculations, the presence of the plasmonic resonance band. However, at longer delay times, the nano-Ls behave like the film and the signal becomes negative, while in the nanorods the signal goes to zero and no negative contribution is present [2].

The pump-probe measurements indicate that the confinement induced by the small nanorod structure allows a very fast decay (100 fs) of the out of equilibrium hot carriers, while in a larger structure, such as nano-Ls or a corrugated film, the carriers relax in a thermalized population that just after 300 fs decays to the ground state [3,4]. The absence of a detectable non-thermal electrons population in the nanorods can be due to a reduction of the density of the available electronic states in the confined nanostructures, or to the extremely rapid relaxation and thermalization of these carriers, occurring on timescales shorter than the experimental resolution of this work. Alternatively, the fraction of non-thermal electrons generated under these excitation conditions may simply be too small for their contribution to produce a measurable signal.

These results indicates that it is possible to modify and control the plasmonic response of AZO metasurfaces through nanofabrication, both statically and dynamically, making them promising building blocks for infrared plasmonics and nanophotonic applications.

IV. Conclusion

We have studied the ultrafast carrier dynamics in arrays of AZO nanostructures, optimized by simulations and fabricated by FIB, by means of optical pump-probe spectroscopy. The study indicates that it is possible to modify both the static and the dynamic behavior of carriers involved in the plasmonic response through nanofabrication, making them promising building blocks for infrared plasmonics and nanophotonic applications, where metal-free and CMOS-compatible platforms are advantageous.

***Abstract*— We present an all-optical strategy for ultrafast, reconfigurable polarisation control using subwavelength epsilon-near-zero transparent-conductor films. Femtosecond pumping transiently reshapes the carrier plasma to induce birefringence, dichroism, and pump-helicity-dependent optical activity within a single unpatterned platform, enabling broadband, sub-picosecond polarisation transformations compatible with compact integrated photonics.**

***Keywords*— Time-varying materials, nonlinear optics, ultra-fast photonics, polarization control.**

I. Introduction

Fast, compact, and programmable polarisation control is a persistent bottleneck for planar photonics, where conventional bulk components are impractical and many on-chip solutions trade speed for tunability or reconfigurability. Resonant metasurfaces and nanoantennas can deliver strong static anisotropy but their functionality is generally fixed by geometry and limited in bandwidth, while electrically or thermally tuned approaches tend to be slow and complex to implement. A complementary route is to encode functionality in time rather than structure. In this regard, time-varying photonics, enabled by extreme ultrafast nonlinearities, can in principle switch a single device between distinct polarisation transformations by changing only the excitation conditions, thus separating fabrication from functionality [1-8]. Transparent conductors operated near the epsilon-near-zero (ENZ) crossover are particularly attractive because their nonlinearity is strong, broadband, and naturally linked to ultrafast free-carrier dynamics, making them promising candidates for "temporal flat-optics" [9-11]. In this paradigm birefringence, dichroism, and optical activity can be induced on demand in the same isotropic film with sub-picosecond response and without relying on permanent geometric anisotropy or narrowband resonant design [12].

II. Methods

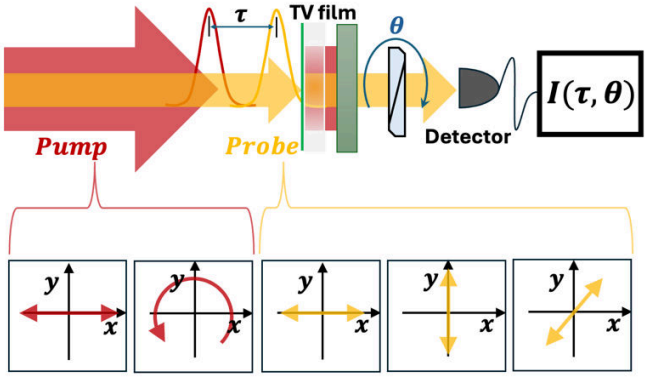

Fig. 1 Schematic of the pump–probe experimental setup used to induce and measure transient polarisation transformations in a time-varying thin film. A femtosecond pump pulse optically excites the film, generating a transient anisotropic plasma response, while a time-delayed probe pulse interrogates the induced optical properties. The transmitted probe passes through polarisation analysis optics before detection, enabling measurement of intensity as a function of pump–probe delay (τ) and analyser angle (θ). The lower panels illustrate representative pump/probe polarisation states.

Our platform employs an unpatterned, isotropic aluminium-doped zinc oxide film of subwavelength thickness operated near its ENZ crossover and driven in a pump–probe configuration, where femtosecond pumping generates a transient non-equilibrium carrier distribution and thus a time-dependent complex dielectric response. The key control dials are pump polarisation (linear or circular), intensity, and pump–probe delay, which determine whether the induced dielectric tensor is predominantly diagonal-anisotropic (supporting birefringence and dichroism) or gains antisymmetric components (supporting gyrotropic behaviour). Polarisation-resolved probe transmission is recorded as a function of analyser angle and delay to extract transient phase retardation, differential absorption, and pump-helicity-dependent rotation, while modelling treats the film as a time-varying plasma in

which pump-driven effective-mass and scattering dynamics reshape both the real and imaginary parts of the response, enabling symmetry breaking without any geometric anisotropy. Importantly, the excitation geometry is chosen so the observed effects are not contingent on Fabry-Pérot enhancement or surface-mode phase matching, keeping the mechanism rooted in intrinsic time variation rather than structural resonances.

III. Results and Discussion

Under linearly polarised pumping, the isotropic film becomes transiently anisotropic on the pump timescale, producing large polarisation coupling in transmission that manifests as a rotation of the transmitted polarisation axis together with induced ellipticity, consistent with simultaneous birefringence (phase retardation between orthogonal components) and dichroism (polarisation-dependent absorption). Retrieval of the transient complex refractive indices along orthogonal axes shows that both the real and imaginary parts are modulated in a direction-dependent manner during temporal overlap, and that the induced anisotropy is substantial over deep-subwavelength propagation distances, demonstrating that time-written anisotropy can be strong enough to compete with, and exceed, structurally written responses at comparable footprints. Beyond maximising magnitude at the ENZ crossover, wavelength detuning provides an additional degree of control over the relative weight of phase- versus absorption-driven effects, allowing partial decoupling between birefringence and dichroism through dispersion engineering of the pumped state and offering a practical route to tailoring the output state (e.g., emphasizing phase retardation while suppressing ellipticity). Switching to circularly polarised pumping produces a qualitatively different response: the probe experiences a helicity-dependent rotation whose sign reverses with pump handedness, indicating a dynamically induced, non-reciprocal optical activity in an otherwise achiral, unpatterned film. In the time-varying plasma model, this behaviour arises when the pump-imprinted symmetry of the carrier distribution generates antisymmetric tensor contributions that are algebraically equivalent to an effective transverse term acting on the probe, providing a microscopic pathway for pump-controlled gyrotropy in a planar isotropic medium. Crucially, this route does not require pre-existing chiral geometry, static magnetisation, or resonant enhancement, and therefore supports broadband operation and rapid reconfiguration among distinct polarisation functions by changing only the pump state [13-18]

IV. Conclusion

Time-varying ENZ transparent-conductor films enable a reconfigurable polarisation-control mechanism in which a single unpatterned, deep-subwavelength platform can be optically switched on sub-picosecond timescales between birefringent, dichroic, and gyrotropic behaviours by selecting pump polarisation and temporal overlap. By transferring programmability from nanofabrication to excitation design, this approach provides a scalable route to broadband ultrafast polarisation modulators and temporally reconfigurable flat-optical elements, with clear opportunities for integrated photonics where compactness, speed, and functional switching are simultaneously required .

***Abstract*— We use tilted achiral metal-dielectric-metal nanocavities in which the top metal layer is patterned into a nanohole array as spectrally tunable metamaterial substrates for enantiomer detection. By combining circular dichroism experiments with simulations, we elucidate the different contributions to the chirality enhancement.**

***Keywords*— Circular dichroism, chirality, enantiomer, plasmonic nanohole array, photonic cavity, biosensing.**

I. Introduction

Distinguishing the chirality of biomolecules is of fundamental importance in biophysics and pharmaceutics. Circular dichroism (CD) spectroscopy provides a non-invasive approach to distinguish right- and left-handed enantiomers[1] and can offer valuable insight into the structure of the investigated molecules. However, CD spectroscopy faces a key challenge: the detection of weak chiroptical signals due to limited chirality-induced interactions with plane wave light fields. Plasmonic nanostructures and metamaterials can be designed to obtain CD enhancement across different wavelengths.

We use tilted achiral gold nanohole arrays whose resonance band could be spectrally tuned by tailoring their geometric parameters and combine them with metal-dielectric-metal optical cavities. [1] The resulting metamaterial substrates provide a flexible platform for enhancing circular dichroism signals of enantiomers through extrinsic chirality. [2]

II. Results and Discussion

We fabricate and investigate the CD response of a tilted single gold nanohole array as a substrate, and we study the CD response of L-phenylalanine as a chiral biolayer in two conditions—isolated and placed on the single gold nanohole array. We then combine plasmonic and photonic resonator effects by fabricating a metal–dielectric–metal (MDM) metamaterial structure composed of Au/Al_2O_3/Au with nanoholes in the top gold layer, and subsequently deposit an L-phenylalanine biolayer on top. This proves to be a highly promising platform for achieving strong CD signal, even compared to that obtained using a single gold nanohole layer as substrate.

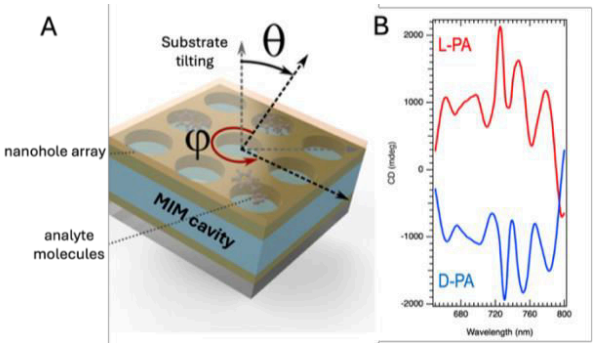

Fig. 1 A) Illustration of the achiral metamaterial substrate consisting of a metal-dielectric-metal cavity with top metal layer as nanohole array. B) Circular dichroism spectra evidencing the chirality enhancement measured in circular dichroism spectroscopy for L- and D-phenylanaline. Adapted with permission from ref. [2], copyright ACS 2025.

III. Conclusion

We establish extrinsic chirality engineering as powerful strategy for advancing chiral sensors, which paves the way for the development of next-generation nanophotonic platforms with high sensitivity and selectivity for enantiomer detection.

Frequency and geometry control enable reconfigurable skyrmions, merons, and related topological textures within a single platform.**

***Keywords*—Photonic topological textures, bound states in the continuum, dielectric metasurfaces, hyperbolic phonon polaritons.**

I. Introduction

Topology provides a general framework for describing robust structures that emerge across a broad range of physical systems, including atmospheric dynamics, oceanic flows, and large-scale astrophysical phenomena. Among its key manifestations are topological defects, which cannot be removed or transformed into a different topology without fundamentally altering the system's overall configuration. A central example is the skyrmion, a topological defect formed by a three-dimensional vector field confined to a two-dimensional plane, whose configuration spans the full unit sphere in order-parameter space. [1] In condensed matter physics, skyrmions have been observed in a variety of platforms, including magnetic materials, superconductors, superfluids, and liquid crystals.

In recent years, skyrmions have been realized in photonics, both in free-space optical topologies [2], [3] and in propagating surface modes. [4], [5] These photonic skyrmions exhibit deeply subwavelength spatial features and demonstrate a degree of robustness against imperfections and environmental perturbations. [6], [7] As a result, they have attracted growing interest for applications in optical computing, nanoscale metrology, and twistronics. Beyond skyrmion configurations, photonic platforms have enabled more complex topological textures, including skyrmion bags, meron lattices, and optical vortices carrying orbital angular momentum. These structures have been generated using both surface phonon polaritons in isotropic materials [8] and hyperbolic phonon polaritons in anisotropic media [9], with potential relevance for structured thermal emission and nanoscale light control.

Despite these advances, existing approaches for generating polaritonic skyrmions rely predominantly on wavelength-specific coupling schemes, such as gratings or phase-matching structures, or on structured excitation fields including radial or circular polarization. [10] These requirements fix the resulting topological configuration for a given structure and prevent continuous tuning within the same device. In contrast to free-space skyrmions, where tunability has been experimentally demonstrated [11], this lack of reconfigurability presents a major obstacle to the integration of polaritonic skyrmions into broadband and scalable photonic architectures. Moreover, the reliance on specialized polarization states often necessitates additional optical components, increasing experimental complexity and limiting practical applicability.

II. Methods

Our approach is based on the excitation of nonlocal photonic resonances in dielectric metasurfaces to generate and control polaritonic topological textures. We employ periodic arrays of high-refractive-index dielectric resonators fabricated on a transparent substrate, designed to support quasi-bound states in the continuum (qBICs) under linearly polarized illumination and normal incidence. The nonlocal character of the qBIC resonance leads to strong mutual coupling between resonators, resulting in uniform out-of-plane electric fields across each resonator surface. This behavior is fundamentally distinct from local dipolar resonances, which produce spatially nonuniform near-field distributions.

Each resonator is covered with a thin layer of hexagonal boron nitride (hBN), and the metasurface resonance is spectrally tuned to the in-plane Reststrahlen-(RS-)band of hBN to enable efficient excitation of hyperbolic phonon polaritons (HPhPs). Due to the uniform phase and amplitude of the driving electric field, these polaritons are launched in phase from all resonator edges, leading to controlled interference at the resonator center and the formation of polaritonic skyrmion lattices.

Optical reconfigurability is achieved by tuning the excitation frequency in small steps within the linewidth of the qBIC resonance itself. Owing to the strong dispersion of HPhPs in

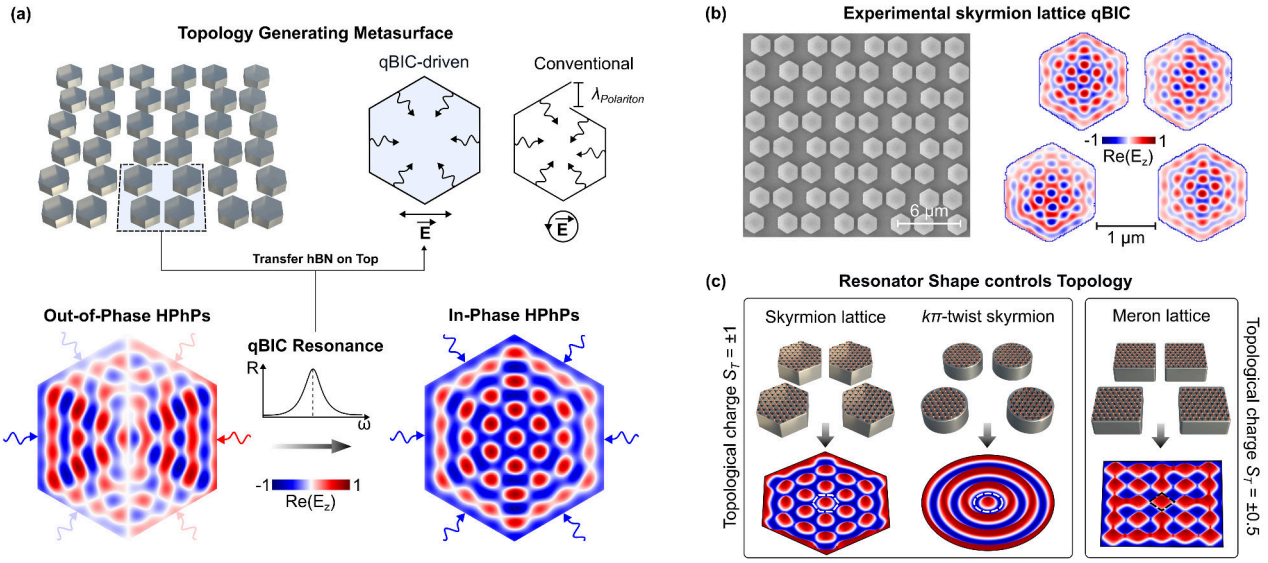

Fig. 1. qBIC-driven generation of polaritonic topological textures. **(a)** Dielectric metasurface supporting a nonlocal qBIC that provides a spatially uniform out-of-plane electric field to launch hyperbolic phonon polaritons (HPhPs) in an hBN layer placed on top. **(b)** SEM image of the metasurface and experimental near-field map of the real part of the out-of-plane electric field, $\mathrm{Re}(E_z)$ showing polaritonic skyrmion lattices on individual resonators. **(c)** Resonator geometry allows changing the resulting polaritonic topology, enabling skyrmions, $k\pi$-twist skyrmions, and meron lattices with distinct topological charge.

the RS-band of hBN, these small frequency changes induce substantial variations in the polariton wavelength, which directly modify the size and spatial arrangement of the resulting topological textures. The overall tuning range is set by the qBIC linewidth, which can be increased through controlled symmetry breaking. In addition to spectral tuning, altering the resonator geometry, enables access to distinct topological configurations such as $k\pi$-twist skyrmions and merons.

Experimental characterization is performed using scattering scanning near-field optical microscopy (s-SNOM) in transmission mode, enabling direct visualization of the deeply subwavelength polaritonic skyrmion lattices and their frequency-dependent reconfiguration.

III. Results and Discussion

Experimental results show:

- Deeply subwavelength Néel-type photonic skyrmions are experimentally resolved with polariton wavelengths ranging from approximately 451 nm down to 271 nm, corresponding to feature sizes of about $\lambda/25$.
- The photonic skyrmion lattices exhibit topological stability, confirmed by quantized winding numbers and by robustness under continuous variation of the optical phase, with the topological charge remaining invariant except at discrete transition points.
- Continuous tuning of the excitation frequency within the qBIC resonance enables dynamic control of skyrmion size on the same resonator, while the topological winding number remains close to the theoretical value of ± 1.
- Changing the resonator geometry from hexagons to disks and squares preserves the nonlocal photonic mode and enables the generation of distinct polaritonic topologies, including $k\pi$-twist skyrmions and meron lattices.

IV. Conclusion

By combining nanophotonic metasurfaces and topological polaritonic textures, our approach allows optical reconfigurability of skyrmion size and topology within the same structure through frequency tuning and resonator geometry. Future work will explore integration with actively tunable materials to extend dynamic control well as investigate more complex resonator geometries to generate higher-order and composite polaritonic topologies, enabling multiplexed and reconfigurable topological states within a single metasurface platform.

Plasmonic Semiconductor Laser Particles Across Surface-Supported, Metal-Coated, and Metalattice Configurations

Sangyeon Cho[1,*]

[1]Wellman Center for Photomedicine, Massachusetts General Hospital and Harvard Medical School, USA

*Corresponding author: scho9@mgh.harvard.edu

***Abstract*— We report plasmonic semiconductor laser particles across three configurations: surface-supported nanocavities enabling coherent emission from 130 nm particles, metal-coated geometries introducing hinge-localized plasmonic modes with enhanced emission, and metalattice-embedded particles supporting stable multimode lasing via internal scattering, all governed by cavity geometry and Purcell-enhanced interactions.**

***Keywords*— plasmonic nanolasers, random lasers, Purcell effect**

I. Introduction

Plasmonic nanolasers enable coherent light generation at deeply subwavelength scales by combining semiconductor gain with strong field confinement. However, metallic losses and mode competition often limit spectral coherence and stability. Here, we study surface-supported, metal-coated, and metalattice-embedded semiconductor laser particles to reveal how cavity geometry and Purcell-enhanced interactions govern coherent emission and multimode lasing.

II. Methods

Our approach combines electromagnetic simulations, nanofabrication, and hyperspectral optical characterization to study plasmonic laser particles across multiple configurations. Surface-supported nanocavities are formed by placing semiconductor particles on metallic substrates, enabling strong confinement and plasmonic resonances. Metal-coated particles support hinge-localized modes with enhanced emission at geometric features.

Metalattice systems are realized by embedding plasmonic nanoscatterers within semiconductor particles to introduce internal scattering and feedback. Optical characterization under pulsed excitation reveals emission spectra, linewidths, and spatial mode distributions, enabling systematic comparison of lasing behavior across configurations.

III. Results and Discussion

Experimental results show:

- InP particles on gold substrate down to approximately 130 nm exhibit coherent lasing on gold substrates at visible wavelengths near 730 nm.
- Metal coated perovskite microcrystals as small as 620 nm show enhanced lasing with reduced thresholds and improved stability due to plasmonic coupling.
- Metalattice embedded particles enable stable multimode lasing with multiple narrow spectral peaks arising from internal scattering.

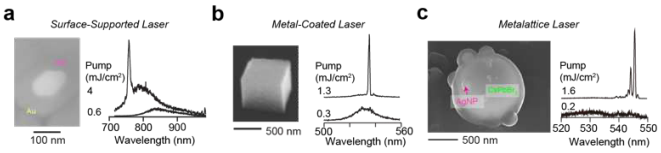

Figure 1. Surface-supported, metal-coated, and metalattice plasmonic laser particles

IV. Conclusion

We demonstrate plasmonic semiconductor laser particles across surface-supported, metal-coated, and metalattice configurations, where cavity geometry governs light–matter interaction from extreme confinement to hinge-localized enhancement and distributed feedback. These results enable programmable nanolasers with tailored emission properties, supporting standalone applications including on-chip light sources and optical communications, as well as biological cell barcoding for multiplexed single-cell tracking and real-time sensing of cellular states.

Nanofocusing of Orbital Angular Momentum Beams for Chirality Imaging

Zhenrong Zhang

Department of Physics, Baylor University, Waco, Texas, United States

Optical vortex beams carrying orbital angular momentum (OAM) and cylindrical vector beams (CVBs) offer unique functionalities in communication, sensing, and chiral light-matter interactions. However, their deployment at the nanoscale remains limited by inefficient coupling arising from intrinsic spatial-mode mismatch. In this talk, I present a fiber-integrated plasmonic nanostructure platform that enables subwavelength confinement of a fiber-guided vortex mode.

I will discuss the design, simulation, fabrication, and characterization of plasmonic OAM probes, as well as an integrated OAM–metasurface platform that couples a vortex laser beam into a hybrid dielectric–plasmonic helical metastructure (Si–Ag) for enhanced chirality sensing. A radial plasmonic nanorod array patterned on the facet of a polarization-maintaining ring-core vortex fiber achieves subwavelength focusing of the OAM mode. Simulations reveal symmetry-selective electric-field enhancement, efficient near-field confinement, and preservation of both polarization state and OAM phase during nanofocusing.

Experimentally, we verify stable propagation of vortex modes with preserved polarization and helicity in the far field, and we observe strong coupling of the nanofocused OAM beam into the Si–Ag helical metastructure. This coupling leads to efficient excitation of chiral molecules, demonstrating the platform's potential for highly sensitive chirality imaging and OAM-enabled nanoscale spectroscopy.

Cross-Shaped Metasurface for Advanced Spectral-Scanning LiDAR

H. Y. Fu* and Yaqi Han

[1]Tsinghua Shenzhen International Graduate School, Tsinghua University, Shenzhen, China
*Corresponding author: hyfu@sz.tsinghua.edu.cn

Abstract

Spectral scanning has emerged as a promising beam-steering technique by combining dispersive optical components with wavelength-swept laser sources for light detection and ranging (LiDAR). Based on our prior research, we have demonstrated several spectral-scanning LiDAR systems capable of high-speed 3D imaging, simultaneous velocity measurement, extended ranging distance and wide field of view detection [1-3].

Metamaterials, with their subwavelength structures and tunable electromagnetic responses, offer transformative capabilities for manipulating light beyond the limits of conventional optics. Their ability to manipulate phase, polarization, and dispersion makes them highly promising for integrated photonics, especially in compact and efficient LiDAR systems [4-6]. In frequency-modulated continuous wave (FMCW) LiDAR systems, metamaterials open new avenues for non-mechanical beam steering, spectral multiplexing, and polarization diversity—critical features for building solid-state, high-resolution 3D imaging systems.

This presentation highlights our recent progress in integrating metasurface-based components into silicon photonic platforms for LiDAR applications. We focus on the design and simulation of the metasurface with dielectric layer sandwiched between a metal ground and a metallic structured layer, specifically cross-shaped Al–SiO_2–Al structures, which enable circular polarization manipulation and broadband spectral beam steering under swept-wavelength excitation, as illustrated in Fig. 1. These metasurfaces significantly enhance the steering range while maintaining stable performance under severe environmental conditions—addressing key limitations of existing LiDAR systems.

Our results suggest that metamaterial-enabled design significantly enhances the functionality and integration level of LiDAR systems, paving the way for the next generation of intelligent sensing platforms. Future work will focus on AI-assisted inverse design of metasurfaces to further improve their performance and accelerate the optimization process, particularly for spectral-scanning LiDAR applications.

***Abstract*— Broadband metamaterial absorbers were applied to ultra-sensitive molecular sensing applications. 3D coaxial metamaterial absorber was developed and applied for the multiple gas sensing with a zepto-molar sensitivity.**

***Keywords*— metamaterials, absorber, molecular sensing**

I. Introduction

Highly sensitive molecular sensing techniques, particularly for biological targets such as disease-associated biomarkers, microRNAs, and circulating tumor DNA, have become increasingly important in modern healthcare. Recently, metamaterial-based devices have been employed to enhance molecular detection sensitivity. Owing to their ability to resonantly amplify molecular signatures—including infrared (IR) absorption, Raman scattering, and refractive index changes—detection limits have reached the atto- to zeptomolar range.

II. EXPERIMENTAL RESULTS

Several years ago, we developed a metamaterial device integrated with nanofluidics to deliver analyte molecules into the hotspot region of the metamaterial, thereby maximizing the resonant interaction between the metamaterial and the molecules. When molecules whose absorption bands are overlapping the metamaterial resonance are introduced into the nanofluidic channel, strong light–matter interactions are induced, leading to enhanced reflection within the metamaterial absorption band. Using this device, we achieved a sensitivity corresponding to a molecular surface density of approximately 10^{-4} molecules/Å^2.

Recently, we proposed a vertically aligned metal–insulator–metal (v-MIM) metamaterial with a 25-nm nanogap for gas-phase molecular sensing. As proof-of-concept demonstrations, this device was applied to the detection of carbon dioxide and butane. Owing to its small footprint, the v-MIM structure enables high integration density, and the incorporation of resonators with different resonance frequencies provides broadband operation. As a result, the fabricated platform achieves zeptomolar-level detection of multiple gas species using distinct resonant elements.

To enable the detection of multiple gas species within a single device, the resonant absorption bandwidth was broadened through structural modification. Moreover, to efficiently utilize unpolarized incident light from a thermal IR source, the resonant elements were redesigned with a cylindrical geometry.

Figure 1(a) shows an SEM image of the fabricated broadband three-dimensional metamaterial absorber, and Fig. 1(b) shows its absorption spectrum, exhibiting an absorption bandwidth more than one octave.

The fabricated metamaterial absorber was placed in a gas chamber, into which a mixture of ethylene, butane, and carbon dioxide was introduced. Figure 2(a) shows the measured IR absorption spectra, where absorption signals from each gas appear as positive peaks. Figure 2(b) presents additional experimental results obtained with carbon dioxide and dimethyl ether.Based on these experimental results, the detection sensitivity of the device was estimated to be 25 zeptomoles.

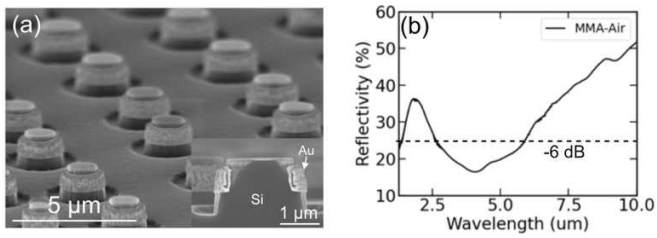

Figure 1 Broadband 3D metamaterial absorber.

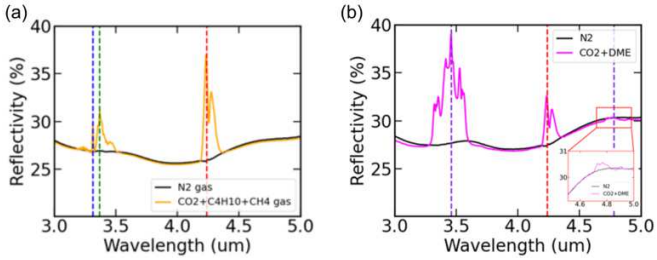

Figure 2 IR spectra of mixed gases.

In addition, a sensitivity-tunable metasurface device for label-free microRNA detection will be presented.

Abstract— **Can nano-mechanical computers be scaled to the nanoscale and compete with electronic architectures? We report the timetron as a central building block for mechanical computation based on the concept of a time crystal, which can be switched with femtojoule-scale energies and sustained with only a few femtowatts of optical power.**

***Keywords*— time crystals, metamaterials, data processing.**

I. INTRODUCTION

The earliest computers, from the abacus to sophisticated clockwork calculators, were mechanical and digital. They dominated computation well into the twentieth century. Why did electronics ultimately prevail? The advantage of electronics was the transition to the nanoscale, where transistors enabled fast operation, dense integration, scalable manufacturing, and cascaded binary Boolean logic.

Can mechanical computers also be scaled to the nanoscale, and if so, could they compete with electronic architectures [1]? We examine the *timetron* as a central building block for mechanical computation that is based on the concept of a time crystal[2-4]. It is a nanomechanical element in which light switches the system between two dynamical states - rest and sustained oscillation - encoding the logical “0” and “1” of timetronics, a data-processing paradigm where information is carried by the dynamical state of nanoscale motion. Based on the timetron, key logical and memory elements can be implemented. It can be switched with femtojoule-scale energies, while the logical state can be sustained with only a few femtowatts of optical power.

Generalized Lorentz Framework for Active Semiconductor Plasmonics at the Deep Nanoscale

Xue-Wen Chen*

School of Physics, Huazhong University of Science and Technology, Luoyu Road 1037, Wuhan, 430074, China

*Corresponding author: xuewen_chen@hust.edu.cn

***Abstract*— We report a generalized Lorentz framework to efficiently capture various nonclassical effects in multiscale three-dimensionally nanostructured semiconductors with arbitrary energy–momentum dispersion relations. The framework enables quantitative treatment of carrier nonlocality, surface accumulation and depletion, and Landau damping under electrical control and widely varying doping densities.**

***Keywords*— Deep nanoscale, Nonlocality, non-Parabolic dispersion, Landau damping.**

I. Introduction

Semiconductors lie at the core of modern microelectronics and, beyond electronic functionality, constitute a versatile platform for light-matter interactions across the mid-to-near infrared spectrum through surface plasmon resonances arising from collective oscillations of charge carriers. Unlike metals, semiconductors exhibit plasmonic properties actively tunable through doping and electrical gating, offering appealing opportunities for on-chip electro-optical modulation, ultrasensitive biosensors, enhanced infrared imaging, nonlinear effects, and all-optical switching. Recent advances in nanofabrication technology have enabled three-dimensional (3D) nanostructuring of semiconductor materials with single-digit-nanometer precisions. Such capability allows precise control of the interactions among light field, charge carriers, and other fields at the deep nanoscale, fostering ultrafast and efficient photonic–electronic convergence. As feature sizes shrink to deep nanoscale (~10 nm scale and below), nonclassical carrier dynamics and plasmonic responses become prominent, posing substantial challenges for a rigorous and efficient theoretical treatment.

Here we present a generalized Lorentz framework to describe the nonclassical effects in 3D nanostructured semiconductors with arbitrary energy-momentum dispersion relations. Building on the framework, we establish a QNM analysis with a consistent orthonormalization and provide accurate characterizations of the carrier dynamics and plasmonic responses of semiconductor nanostructures subject to electrostatic fields and orders-of-magnitude variation in doping density.

II. Methods

Based on a hydrodynamic description of the conduction electrons in n-doped semiconductors, we derive a generalized Lorentz model to effectively account for various nonclassical effects. It reads

$$\omega^2\mathbf{P} + i\omega\frac{\rho}{m^*}\hat{\Gamma}\mathbf{P} - \frac{\rho}{m^*}\hat{\Theta}\mathbf{P} = -\varepsilon_0\omega_p^2\rho\mathbf{E}, \quad (1)$$

where **P** is the polarization of the electrons, m* is the effective mass of the electrons, **E** is electric field, and ρ is the stationary electron density. $\hat{\Gamma}$ and $\hat{\Theta}$ are the damping and restoring (spatial differential) operators. Eq. (1) together with the curl equation of the Maxwell equations constitute the generalized Lorentz framework for effective treatment of the various nonclassical effects of the electrons in heavily doped semiconductors.

III. Conclusion

The generalized Lorentz framework constitutes a theoretical foundation for studying active semiconductor nanoplasmonics and will foster the convergence of electronics and photonics at the deep nanoscale.

Topological metasurface for wavefront manipulation

Qinghua Song[1,*]

[1]Tsinghua Shenzhen International Graduate School, Tsinghua University, Shenzhen, China
*Corresponding author: song.qinghua@sz.tsinghua.edu.cn

***Abstract*— In this talk, we will present topological metasurface based on exceptional points and their applications in wavefront manipulation. Unconventional arbitrary polarized exceptional point and zero-eigenvalue exceptional point are demonstrated.**

***Keywords*— metasurface, exceptional point, non-Hermitian, topological photonics.**

I. Introduction

Exceptional points (EPs) are spectral singularities of non-Hermitian systems that occur whenever complex eigenvalues and eigenstates coalesce, leading to a reduction of the Hilbert space dimension. Traditional photonic systems typically exhibit coalesced eigenstates that correspond to circularly polarized light of a specific handedness, thereby restricting their applicability to only two antipodal points located on top or bottom of the Poincaré sphere. Here, we introduce a continuum of EPs for which the corresponding coalesced eigenstates can access any point on the Poincaré sphere (**Fig. 1**). Our theoretical proposal and experimental implementation overcome the main practical limitation of EPs, extending the applicability of the topological phase to any arbitrarily-polarized light state. In addition, we theoretically and experimentally demonstrate a counterintuitive topological strategy based on zero-eigenvalue EP (**Fig. 2**), in which the complete suppression of the system scattering enables an effective expansion of accessible topological degrees of freedom. The emergence of these non-conventional EPs not only introduces a realm of disruptive applications in wavefront engineering and optical multiplexing, but also brings in new fundamental properties of topological systems in general.

Metasurface-Enabled Solid-State Photon Sources

Fei Ding[1,2,*]

[1] Centre for Nano Optics, University of Southern Denmark, Campusvej 55, DK-5230 Odense, Denmark

[2] School of Electronic Science and Technology, Eastern Institute of Technology, Ningbo, China

*Corresponding author: feid@mci.sdu.dk

***Abstract*— We propose general approaches to designing versatile solid-state photon sources using on-chip quantum-emitter-coupled metasurfaces. This platform enables us to generate spatially propagating photon streams with arbitrary directionality, polarization, and wavefronts via designed metasurfaces.**

***Keywords*—Solod-state quantum emitters, metasurfaces, directionality, polarization, wavefronts.**

I. Introduction

Metasurfaces—ultrathin arrays of engineered meta-atoms—have revolutionized classical optics by enabling unprecedented control over the amplitude, phase, and polarization of light within compact, planar platform [1]s. By replacing bulky optical components with subwavelength nanostructures, metasurfaces have facilitated a new generation of miniaturized and multifunctional photonic devices. Beyond their transformative impact on classical light manipulation, metasurfaces are increasingly emerging as powerful interfaces for tailoring nonclassical optical fields, extending their functionality to the single-photon regime [2].

II. Methods

We introduce a conceptually new paradigm of on-chip emitter-coupled quantum metasurfaces for the room-temperature generation of nonclassical light. In this approach, quantum emitters are non-radiatively coupled to surface plasmons, which are subsequently converted—via interaction with an optical metasurface—into collimated single-photon beams with engineered quantum properties (Fig. 1).

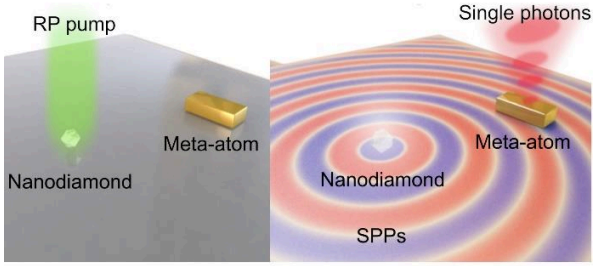

Fig. 1 Schematic of the emitter-coupled quantum metasurface.

III. Results and Discussion

This platform enables deterministic control over emission directionality, and polarization, providing a scalable and chip-compatible route toward integrated quantum light sources for advanced quantum photonic technologies. By unifying near-field light–matter interaction engineering with far-field wavefront shaping in a single metasurface architecture, it bridges the gap between quantum emitter physics and functional photonic circuitry [3-5].

IV. Conclusion

Such an approach not only enhances photon extraction efficiency and state purity at room temperature but also offers multidimensional control of single-photon states, paving the way for compact quantum communication systems, high-dimensional quantum information processing, and on-chip quantum sensing and imaging applications.

Continuous-Wave Chiral Exciton–Polariton Lasers Across the Visible and Infrared

Siying Peng[1,*]

[1]Department of Materials Science and Engineering, Westlake University, China
*Corresponding author: pengsiying@westlake.edu.cn

***Abstract*— Chiral light-matter interactions are emerging as a key frontier in both applied photonics and fundamental optical science. Their ability to control the spin and handedness of light enables unique functionalities relevant to technologies ranging from under-display biometric recognition and stereoscopic 3D imaging to spintronic devices, quantum information processing, and molecular sensing. These diverse applications would greatly benefit from compact chiral light sources capable of emitting light with high directionality, strong polarization purity, and substantial optical power. Nevertheless, creating miniature lasers that intrinsically generate circularly polarized emission remains an outstanding materials and photonics challenge.**

Two principal design routes have been explored to achieve direct circularly polarized lasing. The first relies on chiral photonic architectures surrounding an otherwise achiral gain medium. In such systems, optical chirality arises from structural or phase asymmetry engineered into the cavity, rather than from the emitter itself. While effective, this strategy demands intricate nanofabrication or self-assembly techniques to achieve subwavelength precision. Moreover, because the active medium lacks inherent chirality, spontaneous emission couples inefficiently to the chiral optical modes, which in turn increases the lasing threshold and thermal losses.

An alternative approach introduces chemical chirality directly into the gain medium by incorporating chiral ligands or molecular building blocks. Although this strategy imparts handedness to the emitter, the magnitude of optical chirality achieved under ambient conditions is typically weak. Photoluminescence dissymmetry factors are usually in the range of 10^{-3} to 10^{-2}, leading to modest polarization purity. Consequently, neither photonic structuring nor chemical induction alone has yet produced a compact, circularly polarized laser that simultaneously exhibits strong optical chirality, low threshold operation, and high efficiency.

To overcome these limitations, we exploit strong light-matter coupling between chiral excitons and cavity photons to realize continuous-wave (CW) chiral exciton-polariton lasing spanning both the visible and infrared spectral ranges. We first demonstrate room-temperature CW circularly polarized lasing from a chiral 2D perovskite, $(MBA)_2PbI_4$, where hybrid exciton–polaritons exhibit an ultralow threshold of 0.5 $W{\cdot}cm^{-2}$ and intrinsic circular polarization with a photoluminescence dissymmetry factor of 0.30. The lasing wavelength is tunable via cavity thickness, and the device maintains >95% of its output intensity under prolonged CW operation, showing exceptional material and optical stability.

Building on this platform, we extend the concept to the infrared regime by developing chiral quasi-2D perovskite heterostructures designed through tailored organic cations and spacer layers that enhance excitonic coherence and chiroptical coupling. These engineered materials enable spin-polarized exciton–polariton condensation in the near-infrared, marking the first realization of infrared chiral polariton lasing at room temperature.

Together, these results establish a versatile photonic platform for CW, spin-polarized exciton–polariton lasing across broad spectral ranges. Beyond demonstrating record-low thresholds and high polarization purity, this work provides insights into chirality under strong coupling and paves the way toward spin-polarized quantum fluids of light and next-generation perovskite-based spintronics and photonic technologies.

Photonic inverse design and, especially, topology optimization, enable dielectric cavities with deeply sub-diffraction mode volumes and high quality factors, thus offering a powerful platform for enhanced light-matter coupling. Here, we design and fabricate arrays of CMOS-compatible silicon cavities on sapphire with extreme subwavelength transverse mode sizes of only 30-40 nm. These cavities are engineered for deterministic coupling to a monolayer (or few-layer) excitonic material WSe_2, producing strong near-field localization directly beneath the 2D material. Photoluminescence (PL) measurements show reproducible tenfold raw enhancement relative to bare silicon, which corresponds to a normalized enhancement on the order of 10^3 when accounting for the deeply subwavelength mode volume, consistent with numerical simulations that account for material absorption and fabrication tolerances. Furthermore, time-resolved PL measurements reveal pronounced lifetime shortening and non-exponential dynamics, indicating cavity-mediated exciton-exciton interactions. The optimized cavity geometry enhances the far-field collection efficiency and supports scalable integration with van der Waals semiconductors. Our results show that the arrays of topology-optimized dielectric cavities are a versatile, scalable platform for controlling excitonic emission and interactions, which creates new opportunities in nonlinear optics, optoelectronics, and quantum photonics.

Rigorous and Approximate Electromagnetic Simulators for Free-Form Light-Emitting Device Optimization

Min Seok Jang[1,*]

[1]School of Electrical Engineering, Korea Advanced Institute of Science and Technology, Korea

***Abstract*— This presentation discusses overcoming challenges in free-form light-emitting device optimization via three methods: the diffraction matrix method, differentiable RCWA, and neural operators. These tools enable efficient, robust design of next-generation, high-performance optical technologies.**

***Keywords*— Invers design, light emitting metasurfaces, machine learning, device optimization.**

Free-form optimization of optical devices offers immense performance potential but typically involves millions of design parameters, making the search for optimal structures within these vast combinatorial spaces an intrinsically challenging task. Due to increased simulation complexity, the design problem for light-emitting devices is significantly more difficult than for standard transmission or reflection metasurfaces. In this presentation, I discuss three primary approaches to address these bottlenecks. First, the diffraction matrix method is employed to rigorously simulate periodically corrugated light-emitting devices. Second, I introduce differentiable Rigorous Coupled-Wave Analysis (RCWA) simulation software that enables the efficient back-propagation of figure-of-merit gradients for high-dimensional optimization. Finally, neural-operator-based approximate models are utilized for the rapid determination of complex optical properties. Together, these methodologies provide a robust and efficient toolkit for the design and optimization of next-generation, high-performance light-emitting technologies.

Engineering spontaneous emission with metasurfaces

***Abstract*— Light-emitting metasurfaces enable direct control of emission from incoherent sources without bulky filtering. We design and realize photoluminescent metasurfaces where emitters couple to engineered leaky modes using a Kirchhoff-based absorptivity approach seeking critical coupling condition. Experiments demonstrate directional beams below 20° FWHM and efficient structured light generation.**

***Keywords*— spontaneous emission, metasurface, radiation engineering;**

I. Introduction

Designing a light-emitting system means shaping emission to meet requirements in radiation pattern, polarization, or spectrum. Unlike lasers, most sources such as fluorescent lamps and LEDs rely on spontaneous emission, an intrinsically random process in which photons are emitted with independent phase, polarization, and direction. Their emission is therefore typically isotropic, incoherent, and unpolarized. Wavefront control can be achieved by filtering the emitted light with polarizers, diaphragms, or spectral filters, but this approach discards a large fraction of the generated energy. Although LEDs are efficient sources, their overall efficiency is often reduced by optical shaping elements that may reject up to half of the emitted light and increase system complexity. An alternative approach is offered by Light-Emitting Metasurfaces (LEMs), where luminescent emitters couple to arrays of nanoscale resonators supporting extended electromagnetic modes. Preferential decay of incoherent emitters into a common resonant mode can induce spatial, spectral, or polarization coherence. Here we present advances in the modelling, engineering, and realization of flat structured-light sources based on emitters coupled to metallic or dielectric metasurfaces.

II. Methods

Light emission engineering is achieved by tailoring the properties of a leaky mode. We adopt a Kirchhoff-based approach in which emission properties are designed through the absorptivity of the LEM, aiming to maximize contrast between target modes and the parasitic background. Bare metasurfaces are first numerically designed and dimensioned in the overcoupled regime. Emitters are then incorporated and equalize radiative and non-radiative losses of the target mode. This enables critical coupling between emitters and metasurface, maximizing total absorption. After clean-room fabrication, emission properties are characterized using Fourier-plane imaging and spectral measurements.

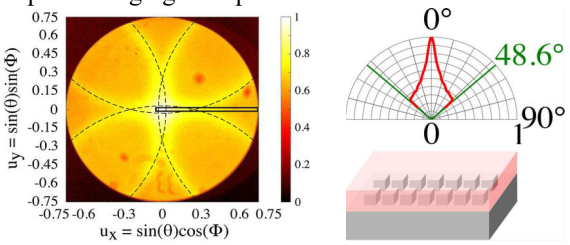

Fig. 1 Fourier plane imaging of a photoluminescent metasurface, consisting of quantum dots deposited on a silver metallic grating. [1]

III. Results and Discussion

We report the realization of directional photoluminescent metasurfaces with less than 20° FWHM emission cone, and above 60% absorptivity in the active medium. We will discuss how this approach combined with symmetry-protected bound states in the continuum (BICs) can be used to achieve other features such as the emission of circularly polarized light, and how the Kirchhoff's approach enables a quantitative modelling of energy efficiency, and how it can be related to usual figures of merit used in light source design such as light extraction efficiency, internal and external quantum efficiency.

IV. Conclusion

Directional, narrowband and polarized photoluminescent sources can be realized by coupling ensembles of incoherent emitters to a leaky mode of a metasurface. Radiation efficiency can be quantitatively modelled and optimized by maximizing absorptivity following a Kirchhoff's law approach. To maximize technological impact, this approach will be applied to design electroluminescent devices incorporating specific technological constraints.

***Abstract*— We theoretically model out-of-equilibrium nonlinear optical dynamics due to collision-driven nonlinearity in ultraviolet epsilon-near-zero materials, particularly sodium and aluminum, exploring their potential for the development of table-top extreme ultraviolet radiation sources and integrated spectroscopy schemes.**

***Keywords*—Epsilon-near-zero media, nonlinear optics, nanophotonics.**

I. Introduction

Nonlinear (NL) radiation-matter interactions give rise to many physical phenomena particularly relevant to quantum mechanical processes, and offer a promising platform to devise compact ultraviolet (UV) radiation sources. Harmonic generation (HG) is one of the main nonlinear effects amplified by photonic materials with low dielectric permittivity, known as epsilon near zero (ENZ) materials.

ENZ materials, thanks to their natural ability to bypass phase-matching, enhance NL radiation-matter interactions and play a crucial role for advanced NL phenomena, e.g., optical switching. Currently, ENZ media are adopted to enhance NL optical effects, particularly in the near-infrared part of the spectrum, where doped semiconductors, oxides, and nitrides display ENZ behavior. Poor materials show marked ENZ features in the UV that are promising for resonant third-harmonic generation (THG) in heterogeneous nanostructures, and for manipulation and guidance of UV radiation.

II. Methods

Here, we investigate the potential of nanostructures based on sodium (Na), aluminum (Al), and sodium-aluminum (Na-Al) heterostructures for NL applications [1-4]. We study the THG due to the out-of-equilibrium (OOE) electron dynamics. In turn, to model NL electron dynamics in the heterogeneous nanostructures we consider the Fokker-Planck-Landau (FPL) theoretical framework. We analytically calculate the Landau collisional integral in the weak coupling limit [5], obtaining a set of hydrodynamical equations (HDEs). By solving perturbatively HDEs, we derive an analytical expression for the dependence of the collision-driven THG NL-susceptibility over the pump field angular frequency. Moreover, to obtain the pump field distribution within the heterogeneous nanostructures, we use the undepleted pump approximation, modeling the THG radiation process accounting for multiple reflections of forward (FW) and backward (BW) waves.

III. Results and Discussion

Due to the coupling of the pump field enhancement and the radiation of the microscopic dipoles, the THG process exhibits a double resonance for transverse magnetic (TM) pump excitation at due to dipolar emission in an ENZ environment. Conversely, for transverse electric (TE) pump excitation we observe THG enhancement due to the excitation of Fabry-Perot resonances of the considered nanostructures. Finally, we find that for specifically incidence angle conditions it is possible to excite surface plasmon polaritons (SPPs) at the Na-Al interface thanks to attenuated total internal reflection (ATIR). This enables to attain a THG enhancement factor of 7 orders to magnitude as compared to non-resonant conditions, thus suggesting that ENZ heterogeneous nanostructures offer a promising platform for the development of integrated XUV sources.

IV. Conclusion

In conclusion, we observe that ENZ nanostructures constitute a promising platform to attain efficient THG in the UV spectral domain. Both Na and Al are promising ENZ media undergoing mitigated absorption. In addition, thanks to the broadband ENZ behavior of Na, we observe that SPPs can get excited at Na-Al interfaces, contributing to the maximization of THG efficiency. Our results indicate that Al/Na ENZ nanostructures are promising for integrated nonlinear conversion platforms.

***Abstract*—We demonstrate metal-dielectric-metal reflective metasurfaces for high-performance broadband THz quarter-wave plates. Four complementary designs operating at 45 degree incidence collectively span 0.25–3 THz. Each device provides near-octave bandwidth with axial ratio below 3-dB and polarization conversion efficiency above 80%. Experiments agree with simulations, confirming scalable broadband THz polarization control.**

***Keywords*— metasurfaces, terahertz, circular polarization, quarter-wave plates.**

I. Introduction

Circularly polarized terahertz (THz) radiation is indispensable for a wide range of applications, including chiral spectroscopy and molecular identification, all-optical manipulation of magnetization without external magnetic fields, and the selective probing or excitation of spin waves (magnons) and chiral phonons. These applications motivate the development of high-performance linear-to-circular polarization converters (i.e., quarter-wave plates) in the THz regime, particularly because most coherent THz sources emit linearly polarized radiation. Conventional narrowband quarter-wave plates can be realized using low-loss birefringent materials such as quartz and liquid crystals, as well as artificially engineered anisotropic effective media exhibiting form birefringence, for example, subwavelength silicon gratings [1]. A strategy widely used in the optical regime and extendable to broadband THz frequencies involves stacking multiple plates with carefully selected thicknesses and relative orientations to compensate for wavelength-dependent phase retardation, thereby forming achromatic THz wave plates [2]. Prism-based polarization elements, such as Fresnel rhombs [3], can provide truly achromatic THz quarter-wave retardation by generating polarization phase delay through total internal reflection rather than material birefringence. Nevertheless, these achromatic THz devices remain physically large and are not readily compatible with compact or integrated THz systems.

II. Results and Discussion

In this work, we present a set of reflective metal-dielectric-metal metasurfaces [4], [5] that function as quarter-wave plates and collectively span the entire THz frequency range accessible to a typical THz time-domain spectroscopy system (0.2–3 THz). Broadband spectral coverage is achieved using four complementary devices, each designed to operate within a specific subband of this range (see Fig. 1). The metal-dielectric-metal metasurfaces function as single-port cavity resonators in which reflective Fabry-Pérot resonances [6] operate in the over-coupled regime. By carefully tailoring the geometric parameters of the anisotropic subwavelength elements and the thickness of the dielectric spacer, we achieve a nearly constant relative phase delay of $\pi/2$ (or $3\pi/2$) over a broad spectral range while maintaining near-unity reflectivity for both orthogonal polarization components. We design these metasurface structures using full-wave electromagnetic simulations to target four distinct frequency windows of interest. The four devices are fabricated using standard photolithography and characterized using THz time-domain spectroscopy. Under 45° incidence and linearly polarized at 45° with respect to the plane of incidence, the results show that the incident THz waves have been converted to left-handed circular polarization, with a high conversion efficiency mostly exceeding 80%, covering an octave bandwidth for each device, and collectively spanning the 0.25–3 THz with four devices, as represented by the ≤ 3 dB axial ratio shown in Fig. 1. The experimental results show excellent agreement with numerical simulations, which also allow further structural optimization through additional simulations. This work demonstrates robust broadband reflective THz quarter-wave plates, enabling advanced THz polarimetric applications and circularly polarized THz light–matter interactions in systems such as biomolecules, chiral phonons, and magnetic materials, as well as potential applications in THz communications and imaging.

III. Conclusion

In conclusion, we have demonstrated high-performance broadband THz quarter-wave plates based on over-coupled metal-dielectric-metal reflective metasurfaces. By harnessing the phase dispersion associated with anisotropic over-coupled Fabry-Pérot cavity resonances and precisely engineering the relative phase delay between orthogonal field components, we achieve efficient linear-to-circular polarization conversion over a broad THz spectral range. Four complementary metasurface designs collectively span the 0.25–3 THz frequency range accessible to a typical THz time-domain spectroscopy system, with each device providing an approximately octave-wide

Building Uncooled Infrared Camera based on One Atom Thick Graphene

Debashis Chanda

NanoScience Technology Center, Department of Physics, CREOL-College of Optics and Photonics
University of Central Florida

Abstract: The talk will outline a novel strategy for uncooled, tunable, multispectral infrared detection. Due to the low photon energy, detection of infrared photons is challenging at room temperature. One atom thick graphene offers an alternative mechanism bypassing material bandgap restriction. Further, the ability of carrier concentration modulation on graphene via external voltage offers dynamic spectral selectivity for "color" night vision/sensing. The performance of preliminary demonstration compares favorably even with present cryogenically cooled detection schemes paving the path for commercial development of many applications from space exploration to healthcare.

Dynamic Surface-Lattice Resonance Metasurface for Time-Varying Photonics

***Abstract*— We realize and study the nonlinear response of a surface-lattice-resonance structure coupled to a TCO, illustrating a 30x reduction in saturation irradiance and the presence of spectral fringes of positive/negative extinction due to time varying effects.**

***Keywords*— Epsilon-near-zero, surface-lattice-resonance, nonlinear optics, time-varying photonics, metamaterials.**

I. Introduction

Time-varying processes in optical materials offer a host of unique interactions such as analog frequency control, photon trapping, sonoluminescence, non-reciprocity, and new methods of photon pair generation [1]. Despite the longstanding theoretical and experimental history studying these effects [2], a limitation has generally been the impracticality to make physical objects move an appreciable fraction of the speed of light. Early works worked toward this through the generation of plasma bubbles where the rapidly expanding plasma volume served as a moving media [1]. More recently, efforts have centered on the concept of synthetic motion which simulates physical motion and its interaction with photon velocity through the analogy between velocity and refractive index (or group index) [1,3]. This has relaxed physical constraints of the moving media, but benefits from strong and temporally fast modification of the refractive index in the media. While early works in silicon platforms counteracted this with long interaction lengths [4], the recent demonstration of nonlinearities in transparent conducting oxides (TCOs) in their epsilon-near-zero (ENZ) regime has provided a new platform where the index (and velocity) can be modified on the scale of 100% and greater [5]. This has led to the demonstration of several time-varying effects including adiabatic frequency shifting and temporal interference, while predictions suggest many more exotic phenomena are on the horizon.

Despite the advantage of TCOs in the ENZ regime, a limitation is that they require substantial irradiance levels on the scale of 0.1 – 1 TW/cm^2. Here, we seek to address this by combining an ENZ layer with an open cavity system in the form of a surface lattice resonance (SLR) structure. We show that this structure can radically reduce the required irradiance while still exhibiting time-varying interactions in the form of negative extinction bands. We develop a model for the system combining temporal coupled-mode theory and our theory of kinetic fast-slow nonlinearities in ENZ materials [5].

II. Methods

Our TCO-SLR samples were fabricated by depositing a thin film of W:In_2O_3 (IWO) on glass substrates. IWO was used due to its improved mobility (~80 cm^2/V-s) and therefore lower optical loss compared to common TCO materials ITO, AZO, and GZO (~30 cm^2/V-s) for carrier densities in the range of 10^{20} cm^{-3}.

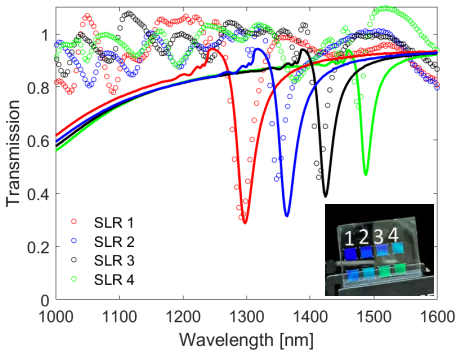

Fig. 1 Linear transmission of TCO-SLR structure. (Inset) Optical image of the TCO-SLR samples.

Following, a liftoff procedure and was used to patter an array of gold nano antennas on top of the IWO layer. The periodicity was tuned across four structures to shift the SLR resonance from ~1300 nm to ~1500 nm. The Q-factor of the SLR was intentionally kept low to match the bandwidth of the excitation beam. The sample was first characterized by linear transmission spectroscopy using a coherent supercontinuum white light

source, see Fig. 1. Subsequently, the nonlinear response of the system was studied using an excite-probe style setup (~60 fs pulses FWHM) where a strong driving pulse on resonance with the SLR was used to excite the system while a broadband supercontinuum probe, delayed from the excitation, was used to observe the spectral response and temporal response of the system. The response of the system was modeled through a three-step combination of finite element method, kinetic fast-slow-nonlinearities, and coupled mode theory techniques (CMT). Ultimately this process allows us to predict the temporal trajectory of the SLR resonance through the excitation and relaxation of the TCO layer. This is then modeled as a time-varying center frequency and damping factor of the cavity resonance in CMT.

III. Results and Discussion

Excite-probe experiments with a single beam on resonance with the SLR illustrate the introduction of the SLR reduces the saturation irradiance to 3 [GW/cm^2], Fig. 2, compared to 100's [GW/cm^2] [6,7] from literature for TCO films at ENZ - a reduction of more than 30x. Spectrally resolved measurements detail a strong nonlinearity, predominantly arising from a red shift of the center frequency of the SLR resonance. This matches phenomenological and numerical predictions wherein the excitation beam excites the intraband nonlinearity of the IWO film, resulting in an increase in the permittivity of the IWO. Of note, however, is the appearance of spectral fringes with negative extinction ratio which arise at and before time zero – when the excite and probe arrive at the sample simultaneously. These fringes were noted for excitation irradiance levels down to 2 [GW/cm^2]. Such effects have been noted in other systems including Mie resonance metasurfaces [8] and ENZ films [9]. To model this interaction, a CMT approach was used to describe the probe beam interaction with the time varying SLR resonance [8]. This was modeled as a dynamic center frequency for the SLR, whose temporal shape was matched to that of the change in linear transmission and magnitude obtained from finite element and kinetic fast slow nonlinear modeling. The result of the simulation effort is shown in Fig. 2, obtaining a good match to experimental results including the appearance of spectral fringes.

IV. Conclusion

Our efforts have demonstrated a moderate-Q SLR structure coupled to a highly nonlinear TCO material where the inherent nonlinearity of the TCO is employed to dynamically tune the resonance of the structure. The result achieved significant reduction in the irradiance necessary to reach saturation of the change in transmission as well as the introduction of negative extinction bands arising from the interaction of the probe beam with a time varying resonant structure. The work demonstrates a new platform to investigate time-varying interactions at significantly lower incident irradiance levels that is compatible with various platforms such as fiber optics.

***Abstract*— We have developed an additive, roll-to-roll printing method for large-area metamaterial fabrication, based on a combination of nanoimprint lithography and ink delivery, which selectively infills the patterned features. We use this method to pattern light emitters, including anisotropic quantum dots, and study the polarization state of the photoluminescence.**

***Keywords*— metamaterials, nanofabrication, quantum dots**

I. Introduction

One of the central challenges facing metamaterials is the need for large-area fabrication methods with excellent control over both nanostructure shape and spacing, that also works for a diverse set of materials. While nanoimprint lithography replicates patterns well at large areas, transferring these patterns into functional materials often requires subtractive processing steps. Here we show a versatile method that combines templating and additive ink filling, produce m^2 metamaterials from a variety of different ink materials.

II. Methods

Our method uses two roll-to-roll lines. The first is roll-to-roll nanoimprint lithography, where the original lithographic pattern is translated to a stamp and imprinted into a UV-curable resin. After imprinting, the patterned resin is heated in an oven, which reduces the surface energy of the template. A second roll-to-roll line is used for ink delivery; a dispersion of ink coated onto the patterned template selectively infills the features.

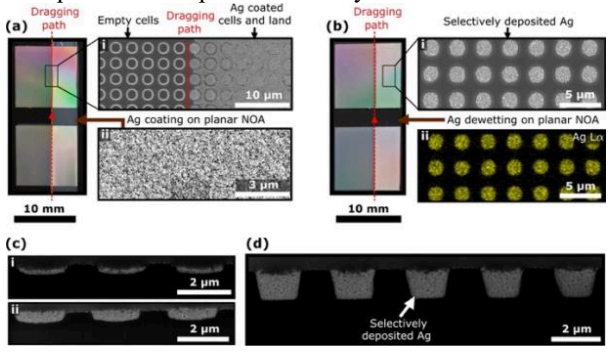

Fig. 1 (a,b) Patterning ink on a non-heat treated template (a) does not result in selective wetting, whereas patterning on a heat-treated substrate (b) facilitates topographic discontinuous dewetting.(c,d) Cross section views of infilled and cured ink into templates.

III. Results and Discussion

Our process is designed to utilize topographic discontinuous dewetting [1,2], where the coating speed and properties of the ink dispersion are tuned on a low energy substrate to enable selective infilling. We show that this process is highly versatile and works with metallic inks (both particle based and particle free), titanium dioxide, polymer blends, and semiconductor nanocrystals, provided the ink and coating conditions are correctly adapted.

To demonstrate the functionality of this system, we created metamaterials comprised of light emitters, including II-VI quantum dots, perovskite quantum dots, and nanocrystals with anisotropic shapes, materials that are challenging to pattern via other routes. We will discuss the directionality, polarization state, absorption, and photoluminescence of these patterned structures, and how the pattern can be used to manipulate the optical response.

IV. Conclusion

We have demonstrated a versatile nanofabrication process that creates large-area metamaterials based on a combination of nanoimprint lithography and additive ink infilling. This method works for a variety of ink materials. We then discuss the use of this method for directing and shaping luminescence from patterned quantum dots, including anisotropic particles.

***Abstract*—Highly precise measurement on moving objects remains challenging, yet crucial for e-mobility, robotics, and related fields. In our work, we utilize resonant metasurfaces for telemetric torque sensing. We show that tunable dual-layer metasurfaces supporting (quasi-) bound states in the continuum offer unprecedented access to motion parameters, essential for developing robust next-generation sensors.**

***Keywords*— metamaterials.**

I. Introduction

Metamaterials have proven to be a powerful approach in the field of sensor technology [1]. Recent research has shown that tuning near-field interactions in metamaterials provides access to the detection of mechanical perturbations and deformations that are orders of magnitude smaller than their unit cell [2]. In our recent work, we exploited the electromagnetic resonance mode of millimeter-wave metasurfaces to conceptualize novel sensor systems [3], [4], [5], [6]. A central topic is metamaterial-based torque sensing. The schematic view of the sensor concept is shown in fig. 1. A picture of the test bench set up is shown in fig. 2. The metamaterial comprises two near-field-coupled metasurfaces (orange in fig. 1) distributed across two disks (green in fig. 1), each fixed separately to the rotating shaft (blue in fig. 1). Torque causes a minute twist on the shaft. Due to the separate attachment of the discs, this twist leads to a displacement of the metasurfaces that ultimately tunes the electromagnetic resonant behavior. This tuning is detectable in reflection using a mm-wave radar chip. We showed that modified Doppler radar and frequency-modulated continuous-wave (FMCW) chips are both applicable to this concept, using broadside-coupled split-ring resonators (BCSRRs) that exhibit a tunable dipole-like resonance [3], [4]. In this work, we aim to advance this sensor concept using metasurfaces supporting bound states in the continuum.

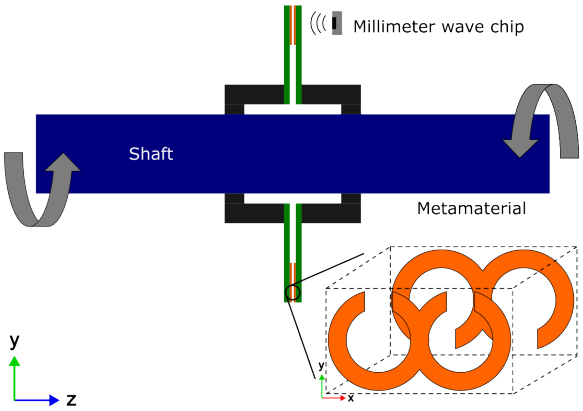

Fig. 1. Sectional view of the torques sensor system for measurement on a shaft

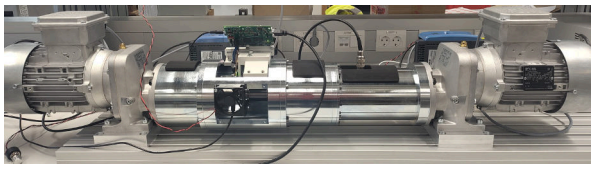

Fig. 2. Picture of the torque test bench used for the study of metamaterial-based torque sensing

II. Bound states in the continuum for torque sensing

Metasurfaces may exhibit a plethora of different resonances depending on their geometry, arrangement, and environment. A special class of metasurface resonances, particularly interesting for sensing applications, are (quasi-) bound states in the continuum (BIC). A BIC, in theory, has an infinite quality factor. However, it cannot be excited by external fields due to symmetry. When breaking the symmetry of a BIC system, for example, by introducing a minor deformation, it turns into a quasi-bound state with a finite yet extraordinarily high quality factor that can be excited from the far-field. In our sensor concept, we exploit the minute torque-induced displacement between the metasurface layers to break symmetry, thereby enabling the excitation of quasi-BICs.

III. Numerical results

The unit cell of the dual-layer metasurface supporting quasi-BICs is shown in the inset of fig. 1. It is arranged in circular arrays on the two discs such that a twist between the discs causes a transverse shift in the x-direction locally in the unit cell. We studied the resonant behavior as a function of this shift with the finite element method using COMSOL Multiphysics®. We built a 3D model of the unit cell, modeling

the conductive structures as 2D boundaries with copper's finite conductivity. The substrates were modeled using the same dielectric-layer setup as in our previous work, which is suitable for manufacturing. The Eigenfrequency analysis shows a BIC-like resonant mode at 60.6 GHz. Figure 3 shows the fields in the top plane of the unit cell, with the surface current density depicted as black arrows, the electric field as red arrows, and the absolute value of the electromagnetic field amplitude displayed in color. The result shows two counter-rotating circular currents in the split rings and two opposing electric dipoles in the gaps. The bottom plane shows the same fields, with the circular currents oriented the same way (not depicted in fig. 3). Therewith, the structure has opposing electric and magnetic dipoles that cancel each other in the far field. Thus, this mode cannot be excited by external fields, such as impinging plane waves. The torque-induced shift in the x-direction between the top and bottom planes of the unit cell breaks the symmetry of a rotation by 180° along the x-axis through the center of the unit cell. This gives small net dipole components in the x-y plane that provide a coupling channel to the far field, turning the metasurface resonance into a quasi-BIC. We analyzed this behavior by calculating scattering parameters for plane waves polarized in the x-direction. Figure 4 shows the calculated spectra of the reflection scattering parameters S_{11}. The curve for zero shift (blue in fig. 4) does not show a minimum at frequencies around 60.6 GHz. The curves for shifts other than zero exhibit distinct minima. The results in fig. 4 show the quasi-BIC behavior of the dual-layer metasurface: In the symmetric configuration, the impinging plane wave does not excite the resonance, but when breaking the symmetry, the resonance is excited by the external field. The results of the Eigenfrequency study for increasing transverse shift values are shown in table I. For the zero-shift case, the Quality factor is finite because our model includes dielectric losses in the substrates and the finite conductivity of copper. The data show that the Quality factor gradually decreases with increasing transverse shift. This is a pivotal feature of this quasi-BIC metasurface. State-of-the-art mm-wave radar chips are not built to track a resonance minimum. However, they are well-suited for detecting changes in the reflected power from a target. The quasi-BIC metasurface enables translating the torque-induced resonance shift into a gradual decrease in reflected power over a narrow bandwidth, thereby paving the way for torque detection with low-cost radar chip technology.

I. Introduction

High power and energy lasers (HPL) are becoming transformative to future technology, which encourages rapid development of its optics. Some potential applications include fusion-based clean energy, compact particle sources for medical and civil engineering, directed energy and basic science. These HPL systems, such as the National Ignition Facility (NIF), require optics with large apertures, high throughput and high durability. Conventional approaches, including multilayer dielectric coatings and bulk optical components, face significant challenges in susceptibility to laser-induced damage, optical performance and thickness. All-glass metasurfaces offer a promising alternative, provided a viable path for aperture size scale up, transmission enhancement close to unity, enhancement of laser-induced damage durability, and for some applications enabled operation at shorter wavelengths (e.g., NIF final optics are about 40 cm x 40 cm and operate at above 10 J/cm^2 of few nanoseconds laser pulse-length at 351 nm wavelength). We present here a specialized metasurface approach that is intended to provide a potential path to address these challenges. These metasurfaces are etch-engraved onto fused silica glass thus preserving the inherent robustness of fused silica. We present here implementation of several key laser optics components: broadband antireflection (AR) layer, thin optical elements (e.g., lens), and birefringent waveplates. We will discuss in this talk the manufacturing approach, the demonstrated components, and the challenges that still lay ahead.

II. Discussion

The baseline metasurface fabrication process utilizes a sacrificial metal nanoparticle (NP) mask created by thermal dewetting of a thin metal film on fused silica, followed by directional etching and mask removal to yield an all-glass nano-structured surface [1]. Thin layers of metal (e.g., Au or Pt) are deposited and dewetted either in a furnace (for uniform AR layers) or by raster-scanned continuous-wave laser (to spatially vary the mask patterning for optical elements implementation). The self-organized nanoparticle (NP) distribution determines the local fill fraction (FF) and period, which in turn set the effective refractive index of the metasurface layer after reactive ion etching (RIE) or reactive ion beam etching (RIBE). The self-generation-based approach for patterning the etching mask NP, where the properties of the NP being controlled by macroscopic properties (such as laser intensity or furnace temperature) set a path for aperture size scale-up, and for access to shorter wavelengths [1,2].

A key limitation to achieve a broad band AR metasurface layer on optical windows with this approach is the erosion of the NP mask during etching. This has previously constrained feature height and thus the AR bandwidth, and was overcome by improving mask materials and processes: Pt was found to have significantly higher etch resistance than Au, and a “seeded dewetting” approach was developed in which repeated deposition and dewetting steps grow NP height and FF while preserving a small period set in the first dewetting cycle [3]. These advancements increase metasurface depth and shape control, enabling ultra-high aspect ratio features and much wider AR bandwidth. Using these improved masks, AR metasurface have been demonstrated that surpass commercial broadband dielectric coatings, including configurations with very low reflection from the UV to the near infrared over large angles of incidence and at both polarizations [4]. Furthermore, these improvements expand the design space and control over the NP shape (e.g., cones, cylinders, flat-top cones, and their depth), providing an ability to optimize simultaneously the optical and physical properties (e.g., mechanical robustness) [3].

The same nanoparticle-based process can be adapted to fabricate metasurface lenses by spatially varying the effective index through laser-controlled dewetting [1]. Raster scanning a CW laser across the metal film with varying power tunes the

local dewetting temperature and hence the NP FF [5]. This "light-printing" approach has been used to realize mm-scale diameter optical elements with negligible reflectivity [6].

To address polarization control needs, the baseline process was modified to produce birefringent all-glass metasurfaces by breaking the in-plane symmetry of the nano-features [7]. For one of the demonstrated approaches, after NP mask formation, the etch is performed at an angle using RIBE, yielding tilted pillar structures whose effective index differs for orthogonal in-plane polarizations. Optical birefringence and controlling physical properties such as water repellency is demonstrated. Other approaches to generating all-glass metasurface waveplates will be discussed. Such robust, UV-compatible waveplates are particularly relevant for systems like NIF, where conversion to circular polarization near the final optics could increase filamentation damage thresholds.

Beyond their targeted optical functions, these all-glass metasurfaces exhibit favorable laser damage and mechanical behavior. Laser-induced damage testing shows comparable behavior to damage treated fused silica glass windows. Mechanical tests, including sonication, drag wiping, fingerprinting, and controlled indentation, show high robustness.

III. Conclusion

A self-generated-based nanoparticle-mask-based process for fabricating all-glass metasurfaces has been demonstrated and refined to meet the stringent requirements of high power and energy laser systems. The process steps of thin metal film deposition, dewetting and directional etching, can be potentially applied using equipment compatible with meter-class optics which could pave a path to large-area all-glass metasurfaces with sub-wavelength features. Enhancements such as seeded dewetting, optimized mask materials, and tailored etch chemistries enable deep, high aspect ratio structures and precise shape control. On this foundation, three key classes of optical functions have been realized: ultra-broadband, large-angle antireflective layers; thin, freeform optical elements generated by laser "light-printing" of spatially varying effective index; and birefringent metasurfaces in fused-silica glass that provide a pathway to robust waveplates. Progress as well as the remaining gaps will be discussed.

Harnessing Epsilon-Near-Zero Effects: Fiber Lasers, Thermo-Optic Dynamics, and Beyond

Qian Li*,†

School of Electronic and Computer Engineering, Peking University, Shenzhen 518055, China
* liqian@pkusz.edu.cn

Abstract—Epsilon-near-zero ENZ materials, with their vanishing permittivity, have emerged as a compelling platform for nanophotonics and nonlinear optics due to extreme field enhancement, phase engineering capabilities, and compatibility with complementary metal-oxide-semiconductor technology. Based on these unique features and great performance, ENZ materials can play a significant role in optical communication, data processing and laser technology. Here, a comprehensive overview of ENZ photonics is presented, revealing its fundamental principles and highlighting our research endeavors. Specifically, we show how ENZ elements can be integrated into complex photonic systems through the demonstration of a fiber laser cavity incorporating indium tin oxide nanolayers. The intra-cavity ENZ component introduces frequency-selective optical potential barriers that fundamentally reshape the mode-locking dynamics, enabling wavelength reselection and spectral redistribution through gain competition. This cavity configuration exhibits behavior analogous to radio-frequency superconducting quantum interference devices (RF-SQUID), illustrating how ENZ photonics can bridge optical phenomena with concepts from other physical domains. What's more, while substantial progress has been made in understanding their linear and Kerr nonlinear properties, the role of temperature in governing ENZ behavior has remained largely unexplored despite its critical importance for integrated photonic systems where heat generation is unavoidable. Here we present a comprehensive investigation of thermo-optic ENZ effects in indium tin oxide nanolayers, revealing that temperature systematically tunes the ENZ frequency across telecommunication bands with modulation rates reaching several gigahertz per kelvin. We demonstrate that the thermo-optic coefficient experiences an unprecedented enhancement of nearly an order of magnitude within the ENZ regime compared to conventional indium tin oxide, accompanied by fast-varying group velocity dispersion up to four orders of magnitude larger than typical optical materials. Remarkably, the thermo-optic nonlinearity exhibits enhancements exceeding 2800 percent, comparable to the renowned ENZ-enhanced Kerr nonlinearity, with an ultrafast pulse-width threshold in the femtosecond to picosecond range where thermal nonlinearities remain dominant. These findings establish that thermo-optic effects represent not merely a perturbation but rather an intrinsic and engineerable dimension of ENZ photonics. The insights provide practical design references for integrated photonic circuits where thermal management is essential, while opening new directions for ultrafast modulation, optical computing, and photonic information processing in next-generation integrated systems.

Optical microscopy remains a cornerstone of biological research, offering indispensable insights into complex cellular processes. Recently, the strategic implementation of structured light has become pivotal in surmounting the diffraction limit and enhancing resolution. Simultaneously, the emergence of metasurfaces—engineered nanostructures capable of precise light manipulation—has revolutionized the field by enabling ultra-compact, high-performance optical functionalities.

This talk showcases recent breakthroughs in structured light and meta-optical systems for biomedical applications. We explore the development of quantitative cell imaging and high-speed optical sectioning, with a focus on integrating metalenses into light-sheet fluorescence microscopy (LSFM) for enhanced deep-tissue observation. Additionally, we discuss the synergy between flat optics and computational imaging—specifically spatially variant aberration correction—as a powerful strategy for achieving exceptional image fidelity. By merging meta-optical design with advanced computational frameworks, this presentation illustrates a transformative frontier for next-generation biomedical diagnostics.

***Abstract*—This talk explores nonlocal meta-optics to bypass traditional imaging size constraints. By engineering momentum-space (k-space), the researchers decoupled system thickness from resolution, achieved label-free super-resolution, and enabled high-dimensional sensing. These advancements pave the way for ultra-compact, wafer-scale photonic systems for 3D vision and metrology.**

***Keywords*— nonlocal, meta-optics, imaging, diffraction limit.**

Conventional imaging is governed by scaling laws where information capacity is coupled to physical dimensions. This talk will discuss an alternative approach using nonlocal meta-optics to address these constraints via momentum-space (k-space) engineering. First, we will revisit the fundamental thickness bound of an imaging system ($TTL_{min} = N\lambda_0/(4n_{max})$). Using high-Q nonlocal dielectric thin films, we show how system thickness can be decoupled from resolvable pixel count, enabling imaging within micron-scale form factors. Second, we present a nonlocal metalens for far-field label-free super-resolution based on an effect we term " k-space superoscillation", which aims to suppress parasitic sidebands and improve efficiency relative to real-space methods. Finally, we discuss applications in high-dimensional sensing, including monocular 3D vision and complex-amplitude reconstruction. These results suggest potential pathways toward integrated, wafer-scale meta-photonic systems for machine perception and metrology.

Nanophotonic Devices and Metasurfaces using High Mobility Transparent Conductive Oxides

Sudipta Biswas[1], Saika Muntaha Bari[2], Sandra Achieng[2], and Alan X. Wang[1,2,*]

[1]Department of Electrical and Computer Engineering, Baylor University, USA

***Abstract*— High mobility transparent conductive oxides (HMTCOs) offer exclusive advantages compared with traditional indium-tin oxide in terms of lower optical loss, stronger plasma dispersion and more prominent epsilon-near-zero effect. We demonstrate high performance nanophotonic microring resonator modulators and metasurface-based optical filters gated by hydrogen-doped indium oxide with mobility above 100 cm²/V-s.**

***Keywords*— metasurface, nanophotonic devices, microring modulators, epsilon-near-zero.**

I. Introduction

Transparent conductive oxides (TCOs) are known for their tunable optical and electrical properties, which enable advanced nanophotonic devices and metasurfaces, especially for Epsilon-near-zero (ENZ) photonics [1-2]. In the near-infrared (NIR) wavelength range, these highly doped oxide semiconductors experience a transition in the real part of their permittivity from positive to negative values and enable highly efficient electro-optic modulation. High-mobility TCO materials such as titanium-doped indium oxide (ITiO), compared with traditional indium-tin oxide (ITO), offer lower optical absorption and even stronger electro-optic effects [3]. Hydrogen-doped indium oxide (IHO) is another type of high mobility TCO that can be deposited at room temperature following a post annealing process. This refined crystalline minimizes grain boundary defects, which boosts carrier mobility and lowers electrical resistivity. We demonstrated high optical mobility polycrystalline IHO by RF-sputtering [4], which exhibits low optical loss in the NIR wavelength range. Compared with commercial ITO with a measured optical mobility of μ_opt=43 cm²/V·s, IHO demonstrates much higher mobility of 111 cm²/V·s, lower effective mass and moderate carrier density, all of which contribute to higher E-O modulation and ENZ effect.

II. Methods

In this work, we demonstrate nanophotonic devices and Metasurface optical filters based on a metal-oxide-semiconductor capacitor (MOSCAP) structure with HMTCO as the gate layer. Especially, we fabricated a silicon microring resonator (Si-MRR) with high-mobility IHO thin film. The passive device was fabricated at Intel's photonics foundry on a silicon-on-insulator (SOI) wafer with p-type doping. The silicon microring has a 300 nm-wide waveguide, chosen to enhance electro-optic efficiency. In the active region, a 10 nm HfO_2 gate dielectric was deposited using atomic layer deposition (ALD), followed by a 14 nm IHO gate layer deposited by RF sputtering and patterned through lift-off using electron-beam lithography (EBL). Ni/Au electrodes were fabricated by a combination of EBL and photolithography, followed by thermal evaporation and lift-off, providing Ohmic contacts to both the IHO and silicon layers. The device achieves extreme wavelength-tuning efficiency. In addition, we designed Metasurface optical filters with large wavelength tunability based on ENZ absorption.

III. Results and Discussion

Experimental results show:

- 175 pm/V E-O tuning efficiency
- A high Q-factor >10,000
- a $V\pi L$ of 0.09 V·cm
- ENZ wavelength tuning of optical filters across the C-band

IV. Conclusion

The demonstration confirms the potential of high-mobility IHO integration to enable highly efficient nanophotonic modulators and Metasurface optical filters and positions IHO as a promising TCO for next-generation low-power, high-speed photonic interconnects and space application.

Deciphering Chirality via Super-Resolution Near Field Chiral Absorption

Yang Zhao[1]

[1]Department of Electrical and Computer Engineering, Grainger College of Engineering, University of Illinois Urbana-Champaign, USA
*Corresponding author: yzhaoui@illinois.edu

***Abstract*—Recent advances in decoupled optical force microscopy instrumentation and signal decomposition will be discussed, highlighting improvements in measurement accuracy, the ability to resolve ultrafast thermomechanical dynamics, and enhanced spatial resolution beyond that achievable with conventional scanning probe techniques.**

***Keywords*— chirality, optical forces, photothermal, scanning probe microscopy.**

I. Introduction

Accurate temperature measurement at the nanoscale remains challenging due to rapid heat dissipation and limitations of existing thermometry techniques. While nanophotonics enables efficient light-to-heat conversion and localized thermal generation, conventional fluorescence-, Raman-, and far-field-based methods are constrained by calibration complexity, environmental sensitivity, and diffraction limits. Tip-based near-field approaches improve spatial resolution but often confound optical and photothermal effects. Here, we present a temperature quantification strategy based on decoupled optical force nanoscopy, which isolates photothermal forces and correlates them with thermally induced expansion. This platform establishes the theoretical sensitivity limits of nanoscale thermometry and enables polarization-dependent thermal analysis of chiral nanoparticles with sub-diffraction spatial resolution.

II. Methods

The decoupled optical force nanoscopy system integrates an inverted optical microscope with an atomic force microscope. A 637 nm laser was used for excitation and photothermal force measurements, with power modulation and polarization precisely controlled. The beam was focused on the back focal plane of the objective to provide wide-field illumination. AFM deflection signals were detected using lock-in amplification, and pixel-wise magnitude and phase were extracted through signal averaging. Trace and retrace signals were further averaged to minimize scanning artifacts and improve measurement reliability.

III. Results and Discussion

Figure 1 demonstrates the average photothermal force and the corresponding photothermal force maps within a chiral plasmonic nanoparticle and across the full field of view as functions of incident light intensity and polarization measured with the decoupled optical force nanoscopy. The lowest intensity (1.5×10^5 W/m^2) was used as the reference for calculating the power ratio. Figure 1(a) shows that the photothermal force within the left-handed (L-) chiral nanoparticle is higher under RCP illumination. At a power ratio of 20, the resulting contrast relative to the background is only ~2 pN, which is comparable to the noise level. In contrast, at a power ratio above 30, the measured forces yield a clear polarization-dependent difference of 10.6 pN, well above the background fluctuations, which is further corroborated by the photothermal force maps shown in Figure 1(b).

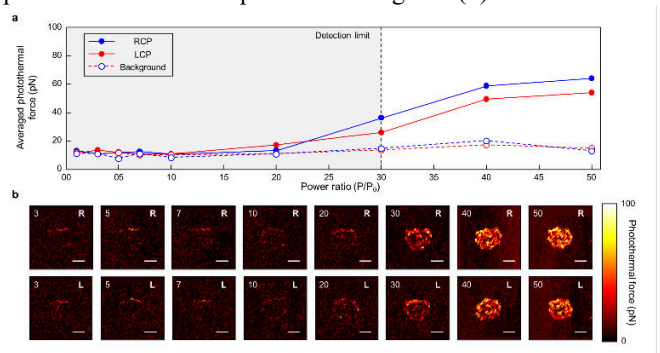

Fig. 1 Temperature mapping of chiral gold nanoparticles. (a) Average photothermal forces across one nanoparticle and background as a function of incident power. (b) Photothermal force maps at varying power ratios and circular polarizations (R/L). Scale bar: 200 nm [1].

***Abstract*— Spectral signatures from molecular ensembles in optical nanocavities are analyzed using a reaction-informed computational framework which integrates density functional theory-based Raman calculations and *ab initio* molecular dynamics. Observed vibrational spectra and simulated molecular trajectories resolve ligand dynamics in nanocavities; these systems can be used to decode signals from biological systems.**

***Keywords*— vibrational spectroscopy, *ab initio* molecular dynamics simulations, machine learning, opto-mechanics**

I. Introduction

Understanding light–matter interactions in optical nanocavities is critical for advancing plasmon-enhanced sensing, catalytic selectivity, and low-power photonic devices. Surface-enhanced Raman scattering (SERS) probes vibrational modes in confined systems yet resolving dynamic conformational behavior is challenging due to rapid time scales of molecular fluctuations and difficulty in defining nanogap chemistry. Here an integrated experimental–computational strategy provides a general framework for uncovering how nanoconfinement governs conformational dynamics and reaction pathways in chemically precise nanogaps. Experimental results further demonstrate that ensemble measurements of chemical reactions in these nanoconfined geometries can be decoded using *ab initio* molecular dynamics (AIMD) simulations and machine learning algorithms to understand biochemical network response of cellular systems for medical diagnostics [1] and environmental monitoring [2].

II. Methods

AIMD simulations sample thermally accessible ligand configurations within plasmonic nanogaps. Feedback between density functional theory (DFT) simulations of AIMD predicted structures and SERS spectra of chemical reactants and products in nanogaps is used to understand how confinement affects reactivity and molecular motion. Cosine-CaPSim similarity metrics evaluate the agreement between experimental DFT-calculated spectra.

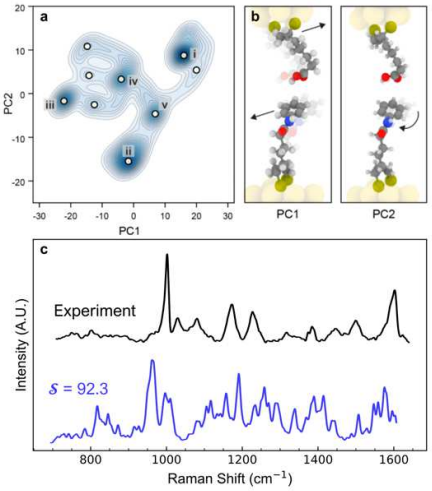

Fig. 1 (a) Two-dimensional conformational probability distributions, projected onto (b) PC1 and PC2 for nanoconfined chemical reactant. SERS experimental spectra compared to DFT simulations of AIMD predicted structures

III. Results and Discussion

Experimental results show:

- Plasmonic nanocavities reshape free-energy landscapes through steric and electrostatic interactions [3], modulating the stability of reaction intermediates and their kinetics.
- Vibrational spectra measure weighted average of high probability conformations.
- Reproducible spectra from complex systems can then be decoded to understand mechanistic chemical processes.

IV. Conclusion

A generalizable framework for elucidating molecular conformation and chemical reactions in optical nanocavities has been developed to improve our ability to design a variety of optically active and passive devices.

Unconventional Semiconductors for Switchable Photonics

Marina S. Leite[1,*]

[1]Department of Materials Science and Engineering, University of California Davis, USA
*Corresponding author: mleite@ucdavis.edu

***Abstract*— We demonstrate reversible and multi-state changes in mid-infrared (MIR) transmission of inorganic halide perovskites with opposite polarity under light and heat. This opposite response results from a polaron-like lattice distortion under illumination (reducing transmission), and from the material's negative thermo-optic coefficient combined with lattice expansion from heat (increasing transmission).**

***Keywords*— switchability, halide perovskites, in situ characterization.**

I. Introduction

To date, the search for switching devices functioning in the mid-infrared (MIR) region of the electromagnetic spectrum has relied on phase-change materials. Yet, these devices usually necessitate >130 mW powered laser pulses for switching in 50 nm thick films, besides being limited to two states while presenting losses in the insulating one. Other platforms have been shown with inducing changes in material composition through metal hydrogenation metal-to-insulator temperature-dependent transitions such as in VO_2, bias-induced switching in vacancy-enriched MoS_2, polymer-dispersed liquid crystals, and mechanically strained metamaterials. However, these approaches are limited to the visible and near infrared (NIR) spectra and PCM's often degrade over several thousand cycles. Thus, there is an urgent need for the identification of materials that can enable hysteresis-free, and multi-state switchability.

II. Results and Discussion

We measure the changes in the optical transmission of bulk $CsPbBr_3$ single crystals under two different stimuli of equivalent energy [1]. First, we detect an increase in the MIR transmission ΔT of ~10% at 20 μm when the sample is heated to 80 °C. For optical visible-pump-MIR-probe measurements, we measure ΔT of the same magnitude when the crystal is excited with above-bandgap excitation (532 nm, 40 mW) at room temperature. Surprisingly, the MIR transmission in this condition shows opposite polarity. The reflectivity of the crystal remains unchanged under the same illumination conditions. The two stimuli (light and heat) embody comparable energies under the assumption that all incident photon energy (532 nm, 40 mW) is converted to thermal energy in the HP. Here, the sample is heated up to 80 °C. We note that the two stimuli, light and heat, provoke antithetical responses from the perovskite crystal suggesting that dissimilar mechanisms rule in each configuration. To confirm whether the two outcomes have conflicting or paired contributions, we perform the same optical pump-probe measurements at 80 °C and uncover that $|\Delta T|$ under illumination at 80 °C is equal to that at room temperature. Thus, the two mechanisms are independent of each other; yet the optical responses from each stimulus could effectually cancel each other. Thus, we rule out any competing influences on ΔT from laser heating and concentrate on the light and heat-induced changes independently. Our optical characterization is corroborated by in situ X-ray diffraction measurements [2].

III. Conclusion

We presented single crystal halide perovskites, a soft-lattice semiconductor material, as a promising candidate for switchable photonics in the MIR. Using above-bandgap laser illumination and heating, we detected reversible changes in transmission >10% with contrary polarities. Our findings are a consequence of the photo-induced structural distortions of the material's lattice (leading to reduced transmission), and the large thermal expansion coefficient and negative thermo-optic coefficient at elevated temperatures – which enhances transparency. These results establish halide perovskites as an alternative platform for reconfigurable photonics.

Can Nanostructures and Metasurfaces Affect the Casimir Force?

Jeremy N. Munday[1,*]

[1]Department of Electrical and Computer Engineering, University of California, Davis USA
*Corresponding author: jnmunday@ucdavis.edu

***Abstract*— The Casimir force arises from quantum electromagnetic fluctuations and depends on the broadband optical response of interacting materials. This talk examines whether nanostructures—often designed for narrowband optical control—can meaningfully modify Casimir interactions. Experiments with engineered nanostructures illustrate how geometry and broadband electromagnetic response jointly determine fluctuation-induced forces.**

***Keywords*— Casimir effect, Casimir force, quantum fluctuations, zero-point energy, metamaterials, metasurfaces, nanostructures.**

I. Introduction

The Casimir force arises from quantum and thermal fluctuations of the electromagnetic field and becomes significant at sub-micrometer separations. Within Lifshitz theory, this interaction depends on the dielectric response of the interacting materials across a broad frequency range, spanning static fields through optical and ultraviolet frequencies. As a result, Casimir forces are inherently broadband phenomena that reflect the integrated electromagnetic response of a system rather than the behavior of a single resonant mode.

At the same time, advances in nanophotonics and metasurfaces have enabled unprecedented control over light–matter interactions using engineered subwavelength structures. Many metasurface concepts rely on narrowband resonant responses that tailor the phase, amplitude, or polarization of propagating optical fields. This raises an interesting question: to what extent can such nanostructures influence dispersion forces that depend on broadband electromagnetic fluctuations? While nanostructuring is often assumed to provide a route to tailoring Casimir interactions, the connection between engineered optical resonances and the broadband response relevant for vacuum forces is not always straightforward.

II. Results and Discussion

In this talk, I will discuss recent experimental and theoretical work exploring how nanoscale structuring influences the Casimir force. Measurements performed with three-dimensional nanostructures—including pillars, hollow cylinders, and periodic arrays—demonstrate that geometry alone can substantially modify the magnitude and distance dependence of the interaction. In some cases, the measured force is suppressed by an order of magnitude relative to planar geometries. These results highlight the importance of electromagnetic boundary conditions and mode confinement in determining fluctuation-induced forces.

More broadly, these studies illustrate how Casimir interactions probe the collective electromagnetic response of structured materials, making it challenging to attribute observed changes to any single optical resonance or design feature. This perspective suggests a useful framework for understanding when nanophotonic structures—whether described as nanostructures, photonic crystals, or metasurfaces—can meaningfully influence dispersion forces.

III. Conclusion

The relationship between metasurface design principles and Casimir interactions is subtle. While metasurfaces are typically engineered to manipulate light within narrow spectral bands, Casimir forces depend on broadband electromagnetic fluctuations and the global optical response of materials. As a result, nanostructuring can influence Casimir forces primarily through geometry and broadband electromagnetic response rather than through isolated optical resonances. Understanding this connection may provide new opportunities for using nanophotonic structures to tailor fluctuation-induced forces in micro- and nanoscale systems.

Confinement-Induced Nonlocality and Optical Nonlinearity in Transdimensional Plasmonics

Igor V. Bondarev*

Department of Mathematics and Physics,
North Carolina Central University, Durham, NC 27707, USA
*Email: ibondarev@nccu.edu

***Abstract*—The latest experimental and theoretical studies are reviewed for electromagnetic (EM) properties of the new emerging plasmonic transdimensional (TD) material platform, including the optical nonlinearity enhancement due to the confinement-induced EM response nonlocality in the epsilon-near-zero region.**

***Keywords*—Transdimensional materials, Optical Nonlinearity, Confinement-Induced Nonlocality.**

Plasmonic TD materials are atomically thin metal, semimetal or doped semiconductor films of precisely controlled countable number of monolayers [1]. Due to the current progress in nanofabrication techniques [2-7], such materials can be reproducibly grown to offer high tailorability of their electronic and optical properties not only by altering their chemical and/or electronic composition (stoichiometry, doping), or strain [4], but also by varying their thickness [5,6]. While ultrathin metallic films have been quite extensively studied [2-4], the EM properties of TD plasmonic materials remain underexplored [5,6]. So far, the focus has largely been on either purely 2D structures including metal-dielectric interfaces, graphene and novel 2D semiconductors [7], or on conventional bulk materials where the dimensionality and chemical composition are the primary factors influencing the EM response. Recently, it was proposed that ultrathin TD nanostructures provide a new regime—transdimensional, in between 3D and 2D, turning into 2D as the film thickness tends to zero, challenging to study what the 3D-to-2D continuous transition has to offer to improve material functionalities [5,6,8-11]. In this regime, the strong vertical quantum confinement makes the linear EM response of the film nonlocal (spatially dispersive), and the degree of nonlocality can be controlled by the film thickness [8-12]. This makes plasmonic TD materials indispensable for research into the nonlocal light-matter interactions at the nanoscale [10-15], where they exhibit extraordinary tailorability including the capabilities of active tuning of their EM response and thus enabling new unique light-matter coupling phenomena [16,17]. The remarkable opportunities for tuning their highly confined in-plane plasma modes open access to novel quantum, nonlocal and nonlinear EM effects [10-21] in both near-infrared [14,15] and visible ranges [18]. Over the past few years, TD plasmonics has grown into a promising research direction aiming to enhance plasmonic functionalities through unparalleled tailorability of confinement-induced nonlocal and nonlinear EM response effects [11,18-21].

***Abstract*— Recent advances in resonant metasurfaces have enabled unprecedented control over optical fields. Deploying dense arrays of resonant optical nanostructures, typically at a subwavelength scale, this type of approach has opened spatial wavefront engineering. Such local control, however, provides functions that are hardly selective in frequency and angle domains. In this talk, a new class of metasurfaces, nonlocal flat optics, is introduced to overcome this limitation through spatially extended light-matter interactions. The translational symmetry of these resonances enables highly selective optical responses at programmed frequencies and angles. Representative examples, including a nonlocal free-space light modulator, will be presented to highlight new opportunities for such frequency- and angle-selective optical control for emerging technologies spanning communication, display, and imaging.**

***Abstract*—We report a graphene-based active metasurface achieving a 73.3% transmission modulation efficiency. An analytic circuit model elucidates the resonance mechanism controlled by Fermi levels. This high-efficiency platform overcomes previous limitations, enabling ultra-compact, on-chip spectroscopic systems.**

***Keywords*—active metasurface, transmission modulation, graphene, equivalent circuit model, single-chip spectrometer.**

I. Introduction

Mid-infrared (mid-IR) optoelectronics are essential for sensing and spectroscopy, serving as the key to detecting molecular fingerprints. Graphene metasurfaces have emerged as a solution for dynamic light control, yet they face a physical hurdle: atomic thinness limits light-matter interaction. To compensate, most designs rely on reflective back-mirrors like Salisbury screens [1]. But this reflection-based geometry creates a bottleneck. It prevents monolithic integration with standard transmission sources (e.g., VCSELs), effectively blocking the path to compact, on-chip optical systems.

Here, we report an electrically tunable transmission modulator designed as a graphene-gold nanograting. We specifically chose a CaF_2 substrate combined with ionic gel gating. This choice avoids the phonon absorption found in common substrates while enabling effective Fermi level tuning. As a result, our device delivers a modulation efficiency of 73.3% for TM-polarized light. This performance represents a major leap over existing transmissive devices, which typically perform below 41% [2-4]. We further clarify the mechanism behind this transparency using an analytic circuit model and validate the platform's potential as a single-chip spectrometer.

II. Results and Discussion

A. Active Transmission Modulation

The device schematic is detailed in Figure 1a. We patterned periodic gold nanogratings with 10 nm thickness on a 500 μm-thick CaF_2 substrate, specifically chosen for its mid-IR transparency. Next, we transferred monolayer graphene onto the patternd structure, followed by a 3 μm-thick ionic gel ([BMIM][PF_6]) layer for electro-optic modulation. The SEM image in Figure 1b confirms the structural quality of our optimized design, period $p = 3$ μm and gap width $g = 50$ nm. To dynamically modulate the Fermi level, we swept the gate voltage (V_g) from the charge neutrality point (~1 V) down to -3 V, driving the device deep into the hole-doped regime.

Figure 1c displays the FTIR transmission spectra collected with a numerical aperture of 0.71. We observed intrinsic ionic gel absorption bands (850, 1170, 3000 cm^{-1}) and Fabry-Perot ripples superimposed on the signal. While the TE mode remained insensitive to gating and was dominated by structural parameters, the TM mode revealed strong active modulation. At the optimal frequency of $\omega_0 = 1265$ cm^{-1}, the transmission T increased from 1.4% to 5.3% as we swept V_g from 0.75 V to -3 V. This yielded a peak efficiency of $\eta_T = 1\text{-}T_{min}/T_{max} = 73.3\%$. Notably, we sustained high performance (average efficiency of 60.1%) across a broad window from 931 to 1755 cm^{-1}.

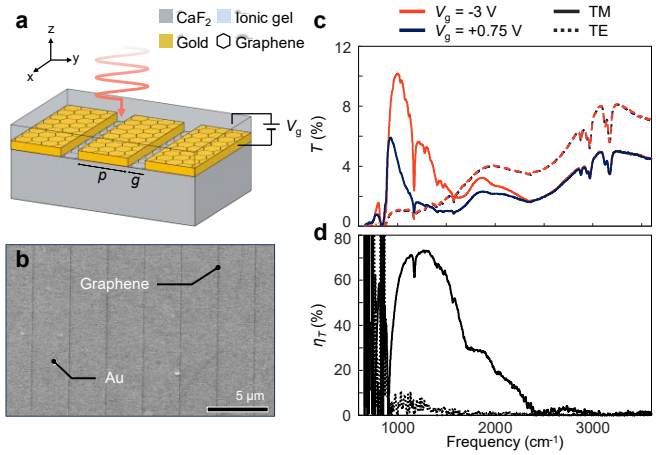

Fig. 1 Active transmission modulation metasurface. (a) Schematic of the device structure comprising a gold grating and monolayer graphene on a CaF_2 substrate, covered with ionic gel for top-gating. (b) Top-view SEM image of the fabricated device. (c) Measured transmission spectra for TM (solid lines) and TE (dashed lines) polarizations at gate voltages of V_g = -3 V (red) and +0.75 V (dark blue). (d) Transmission modulation efficiency (η_T) calculated from the spectra.

To understand the physics underlying this modulation, we employed an equivalent circuit model [5]. As shown in the

lower panels of Figures 2a and 2b, this model successfully reproduces the experimental trends. We mapped the applied gate voltages (+0.75 V to -3 V) to Fermi levels ranging from 0.16 to 0.92 eV, assuming a fixed scattering rate of $\Gamma = 0.084$ eV. These results are also consistent with full-wave RCWA simulations.

Using the equivalent circuit model, we treated our metasurface as an effective surface admittance, approximated as $Y_S \approx Y_C + Y_{Gr}$. Here, Y_C captures the capacitive nature of the metal grating, while Y_{Gr} represents the inductive contribution of the graphene. We note that this approximation is only valid for operating frequencies below $\omega_0 = 1500$ cm^{-1}, where the inductive characteristics of the metal grating can be ignored. At the charge neutrality point ($E_F = 0.16$ eV, Figure 2a), Y_{Gr} is negligible due to the low concentration of the charge carriers. Thus, the large capacitive admittance Y_C dominates, making the device opaque. Conversely, under high doping ($E_F = 0.92$ eV, Figure 2b), the inductive response of graphene increases. This inductance effectively cancels the metallic capacitance at the resonance frequency $\omega_0 = 1074$ cm^{-1}, and this impedance matching maximizes transmission.

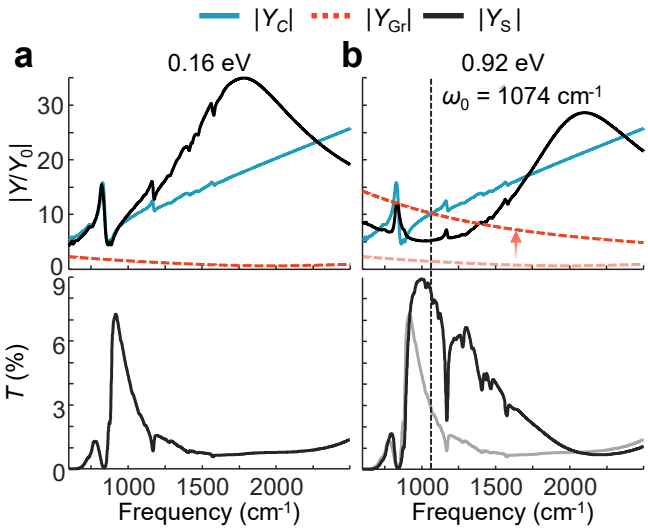

Fig. 2 Theoretical analysis of transmission modulation using an equivalent circuit model. (a, b) Calculated normalized admittance spectra ($|Y/Y_0|$, top) and corresponding transmission spectra (bottom) at Fermi levels of (a) \$0.16 eV and (b) 0.92 eV. The blue solid, red dashed, and black solid lines represent the capacitive admittance of the metal grating ($|Y_C|$), the inductive admittance of graphene ($|Y_{Gr}|$), and the total admittance ($|Y_S|$), respectively.

This transparency mechanism is further visualized by the magnetic field distributions simulated via RCWA. At 0.16 eV (Figure 3a), the incident field is strongly reflected by the metallic grating, showing low transmission. In contrast, at the resonant condition of 0.92 eV (Figure 3b), the field distribution shows minimal perturbation across the grating layer. This confirms that when the admittance is minimized, the metallic structure becomes effectively invisible to the incident wave, allowing the field to propagate through the substrate with high transmittance.

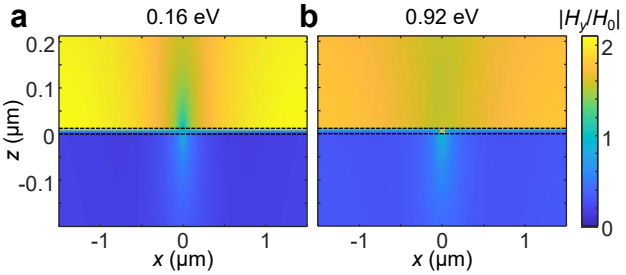

Fig. 3 Normalized magnetic field distributions ($|H_y/H_0|$) calculated using RCWA at the resonance frequency ($\omega_0 = 1074$ cm^{-1}) for (a) $E_F = 0.16$ eV and (b) 0.92 eV.

B. Single-Chip Spectrometer Application

As demonstrated in earlier sections, our metasurface has broad tunability and high modulation efficiency. By utilizing these features, we propose that our active transmission filter can be transformed into a computational single-pixel spectrometer, which reduces the footprint of the device significantly compared to conventional approaches such as spatially distributed arrays. We optimized the device geometry ($p = 800$ nm and $g = 150$ nm) and frequency band (1400–2500 cm^{-1}), to balance the modulation efficiency and operating bandwidth. By sweeping E_F from 0.1 to 1.0 eV, the generated 91 distinct transmission spectra function as a quasi-orthogonal basis set.

Since spectral reconstruction is inherently an ill-posed inverse problem, a Compressed Sensing (CS) algorithm is employed [6]. We implemented a dual-component method, where each component represents sharp peak and broadband features. To consider real-world sensing conditions, we introduced 0.5% Gaussian noise into the simulation. Figure 4a shows the reconstruction performance for narrowband inputs. The result showed high fidelity (F) for the median case, exceeding 99%. Even for broadband or complex signals (Figure 4b), our device captured the spectral features with high accuracy ($F > 99\%$) in the best case, validating the platform's potential.

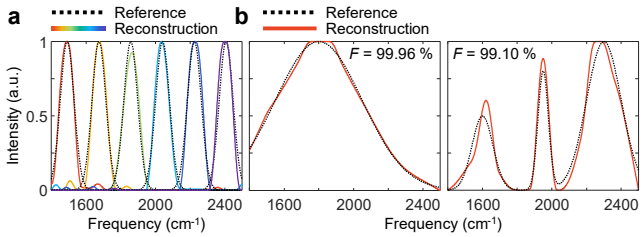

Fig. 4 Spectral reconstruction performance of the single-chip spectrometer for (a) multiple narrowband Gaussian spectra, (b) broadband (left) and complex multi-peak (right) spectra. Dotted lines indicate reference inputs, while solid colored lines represent reconstructed outputs.

III. Conclusion

In summary, we achieved a high modulation efficiency of 73.3% for TM-polarized light using a graphene-gold nanograting metasurface, surpassing previous conventional approaches. Our design employed a phonon-free CaF_2 substrate

to avoid strong absorption in the operating frequency range, and an ionic gel based top-gating method to achieve high Fermi level modulation, thereby avoiding the reflective back-gating method. While this gating method trades off switching speed, it remains the most practical route to achieve such high modulation efficiency in this spectral range.

Using equivalent circuit model analysis, we clarified the underlying LC resonance mechanism between the capacitive metal grating and the inductive graphene layer, revealing that the modulation of Fermi level results in spectral shifts. Finally, we showed that our platform, which possesses high modulating efficiency and broad tunability simultaneously, can be applied as a single-chip spectrometer with the help of CS-based reconstruction algorithm. This versatility positions our device as a key building block for future on-chip sensing and spectroscopy.

Short Abstract:
This talk is focused on using on-chip metaphotonic elements to enable a series of new integrated photonic structures that enhance light-matter interaction. Using new design techniques, it is shown how the use of metaphotonic elements increases the intensity of the optical field at the interaction region of light with matter in different classes of integrated photonic chips. In addition, metaphotonic elements can facilitate interaction by engineering the optical wavefront. Theoretical and experimental results will be used to demonstrate the unique features of these structures.

Biography

Ali Adibi is the director of Bio and Environmental Sensing Technologies (BEST) and a professor and Joseph M. Pettit chair in the School of Electrical and Computer Engineering, Georgia Institute of Technology. He is also a member of the Winship Cancer Research Center at the Emory University. His research group has pioneered several structures in the field of integrated nanophotonics for both information processing and sensing. He has also pioneered new sensing solutions for medical diagnosis as well as AI algorithms for diagnosis and prognosis in medicine. He is the author of more than 260 journal papers and 600 conference papers. He has served as the editor, conference chair, and technical committee members in over 30 different conferences and journals. He has also led several multidisciplinary research teams in the areas of integrated optics and metaphotonics for sensing, interconnection, and imaging. He is the recipient of several awards including Presidential Early Career Award for Scientists and Engineers, Packard Fellowship, NSF CAREER Award, and the SPIE Technology Achievement Award. He is also a fellow of OSA, SPIE, and AAAS.

Squeezing Light Fields for Ultrafast Detectors and Single Photon Sources

Maiken H. Mikkelsen[1,*]

[1]Niels Bohr Institute, University of Copenhagen, Denmark
*Corresponding author: maiken.mikkelsen@nbi.ku.dk

***Abstract*— Here, we leverage nanogap cavities—creating strongly enhanced local electromagnetic fields—to modify light-matter interactions. First, thermal detectors integrated with nanogap plasmonic structures reveal ultrafast detection speeds along with spectral and polarization sensitivity. Next, spontaneous emission rates of single solid-state emitters are enhanced up to 10,000x for quantum science applications.**

***Keywords*— plasmonics, nanogap cavity, Purcell factor, metasurface, spontaneous emission, quantum dot, photodetector**

I. Introduction

Nano- and quantum materials with unique optical properties hold the potential for breakthroughs in a wide range of areas from ultrafast optoelectronics and on-chip components for quantum information science to improved photodetection and bio-sensing. An exciting opportunity to realize such new materials lies in controlling the local electromagnetic environment on the atomic- and molecular-scale (~1-10 nm), which enables extreme local field enhancements and drastically modified local density of states. A well-controlled platform to study the emergence of extreme photonic behavior is provided by plasmonic nanogap cavities, which consist of ultrathin dielectric gaps between metals.

II. Results and Discussion

First, a room-temperature, pyroelectric photodetector will be discussed, which couples a thermally-sensitive aluminum nitride (AlN) layer with a metallic metasurface. The metasurface acts as an efficient, spectrally-selective photothermal converter [1-3] and depending on the shape of the metasurface structures, it can also be sensitive to the polarization-state of the incoming light [4]. These pyroelectric detectors exhibit record-breaking speeds, with 3 dB bandwidths up to 2.8 GHz, which corresponds to a rise time of 125 ps.

Next, using similar plasmonic nanogap structures, but now with single emitters sandwiched in the dielectric layer between the metal film and nanoparticle, strongly enhanced spontaneous emission rates are studied. We demonstrate picosecond single photon emission from SiVs in diamond [5-7] and Purcell factors greater than 10,000 for single colloidal quantum dots emitting in the telecom band at 1550 nm [8].

III. Conclusion

We have demonstrated how strongly enhanced local electromagnetic fields can modify a range of light-matter interactions. In particular to enable ultrafast detection speeds from a metasurface-coupled thermal photodetector and ultrafast single photon sources from both SiV centers in diamond and colloidal quantum dots in the telecom range.

Time Reflection of Guided Light in Optically Switched Metasurfaces: Generating Magnetic Field on the Nanoscale

Shivakh Rawat[1,*], Samyobrata Mukherjee[1], Gennady Shvets[1,*]

[1]School of Applied and Engineering Physics, Cornell University Ithaca, USA

***Abstract*— Time-varying dielectric metasurfaces supporting sharp optical resonances with non-trivial electromagnetic fields distribution is used for realizing temporal interfaces for metasurface-guided waves (MGWs). We demonstrate that such time-interfaces can be used to generate large, highly localized quasi-static magnetic fields inside the metasurfaces that persist after the departure of the time-scattered MGWs.**

***Keywords*— photonic time interfaces, metasurface optics.**

I. Introduction

We propose a mechanism, backed by numerical simulations and analytic perturbation theory, for tunable red- and blue-shifting of the metasurface resonance using free carrier generation by a pump laser beam. An ultrashort high-frequency pump pulse can produce temporal reflections via localized metallization for a lower-frequency MIR mode while also red-shifting the mode. Additionally, a quasistatic magnetic field mode is also formed during a time interface.

II. Methods

I will discuss analytic expressions for the total energy density in a time-varying Drude-Lorentz medium, and how to use it to demonstrate that the optical energy decreases while the quasi-static magnetic energy and the carrier temperature increase after the TI. While time-variant lumped-element metasurfaces in the microwave frequency range have been proposed for generating the so-called "wiggler" magnetic fields, our work is the first (to our knowledge) to demonstrate how such "rectification" of the magnetic field can be carried out for optical frequencies. Because optical pulses can be many orders of magnitude more compact and intense than their microwave counterparts, the resulting quasi-static magnetization is proportionally stronger and localized to sub-micron regions – something that cannot be accomplished using conventional static magnets. To date, such ultra-short and localized magnetic fields – highly desirable for exploring ultra-fast magnetic recording – could only be produced using relativistic electron bunches at major accelerator facilities (e.g., SLAC). This work paves the way to novel approaches to generating ultra-high magnetic fields on the nanoscale.

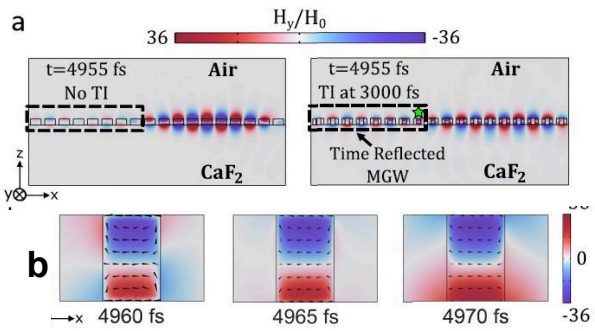

Fig. 1 **Using time interfaces (Tis) to generate dc magnetic fields**. **(a)** In the absence of a TI (left), a metasurface-guided optical wave propagates from left to right and eventually leaves the domain. With a TI (right), a time-reflected signal propagates in the backward direction. **(b)** Three sequential snapshots of the quasi-static magnetic field Hy in the x-z plane passing through the middle of a meta-atom marked by a green star. Free carriers generation at t=3,000fs inside the cylinder marked by solid lines produces a TI.

III. Results and Discussion

Our results show:

- temporal reflections from this sharp TI, including a redshift of the time-reflected waves
- after the TI, we also found a large, highly localized quasistatic magnetic field (wiggler mode) consumes a substantial part of the electromagnetic energy: see Fig.1.
- by comparing the cases with/without a TI, we validated that the total energy in a time-varying system remains unaffected by the free carriers created at rest during a TI.

***Abstract*— We describe the design, fabrication, and testing of a leaky-wave metasurface that is tunable at femtosecond speeds. The device incorporates an arsenic sulfide thin film, leveraging its Kerr nonlinearity to achieve tuning. It is designed to focus light to a point with a position that varies with pump power.**

***Keywords*— metamaterials, high-speed tuning, leaky-wave metasurfaces, chalcogenide glass.**

I. Introduction

High-speed tuning of photonic devices is of interest for applications such as pulse shaping, rapid processing of optical data, spectroscopy of rapidly changing media, and the laboratory study of high-speed phenomena. Most existing tuning methods, however, are limited to speeds no faster than the nanosecond time scale.

This work demonstrates tunable metasurfaces incorporating arsenic sulfide (As_2S_3) glass thin films. The refractive index of As_2S_3 can be readily changed at the sub-femtosecond time scale through its high Kerr nonlinearity, enabling metamaterials with femtosecond timescale tunability.[1] Recent work has shown that leaky-wave metasurfaces (LWMs) can provide control over all four free parameters of an optical field.[2] Here, we present a LWM devices that incorporate an As_2S_3 layer, shown schematically in Fig. 1(a) and in cross section in Fig. 1(b), designed to focus light to a point with a position that varies with pump power at high speed.

II. Methods

High-purity As_2S_3 bulk material is batched, and small pieces are used as deposition sources. An As_2S_3 film is deposited via thermal evaporation onto a silicon substrate. A PMMA layer is spun on and patterned vie E-beam photolithography. Light with a wavelength of 1 μm is coupled into the waveguide. The refractive index of the As_2S_3 is modulated using a femtosecond laser, and the position of the focused spot is measured as a function of the power density of the pump.

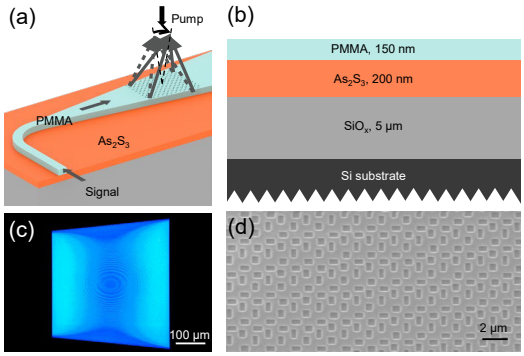

Fig. 1 (a) Schematic diagram of LWM device; (b) cross section showing device layers; (c) dark field microscope image of fabricated LWM; and (d) SEM image of patterned PMMA layer of a LWM.

III. Results and Discussion

The waveguide mode propagates in both the As_2S_3 and PMMA layers. The unit cells are optimized such that the LWM has different focal positions with different refractive indices of the As_2S_3. A dark field microscope image of a completed device is shown in Fig. 1(c), and an SEM image of multiple unit cells is shown in Fig. 1(d).

IV. Conclusion

We have designed, fabricated, and tested As_2S_3-based LWMs with the potential for femtosecond timescale tuning of the position of a focused spot.

Towards dynamic metasurfaces and nanophotonics in barium titanate on insulator

David Barton*[1], Sarah Berman[1], Sina Abedini Dereshgi[1], Ethan Ray[1]

[1]Department of Materials Science and Engineering, Northwestern University, USA
*Corresponding author: dbarton@northwestern.edu

***Abstract*— Tunable subwavelength metasurfaces will enable low energy consumption and compact computing, communications, and sensing devices. Towards this, we will discuss our work fabricating subwavelength structures in thin film barium titanate on insulator and applying it for electro-optic modulators and optical metasurfaces.**

***Keywords*— nanophotonics, metasurface, barium titanate, electro-optic.**

I. Introduction

The ability to sculpt electromagnetic radiation with subwavelength optical antennas has enabled fundamental advances in small form-factor and high performance optical devices[1]. Reconfigurable metasurfaces can advance key optical technologies[2,3] including light detection and ranging[4], optical communications[5], and augmented or virtual reality. However, it remains a fundamental challenge to create dynamical optical devices that have simultaneously high efficiency, contrast, low switching voltages, and high modulation bandwidths, as either the optical properties or geometry much change by a significant amount to modify the optical transfer function.

Demonstrations of dynamic devices based on phase change materials[6], liquid crystals[7], and doped semiconductors[8] have shown promise in this space. In addition, electro-optic materials provide a platform for high speed and low-loss modulation[9-13], but are limited in the refractive index difference because of the second order nonlinearity being used. Indeed, the electro-optic coefficient of commonly available lithium niobate is approximately 31 pm/V, requiring integrated photonic modulators to be much longer (~1 cm) than metasurface devices can allow for significant optical phase shifts.

II. Results and Discussion

Here, we will show our progress in developing monolithic barium titanate-based nanophotonic structures. Barium Titanate (BTO) is a CMOS-compatible oxide that features a high electro-optic coefficient (>900 pm/V)[13] and is recently available as commercially available thin films. However, monolithic fabrication of these films is challenging[14]. We have developed an etching protocol that allows for low loss nanophotonic structures, including photonic crystals[15]. Poling protocols and electro-optic measurements demonstrate pockels coefficients over 150 pm/V and modulation efficiency greater than 10 GHz. Resonant cavities also show the possibility to use nanophotonic structures to confine light with quality factors exceeding 100,000 at telecommunications wavelengths.

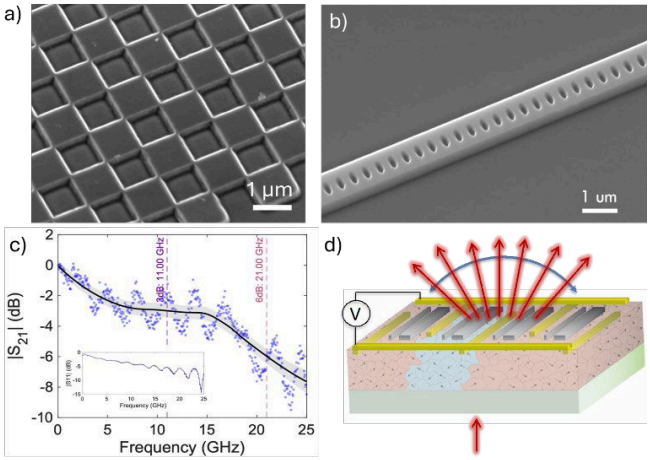

Figure 1: monolithic barium titanate on insulator nanophotonics. a) SEM image of ~1 micron scale structures etched into surface of BTO. b) SEM image of photonic crystal waveguide with subwavelength structured components. c) VNA modulation spectrum at edge of photonic crystal band gap, demonstrating greater than 10 GHz modulation bandwidth. d) future device implementation using nanoantennas interfaced with BTOI. Control of domain orientations

We will additionally discuss our progress developing reconfigurable and programmable nanophotonic devices via resonant metasurfaces. First, we will show our work understanding the ferroelectric poling and depoling dynamics in this platform using polarization-resolved confocal second harmonic generation microscopy[16]. We track the onset of poling and temporal dynamics of depoling in device-relevant geometries. Finally, we show our work developing dynamical metasurfaces using this platform.

III. Conclusion

Together this work demonstrates the value of wide bandgap nonlinear materials for electrically-controllable wavefront shaping devices, and further demonstrates that combined electronic-photonic interfaces for control of free-space light is

a meaningful platform for future photonic systems.

Theory of Spin-Chiral Phonon Coupling in Chiral Crystals

Dapeng Yao[1], Gen Tatara[1]

[1]RIKEN Center for Emergent Matter Science (CEMS), 2-1 Hirosawa, Wako, Saitama, 351-0198, Japan

***Abstract*—We microscopically show spin-chiral phonon coupling in three-dimensional chiral crystals. We consider that phonons modulate the electron motions, leading to an effective magnetic field on electron spins via spin-orbital coupling. By integrating out the field of conduction electrons, we derive an effective Hamiltonian which couples the phonon and spin degrees of freedom.**

***Keywords*— chiral phonon, chiral crystal, spin-orbital coupling.**

I. Introduction

Chiral phonons accompanying rotational motions of nuclei represent circularly polarized modes, which carry phonon angular momentum [1]. Such phonons have been confirmed by recent experiments [2], [3], and the their various aspects have been revealed, such as the conversion of chiral phonons into the electric current [4], the spin excitation [5], the spin [6], [7] and orbital magnetizations [8], [9]. However, the coupling between electron spin and lattice in three-dimensional (3D) chiral crystals remain poorly understanding. Even though the so-called Raman-type spin-phonon coupling has been widely used to phenomenologically describe the coupling between the chiral lattice motion and local electron spins, the microscopic mechanism is still lacking. Furthermore, a quantitative estimate of the coupling constant was not feasible.

In this work, we microscopically derive the spin-chiral phonon coupling in 3D chiral crystals. We introduce the tight-binding model of electrons and the spring-lattice model of phonons for a 3D chiral chain. They can be simplified by a two-band model of electrons and a three-band model of phonons via the unfolding of the Brillouin zone. We then consider that phonon modulate the electron motion through the electron-phonon coupling, leading to an effective magnetic field on electron spins via spin-orbital coupling. By integrating out the field of conduction electrons, we derive an effective Hamiltonian which couples the phonon and spin degrees of freedom.

II. Methods

Here we consider a one-dimensional chiral chain with three atoms per unit cell, and we introduce the tight-binding model of electrons and spring-lattice model of phonons. Since the chiral chain has the screw symmetry, which is a combination of translation and rotation operations. By reducing the number of atoms pre unit cell from three to one, we can extend the Brillouin zone by three times. In this case, our tight-binding and spring-lattice models can be simplified by a two-band and three-band models, respectively. Then we can rewrite the electron-phonon coupling for the reduced unit cell, which is used to a two-phonon process. By integrating the field conduction electron, we can obtain the coupling between spins and lattice in chiral crystals.

III. Results and Discussion

We eventually derive the coupling between the phonon angular momentum and the electron spin, which is given by

$$H_{\text{ph-s}} = \alpha \boldsymbol{S} \cdot (\boldsymbol{Q} \times \dot{\boldsymbol{Q}}) + \beta \boldsymbol{S} \cdot (\boldsymbol{Q} \times \nabla \boldsymbol{Q}), \tag{1}$$

where $\boldsymbol{Q}$ is the phonon displacement, $\boldsymbol{S}$ is the electron spin, and α and β are their coupling constants. The first term is the so-called Raman-type spin-phonon coupling.

IV. Conclusion

We microscopically formulate the spin-chiral phonon coupling in three-dimensional chiral crystals, which requires both electron-phonon and spin-orbital couplings.

Orbital optical chirality: Spectrally and spatially resolved measurements of multipolar chiroptical responses for optical vortex beams

Yoshito Y. Tanaka

Research Institute for Electronic Science, Hokkaido University, Japan
*Corresponding author: ytanaka@es.hokudai.ac.jp

***Abstract*— We demonstrate spatially and spectrally resolved chiral dichroism using a single twisted nanorod pair with spectrally separated plasmon resonances and rapid modulation of optical vortex handedness. At the vortex center, dichroism arises from novel optical chirality dependent on orbital angular momentum, which interacts with hybridized twisted quadrupole plasmon modes.**

***Keywords*— chiral nanostructures, optical vortex, vortex dichroism, helical dichroism, chiroptical responses, plasmon, metamaterials.**

I. Introduction

Chiral light–matter interactions are central to optical spectroscopy and nanophotonics, yet have conventionally been understood as arising from electric–magnetic dipolar interference driven by circularly polarized light with spin angular momentum ($s = \pm 1$). Recently, chiral interactions with optical vortex beams carrying orbital angular momentum (l) have attracted considerable attention from both fundamental physics and application perspectives, owing to the infinite degrees of freedom that l offers beyond s. Unlike spin angular momentum, which is determined by local polarization properties, orbital angular momentum is encoded in the spatial phase distribution of the beam. Consequently, the resulting chiroptical responses are expected to more strongly reflect the geometrical characteristics of chiral matter. However, a critical challenge arises from the size mismatch between the wavelength-scale optical vortex and nanoscale chiral structures. Here, we investigate the chiroptical response arising from interactions between plasmonic chiral nanostructures and optical vortex beams carrying both spin and orbital angular momentum, and demonstrate that this response is mediated by higher-order multipolar interactions beyond the conventional dipolar regime.

II. Sample and Methods

The subwavelength-sized twisted gold nanorod dimer (TND) shown in Fig. 1a was fabricated by three-dimensionally controlling the distance between the two rods with a spatial resolution of 10 nm or less. This chiral structure exhibits a giant chiroptical response with simple, analyzable modes through plasmonic coupling between the rods [1]. Additionally, we proposed and developed a method to achieve high-speed modulation of left- and right-handed optical vortex beams, which has been considered difficult conventionally, and to measure the difference in transmittance between left- and right-handed optical vortices (optical chiral dichroism) with high precision using a lock-in amplifier [2]. This enables spectrally and spatially resolved measurements of the chiral dichroism of a single TND (Fig. 1b).

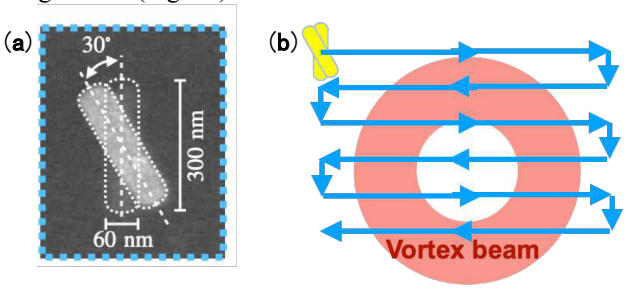

Fig. 1 (a) Twisted nanorod dimer (TND) structure. (b) Dichroism mapping of TND under left- and right-handed circularly polarized vortex beams.

III. Results and Discussion

As shown in Fig. 2a, we demonstrated that distinct dichroic responses emerge at the center and donut-shaped regions of circularly polarized optical vortex beams ($s = \pm 1, l = \pm 1$) [3]. In the donut-shaped region, no significant spectral variation was observed within the wavelength range near the quadrupole plasmon resonance. In contrast, at the beam center, the dichroic response exhibited a clear spectral dependence: negative at 800 nm, zero at 825 nm, and positive at 850 nm. Furthermore, only the sign of the dichroism at the center was reversed depending on the sign of l in the incident optical vortex ($s = \pm 1, l = \mp 1$). Reciprocity tests and angular momentum dissipation analysis [4] confirm that this response is a genuine chiral interaction dominated by orbital, rather than spin, angular momentum. Additionally, numerical simulation analysis revealed that the dichroism in the donut portion is mainly attributed to the coupling mode between dipoles (Fig. 2b), while the dichroism at the center arises from the coupling mode between

quadrupoles (Fig. 2c), which is normally forbidden. Interestingly, such dichroic response at the center cannot be explained within the framework of optical chirality as conventionally defined, and for the first time, we revealed the interaction with a novel optical chirality unique to optical vortices that depends on the order l of orbital angular momentum.

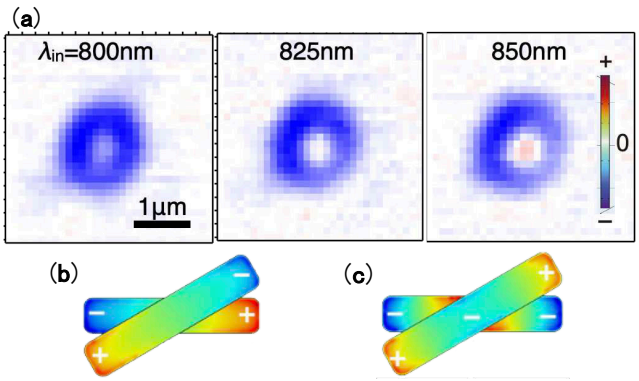

Fig. 2 (a) Measured dichroism maps at different incident wavelengths. Calculated charge distributions for (b) dipole and (c) quadrupole chiral modes excited at the donut and center positions in (a).

IV. Conclusion

We have demonstrated for the first time spatially and spectrally resolved chiral dichroism by utilizing a single twisted nanorod pair, which serves as an excellent probe due to its spectrally separated plasmon resonances, combined with rapid modulation and lock-in detection of left and right chiral light with spin and orbital angular momentum. Our key findings have revealed that the dichroism observed at the vortex center can be due to optical chirality governed by orbital angular momentum, and Its optical chirality interacts with the hybridized modes of two twisted quadrupole plasmons, resulting in a pronounced chiroptical response.

***Abstract*—We consider a Fabry-Pérot resonator supporting photonic modes with non-zero handedness. By placing chiral material into such a resonator, we demonstrate chiral strong coupling. The interaction strength depends on the chiralities of both the medium and the photonic mode, enabling selective optical sensing of molecular enantiomers for pharmaceuticals and chemistry.**

***Keywords*— chirality, metasurfaces, strong coupling.**

Fundamental studies of the interaction between chiral light and chiral matter are crucial for advancing technologies that can optically distinguish different left and right enantiomers of chiral organic molecules. One promising approach in developing such technology involves creating a resonator that sustains photonic modes with non-zero electromagnetic handedness, a feature that causes these modes to interact differently with chiral molecular enantiomers. When chiral molecules are positioned in resonator hotspots, they can alter the system's characteristics due to their electric and magnetic transition dipole moments.

In this study, we explore this interaction by incorporating the Lorentz pole into the macroscopic parameters of the chiral medium: dielectric permittivity, magnetic permeability, and chirality coefficient [1]:

$$\begin{aligned}\varepsilon(\omega) &= \varepsilon_\infty + f_e \frac{\omega_0^2}{\omega_0^2 - \omega^2 - i\gamma\omega},\\ \mu(\omega) &= \mu_\infty + f_m \frac{\omega_0^2}{\omega_0^2 - \omega^2 - i\gamma\omega},\\ \kappa(\omega) &= f_{me} \frac{\omega}{\omega_0} \cdot \frac{\omega_0^2}{\omega_0^2 - \omega^2 - i\gamma\omega}.\end{aligned} \tag{1}$$

The latter, also known as the Pasteur parameter, is a dimensionless macroscopic measure indicating the medium's chirality, connecting electric and magnetic fields in the constitutive relations. Our theoretical results are the following:

- Designed a wideband handedness-preserving mirror using one-dimensional periodic gratings on a Bragg mirror [2], enabling the construction of a Fabry-Pérot resonator with chiral modes whose frequencies are tunable via grating orientation, as shown in Fig. 1(a).
- Demonstrated strong coupling between chiral cavity modes and a chiral (Pasteur) medium, showing that the Rabi splitting is directly governed by the enantiomeric compatibility of the mode and the medium [3].

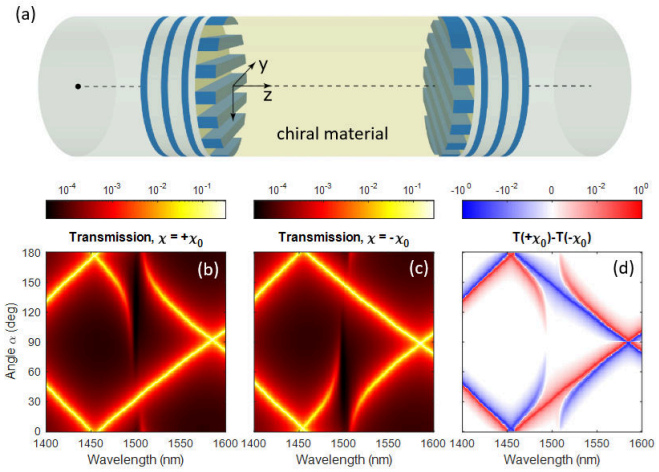

Fig. 1. (a) The sketch of a chiral Fabry-Pérot resonator. (b–d) The wavelength and twist-angle dependencies of the resonator transmission coefficient and the differential transmission coefficient.

- Validated the theoretical model by confirming Jones matrix formalism results against full-wave Fourier modal method simulations, ensuring the accuracy of the predicted light-matter interaction.
- Proposed a direct experimental method to optically distinguish left-handed and right-handed media by identifying spectral shifts of Fabry-Pérot resonances in transmission spectra near chiral transitions.

Our findings provide a foundation for designing advanced optical sensors that can selectively detect chiral molecules, with potential applications in pharmaceuticals and chemistry.

***Abstract*—Balancing dc spin torque against Gilbert damping stabilizes a self-organized spin-superfluid limit cycle in a chiral ferromagnetic multilayer. The resulting superflow is inherently nonreciprocal, enabling direction-selective magnon transport. In a comoving frame the long-wavelength dynamics map onto an effective acoustic metric, allowing sonic horizons and Hawking-like emission.**

***Keywords*—nonequilibrium dynamics, spin superfluidity, limit cycle, nonreciprocity, magnons, analogue gravity**

I. Introduction

Open, driven systems can self-organize into steady states with no equilibrium analogue [1]. Here we summarize a magnetic realization: a dc spin current counteracts intrinsic damping and stabilizes a chiral spin-superfluid limit cycle (SFLC) carrying a persistent spin supercurrent. The SFLC breaks both spatial and continuous time-translation symmetry, intertwining transport with spatiotemporal order [2].

II. Model and Methods

We consider a ferromagnetic multilayer with interlayer exchange and Dzyaloshinskii–Moriya interaction, subject to a field along $\hat{\mathbf{z}}$ and a dc spin-current-induced antidamping torque. In a continuum description, the unit magnetization $\mathbf{m}(x,t)$ obeys Landau–Lifshitz–Gilbert dynamics

$$\partial_t \mathbf{m} = -\mathbf{m}\times\mathbf{h} + \alpha\,\mathbf{m}\times\partial_t\mathbf{m} + J_s\,\mathbf{m}\times(\mathbf{m}\times\hat{\mathbf{z}}). \quad (1)$$

A uniformly precessing, current-carrying SFLC solution takes the form $\varphi_{\mathrm{LC}}(x,t) = kx + \Omega t$ with $\Omega = J_s/\alpha$, yielding a steady superflow whose chirality is set by the DMI.

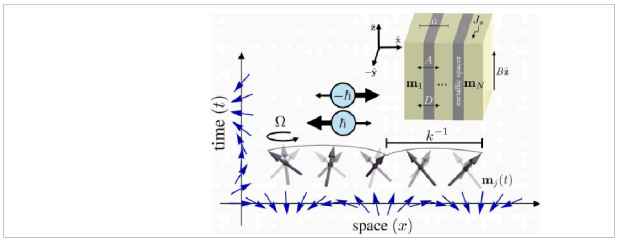

Fig. 1. Schematic SFLC background and direction-selective magnon propagation in a driven multilayer ferromagnet (adapted from Ref. [2]).

III. Results and Discussion

Our analysis demonstrates:

- Emergence of a dynamically stabilized spin superfluid limit cycle, even in parameter regimes where equilibrium superfluid states are forbidden.
- Intrinsic nonreciprocal magnon dispersion arising from flow-induced breaking of Galilean invariance.
- Regimes of fully unidirectional long-wavelength propagation.
- Exceptional-point structure at zero momentum associated with the Goldstone mode.
- Effective acoustic-metric description of long-wavelength phase dynamics.
- Formation of sonic horizons under spatial modulation of the spin torque.
- Hawking-like particle–hole pair emission from horizon interfaces.

IV. Conclusion

Driven magnetic heterostructures provide a tunable tabletop platform linking spin superfluidity, nonreciprocal transport, and analogue-gravity kinematics within a single nonequilibrium phase.

Breaking of time-reversal symmetry and Onsager recirprocity in chiral molecule interfaced with an enivronment

Jonas Fransson

Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden
*Corresponding author: Jonas.Fransson@physics.uu.se

***Abstract*— Molecular closed shell structures are known to form spin-singlet configurations, resulting from the spin-exchange associated with electron-electron interactions. While the vanishing total spin-moment is an immanent property of the spin-singlet, the vanishing local moments is a result of fluctuations between degenerate spin-configurations. Here, it is demonstrated that the spin-configuration of a chiral molecule is enantiospecifically locked when coupled to an electron reservoir. The coupling opens up the molecular closed shell structure, which broadens the energy levels. Together with the molecular spin-orbit coupling, this dissipative coupling generates an effective spin-splitting of the molecular energy levels and facilitates stabilization of a chirality determined spin-configuration. Simultaneously, the charge molecular charge distribution is shown to depend linearly on the magnetization of the reservoir such that no linear response regime is established with respect to the external magnetization. Accordingly, the Onsager reciprocity theorem does not apply to a chiral molecule attached to a reservoir, hence, providing a theoretical foundation for the chirality induced spin selectivity effect.**

Nonlinear terahertz magnetoelectric coupling of electromagnons in multiferroics

Youtarou Takahashi

Quantum-Phase Electronics Center (QPEC) and Department of Applied Physics, The University of Tokyo, Tokyo, Japan
*Corresponding author: youtarou-takahashi@ap.t.u-tokyo.ac.jp

***Abstract*— Multiferroics of spin-driven ferroelectricity provide strong dynamical magnetoelectric coupling, leading to versatile nonreciprocal optical responses. Here, we show the nonlinear magnetoelectric coupling of spin excitations of multiferroics, electromagnons, by using the strong terahertz field. The different nonlinear responses, anharmonic coupling of electromagnons and higher harmonic generation, have been demonstrated.**

***Keywords*— metamaterials, terahertz, machine learning, photonic crystals.**

I. Introduction

Spontaneous breaking of space inversion symmetry is often caused by the spin orderings, which is classified as type-II multiferroics, leading to spin-driven ferroelectricity and chirality (Fig. 1). The strong magnetoelectric effects, magnetization induced by electric field and electric polarization induced by magnetic field, have been discovered in multiferroics. The fluctuation of spin ordering, spin excitation, in multiferroics always exhibits the electric dipole activity, which is called as electromagnon [1]. The electromagnon resonance, which is observed in gigahertz and terahertz region, shows resonantly enhanced magnetoelectric coupling, leading to the giant nonreciprocal optical responses [2]. In the linear response regime, nonreciprocal optical absorption and gyrotropy enhanced by the electromagnons have been reported. Recently, the bulk photovoltaic effect of electromagnon, which converts the terahertz photon into charge current, has been found in type-II multiferroics [3]. In addition to the photovoltaic effect, many second order nonlinear effects are expected to appear through the large magnetoelectric coupling of electromagnon. In this talk, we demonstrate two types of nonlinear responses of electromagnons in spin-spiral magnets. The magnetoelectric effect in the strong resonant terahertz field causes higher harmonic generations with nonreciprocity. The high field excitation also drives the off-resonant creation of electromagnon through the anharmonic coupling of electromagnons.

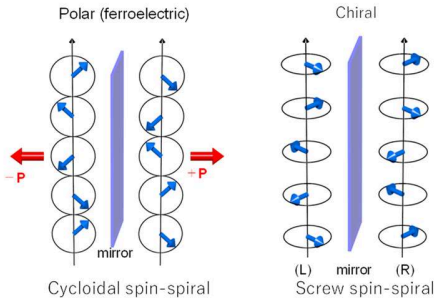

Fig. 1 Inversion breaking by spin-spiral orders.

II. Methods

Representative spin-spiral multiferroics, perovskite manganites and hexaferrites, are targeted in this work. The electromagnons in terahertz region is created by high field terahertz pulses with field strength of 600 kV/cm. To detect the anharmonic coupling, the pump-probe measurements was conducted. The terahertz emission spectroscopy was used to observe the higher harmonic generation through the magnetoelectric coupling.

III. Results and Discussion

Presence of strong anharmonic coupling among the electromagnons is found in spin-spiral phase of hexaferrite. The coherent creation of electromagnon induces off-resonant excitation of low energy electromagnon as manifested by the pump-probe measurements. The amplitude of off-resonant excitation is proportional to the square of terahertz field, indicating the second order nonlinear effect. In the centrosymmetric matter, the second order anharmonic coupling between infrared active modes is prohibited; the coupling between infrared active and Raman active modes is allowed. Although the chemical lattice of hexaferrite is centrosymmetric, the spin-spiral order breaks the space inversion symmetry and enables the anharmonic coupling of infrared active electromagnons.

***Abstract*—Topological bosonic excitations must, in contrast to their fermionic counterparts, appear at finite energies. This is a key challenge for magnons, as it prevents excitation and detection of topologically-protected magnonic edge states and their use in magnonic devices. We show how the edge states can be lowered to zero frequency.** ***Keywords*— magnonics, topology, chiral edge states, spintronics**

I. Summary

In this work [1] we propose a method to lower the topologically-protected chiral edge states in magnon Chern insulators to zero frequency, such that they are easily accessible by microwave techniques. This is achieved by considering magnon excitations on top of a uniform magnetization that is pointing *against* the applied external magnetic field, as opposed to considering excitations on top of a magnetization parallel to the magnetic field, as shown in Fig. 1(a-b). In such a *non-equilibrium* setup, the magnon excitations decrease the energy of the system, allowing us to tune the frequency of the edge modes to zero frequency. Since the non-equilibrium state is energetically unstable, it has to be rendered dynamically stable, which is achieved by an appropriate spin-orbit torque. Using numerical Landau-Lifshitz-Gilbert simulations we show that the edge modes can be excited at low frequencies, and are topologically protected against backscattering. Finally, we consider a propagating spin-wave spectroscopy (PSWS) experiment with two antennas, and demonstrate that the edge modes can be directly detected at gigahertz frequencies, even in the presence of disorder.

***Abstract*— We theoretically show how Gaussian quantum magnonic states, both propagating and confined, can be prepared using only external drives, by harnessing the intrinsic magnon nonlinearity.**

***Keywords*— magnons, quantum states, quatum magnonics.**

I. Introduction

Preparing certifiably quantum states of magnons represents a central milestone in the emerging field of quantum magnonics. Among these, Gaussian states are particularly attractive, as they can be prepared and manipulated without direct coupling to qubits, thereby allowing a wide range of current solid-state experiments to access the quantum regime.

II. Methods

We propose a method to prepare Gaussian quantum states of magnons. First, we propose to generate squeezed states and entangled states in the FMR modes of ellipsoidal magnets using parametric drive [1]. Then, we propose to prepare similar states in the continuum using phonons and magnetoelastic nonlinearity. We develop a comprehensive theory of nonlinear magnetoelasticity in thin films, quantize it, and use it to predict mean-field vacuum fluctuations of the magnetization [2]. We proceed to show that phonon-to-magnon down-conversion can result in the preparation of entangled propagating magnon states in state of the art thin film geometries.

III. Results and Discussion

- We predict vacuum squeezing up to 3dB in YIG ellipsoids.
- We predict strong entanglement between the FMR modes of two ellipsoids coupled via a cavity mode
- We propose detection methods that do not rely on single photon emitters, such as FMR and local coils.
- We analytically compute nonlinear coefficients associated with three-magnon, four-magnon, and magnon-phonon scattering in thin film geometries.
- We quantitatively predict experimental observations [3].
- We theoretically compute parametric instavility thresholds and predict that phonon-to-two magnon processes can dominate over Suhl instability process in state of the art geometries.
- We quantize our theory and provide exact nonlinear Heisenberg-Langevin equations for magnon and phonon amplitudes.
- We produce a mean-field theory of magnetization dynamics under 3-magnon Suhl instability process and compute the magnetization vacuum fluctuations across the parametric instability threshold.

IV. Conclusion

We demonstrate the possibility of preparing univocally quantum magnonic states and to detect and certify them using exclusively classical fields and classical measurements. Our work paves the way towards quantum magnonics without qubits.

Symmetry Principles and Topology-Driven Design of Knot-Particle Metasurfaces

Nadav Goshen[1], Yarden Mazor[1*]

[1]School of Electrical and Computer Engineering, Tel-Aviv University, Tel-Aviv, Israel
*Corresponding author: yardenm2@tauex.tau.ac.il

***Abstract*—We present a topology and symmetry driven design framework, for single-layer bianisotropic metasurfaces based on knot particles. Knot topology ensures intrinsic electric–magnetic balance and strong chiral response, while controlled mirror-symmetry breaking enables hybrid chiral–omega coupling. Experiments validate efficient polarization rotation and tunable asymmetric scattering without multilayer architectures.**

Summary

Bianisotropic metasurfaces enable advanced electromagnetic wave manipulation through engineered magnetoelectric coupling. However, achieving balanced electric-magnetic responses and simultaneous control over transmission and reflection asymmetries typically requires multilayer architectures or intensive numerical optimization. Here, we introduce a unified design framework in which *topology* and *symmetry* serve as the primary control parameters for single-layer bianisotropic metasurfaces based on nontrivial knot particles. Toroidal knots, characterized by integer winding numbers (p, q) (Fig. 1(a)) are inherently chiral and support resonant closed-loop current distributions. When arranged in periodic arrays and operated near their first resonance (where the total wire length is $\approx \lambda$), we show that for specific types of knots the excited current is dominated by its first harmonic. This enables analytical multipole modeling and direct derivation of electric and magnetic dipole moments from the knot geometry which yield the scattering response.

A key result is that knots satisfying $p = q \pm 1$ naturally fulfill the dipolar balance condition required for matched polarization rotation. In particular, the trefoil exhibits near-optimal performance. Its electric and magnetic dipoles satisfy a generalized Huygens condition,

$$\tilde{p}_{x,y} = \pm \tilde{m}_{y,x}, \tag{1}$$

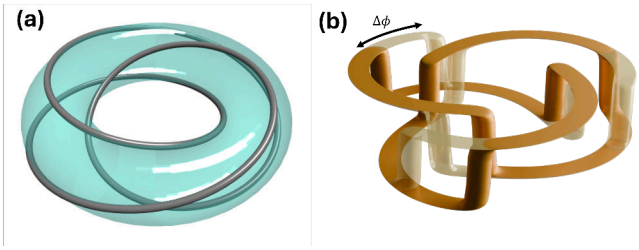

Fig. 1. (a) A toroidal trfoil knot. (b) A flattened trefoil, with controlled symmetry breaking by via offset $\Delta\phi$.

with a $\pi/2$ phase difference between orthogonal components. This balanced coupling suppresses reflection and enables efficient linear-to-linear polarization conversion. Retrieved surface susceptibilities confirm strong chiral bianisotropy originating directly from the knot topology.

While topology governs intrinsic chirality, symmetry controls the allowed coupling pathways. To extend beyond purely chiral behavior, we introduce controlled mirror-symmetry breaking in a quasi-planar trefoil implementation (Fig. 1(b)). The three-dimensional knot is projected onto a substrate and interconnected through vertical vias. When offsetting alternating vias by a geometric phase $\Delta\phi$, mirror symmetry between the two faces is broken while preserving the underlying topology. This single geometric parameter activates additional orthogonal dipole coupling, yielding a richer bi-anisotropic response.

Dipole decomposition shows that symmetric via placement ($\Delta\phi = 0$) permits only parallel electric–magnetic coupling, corresponding to pure chiral response ($\mathbf{p} \parallel \mathbf{m}$). When $\Delta\phi \neq 0$, orthogonal coupling ($\mathbf{p} \perp \mathbf{m}$) emerges, enabling omega-type bianisotropy alongside the chiral response. The resulting hybrid chiral-omega metasurface simultaneously supports cross-polarized transmission and asymmetric co-polarized reflection within a single-layer structure.

We experimentally validate these principles using both fully three-dimensional additive manufacturing and low-loss printed circuit board (PCB) implementations. Despite geometric simplification in the planar PCB realization, the essential topological and symmetry features are preserved. Measurements confirm strong polarization rotation near resonance (approaching 90° in optimized PCB samples) and demonstrate controllable hybrid behavior through symmetry engineering.

Together, these results establish a design paradigm for knot-particle metasurfaces: topology sets electric-magnetic balance and intrinsic chirality, while symmetry provides continuous control over bianisotropic coupling. This approach enables compact, single-layer realization of pure chiral or hybrid chiral–omega responses without multilayer stacking or material anisotropy, opening pathways toward advanced polarization control, asymmetric scattering, and reconfigurable electromagnetic devices.

Dynamical orbital magneto-electric response in complex materials

Yuriy Mokrousov

Peter Grünberg Institut, Forschungszentrum Jülich, Jülich, Germany
Institute of Physics, Johannes Gutenberg University Mainz, Mainz, Germany

Electrons' spin angular momentum has revolutionised magnetic technology, pushing its energy efficiency and speed to new heights. However, controlling orbital angular momentum (OAM) still remains a significant challenge, with significant advances made only very recently. OAM's origins lie in the spatio-temporal dynamics of atoms, electrons, spins and light, making it a unique force capable of igniting coupled dynamics across various order parameters and quasiparticles. This potential unlocks novel exotic properties and functionalities in hybrid magnon-phonon-electron architectures. The emerging field of orbitronics, i.e. OAM generation, manipulation and conversion, is considered one of the most promising areas within magnetism and its applications. In my talk I will explore the idea that structurally complex materials such as chiral and low-symmetry two-dimensional materials can naturally develop non-local electronic orbital response to external magnetic fields, light and lattice vibrations, which allows to transform chirality – statically or dynamically inherent either to structure, spin order or electro-magnetic field – into prominent orbital magnetism [1,2]. Moreover, I will show that in materials with non-trivial magnetic structure such as magnetic oxides [3], where the non-equilibrium magnetic properties have been traditionally interpreted in terms of spin, the strong orbital magneto-electric response can be utilized to drive strong unexpected torques and give rise to novel magnetoresistance phenomena. Overall, I will aim to identify novel avenues in engineering orbital coupling and angular momentum transfer which may resonate within the paradigm of hybrid angular-momentum-based electronics.

Pure moving optical media at microwave frequencies using magnetochiral metasurfaces

Toshiyuki Kodama

Institute for Excellence in Higher Education, and Organization for Advanced Studies, Tohoku University, Sendai, Japan
*Corresponding author: tkodama@tohoku.ac.jp

***Abstract*—We study microwave bianisotropies using magnetochiral (MCh) metasurfaces consisting of double Z-type gammadions with perpendicularly magnetized substrates. Combination of the metasurfaces with contraposition MCh metasurfaces cancels both the chiral-type bianisotropy and MO effect, resulting in pure moving optical media.**

***Keywords*— metasurface, magnetchiral effect, non-reciprocal moving-type bianisotropy.**

I. Introduction

In optics, discrete symmetries such as space-inversion (P) and time-reversal (T) govern physical restrictions. Breaking these symmetries gives rise to bianisotropy —magnetoelectric couplings categorized into four types (chiral, omega, Tellegen, and moving) based on reciprocity and polarization dependence [1]. The control of the bianisotroies is a challenge in natural materials with broken symmetries such as multiferroic materials [2]; therefore, man-made structured materials, referred to as metamaterials, are suitable to explore bianisotropies [3]. In particular, metasurfaces with two-dimensional planar structures are good playgrounds to embody a tailor-made bianisotropic medium [4].

II. Numerical simulation setup

Figure 1(a) illustrates a cell of the metasurface consisting of double Z-type gammadions with perpendicularly magnetized substrates, while (b) is a unit cell of composite metasurfaces [5]. The gammadions are made of perfect electric conductor. The unit cell is repeated in the x and y directions by a periodic boundary condition. The relative electric permittivity of the substrate is constant ($\varepsilon_{\rm r} = 3.3$). The permeability tensor $\mu_{\rm r}$ for lossless substrates is described by

$$\mu_{\rm r} = \begin{bmatrix} 1 & jm & 0 \\ -jm & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad (1)$$

where a parameter denoted by m is related to magnetization of the substrates. The S-parameters for microwave transmission and reflection are numerically calculated using RF module of COMSOL Multiphysics. Incident microwave in $-z$ direction is linearly polarized along the x-direction as indicated by a green arrow in Fig. 1(a).

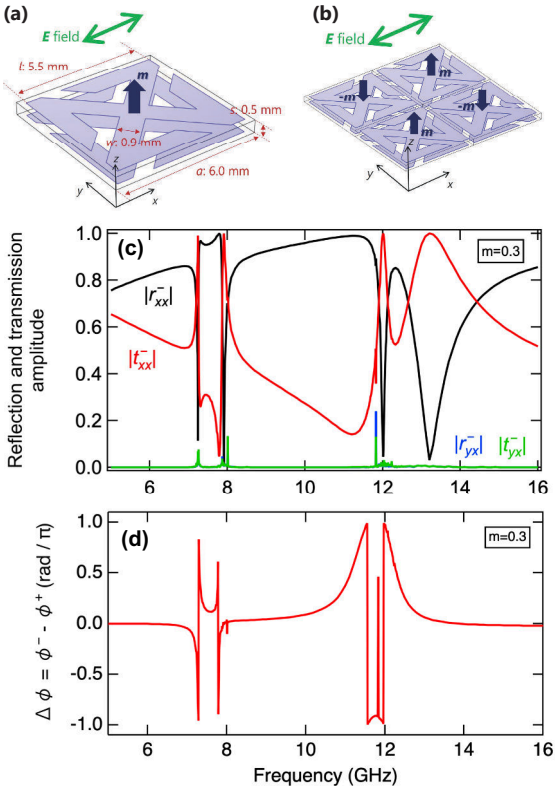

Fig. 1. (a) A calculated MCh metasurface. (b) A unit cell of a calculated composite metasurface including ordinary and contraposition MCh metasurfaces. (c) Calculated spectra and (d) directional phase difference spectra with $m = 0.3$ for the composite MCh metasurface.

III. Results and Discussion

Figure 1(c) shows the transmission and reflection coefficients spectra of the composite MCh metasurface. The subscripts denote the polarization planes of the electric field. $|r^{-}_{yx}|$ (blue) and $|t^{-}_{yx}|$ (green) accompanied by polarization rotation are almost zero, indicating that both the chiral-type bianisotropy and MO effect with polarization rotation are no longer functioning in the composite metasurface. Contrastingly, the directional phase difference spectrum plotted in Fig. 1(d) demonstrates the moving-type bianisotropy survives at approximately 7.5 GHz and 12 GHz.

Moreover, the transmission and reflection amplitude spectra in Fig. 1(c) show that perfect transmission and no reflection are achieved at 12 GHz, indicating the impedance matching. In addition, Figure 1(d) indicates that the phase difference is π at 12 GHz. This way, the ideal gyrator for arbitrary polarizations is realized using the composite metasurface with ordinary and contraposition MCh metasurfaces.

IV. Conclusion

Bianisotropies in MCh metasurfaces are studied. The chiral-type bianisotropy and MO effect are eliminated by the combining the ordinary MCh metasurfaces with the contraposition MCh metasurfaces, brings pure moving optical media. The pure moving optical media demonstrate perfect transmission with phase difference of π, which is a key to embody an ideal gyrator for arbitrary spatial and polarization modes.

Intrinsic Hyperbolic Anisotropy for Low-Loss Polarization Control and Chiral Light–Matter Interaction

N. Melchioni, A. Mancini, G. Venturi, L. Nan, A. Efimova, S. Chiodini, A. Ambrosio

Istituto Italiano di Tecnologia, Via Rubattino 81, 20134 – Milano, Italy

Abstract: The ability to control light polarization at the nanoscale is central to chiral and magnetoelectric light–matter interactions, particularly in regimes combining strong field confinement with low optical losses. Here we investigate natural van der Waals hyperbolic crystals as a platform for intrinsic, lithography-free polarization control enabled by extreme in-plane optical anisotropy. Focusing on molybdenum oxychloride ($MoOCl_2$), we show that broadband hyperbolicity in the visible and near-infrared arises from a strongly anisotropic Drude response, yielding metallic and dielectric behavior along orthogonal crystal axes. This intrinsic symmetry breaking enables polarization-selective reflection and transmission with minimal dissipation, as well as highly confined hyperbolic plasmon polaritons with polarization-dependent dispersion. These results establish natural hyperbolic materials as a promising route toward low-loss polarization engineering and chiral light–matter interaction in nanophotonic and quantum platforms.

Polarization is a fundamental degree of freedom governing symmetry, selection rules, and angular momentum exchange in light–matter interaction. In chiral and magnetoelectric photonics, efficient polarization control must be achieved at deeply subwavelength scales while preserving low optical losses, a condition that remains challenging for conventional metasurfaces and metallic nanostructures. Natural hyperbolic materials provide an alternative route, where polarization selectivity emerges intrinsically from crystal symmetry rather than artificial patterning.

In this work, we focus on the van der Waals crystal $MoOCl_2$, a low-symmetry biaxial material exhibiting broadband in-plane hyperbolicity spanning the visible to the near-infrared. Owing to a strongly anisotropic Drude response, $MoOCl_2$ displays metallic behavior along one in-plane axis and dielectric behavior along the orthogonal one, resulting in record-high in-plane permittivity anisotropy. Thin flakes enable near-unity polarization extinction through simultaneous high reflectivity and high transmission along orthogonal axes, without relying on absorption-driven dichroism. This behavior enables ultrathin, low-loss polarization elements operating well below the diffraction limit.

Beyond far-field polarization control, the hyperbolic nature of $MoOCl_2$ supports highly confined plasmon polaritons with polarization-dependent dispersion and propagation direction. Near-field nano-imaging reveals hyperbolic and canalized propagation regimes governed by the interplay between polarization, momentum, and crystal anisotropy, including topological transitions between elliptic and hyperbolic dispersion. These symmetry-driven regimes provide direct access to polarization-selective electromagnetic environments.

By combining extreme spatial confinement with intrinsic polarization selectivity, natural hyperbolic crystals offer a powerful platform for chiral and symmetry-sensitive light–matter interactions. Our results pave the way toward polarization-engineered coupling to quantum emitters, chiral nanophotonics, and magnetoelectric phenomena in structured electromagnetic fields, without the need for complex nanofabrication.

***Abstract*— We present optical manipulation of nanoparticles using focused beams carrying angular momentum. Generalized optical binding stabilizes rotational motion of nanoparticle assemblies and enables fusion-driven self-ordering via scattered-light interactions. We also analyze how stimulated recoil force (SRF) from resonant stimulated emission modifies optical-vortex-driven rotation, suggesting experimental signatures such as rotation reversal.**

***Keywords*— optical forces, optical vortices, nanoparticles, stimulated recoil force.**

I. Introduction

Since the invention of optical tweezers by Ashkin et al. [1], optical manipulation techniques for nano- and microparticles have advanced significantly. These techniques are now widely used across various fields of fundamental research and practical applications. A particularly promising direction is the manipulation of nanoscale materials, where precise control remains challenging.

Recently, optical forces associated with angular momentum have attracted significant interest. For instance, optical binding and rotation of metallic nanoparticle assemblies have been demonstrated under circularly polarized light [2,3], where hexagonal assemblies form beyond the focal spot and exhibit rotational motion. Optical vortices can also induce particle rotation that follows the sign of the light's orbital angular momentum, and chiral surface structures can be generated by optical vortices, reflecting their angular momentum [4]. In this paper, we introduce generalized optical binding in nanoparticle assemblies and the formation of ordered structures using two circularly polarized laser beams. We further explore, theoretically, how stimulated emission affects optical-vortex-driven rotation.

II. Results and Discussion

(1) It is known that when a focused laser beam traps gold nanoparticles, additional particles can become bound outside the focal spot, forming structures often at distances corresponding to integer multiples of the incident wavelength (in the surrounding medium). When the beam is circularly polarized, a hexagonal pattern forms and the assemblies rotate. Notably, the rotation direction does not necessarily align with the handedness of the circular polarization [2,3]. In our study [5], we analyzed this rotational motion in terms of spin–orbit coupling and angular momentum generation, and showed that the rotation direction of bound particles can be controlled by adjusting the numerical aperture of the focused beam. These results provide insights into the creation and control of large-area ordered nanoparticle assemblies using scanning laser beams.

(2) We extended the above theoretical study to the case of two laser beams and investigated generalized optical binding [6]. When particle assemblies are irradiated with two beams, two hexagonal arrays form, and their mutual interaction begins through the scattered field. Their rotations stop at specific separations and relative angles, forming distinctive standing-wave-like intensity patterns between them. This behavior differs from conventional optical binding between two individual particles, because the assemblies possess additional degrees of freedom, including collective rotation. Interestingly, when the two beams approach each other with a slight tilt, the assemblies can fuse and undergo reordering. This fusion-driven mechanism may provide a step-by-step route to large-area ordered nanoparticle structures

(3) For effective optical manipulation of nanoparticles, a promising approach is to use light resonant with electronic transitions in nanostructures [7]. Conventional resonant manipulation relies on absorption or scattering. We proposed a recoil optical force induced by stimulated emission, known as the stimulated recoil force (SRF) [8]. In relevant regimes, SRF can be less susceptible to saturation under strong driving than absorption-based forces, depending on the level structure and pumping scheme, leading to a substantially enhanced force. Experimental confirmation of SRF has been reported [9], and we proposed a scheme to sort nanodiamonds using SRF [10]. A key question is how SRF influences optical-vortex-driven rotation. We present a theoretical demonstration suggesting that SRF can be detected by monitoring changes, including possible inversion, of nanodiamond rotational motion in experiments

III. Conclusion

We reviewed our recent studies on angular-momentum

optical forces, highlighting generalized optical binding that stabilizes and reconfigures rotating nanoparticle assemblies, including fusion-driven self-ordering. We further showed that SRF can qualitatively alter optical-vortex-driven rotation, offering a practical signature for identifying SRF via rotational reversal and related changes.

***Abstract*—We theoretically investigate photoinduced magnetic phase transitions in the cubic Kondo-lattice model and show that light irradiation drives a magnetic phase transition from a ferromagnetic ground state to three-dimensional antiferromagnetic nonequilibrium steady state. This transition is induced by photoinduced pseudo half-filling of the exchange-split band and is accompanied by transient antiferromagnetic correlations.**
***Keywords* photoinduced magnetic phase transition, Kondo-lattice model, nonequilibrium steady state**

I. Introduction

Light-matter interaction enables ultrafast and energy-efficient control of nonequilibrium material states, and photoinduced magnetic phase transitions have attracted great interest, especially in spin-charge coupled systems such as Kondo-lattice magnets [1]. While previous theoretical studies have mainly focused on two-dimensional systems, understanding photoinduced magnetism in three dimensions is essential for realistic materials. We thus theoretically study photoinduced phase transitions in a cubic Kondo-lattice model [2].

II. Methods

We numerically simulate spatiotemporal dynamics of itinerant electrons and localized spins in the photodriven cubic Kondo-lattice model described by the time-dependent Hamiltonian $\mathcal{H}(\tau) = \mathcal{H}_{\rm kin}(\tau) + \mathcal{H}_{\rm exc}(\tau)$ with

$$\mathcal{H}_{\rm kin}(\tau) = \sum_{\langle i,j\rangle,s} t_{ij}(\tau)\, c_{is}^{\dagger} c_{js} + \text{h.c.} \tag{1}$$

$$\mathcal{H}_{\rm exc}(\tau) = -\frac{J}{2S} \sum_{i,s,s'} \boldsymbol{S}_i(\tau) \cdot c_{is}^{\dagger} \boldsymbol{\sigma}_{ss'} c_{is'}, \tag{2}$$

where

$$t_{ij}(\tau) = \begin{cases} -t & (\tau < 0) \\ -t \exp[-i\boldsymbol{A}(\tau)\cdot(\boldsymbol{r}_i - \boldsymbol{r}_j)] & (\tau \geq 0). \end{cases} \tag{3}$$

Here $\boldsymbol{A}(\tau)$ is a time-dependent vector potential of the light electromagnetic field. The following three cases with different light polarizations are examined: (1) linearly polarized light with $\boldsymbol{E} \parallel [100]$, (2) linearly polarized light with $\boldsymbol{E} \parallel [110]$, and (3) circularly polarized light.

We study the spin-charge dynamics of this model by numerically solving the time-dependent Schrödinger equation and the Landau-Lifshitz-Gilbert equation simultaneously [3]. The equations are given, respectively, by,

$$i\frac{\partial}{\partial \tau} |\tilde{\Psi}_\alpha(\tau)\rangle = \mathcal{H}(\tau) |\tilde{\Psi}_\alpha(\tau)\rangle \tag{4}$$

and

$$\frac{\partial \boldsymbol{S}_i(\tau)}{\partial \tau} = \boldsymbol{h}_i^{\rm eff}(\tau) \times \boldsymbol{S}_i(\tau) + \frac{\alpha_{\rm G}}{S} \boldsymbol{S}_i(\tau) \times \frac{\partial \boldsymbol{S}_i(\tau)}{\partial \tau}. \tag{5}$$

III. Results and Discussion

We find that light irradiation drives a transition from a ferromagnetic ground state to three-dimensional antiferromagnetic nonequilibrium steady state in the cubic Kondo-lattice model. This photoinduced magnetic phase transition originates from pseudo half-filling of the exchange-split band and is accompanied by transient antiferromagnetic correlations.

IV. Conclusion

We theoretically investigated photoinduced magnetic phase transitions in the cubic Kondo-lattice model and demonstrated that light irradiation drives a transition from ferromagnetism to three-dimensional G-type antiferromagnetism via dynamical localization and pseudo half-filling of the exchange-split band. Transient A-type or C-type antiferromagnetic correlations emerge depending on light polarization. We have also performed a Floquet magnon analysis which reveals that polarization-dependent magnon softening underlies these nonequilibrium magnetic instabilities. Our findings provide important insights into the understanding of photoinduced magnetic phase transitions in the three-dimensional Kondo-lattice magnets.

GHz acoustic vortex for the manipulation of orbital angular momentum of light

Alessandro Pitanti[1,2,*], Paulo V. Santos[3]

[1]Department of Physics, University of Pisa, Italy

***Abstract*—Acoustic perturbation of photonic structures enables dynamic modulation of light amplitude and phase at ultra high frequencies. By shaping acoustic fields, fast control of light angular momentum becomes possible. We report GHz acoustic vortices for advanced light modulators.**

***Keywords*— acoustic vortex, ultra-high frequency, OAM.**

I. Introduction

Light based telecommunication promises to overcome the limitations of microwave systems by enabling amplitude and phase modulation well beyond the 100s of GHz range. However, its large scale adoption is still hindered by sensitivity to atmospheric perturbations, power consumption, and the need for compact integrated devices. A promising strategy is to exploit additional degrees of freedom of light, such as spin and orbital angular momentum (OAM), to fully leverage the vectorial nature of photons [1], [2]. Encoding information in polarization or OAM improves robustness in highly scattering environments [3] and enables massive data rate increases via multiplexing [4]. Currently, accessible OAM bases are limited by quasi-static generators relying on phase masks or metasurfaces. A fast, tunable, free space OAM generator would therefore be transformative. Here we propose controlling light OAM using GHz mechanical vortices generated by bulk acoustic waves (BAW) [5].

II. Methods

BAW based devices are an established and robust technology for high frequency microwave filtering, operating in the tens of GHz range and beyond. They rely on longitudinal acoustic resonances confined between the top and bottom surfaces of a substrate and excited by a bulk acoustic wave resonator (BAWR) consisting of a piezoelectric layer between metallic electrodes.

Acoustic vortex generation is achieved by engineering the geometry of the BAWR top electrode, which shapes the transverse acoustic wavefront. An Archimedean spiral of order M, defined as $\mathrm{AS}(\theta) = R_0 + \delta R \mod (M\theta, 2\pi)/2\pi$, imposes the phase condition for an acoustic vortex with topological charge $\ell = \delta R/\lambda$, where λ is the acoustic wavelength. Using a 700 nm ZnO BAWR on sapphire operating from 0.5 to 7.5 GHz, we demonstrate tunable ℓ values from 1 to 13 and beyond, validating the device as a high frequency, tunable acoustic vortex generator.

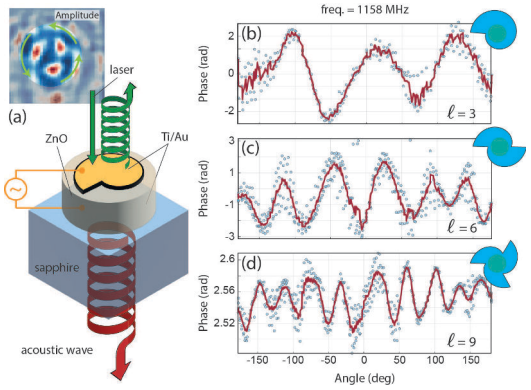

Fig. 1. (a) Device concept and acoustic map. (b) Topological charge scaling with spiral order.

III. Results and Discussion

Using laser interferometry, we mapped the acoustic vortex and demonstrated coherent phase transfer from acoustic excitations to optical fields via the moving boundary effect. Future work will focus on optimizing optomechanical coupling to achieve strong phase modulation and obtain an orthogonal angular momentum basis for light. Promising directions include copropagating schemes and the integration of tailored photonic cavities within the substrate.

***Abstract*—The measurement and description of light-matter interactions at the nanoscale lie at the heart of most nano-optics applications. Here we present a combination of nano-optics experiments and reconfigurable photonic integrated circuits, establishing the basis for nanoscale particle localization and multipolar decomposition of scattered fields.**

***Keywords*— nanooptics, integrated photonics, particle metrology.**

I. Introduction

Understanding light-matter interactions at the nanoscale is central to nano-optics, with applications in high-resolution microscopy [1], sensing [2], and optical manipulation [3]. Light scattered from nanoscale structures carries detailed information encoded in intensity, phase, and polarization, which are governed by a scatterer's characteristics, such as the geometry, material composition, and the resulting multipolar contributions. However, accessing the scattered light fields at the nanoscale remains challenging, as conventional cameras are restricted to intensity-based measurements only. Over the past years, reprogrammable photonic integrated circuits (rPICs) have emerged as a versatile solution for polarization- and phase-resolved measurement [4], [5] and generation [6] of (structured) light fields, thus allowing for flexible use in nano-optics applications.

II. Methods

In this paper, we present a custom-built nano-optics setup [7], [8] combined with an rPIC for the localization and multipolar scattering decomposition of individual nanoparticles. This approach is enabled by spatially sampling and analyzing the response of a nanoparticle to excitation with a tightly focused laser beam. Our setup consists of a high numerical aperture objective (NA = 0.9) that tightly focuses a linearly polarized Gaussian beam onto a nanoparticle located on a glass substrate (see Fig. 1). A second high NA objective (NA = 1.3) index matched to the substrate collects both the incoming and scattered light fields. By imaging the back focal plane of the collection objective, we map the angular spectrum (k-space) of the scattered fields onto the free-space interface of our photonic chip. An array of circularly arranged grating couplers spatially samples and distributes light into a mesh of Mach-Zehnder interferometers of the PIC [4], [5] (see Fig. 2). By actively reconfiguring the on-chip interferometers, we guide light across the photonic circuit, enabling the analysis of scattered light fields as the particle is moved across the tightly focused laser beam.

Fig. 1. Schematics of the nano-optics free-space setup combined with a photonic integrated circuit for particle metrology. An incoming Gaussian beam is tightly focused onto a nanoparticle using a high NA objective (NA = 0.9). The scattered light is collected with another high NA objective (NA = 1.3, index matched) and imaged onto the free-space interface of the photonic chip (see also Fig. 2).

III. Results and Conclusion

We analyze the sampled light by employing our theoretical framework based on transmission-matrix theory to infer detailed information about the intensity, phase, and polarization of the scattered light field, ultimately providing the basis for particle parameter retrieval such as position and multipolar contribution to the scattering. This is supported by a calibration

of the PIC outside the imaging path, where we use a well-defined reference beam with a flat phase front and uniform intensity distribution [5].

Fig. 2. Schematics of the photonic integrated circuit for processing light fields, as obtained by sampling the back-focal plane of the collecting objective through an array of circularly arranged grating couplers. On-chip processing of the incoming light is performed by a reconfigurable mesh of Mach-Zehnder interferometers, providing information about the intensity, phase, and polarization of the scattered light by analyzing the output ports of the photonic circuit.

We discuss the basic physical principles underlying our retrieval approach and demonstrate its applicability on the example of a silicon nanoparticle featuring rich resonance spectra.

Our results prove that the combination of tightly focused light fields with a reconfigurable photonic chip provides a versatile platform for field-resolved particle localization, sensing, and future nano-optics applications [9].

Magnetic Multipole Dependent Dichroism Arising from Vortex Light

A. Salam

Department of Chemistry, Wake Forest University, Winston-Salem, NC 27109, USA
salama@wfu.edu

Abstract: QED theory is used to calculate circular and vortex dichroism induced by structured light in a magnetically susceptible molecule. The magnetic dipole-quadrupole cross term arising from the interference of transverse and longitudinal magnetic fields results in non-vanishing dichroic effects, explaining the recent observation of helical dichroism in artificial propeller meta-molecules.

Recently, a propeller meta-molecule was fabricated via the nano-Kirigami method [1]. On irradiation with vortex light, helical dichroism was observed and attributed to orbital angular momentum possessed by the twisted beam. A novel mechanism was proposed to explain the differential absorption in this property of light, whose wavefronts propagate as left- or right-handed helices. This involved the interference of magnetic dipole and magnetic quadrupole coupling terms induced in the stereo-twisted blades of the meta-molecule. Often the dipole approximation is sufficient to describe dichroic effects occurring in chiral species such as molecules [2], for example the differential absorption of circularly polarized light, also known as circular dichroism (CD) [3]. Lower elements of symmetry in such handed forms of matter justifies including the next higher term beyond the dominant electric dipole interaction in the multipole expansion of the charge and current density distributions, namely the magnetic dipole coupling term, with the interference of these two contributions yielding a time-even parity-odd pseudoscalar quantity that changes sign when one structural isomer is substituted by its mirror-image form. In situations where the dipole approximation needs to be relaxed, such as when the dimensions of the absorber are large relative to the wavelength of light, the electric quadrupole interaction term is also added, with CD arising from the electric dipole-quadrupole interference contribution non-vanishing for anisotropic systems [3]. Chiroptical phenomena of this type have commonly been examined when electromagnetic radiation is described as a plane wave. Higher-order magnetic multipole coupling terms are therefore rarely invoked.

We present a quantum electrodynamical theory [2,4,5] of one-photon absorption induced by a circularly polarized optical vortex beam in a molecule characterized by magnetic dipole and magnetic quadrupole moments. The structured light is described by a Laguerre-Gaussian form which is a solution of the paraxial wave equation in plane polar coordinates [6]. Such a light field possesses orbital angular momentum in addition to spin angular momentum, with the former represented by the topological charge or winding number, l, and azimuthal phase angle, φ, and the latter by left- and right-handed circularly polarized vector components, σ. This results in the possibility of not only CD occurring, but also helical or vortex dichroism (VD) taking place, as well as coupling of spin and orbital angular momentum components of light, giving rise to circular vortex dichroism (CVD) [7]. The matrix element and Fermi golden rule absorption rate is calculated, along with formulae for the various dichroic effects, for contributions that are dependent on magnetic dipole and quadrupole moments.

Proceedings of META 2026 · Dublin, Ireland · 14–17 July 2026 · ISSN 2429-1390 · pp. 532–533

To ensure that no differential spin and orbital angular momentum effects are overlooked, the longitudinal magnetic field and its gradient, as well as the usual analogous quantities involving the transverse field, are included in the development. Previously, it was shown that only accounting for transverse fields led to zero VD for oriented and isotropic dipolar systems [6], while a non-vanishing VD occurs when longitudinal fields are added [8]. Since the action of the gradient operator on both the transverse and longitudinal structured light forms of the electric displacement field introduce a linear dependence on the topological charge, l, the electric dipole-quadrupole cross-term results in VD manifesting for the anisotropic situation [8].

In the present case, in which only magnetic dipole and quadrupole coupling terms are considered, it was found that the rates for CD, VD or CVD arising from the transverse magnetic field are all zero for the isotropic purely magnetic dipole contribution, while the corresponding contribution due to the longitudinal field exhibited CD only. Furthermore, all three forms of dichroism are found to be non-vanishing when the magnetic dipole-quadrupole cross-term is extracted from the interference of the transverse and longitudinal field and field gradient components, holding for oriented species and surviving a free rotational average. This explains the observation of helical or vortex dichroism in propeller meta-molecules and allows for the possibility of CD and CVD to also be detected.

Abstract— We investigate the relationship between crossings in Spin-Orbital-texture and the Berry-curvature-flux, in terms of divergence and vorticity, on avoided-crossing-manifolds in the Brillouin zone of analytic models and Van-der-Waals materials with Spin-Orbit coupling.

Keywords— Chirality, Spin-Orbital Texture, Spin-Hall Effect, Berry Curvature, Electrodynamics.

I. Introduction

While the topological classification of band structures has expanded rapidly, some of its foundations remained inconsistent: Could avoided crossings be the main sources of Berry curvature [1], rather than Dirac points ? Having a singularity at such, how do the textures of Spin/Orbital polarization translate to their Berry curvature counterpart ? And do these fields contain more than just scalar charges, possibly vorticity ? While Spin Weyl insulators [2], and pseudo-nodal line/ -sphere semimetals [3] have been studied by the community, it is necessary to employ Gauss+Stokes analysis of the vectorized BC to account for the chiral spin texture with a modified gauge [4] of the full perturbative spin current formula below.

II. Methods

We map the Spin texture and associated Berry curvature in momentum space, which allows to identify Bloch points at which the polarization vanishes or rotates in-plane, such that the Spinor wave-function gets twisted. We find that such SU(2) curvature is composed of 3 terms, namely an ordinary U(1) curvature within the spin channels, a twist of the channels resembling the skyrmion index, and a mixed torque of the spin texture under change of momentum.

$$\begin{aligned}\boldsymbol{\Omega}^{SU(2)}_{k_xk_y} &= -2\,\mathrm{Im}\left\langle \partial_{k_x}\begin{pmatrix}\chi_\uparrow\\ \chi_\downarrow\end{pmatrix} \middle| \partial_{k_y}\begin{pmatrix}\chi_\uparrow\\ \chi_\downarrow\end{pmatrix}\right\rangle \\ &= \nabla_{\mathbf{k}} \times \mathbf{A}_{U(1)} - i\left[\frac{\partial H}{\partial S_x},\frac{\partial H}{\partial k_y}\right] - i\left[\frac{\partial H}{\partial S_y},\frac{\partial H}{\partial k_x}\right] \\ &= \boldsymbol{\Omega}^{U(1)}_{kk} + \boldsymbol{\tau}_{sk} + \mathbf{S}\cdot\left(\partial_{k_x}\mathbf{S}\times\partial_{k_y}\mathbf{S}\right) \\ &= \sum_{n\neq m}\left[\frac{\langle n|v_{k_x}|m\rangle\langle m|v_{k_y}|n\rangle}{(E_n-E_m)^2} + \frac{\langle n|v_{S_x}|m\rangle\langle m|v_{S_y}|n\rangle}{(S_n-S_m)(E_n-E_m)} + \frac{\langle n|v_{S_x}|m\rangle\langle m|v_{S_y}|n\rangle}{(S_n-S_m)^2}\right]\end{aligned}$$

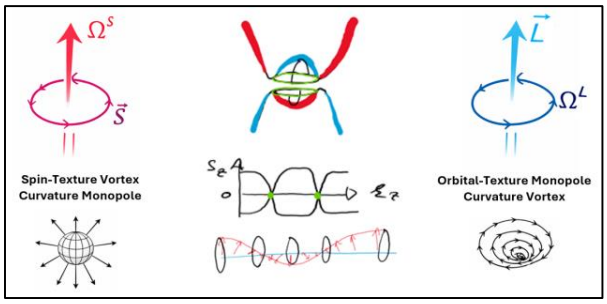

Fig. 1 Mechanism of Texture / Curvature conversion at avoided crossing.

III. Results and Discussion

We find in analytic derivation, simple models and DFT calculations of real systems that (Fig.1):

- SU2 curvature has divergence, torque and vorticity
- interaction manifolds with $S_z = 0$ are sources of Ω_S
- Rotation of Spin texture is a source of curvature
- A source of Oribtal texture rotates the Spin texture
- Spin-Orbit coupling transfers and adds curvatures

These results shed light on the curvature generating effects of Spin-Orbit coupling and similar symmetry-breaking terms which are the origin of abundant avoided crossing manifolds in the Brillouin Zone of materials.

IV. Conclusion

We show solid evidence to construct an effective Electromagnetism between Spin/Orbital texture and their Berry curvatures. Progress and limitations of these developments are discussed and connected with multiple fields in the community.

***Abstract*—We analyze a half-filled four-band ladder with a relative shift between legs that generates a moiré supercell and narrows minibands near the Fermi level. Short-range interactions produce an excitonic incommensurate CDW with a gapped Higgs mode and neutral phasons, whose velocity depends on the mismatch, suggesting an excitonic origin for $HfTe_3$.**

***Keywords*— Incommensurate charge density wave, excitons, moire, phason, ladder.**

I. Introduction

Layer mismatch in real materials often arises from differences between intra- and interlayer bonding, or from twisting, pressure, and strain. Such incongruities are common in low-dimensional systems and frequently lead to charge-density-wave (CDW) instabilities. While CDWs are often associated with the Peierls mechanism driven by electron–phonon coupling, many materials display charge ordering that cannot be explained by simple Fermi-surface nesting, pointing instead to interaction-driven or excitonic scenarios. In a CDW state, the charge density forms a standing-wave pattern described by a complex order parameter with amplitude and phase components. Fluctuations of these components give rise to collective modes: a gapped amplitudon and a phason, which becomes gapless in incommensurate states. Neutral phasons are of particular interest, as they may enable dissipationless collective transport and shed light on the interplay between charge order and superconductivity.

II. Model

We study a toy model of a heterostructure consisting of a half-filled, four-band ladder with a relative shift between the legs $\delta = p/q$, which creates a moiré supercell of q composite cells and a moiré potential that compresses layer bands into flat minibands near the Fermi level. The ladder of Fig.1(a) consists of two coupled legs, each with two sites (A and B) per unit cell. The composite ladder unit cell contains a total of four sites $\{A_1, B_1, A_2, B_2\}$ (subscripts $1, 2$ label legs). Throughout, we choose a, half the legs lattice constant, as the length unit, so the composite cell has a length equal to 2, and the original reciprocal period is $G_0 = \pi$. Leg-1 is uniform, while leg-2 is dimerized by a shift δ per cell. This becomes the moiré parameter of the ladder, $\delta = p/q \in (0, 1)$, where p and q are coprime integers.

III. Results and Discussion

The relative mismatch between legs yields a moiré supercell of q composite cells with $4q$ sites in total, a moiré reciprocal vector in the reduced Brillouin zone (RBZ) $b_s = \frac{G_0}{q} = \frac{\pi}{q}$, and a real-space supercell length $L_s = 2\,q$. The intra-leg nearest neighbor hopping, t, sets the bandwidth $W \sim 4t$. Inter-leg hopping (rung tunneling) occurs between the same sublattice, and its average is t. Schrieffer–Wolff perturbation theory [1] gives rise to a first-harmonic rung tunneling of amplitude $t_1 = (1-\delta)t$ modulated by the envelope $t_\perp(n) = t + t_1 \cos\left(\frac{2\pi n}{q}\right)$. The kinetic Hamiltonian is $H = \sum_k \Psi_k^\dagger\, H(k)\, \Psi_k$, with $\Psi_k = (c_{1,A,k}, c_{1,B,k}, c_{2,A,k}, c_{2,B,k})^\top$, and

$$H(k) = \begin{pmatrix} 0 & c(k) & t_\perp(k) & 0 \\ c(k) & 0 & 0 & t_\perp(k) \\ t_\perp(k) & 0 & 0 & c_\delta(k)\, e^{+i\phi(k)} \\ 0 & t_\perp(k) & c_\delta(k)\, e^{-i\phi(k)} & 0 \end{pmatrix}, \tag{1}$$

The Hamiltonian matrix of Eq.1 is given in the extended Brillouin zone (EBZ), $\mathrm{k} \in (-\mathrm{qG}_0, \mathrm{qG}_0)$. For a given δ, the similarity transformation $\Delta = \pi q$ applied to $H(k)$ imposes constraints on p and q that determine the generic global period $2\pi q$ that gives rise to EBZ.

Including Coulomb interactions within a mean-field approach, we find an excitonic incommensurate CDW phase characterized by a rung-odd charge-density modulation, leading to long-lived neutral phason excitations. We show that the moiré phasons of our model are Goldstone modes of the effective interacting theory in which the CDW slips, with a speed controlled by δ and the inter-leg tunneling amplitude.

The moiré-based framework developed here is naturally suited to quasi-1D materials with chain-like structural motifs. As a concrete example, we examine the transition-metal trichalcogenide $HfTe_3$, whose bulk displays charge-density-wave order [2], [3]. DFPT calculations on the surface reveal a phonon instability at $q \simeq 0.06\mathbf{b}^*$ involving out-of-plane motion of the dimerized Te chains, generating a long-wavelength structural modulation. This distortion is accommodated in a $12\times1\times1$ supercell, whose relaxed geometry develops a chain-dependent phase shift—an explicit real-space moiré pattern emerging at negligible energetic cost. A Wannier analysis shows dominant intra-chain dimerization and weak inter-chain tunneling, motivating a reduced strong-coupling model with chain-dependent oscillatory hoppings. The resulting moiré

Hamiltonian reproduces the flat minibands, band reconstruction, and gap openings obtained in the DFT supercell, demonstrating that the instability-driven modulation reshapes the low-energy electronic structure in direct analogy with moiré systems. The changes in the charges due to modulation have a dipolar pattern consistent with long-range neutral excitations.These results highlight chain-dependent phase shifts and structural incongruities as a microscopic pathway to electronic instabilities in quasi-1D materials.

Fig. 1. (a) Schematic illustration of the effective moiré ladder model. The moiré modulation does not arise from a geometric lattice mismatch but from a long-wavelength modulation of the inter-leg tunneling, representing an emergent symmetry-broken state (b-d) Band spectra of the kinetic Hamiltonian $H(k)$ in the EBZ at (b) $\delta = 1$, (c) $\frac{19}{20}$ and (d) $\frac{17}{20}$.

IV. Conclusions

In this work, we demonstrate that the ordered phase of the moiré-modulated two-leg ladder realizes an excitonic charge-density wave. Microscopically, it is characterized by a particle–hole condensate formed between two flat minibands. Rung modulation produces a small indirect band gap, which permits interband particle–hole pairing, analogous to the mechanism of excitonic insulators in multiband semimetals. At the mean-field level, the resulting Hamiltonian is algebraically equivalent to a BCS Hamiltonian, except that the usual pairing sector is replaced by particle–hole coherence. Because the CDW in this electronic model does not couple to the lattice and breaks a continuous symmetry, the system hosts a neutral acoustic phason, which is the Goldstone mode of the excitonic condensate. The dispersions of the CDW collective modes, the phason and the amplitudon, appear in the two-particle spectral function computed from the retarded susceptibility, whose imaginary part also depicts the CDW continuum at higher energies.

As the effective interleg modulation amplitude is proportional to $(1-\delta)$, both the miniband width and the relevant Fermi velocity scale as $(1-\delta)t$, the phason stiffness scales as $(1-\delta)^2 t$, whereas the phason inertia maintains the $1/t$ scaling, up to weak δ-dependent corrections. Consequently, the phason velocity scales as $t(1-\delta)$.

RKKY-like interactions between two magnetic skyrmions

X. R. Wang

phxwan@cuhk.edu.cn

Abstract

Interaction between two tilted skyrmions in a chiral magnetic film changes from replusion to attraction periodically with skyrmion-skyrmion distance along certain direction, akin to the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. The essential physics is behind a previously unrecognized universal wavy tail in the skyrmion spin texture. The RKKY-like interaction is universal for all tilted skyrmions.

1 Introduction

It is well known that two isolated skyrmions in a vertically magnetized chiral film always repel each other [1–6]. However, recent studies have found that skyrmion-skyrmion interaction can be attractive under the tilted external fields [7–9], or through thermal frustration [10], or by varying sample thickness [11, 12], and or through frustrated exchange interactions [13–15]. Despite of all progress, the underlying physics of these interactions remains poorly understood, and a clear understanding of the conditions under which two skyrmions in a chiral film can attract each other is still lacking.

We demonstrate here that skyrmion–skyrmion interactions in titled (from the film perpendicular direction) chiral magnetic films, caused by either a tilted magnetic field or magnetic anisotropy, are intrinsically Ruderman-Kittel-Kasuya-Yosida-type (RKKY-type), periodically alternating between attraction and repulsion. The tail of an isolated in-plane skyrmion inherently possesses a periodic spin structure along the direction of the skyrmion's center spin, with the same period as that of the interactions. When two skyrmions are aligned along this periodic direction and separated by an integer multiple of the period, their wavy tails coincide, allowing them to share the same wavy tail, which results in a reduction in total energy and an attractive interaction. Conversely, at separations of half-integer multiples of the period, the two tails are out of phase, and significantly deformation is needed in order for two skyrmions to connect each other smoothly, leading to an increase in total energy and a repulsive force between them. These findings provide new insights into the nature of skyrmion–skyrmion interactions and open up avenues for engineering skyrmion-based devices with controllable collective behavior.

A chiral magnetic film of thickness d lying in the xy-plane is modeled by the magnetic energy E, which consists of several components: the exchange energy $E_{\rm ex} = \frac{Ad}{2}\int |\nabla \mathbf{m}|^2 \,\mathrm{d}^2\mathbf{x}$, where the exchange stiffness $A = 30\,\mathrm{pJ/m}$ is fixed and $\mathbf{m}$ is the direction of magnetization with a saturation magnetization $M_s = 1\,\mathrm{MA/m}$; the Dzyaloshinskii–Moriya interaction (DMI) $E_{\rm DM} = \frac{Dd}{2}\int [\mathbf{m}\cdot(\nabla\times\mathbf{m})]\,\mathrm{d}^2\mathbf{x}$ with DMI strength $D = 4\,\mathrm{mJ/m^2}$; the anisotropy energy $E_{\rm an} = d\int -\frac{K}{2}(m_y\sin\theta + m_z\cos\theta)^2\mathrm{d}^2\mathbf{x}$ where K is the anisotropy constant along the easy axis in the yz-plane, determined by the angle θ; the magnetic dipolar energy, which can be incorporated into the effective anisotropy term $\frac{\mu_0 M_s^2 m_z^2}{2}$, with μ_0 being the vacuum permeability; and the Zeeman energy $E_{\rm Ze} = -\mu_0 M_{\rm s} d\int \mathbf{H}\cdot\mathbf{m}, \mathrm{d}^2\mathbf{x}$, where $\mathbf{H}$ is the external magnetic field. Only K,

θ, and $\mathbf{H}$ vary to model different situations [16–18]. Two cases are considered: the first is $\mathbf{H}$ controlled anisotropy, where $\theta = 0$ and $K = 1.256\,\mathrm{MJ/m^3}$ are set to cancel the shape anisotropy, making the easy axis unsymmetrical and preferably aligning spin with $\mathbf{H}$. The second case involves setting $\mathbf{H} = 0$ and using K and θ to control the magnetic anisotropy, resulting in a symmetrical axis.

2 Skyrmion-skyrmion interaction

We fix the center of one skyrmion at the sample center $(0, 0)$ and the other at (x, y), with their center spin direction set to $\mathbf{m} = (0, 1, 0)$ in the background of spin states of $\mathbf{m} = (0, -1, 0)$ (far from two skyrmion centers). The remaining spins in the film follow the Landau-Lifshitz-Gilbert (LLG) equation and settle into a stable configuration. Figure 1(a) is the energy surface $E(x, y)$ of the two skyrmions in their stable configuration when an external field of $H = 0.164\,\mathrm{T}$ is applied along the $-y$-direction. Notably, $E(\pm x, \pm y) = E(x, y)$, so it is sufficient to plot $E(x, y)$ in just one quadrant. The energy function $E(x, y)$ is clearly anisotropic, and the interaction between the two skyrmions is also anisotropic. Along the x-axis ($y = 0$), the total energy decreases monotonically with x (black line in Fig. 1(b)), indicating that the two skyrmions repel each other. In contrast, along the y-axis ($x = 0$), the energy profile exhibits RKKY-like oscillatory behaviour with multiple energy minima at $y_{min} = 66.5, 156.5, 247.5\,\mathrm{nm}$ (red line in Fig. 1(b)), implying an alternating attractive and repulsive interactions between the two skyrmions. In other directions, oscillatory behaviour persists with the period of $\lambda/\sin\phi$, where ϕ is the angle between the skyrmion-skyrmion displacement (x, y) and y-axis, $\lambda \approx 156.5 - 66.5 \approx 247.5 - 156.5 \approx 90 \sim 91\,\mathrm{nm}$ which is not sensitive to H and ϕ. The blue curve in Fig. 1(b) is the energy variation along $y = x$ direction. According to energy surface $E(x, y)$, the skyrmion centred at (x, y) will relax to its local minimum at $(0, y_{min})$ when the skyrmion is allowed to move. Which y_{min} will end up with depends on the initial location of the skyrmion. Our simulations have confirmed this expectation.

Figure 1: (a) Energy surface $E(x, y)$ of two skyrmions for $H = 0.164\mathrm{T}$ along the y-axis. $E = 0$ is chosen for two isolated skyrmions infinitely apart. (b) $E(x, y)$ as a function of x along $y = 0$ (black line), or y along $x = 0$ (red line), or $\sqrt{x^2 + y^2}$ along $y = x$ (blue line). The vertical blue dash-lines indicate local minima.

3 Conclusion

In conclusion, skyrmions in a tilted magnetic field or in a title magnetic anisotropy with a sufficient large component in the film plane are anisotropic and have periodically wavy tails. This wavy tail leads to skyrmion–skyrmion attraction when the two tails match with each other in the overlapped region, and repulsion when their tails mismatch with each other. As a result, two tilted skyrmions exhibit RKKY-like interaction, oscillating between attraction and repulsion with a period that is determined by the period of wavy tail.

Anisotropic and oscillatory skyrmion–skyrmion interaction gives rise to new possibilities in skyrmion-based spintronics. The presence of multiple optimal skyrmion–skyrmion separations

offers an additional degree of freedom for controlling the dynamics of isolated skyrmions. Our findings thus open a promising avenue for advanced skyrmion manipulation such as creating skyrmion molecules or more complicated skyrmion superstructures.

Microwave radiation from high chirality vortex dynamics.

Feodor Y. Ogrin

School of Physics and Astronomy, University of Exeter, UK
*Corresponding author: f.y.ogrin@exeter.ac.uk

***Abstract*— Here I present a model which uses 3D finite-difference-time-domain (FDTD) approach together with Landau-Lifshits_Gilbert (LLG) equation to find the exact solutions for electromagnetic radiation from magnetic vortex structures in cylindrical elements. Using this model I demonstrate the spectrum of radiation and explore the system in terms of geometrical parameters as well as the collective excitation properties within a macroscopic pattern.**

***Keywords*— metamaterials, magnetization dynamics, highly chiral anisotropic systems.**

I. Introduction

Vortex closure domains, such as Landau pattern, have been a focus of interest for several decades. As well as being fascinating from purely fundamental perspective (including symmetry, nonlinearity, dynamics, and coupling effects), these systems find increasing attention with respect to potential technological applications. For example, if excited by a short electromagnetic pulse the vortex core can start a gyration motion around its equilibrium position, or serve as a source of spin waves. Effectively the vortex behaves as a harmonic oscillator [1-4]. The core dynamics is however very much dependent on the structures of both the domains and the domain walls. In thin film elements, the domain walls have a Néel configuration, with purely in-plane magnetisation. However, once the thickness is increased the topology is significantly modified, and due to the increased dipolar fields, the polarisation of the moment within the domain wall gains an out-of-plane component. In our recent experiments [5] we demonstrated that this additional polarisation can lead to a range of dynamic effects, such as a change in polarisation of the magnetic singularities associated with the Landau pattern. Moreover, our subsequent micromagnetic simulation studies suggest that in thicker elements one can also create spiral spin-wave modes, propagating in the domain walls as well as the surface of the elements. These modes have shown to develop amplitudes significantly exceeding those in the bulk of the material Furthermore, their dispersion characteristics can be easily tuned by the applied magnetic field, via the manipulation of the vortex core position in the sample. Such properties are extremely interesting for spin-wave logic devices, in which the ability to control the spin-wave dynamics is one of the main challenges faced in the development of future magnonic technologies.

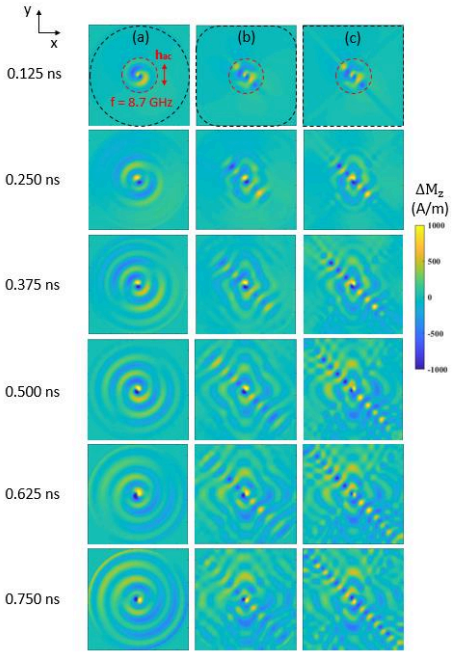

Fig. 1 . Micromagnetic simulation (using Mumax3 code) of spiral spin wave modes obtained in 80 nm thick circular (a) and square (b,c) permalloy elements. The spiral mode is initiated in the core and propagates outwards to the boundaries. In square elements, there is also a mode propagating in the domain wall (Winter's magnon) that interacts with the spiral mode and changes its topology.

II. Results and Discussion

While being a purely magnetic phenomenon vortex dynamics has also found its contribution to some electromagnetic applications. In the last two decades there have been an increased interest spin-torque oscillators, as microscopic microwave sources. A particular class of these devices relied on the vortex gyration in confined cylindrical ferromagnetic elements, where the vortex core gyration could be obtained in the microwave frequency range [6]. The main focus of the practical interest was based on the application of the devices serving as electrical sources (e.g. obtained via

magneto-resistance), however the direct radiation of microwaves from the oscillators was mainly discarded. The main difficulty is the low intensity for the direct observation of the signal, as well as the unavailability of the numerical tools to explore the effects. The 'usual' magnetostatic solvers, such as OOMMF or Mumax, while being the standard benchmark tools and usually provide a precise description of the magnetisation processes in thin-film ferromagnetic structures, are however limited in applications where full account of electric fields is required, especially when the material properties are extremely non-uniform (e.g. dielectric/metal interfaces). In such cases one needs to consider a modelling approach where a full solution of Maxwell equations is needed alongside the materialistic equations, such as e.g. Landau-Lifshits-Gilbert (LLG) providing the relation between the magnetisation and the magnetic field [7]. Here we demonstrate an application of such a model (MaxLLG ®) which uses 3D finite-difference-time-domain (FDTD) approach together with LLG to find the exact solutions for radiation effects produced by magnetisation dynamics in purely micromagnetic regime [8]. As an example we demonstrate a study of gyration effects in thin microscopic ferromagnetic discs, which exhibit vortex gyration as well as the excitation of the spiral magnetostatic waves, leading to microwave radiation. We explore the spectra of radiation from a single element and an array of elements and provide a practical assessment on potential application in practical microwave devices.

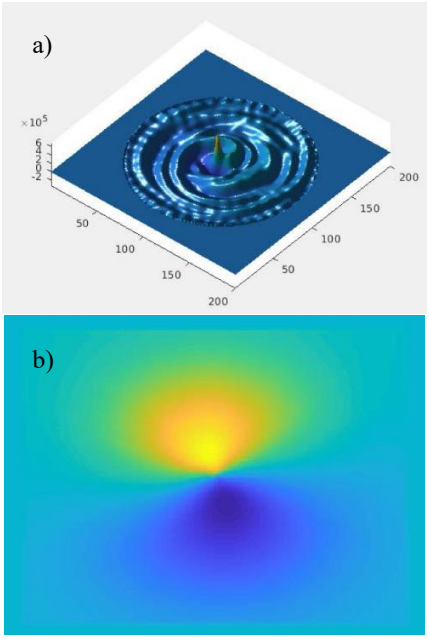

Fig. 2 . MaxLLG simulated vortex gyration in 2 µm disc. a) The core and the spiral waves, excited continuously with in-plane magnetic field. b) resulted electric field radiation pattern, spiralling clock-wise together with the core.

Feedback effects of electromagnetic interactions in bianisotropic media

Kei Sawada[1,*]

[1]RIKEN SPring-8 Center, Japan
*Corresponding author: sawada@spring8.or.jp

***Abstract*— An effective theory is developed for metamaterials exhibiting bianisotropy, with particular emphasis on magnetoelectricity and chirality classified by the space-time inversion symmetry. This approach gives a framework for representing the susceptibility functions including feedback effects due to magnetoelectric couplings.**

***Keywords*— chirality, magnetoelectricity, bianisotropy**

Metamaterials exhibiting bianisotropy have been of much interest for decades [1-2]. The bianistropy arises from symmetry breakings of the space-inversion and time-reversal, and describes electromagnetic couplings in media having non-reciprocal phenomena [3-6].

Consider an effective Lagrangian density describing light, matter and light-matter interaction:

$$\mathcal{L} = \mathcal{L}_{\text{light}} + \mathcal{L}_{\text{light-matter}} + \mathcal{L}_{\text{matter}}, \quad (1)$$

$$\mathcal{L}_{\text{light}} = \frac{1}{2}\varepsilon_0 \vec{E}^2 + \frac{1}{2\mu_0}\vec{B}^2, \quad (2)$$

$$\mathcal{L}_{\text{light-matter}} = \vec{j}\cdot\vec{A}, \quad (3)$$

$$\mathcal{L}_{\text{matter}} = f\left(\partial_x, \partial_y, \partial_z, \partial_t;\ \vec{P}, \vec{M}\right), \quad (4)$$

where ε_0 and μ_0 are the electric permittivity and the magnetic permeability of vacuum. The electromagnetic fields, electric polarization and magnetization are respectively written as $\vec{E}$, $\vec{B}$, $\vec{P}$, and $\vec{M}$, with the current, $\vec{j} = \partial_t \vec{P} + \frac{1}{\mu_0}\nabla \times \vec{M}$, and the vector potential, $\vec{A}$. The first term on the right-hand side of Eq. (1), $\mathcal{L}_{\text{light}}$, gives Maxwell equations, and the second term represents light-matter interaction. The third term, $\mathcal{L}_{\text{matter}}$, is a function of the electric polarization and the magnetization with space-time derivatives, and consists of all possible terms describing interactions inside the media as partly represented and classified in Table 1. The terms which are odd for space-inversion and/or time-reversal operations are origin of bianisotropy.

From Euler-Lagrange equations for each parameter in Eq. (1), we obtain the dielectric function, the magnetic permeability, and the chiral parameter tensor, which are self-consistently determined. This result demonstrates feedback behaviors arising from magnetoelectric couplings as well as electromagnetic inductions.

Table 1 Classification of parameters and typical examples of interactions in media under space-inversion and time-reversal operations. The subscripts, i, j, k, are x, y, or z.

	space inversion	time reversal
electric polarization $\vec{P}$	odd	even
magnetization $\vec{M}$	even	odd
spatial derivatives $\partial_x, \partial_y, \partial_z$	odd	even
time derivative ∂_t	even	odd
typical interactions:		
dielectric $P_i P_j$	even	even
chiral $P_i(\partial_j P_k)$	odd	even
magnetic $M_i(\partial_t M_j)$	even	odd
magnetoelectric $P_i M_j$	odd	odd

Towards compact microfluidic chips for efficient chiral recognition

David Ayuso[1,*]

[1] Department of Chemistry, Molecular Sciences Research Hub, Imperial College London, W12 0BZ London, United Kingdom

*Corresponding author: d.ayuso@imperial.ac.uk

***Abstract*— We present a route towards developing compact microfluidic platforms for efficient chiral sensing and manipulation. Our approach relies on creating synthetic chiral light inside compact microfluidic microchannels, so that the engineered light field can interact with liquid samples carrying chiral molecules in a highly enantiosensitive manner.**

***Keywords*— chirality, light-matter interaction, ultrafast science, microfluidics.**

Apart from their well-established roles in nanotechnology and drug discovery, small chiral molecules are emerging as biomarkers for early-stage diagnosis, prognosis, and personalised medicine [1]. However, unlocking the biomedical potential of small-molecule chiral detection requires being able to detect small variations in the concentration of a highly diluted biomarker (e.g. D-serine [1]) in a biological sample containing a large excess of the opposite enantiomer (L-serine). Traditional optical methods, namely polarimetry and circular dichroism, lack the sensitivity to resolve such differences, whereas chemical methods involving chromatographic columns or sophisticated analysis are not sufficiently general, rapid, and cost-effective [1].

The possibility of shaping light in 3D to shape the electronic response of chiral molecules on ultrafast timescales creates an opportunity to overcome these limitations [2]. Locally chiral light [3-6], where the tip of the electric-field vector draws a chiral Lissajous figure in time [3], can drive ultrafast electronic currents inside the molecules that interact with the chiral molecular potential in a highly enantiosensitive manner. It allows us to enhance the enantiosensitivity of traditional chiral spectroscopy from 0.1% up to 100% [3-6].

In this presentation, I will show how we can engineer compact microfluidic platforms to create locally chiral light inside their microchannels carrying liquid samples. Our ideas are supported by state-of-the-art numerical simulations showing that bringing the high chiral sensitivity from free-space optics [3-6] to confined microfluidic environments is very feasible. This creates an opportunity for designing compact microfluidic technology for efficient chiral recognition in the liquid phase, the natural environment of biological samples.

Chiral Metamaterials with Twisted Metallic Wire Structures

Ming-Li Chang[1], C. T. Chan[1,*]

[1]Department of Physics, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China

*Corresponding author: phchan@ust.hk

***Abstract*— Some chiral metallic photonic crystal exhibits unusual band structures. We show that chiral metallic twisted wire bundle structures can host zero frequency solutions at off-Γ k points, which can be explained by the real space topology of structures, and the results can be modeled by circuit models.**

***Keywords*— metallic photonic crystal, chiral system, Betti number, LC circuit.**

I. Introduction

Metallic photonic crystals (MPC) can exhibit strange band dispersions including multi-degeneracies [1], off-Γ point index ellipsoid [2], and quadratic dispersion at zero frequency at the quasistatic limit [3], and the results cannot be explained using standard effective medium theories even at close to zero frequency. Here, we investigate the extent to which the low-frequency bands in these chiral metamaterials can be modeled using circuit models and how these models relate to real-space topology..

II. Methods

We can obtain the band dispersion of twisted metallic wire systems (see an example in Fig. 1) using full wave simulation. One characteristic of these chiral systems is the existence of multiple off-Γ zero frequency solutions. The emergence of zero frequency solutions away from the zone center can be explained by an effective gauge potential induced by the chirality. We also note that the quasistatic bands of chiral MPC are TEM modes and the number of modes is determined by the real space topology. If there are N metallic components piercing the periodic boundary, there are N-1 modes emerge at zero frequency. It turns out the number of zero frequency solution related to the de Rham cohomology, and N is related to the second Betti number, which measures the number of independent harmonic 2-forms on a manifold. **Error! Bookmark not defined.**

We also note that the TEM modes in chiral MPCs show in Fig. 1a (a twisted bundle of 6 metallic wires, encapsulated in a hexagonal metallic wall). The full wave band structure is shown in Fig. 1d. Fig 1b shows a LC circuit model, employing the potentials and currents (ϕ_n, I_n) of each metal components as parameters. Fig. 1e shows the band dispersion of this simple model. Fig. 1c shows an "arbitrarily connected" metal wire system, in which only the permutation is the same as Fig. 1a. Fig. 1f shows its band (full wave). We found that for twisted MPC, the number of zero frequency solutions are given by

$$Nka = 0(mod\ 2\pi) \quad , \tag{1}$$

where a is the period in the twisting direction.

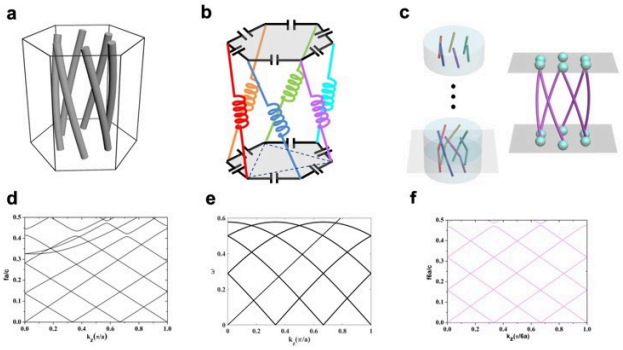

Fig. 1 Unit cells of twisted MPC and their corresponding dispersions.

III. Results and Discussion

Some salient features of the band dispersion of the twisted metal wires show in Fig 1a:

- Zero frequency solutions can be found at $k = 0, \pm\frac{1}{3}\pi, \pm\frac{2}{3}\pi, \pm\pi$ for the six twisted wires (Fig. 1a and d).
- These low frequency modes are TEM modes and their dispersion can can be captured by the LC model (Fig. 1b)
- There is good agreement of dispersions between the full wave simulation and circuit model (Fig. 1e)
- The number of zero frequency solutions is determined by the Betti number and the dispersion is primarily determined by the connectivity. Even if the wires are deformed inside the unit cell, but if they exhibit same permutation (how the wires connect from one side to another side of unit cell) as in Fig. 1a, they display essentially the same quasistatic bands (Fig. 1c and f).

When the wires are twisted in one dimension as shown in Fig.

1, the dispersion are well captured by the LC circuit and the bands are basically determined by connectivity. In higher dimension, there are modes that are not TEM modes and nonlocal effect will emerge if longitudinal component exists [4]. In these cases, their interaction by the EM waves in background medium should also be included for dispersion description.

IV. Conclusion

We have demonstrated the zero frequency solutions can be explained by topological number and their dispersions can be related to the LC circuit model. These chiral systems exhibit multiple solutions at different k values for the same frequency, and might be useful for suppressing cross talks among adjacent waveguides.

When Chirality Protection Fails: Bulk-Mediated Reflection of Surface Spin Waves

Alexander A. Serga[1,*]

[1]Fachbereich Physik and Landesforschungszentrum OPTIMAS,
Rheinland-Pfälzische Technische Universität Kaiserslautern-Landau, Kaiserslautern, Germany
*Corresponding author: serha@rptu.de

***Abstract*—Chirality protects Damon–Eshbach surface spin waves against direct backscattering, yet this protection breaks down in thick magnetic films. We show that reflection proceeds via bulk-mode conversion, producing localized energy deposition. Thermal imaging, Brillouin light scattering, and simulations directly resolve this bulk-mediated reflection pathway.**

***Keywords*— magnons, surface spin waves, chirality, nonreciprocal transport, Brillouin light scattering, yttrium iron garnet, magnonics.**

I. Introduction

Chiral Damon–Eshbach surface spin waves [1] exhibit intrinsically nonreciprocal transport and asymmetric localization at opposite film surfaces. This chirality has been linked to suppressed direct backscattering and robust propagation in thin films [2]. Earlier experiments in micrometer-thick yttrium iron garnet films likewise showed that surface modes are less sensitive to defects than backward-volume waves [3].

In thick films, however, bulk modes form a dense continuum that opens additional scattering channels. Here, we examine how surface waves reflect in this regime and demonstrate that reflection occurs via conversion into bulk excitations rather than direct reversal of the surface mode.

II. Methods

Experiments were performed on micrometer-thick yttrium iron garnet films supporting long-lived dipole surface spin waves. Space- and time-resolved Brillouin light scattering spectroscopy was employed to map the spatial distribution and temporal evolution of magnon populations during propagation and reflection. Infrared thermography monitored local energy dissipation associated with reflection events. Micromagnetic simulations complemented the measurements and provided microscopic insight into mode conversion between surface and bulk excitations.

III. Results and Discussion

Surface waves propagate robustly along the film boundaries while preserving their chiral localization. When encountering edges or inhomogeneities, reflection does not occur through direct reversal of the surface mode. Instead, the waves convert into bulk modes that traverse the film thickness and subsequently re-emerge at the opposite surface with reversed propagation direction.

Space- and time-resolved measurements reveal a delayed reappearance of the reflected signal, consistent with propagation through the film interior. Simultaneously, infrared thermography detects localized heating at the reflection sites, indicating accumulation and dissipation of magnon energy. Micromagnetic simulations reproduce the conversion dynamics and confirm the formation of standing bulk excitations that mediate the transfer of energy and momentum between counter-propagating surface states.

Together, these observations identify bulk-mode conversion as the dominant mechanism governing reflection in thick films. The results define the limits of chirality-based backscattering protection beyond the thin-film regime and establish bulk modes as an intrinsic reflection channel in realistic geometries.

IV. Conclusion

We demonstrate that reflection of chirality-protected surface spin waves in thick magnetic films is governed by bulk-mode conversion rather than direct backscattering. This mechanism explains localized energy deposition and clarifies the limits of protection in extended systems. The results provide a general framework for understanding and controlling magnon transport and dissipation in nonreciprocal spin-wave devices.

Symmetry Behavior of Chiral Disordered Metamaterials

Simone Zanotto[1*]

[1]Istituto Nanoscienze – CNR, and Laboratorio NEST – SNS, Pisa, Italy
*Corresponding author: simone.zanotto@nano.cnr.it

***Abstract*—Metamaterials properties are strongly determined by symmetry. In particular, chirooptical effects are expected in systems that lack any mirror plane. Less is known about systems trat are locally asymmetric but globally symmetric, due to randomization. Here we show data about chiral metamaterials with rotational, positional, and racemic disorder.**

***Keywords*— symmetry, chirality, anisotropy, disorder.**

I. Introduction

Chirooptical effect in natural materials are typically very small, and metamaterials have proved being a key milestone towards compact, yet efficient, optical devices with a chiral response. However, the vast majority of studies on chiral metamaterials have been dealing with ordered nanoparticle (or nanohole) arrays, leaving open the question about the role of disorder in conjunction with photonic chirality.

II. Methods and Results

Our base platform is a photonic slab metamaterial made of a high-index dielectric (gallium arsenide, ε = 12) patterned with an array of L-shaped holes, as depicted in Fig. 1a. In first instance, we consider a periodic array with no disorder. The system is investigated with angle- and polarization-resolved transmission spectroscopy, where the incident polarization is either right- or left-polarized. Similarly to what reported in [1], as long as the polarization-averaged transmission is concerned (Fig. 1b), we observed a clear bandstructure, with branches originating from both TE-like and TM-like slab modes. Such branches are visible also on the transmission circular dichroism (Fig. 1c), with features of both signs that lack any symmetry upon exchange of positive with negative in-plane wavevectors.

We then investigated a sample consisting of an equal mixture of "original" and "mirrored" L-shaped holes, mimicking the composition of a chemical racemic mixture (Fig. 2a). In analogy to the previous case, we preformed angle- and polarization-resolved transmission measurements, obtaining radically different results (Fig. 2b-c). At first, the polarization-averaged transmittance shows a drastically simplified mode structure, where only a subset of the original modes have survived. Moreover, the transmission circular dichroism – which also features a minor number of dispersive structures – is very weak when the in-plane wavevector is close to zero.

In addition to the "racemic disorder", we have also

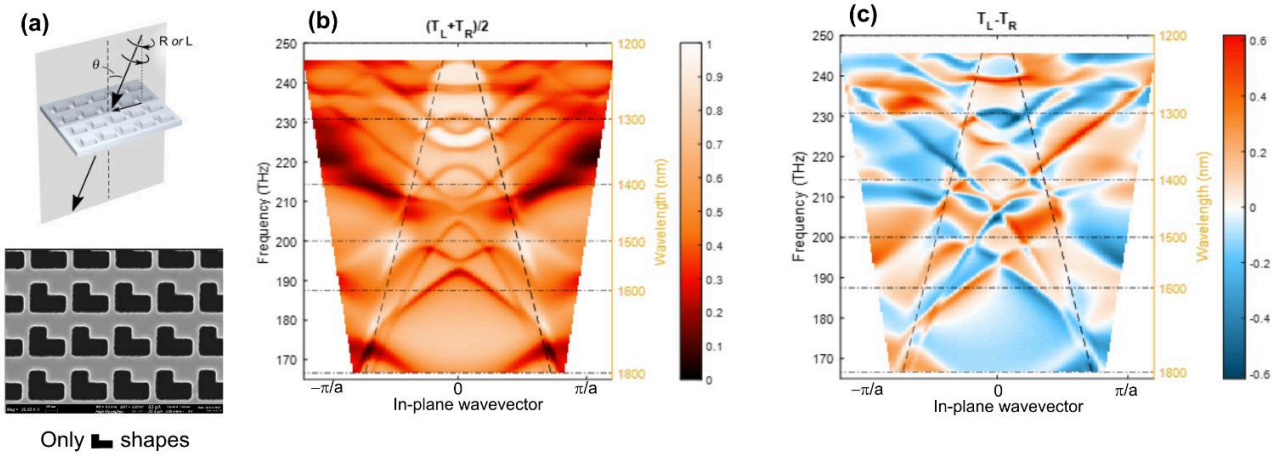

Fig. 1. Dispersive mode structure of a non-disordered chiral photonic slab metamaterial. (a), schematic of the experimental conditions and SEM image of the sample. (b), polarization-averaged transmission map, resolved in wavelength and in-plane wavevector (originating from the projection of incident wavevector un the sample plane, see (a)). Here, *a* is the pattern periodicity (approx. 1 μm). (c), transmission circular dichroism map.

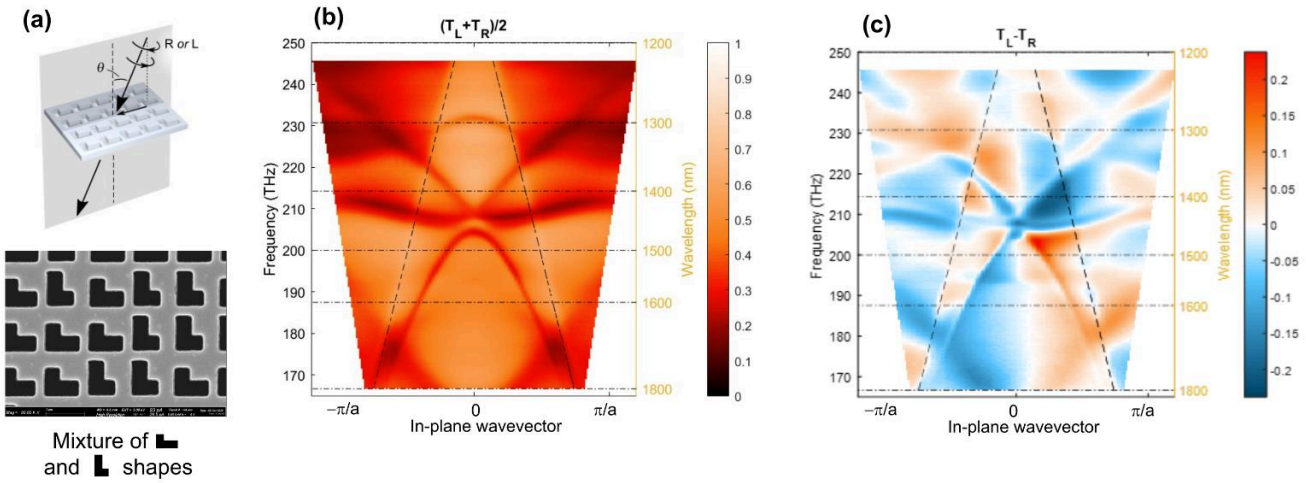

Fig. 2. Dispersive mode structure of a disordered chiral photonic slab metamaterial. The sample resembles a racemic mixture of enantiomeric chemical species. (a), schematic of the experimental conditions and SEM image of the sample. (b), polarization-averaged transmission map, resolved in wavelength and in-plane wavevector (originating from the projection of incident wavevector un the sample plane, see (a)). Here, *a* is the pattern quasi-periodicity (approx. 1 μm). (c), transmission circular dichroism map.

investigated samples with positional disorder and with orientational disorder, i.e., samples where homochiral L-shaped holes are either placed at randomly chosen positions, or with a random angle with respect to the coordinate axes. Also in these cases we have observed a selective suppression of resonant modes, as well as symmetry-driven selection rules on the transmission circular dichroism.

III. Conclusion

We have analyzed chiral dielectric metamaterial slabs with different types of disorder, and we have observed significant deviations from the resonant mode structure specific of the corresponding non-disordered structures.

***Abstract*—Magnonics studies spin waves and their quasiparticles, magnons, often with use of micro-focused Brillouin light scattering (BLS). We develop a model describing BLS signal formation and use it to design dielectric nanoresonators, which enabled detection of nanoscale spin waves and allowed mapping of the dispersion relation across unprecedented ranges.**

***Keywords*— Spin-wave, magnonics, Mie resonances, Brillouin light scattering.**

Spin-wave research explores collective magnetic excitations (magnons) as a platform for energy-efficient information processing and as a probe of fundamental material properties. In mesoscopic magnonics, spin waves with relatively small wavevectors (i.e., large wavelengths) are typically investigated using magneto-optical techniques, most notably micro-focused Brillouin light scattering (μ-BLS), or electrical detection methods. These approaches enable studies of micro- and nanoscale phenomena as well as device-level concepts.

In contrast, investigations of fundamental magnetic excitations—such as chiral or high-energy spin dynamics—require access to magnons across the full Brillouin zone, corresponding to much larger wavevectors (shorter wavelengths) and higher frequencies. Such regimes are commonly addressed using neutron or X-ray scattering techniques.

However, no single experimental technique currently provides access to the entire Brillouin-zone range in both wavevector and frequency space (Fig. 1) [1]. As a consequence, a pronounced experimental blind spot exists at intermediate to large wavevectors (30–300 rad/μm). In this regime, conventional optical techniques are limited by momentum conservation and spatial resolution, whereas neutron-based techniques lack sensitivity to low frequencies and long wavelengths.

Here, we introduce a theoretical modeling framework combined with an optical approach that bridges this gap by integrating micro-focused Brillouin light scattering (μ-BLS) with Mie resonators placed on top of a magnetic thin film [1], [2], [3]. Using this concept, we demonstrate access to spin waves in a previously inaccessible k-vector regime, including incoherent magnons. The measurement can be configured either to probe a broad range of wavevectors or to selectively access specific k-vector magnitudes and directions through periodic stripe arrays. The accompanying modeling provides insight into the signal strength and spectral shape of the measured BLS response, enabling extraction of additional information about the underlying spin-wave system through detailed analysis of the resulting spectra.

Fig. 1. Schematics of a spin wave dispersion relation in a permalloy thin film spanning over the whole Brillouin zone. Various experimental techniques are highlighted with their corresponding accessible frequency and wavenumber ranges. The range achieved using Mie-enhanced μBLS in this work is emphasized.

***Abstract* —We study metasurfaces with quasi-bound state in the continuum with gutter-like dispersion remaining maximum chiral over broad areas of the momentum space. We employ them across different material platforms - van der Waals and polymer-based nanostructures - to demonstrate the formation of chiral exciton-polaritons and to engineer maximally chiral flatbands.**

***Keywords*— metasurfaces, optical chirality, momentum space, light-matter coupling, flatbands.**

I. Introduction

Metasurfaces supporting chiral photonic quasi-bound states in the continuum (qBICs) [1,2], whose polarization and Q-factor are controlled by structural asymmetry, provide a versatile platform for chiral light sources and detectors [3-6]. Typically, the qBIC's circular polarization originates from a topological singularity located at a specific point in momentum space (*k*-space) [2,3]. Small deviations in structural parameters or detuning in the *k*-space substantially degrade their circular polarization, limiting practical metasurface applications. Maintaining robust circular polarization over broad ranges of the momentum space is a recognized challenge and various approaches are being proposed based on complex geometries [6] while still remaining restricted for relatively narrow ranges of incidence angles [7].

Here we present a chiral qBIC that breaks the conventional trade-off between chirality and momentum selectivity, sustaining near-unity circular polarization over an extended k-space range: $-0.2 \leq k_i/k_0 \leq 0.2$, $i = x, y$. Furthermore, we employ the eigenstate's wavelength dispersion as an additional degree of freedom to control light-matter interaction and the formation of chiral flatbands.

II. Results and Discussion

We start from a metasurface composed of pairs of nanorods, sustaining a BIC in the form of an antiparallel dipole resonance. As demonstrated in [1], careful adjustment of the asymmetry parameters, namely the spreading angle and the vertical displacement within the singular pair, allows one to uncouple the mode from one circular polarization and form maximally chiral qBIC, whose coupling with the far-field is accompanied by a near-unity transmittance difference, defined as $\Delta T = |T_{RR} - T_{LL}| \approx 1$.

However, all previous studies considered only normally incident light, neglecting the role of in-plane momentum. Here, we address this gap and show that a maximally chiral antiparallel dipole resonance preserves stable circular polarization over a wide *k*-space range: $-0.2 \leq k_i/k_0 \leq 0.2$, $i = x, y$ (see Fig.1(a)). As for the resonance wavelength, it exhibits either parabolic dispersion along the k_x-direction ($k_y = 0$) or remains dispersionless along the k_y-direction ($k_x = 0$), forming a gutter-like landscape (see Fig.1(b)). Thus, in-plane momentum is no longer a limitation but an additional degree of freedom, enabling convenient post-fabrication control of the resonance, as discussed below.

We first discuss the advantages of parabolic dispersion for the formation of chiral exciton-polaritons. The fabrication technique for metasurfaces supporting chiral qBICs [1] is not restricted to a specific material platform and can be applied to bulk van der Waals materials such as WS_2, which hosts stable excitons at room temperature. Hybridization between achiral excitons, acting as emitters, and a chiral photonic mode, acting as a cavity, leads to the formation of chiral exciton-polaritons. To reveal the chiral strong coupling regime and estimate the Rabi splitting, the cavity wavelength must be tuned while maintaining stable polarization. In-plane momentum along the $k_y = 0$ direction provides this required degree of freedom: tilting the incident light redshifts the qBIC, allowing it to cross the excitonic resonance (629 nm in bulk WS_2) and clearly reveal the upper and lower chiral polariton branches, which we also confirm experimentally [8]. Notably, this post-fabrication tuning provides an accessible and convenient route to control hybrid polaritons, which is crucial for nonlinear optical regimes and Bose-Einstein condensation.

Next, we analyze the potential of the qBIC for realizing a chiral flatband along the $k_x = 0$ direction. The mode itself consists of dipoles, which can't radiate along their orientation axis. Although the nanorods are slightly rotated to break the required mirror symmetry, they remain predominantly oriented along the y-direction. As a result, dipole-dipole coupling between neighboring unit cells along this direction is weak. Consequently, the phase mismatch of dipole oscillations induced by oblique incidence along the $k_x = 0$ direction has a negligible effect on the resonance, leading to a stable wavelength position.

To demonstrate this in practice we employ a previously developed approach for breaking the out-of-plane symmetry using a polymethylmethacrylate (PMMA) overlayer in combination with silicon nanorods [9] to realize a metasurface supporting a chiral qBIC. This system exhibits the same *k*-space characteristics shown in Fig. 1(a) and (b) and thus supports chiral flatbands (Fig. 1(d)). Moreover, the PMMA thickness can be gradually reduced via post-fabrication low-dose reactive ion etching. By varying the overlayer thickness, the qBIC polarization (and thus the flatband polarization) can be tuned from circular to elliptical, then to linear, and finally to elliptical with opposite handedness, as demonstrated both theoretically and experimentally.

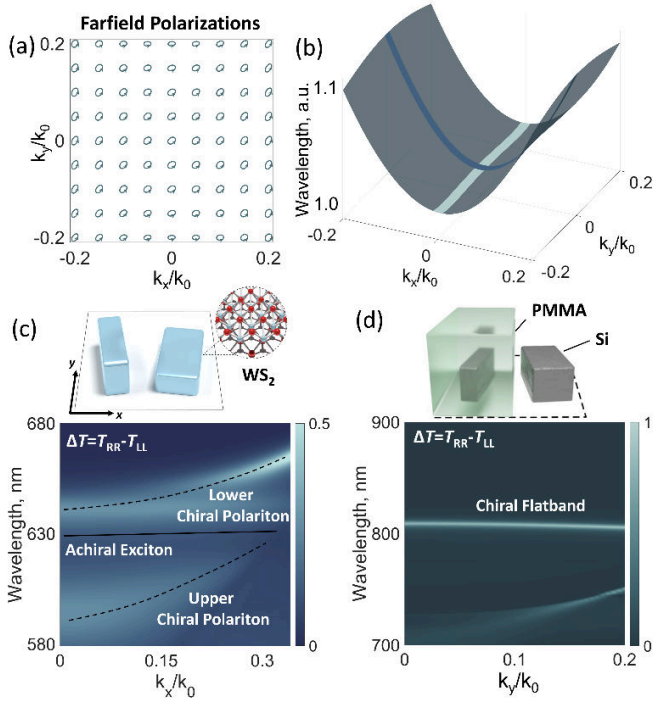

Fig.1. (a) Far-field polarization map in *k*-space of a maximally chiral antiparallel dipole qBIC and (b) its resonance position, showing parabolic dispersion (dark blue line at $k_y = 0$) and a flatband (light blue line at $k_x = 0$) in orthogonal directions. (c) Simulated transmittance difference of a metasurface made of bulk WS_2, where hybridization between an achiral exciton and a chiral qBIC with parabolic dispersion ($k_y = 0$) results in chiral polaritons. (d) Simulated transmittance difference of a silicon metasurface with a PMMA overlayer acting as an out-of-plane symmetry breaking element, exhibiting chiral flatband along the $k_x = 0$ plane.

III. Conclusion

We demonstrated that a chiral qBIC can sustain stable circular polarization over a broad region of momentum space. By exploiting the mode's gutter-like wavelength dispersion, we realize distinct regimes across different material platforms. Using parabolic resonance dispersion and bulk excitonic WS_2 we demonstrated the strong coupling regime with the formation of chiral polaritons and the corresponding Rabi-splitting. In the orthogonal direction of momentum space, a PMMA-based system enables the formation of chiral flatbands whose polarization (ranging from circular to elliptical with opposite handedness) is controlled by the overlayer thickness. All results are supported both theoretically and experimentally.

***Abstract*—We present topology optimized aluminum chiral nanogap antennas operating at 266 nm in the deep ultraviolet. A stable inverse design scheme for metallic structures was developed. The optimized antenna exhibits strong near-field dissymmetry and high enhancement, making it a promising platform for sensitive DUV circular dichroism spectroscopy.**

***Keywords*— aluminum, deep ultraviolet (DUV), optical antenna, circular polarization, topology optimization, computational inverse design.**

I. Introduction

Topology optimization is a machine-aided design technique that enables the derivation of an optimal structure shape that meets specified physical conditions. This technique has been utilized in mechanics and has recently been applied to problems in electromagnetic fields [1]. We employed topology optimization to design a dielectric gap antenna to maximize field intensity at the nanogap when illuminated with circularly polarized light (CPL) of a specific handedness [2]. The polarization-handedness-induced dissymmetry in near-field intensity was analyzed, revealing a notably high *g*-factor of approximately 1.7 in the topology-optimized nanogap antenna. Furthermore, we demonstrated an enhanced optical chirality density within the nanogap at a nanoscale mode volume [2]. Despite the demonstrated feasibility of using topology optimization to design chiral nanophotonic structures, we have encountered a challenge in extending the technique to metal-based structures. Unlike dielectrics, metallic materials exhibit complex permittivity, which adversely affects the convergence of topology optimization algorithms, leading to stagnation during optimization.

In this study, we overcame this challenge by interpolating the refractive index rather than the permittivity as the design variable [3]. This approach effectively avoids convergence stagnation and yields a metallic chiral-gap antenna. Specifically, using aluminum, which supports surface plasmon resonance in the deep ultraviolet (DUV) range [4,5], we demonstrate a metallic chiral gap antenna optimized for 266 nm in the DUV. This development enables highly sensitive circular dichroism spectroscopy for proteins and pharmaceuticals that exhibit pronounced absorption in the DUV range.

II. Refractive Index Interpolation for Metal Structure Design

The topology optimization seeks the optimal distribution of a material region Ω and its complementary region $D\backslash\Omega$ within the design domain D. The material distribution is represented by a design variable $\rho(\mathbf{r})$, where:

$$\rho(\mathbf{r}) = \begin{cases} 1 & (\mathbf{r} \in \Omega) \\ 0 & (\mathbf{r} \in D\backslash\Omega) \end{cases} \quad (1)$$

Here, $\mathbf{r}$ is the position vector within the design domain D, and a value of $\rho(\mathbf{r}) = 1$ indicates the presence of material, while $\rho(\mathbf{r}) = 0$ indicates its absence.

In the optimization process, the design variable ρ is allowed to continuously change between 0 and 1, ultimately converging to 0 or 1. Maxwell's equations are solved by treating the permittivity ϵ as a function of ρ, which necessitates interpolation between the permittivity values of the medium (usually air) and the material. Conventionally, this interpolation is expressed as:

$$\epsilon(\rho) = \epsilon_{M1} + \rho(\epsilon_{M2} - \epsilon_{M1}) \quad (2)$$

where M_1 and M_2 are the permittivity values of the medium and the optimization material, respectively.

Figure 1 illustrates the transition of permittivity as ρ changes from 0 to 1 using Equation (2) (dashed lines). The permittivity remains positive for dielectric materials such as titanium dioxide, thereby avoiding a zero crossing. However, in metallic materials, the real part of the permittivity is negative, leading to a near-zero crossing at the origin. This causes instability in solving Maxwell's equations, making the optimization process infeasible.

To address this issue, we investigated interpolating the refractive index η and extinction coefficient κ instead of permittivity [3]:

$$\eta(\rho) = \eta_{M1} + \rho(\eta_{M2} - \eta_{M1}) \quad (3)$$

$$\kappa(\rho) = \kappa_{M1} + \rho(\kappa_{M2} - \kappa_{M1}) \quad (4)$$

$$\epsilon(\eta(\rho), \kappa(\rho)) = (\eta(\rho)^2 - \kappa(\rho)^2) - i(2\eta(\rho)\kappa(\rho)) \quad (5)$$

This method ensures that permittivity avoids zero crossings (Fig. 1, solid line), enabling the optimization process to converge even for metallic materials.

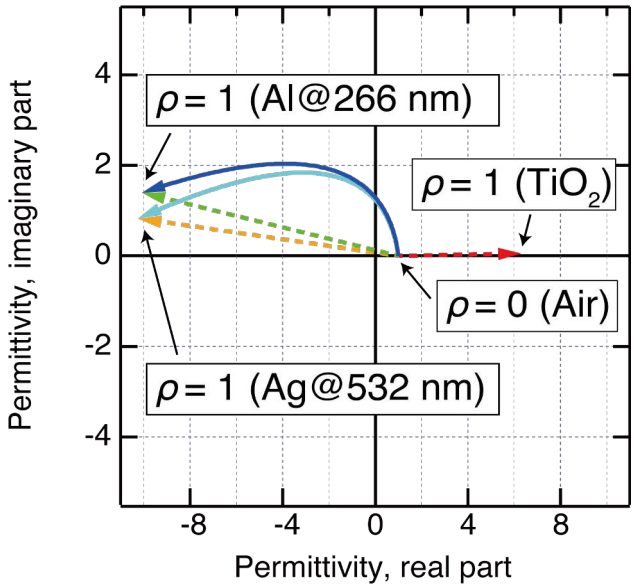

Fig. 1 The trajectories of complex permittivity as the design variables vary from 0 to 1 for dielectric (TiO_2) and metals (Ag and Al). The dashed lines represent interpolation using permittivity, while the solid lines represent interpolation using refractive index.

III. Topology Optimization of Aluminum Chiral Nanogap Antenna at the DUV Wavelength

Biomolecules such as proteins and pharmaceuticals exhibit characteristic absorption in the DUV range. Chiral spectroscopic analysis of these materials can benefit from combining DUV plasmon polaritons, which offer anticipated high enhancement and sensitivity. Among materials exhibiting metallic properties in the DUV range, aluminum is particularly promising due to its chemical stability, non-toxicity, and abundance. We apply the topology design of a chiral nanogap structure made of aluminum, using 266 nm incident light.

The topology-designed structure optimized for *r*-CPL is shown in Fig. 2(a). The cross-sectional slices of the optimized aluminum structure are shown. A gap is formed at Z = 20 nm. The electric field enhancement in the gap was calculated using finite-difference time-domain (FDTD) simulations for right- and left-handed CPLs. The volume-averaged electric field enhancement within the 4 nm×4 nm×2 nm gap region for *r*-CPL was 875-fold (Fig. 2(b)). For left-handed CPL, the same volume-averaged electric field enhancement was 34-fold. The calculated *g*-factor for the near-field intensity was 1.85, confirming the chiral nanogap antenna's highly asymmetric response to the incident CPL polarization.

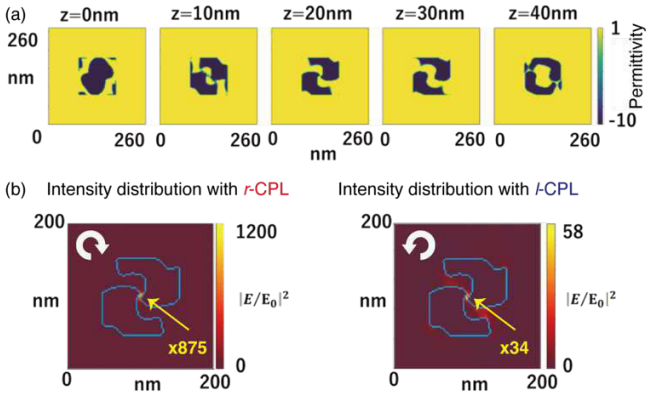

Fig. 2 (a) Z-sliced representations of the structures optimized for right-handed circularly polarized light (*r*-CPL). (b) Field intensity distributions for the structure optimized for *r*-CPL, excited by different polarizations: *r*-CPL (left) and *l*-CPL (right).

IV. Conclusions and Future Outlook

In this study, we extended topology optimization to the design of metallic chiral nanogap antennas by employing refractive-index interpolation, thereby overcoming the convergence issues traditionally associated with metallic materials. We designed a chiral gap antenna optimized for 266 nm DUV light using aluminum. Our results demonstrated significant dissymmetry in near-field intensity, achieving a g-factor of 1.85 and substantial field enhancement within the nanogap. This high dissymmetry highlights the potential of the developed structure for applications in highly sensitive circular dichroism spectroscopy, particularly for biomolecules such as proteins and pharmaceuticals that exhibit strong absorption in the DUV range. The demonstrated approach opens new possibilities for designing metallic structures in the ultraviolet and visible ranges with enhanced chiroptical responses. Future work could explore integrating these antennas into experimental setups for circular dichroism spectroscopy, potentially advancing protein analysis, pharmaceutical development, and other bioanalytical fields.

On the relation between local optical chirality and circular dichroism in enantiomeric sensing

Diana Shakirova,[1] Adrià Canós Valero,[1] and Thomas Weiss[1,*]

[1]Institute of Physics and NAWI Graz, University of Graz, Austria

***Abstract*—The local optical chirality provides information on how single molecules absorb left- and right-handed circularly polarized light. It might as well seem appropriate to optimize this quantity for enhancing the circular dichroism of chiral media in the vicinity of nanoresonators. We show that this is in general not correct.**

***Keywords*— plasmonics, dielectric nanophtonics, chiral sensing.**

I. Introduction

Detecting the handedness of chiral molecules is of utmost importance for chemical, biological, and pharmaceutical applications, since the handedness of a molecule determines its interaction with the environment. This includes chemical interactions as well as the interaction with light. Hence, it is possible to determine the handedness of chiral molecules by optical measurements, but the chiroptical response of such molecules is usually rather weak. Therefore, conventional approaches require using large numbers of chiral molecules.

Nanophotonic resonators such as plasmonic and dielectric nanoantennas can enhance the chiroptical response. However, two questions naturally arise: What are the dominant mechanisms of this enhancement and how can we actually optimize a system for maximum chiral response?

II. Methods

A widespread approach to address these questions is to consider the local optical chirality $C \propto \mathrm{Im}\ \mathbf{E}^* \cdot \mathbf{H}$ (prefactor depends on unit system), which has been shown to quantify the absorption difference between left- and right-handed circularly polarized light by single molecules [1]. At a first glance, this seems quite reasonable, because the contribution of a chiral medium with Pasteur parameter κ to the absorption difference between left- and right-handed circularly polarized light, known as circular dichroism, can be shown to have a term of the form

$$\mathrm{CD}_{\mathrm{int}} \propto \kappa'' \int \mathrm{d}V\ \mathrm{Im}\ \mathbf{E}^* \cdot \mathbf{H}, \tag{1}$$

where κ'' is the imaginary part of κ, and the integration is carried out over the volume of the chiral medium. Since this expression is directly linked to the absorption in the chiral medium, we call this term *intrinsic circular dichroism*.

Assuming that the modification of the electromagnetic fields due to the chiral medium are on the order of κ, i.e., rather small, one can get a very good approximation of the intrinsic chirality by evaluating equation (1) for the fields in the absence of chirality in the medium ($\kappa = 0$). This is more straightforward and less computationally expensive than full-wave simulations for $\kappa \neq 0$.

III. Results and Discussion

When evaluating the circular dichroism for typical nanophotonic geometries, however, we find that the contribution of intrinsic circular dichroism to the total circular dichroism is often negligible, see figure 1. The dominant contribution is *induced circular dichroism*, which appears because the chiral near fields result in absorption differences in the achiral media of a given resonator. To lowest order, it is proportional to κ' as the real part of κ. Since in most spectral regions, $\kappa'' \ll \kappa'$, intrinsic circular dichroism can be often neglected.

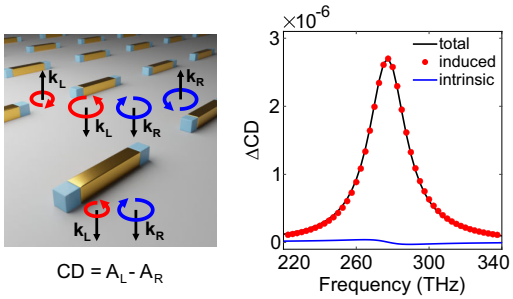

Fig. 1. Example of plasmonic rod antennas with chiral media patches [2]: Dissecting the total circular dichroism (CD) into induced and intrinsic parts, the dominant contribution turns out to be induced circular dichroism.

IV. Conclusion

We have demonstrated that the local optical chirality is often related only to a minor contribution to the circular dichroism signal. A deeper theoretical insight is provided, which opens routes for tailoring near fields to obtain circular dichroism signals that resemble the dispersion of κ'', i.e., the sole circular dichroism signal from the chiral medium.

Spin-Wave Amplification via Phase-Transition-Driven Temporal Interfaces

Pawel Gruszecki[1,*], Krzysztof Sobucki[1]

[1]Institute of Spintronics and Quantum Information, Faculty of Physics, Adam Mickiewicz University, Poznan, Poland
*Corresponding author: gruszecki@amu.edu.pl

***Abstract*—We show that temporal modulation of magnetic field near phase transitions enables giant spin-wave amplification. Combining temporal-interface scattering with phase-transition-driven instability near an exceptional point, we achieve up to 175-fold gain. In this slow-instability regime, the growth rate scales linearly with Gilbert damping, so dissipation enhances rather than suppresses amplification.**

***Keywords*— spin waves, temporal interfaces, exceptional points.**

I. Introduction

Time-varying media have transformed photonics by enabling wave manipulation impossible with static structures: time refraction, reflection, and frequency conversion [1], [2]. Yet implementing analogous temporal control in magnonics—where Gilbert damping fundamentally limits spin-wave propagation—remains unexplored. Existing amplification schemes rely on parametric pumping or spin-torque mechanisms requiring continuous power injection, achieving gains of 10–50-fold [3], [4].

We establish a framework for magnonics of time-varying media and demonstrate that Gilbert damping, conventionally the primary obstacle to spin-wave transport, can be transformed into the engine of amplification [7]. Using ultrathin CoFeB films with perpendicular magnetic anisotropy (PMA) and interfacial Dzyaloshinskii–Moriya interaction (DMI), we show that temporal modulation of the bias magnetic field near a field-driven phase transition enables 175-fold amplitude gain without continuous pumping. In this contribution, we summarize the framework and main findings reported in Ref. [7].

II. Methods

We derive spin-wave scattering at temporal interfaces from the linearized Landau–Lifshitz–Gilbert equation. Continuity of magnetization at a temporal boundary requires wavevector conservation while frequency adjusts to the new dispersion. This yields transmission and reflection coefficients governed by the precession ellipticity ε_i, which we identify as the *magnonic impedance* $Z_i = \varepsilon_i = |m_z|/|m_x|$, where m_x and m_z are the in-plane and out-of-plane magnetization components. The coefficients take the form $T = \frac{1}{2}(1 + Z_1/Z_2)$, directly analogous to electromagnetic wave impedance matching.

For smooth temporal interfaces, we predict exponential suppression of reflections following Landau–Zener dynamics, enabling clean frequency conversion. Micromagnetic simulations using MuMax3 validate the analytical predictions for 2-nm CoFeB films with saturation magnetization $M_s = 1420$ kA/m, exchange constant $A_{\mathrm{ex}} = 13$ pJ/m, reduced perpendicular anisotropy constant $Q = 1.1$, DMI strength $D = 0.5$ mJ/m^2, and damping constant $\alpha = 0.002$.

III. Results and Discussion

Analytical model and dynamical regimes. As the bias field is lowered, the spin-wave dispersion softens until, at the critical field H_c, the frequency vanishes at a finite wavevector k_{soft}, signaling the onset of the phase transition from the uniform magnetic state to the stripe-domain pattern[6]. The spin-wave dispersion near this transition exhibits a complex dispersion relation [8] and rich non-Hermitian physics [7]. Figure 1(a,b) shows the real and imaginary parts of the complex frequency $\Omega(k)$ for several magnetic field values in the conservative case ($\alpha = 0$): instability occurs only below the exceptional point field H_{EP}. In stark contrast, finite Gilbert damping [Fig. 1(c,d)] opens a new dynamical regime: in the window $H_{\mathrm{EP}} < H < H_c$, both the real and imaginary parts of frequency change sign simultaneously—$\mathrm{Re}(\Omega_+) < 0$ and $\mathrm{Im}(\Omega_+) > 0$—enabling exponential amplification even though the system would be stable without damping. The degeneracy at the exceptional point is lifted with characteristic splitting $|\Omega_+ - \Omega_-| \propto \sqrt{\alpha}$. In this slow-instability regime, the growth rate scales linearly with Gilbert damping. For $H > H_c$, spin waves exhibit conventional behavior with $\mathrm{Re}(\Omega_+) > 0$ and $\mathrm{Im}(\Omega_+) < 0$ (oscillation with damping). This counterintuitive result—where dissipation enables amplification by opening a window with inverted signs of both frequency components—has no conservative-system analog.

Temporal interface scattering. Figure 1(e,f) demonstrates spin-wave behavior at a smooth temporal interface. When the bias field is adiabatically ramped from $\mu_0 H_1 = 300$ mT to $\mu_0 H_2 = 225$ mT, the spin-wave packet preserves its wavelength while the frequency adjusts to the new dispersion. The space-time evolution (e) shows continuous phase velocity change without back-reflection. Spectral analysis (f) confirms frequency conversion: the incident wave at $f_0 = 4.09$ GHz generates a negative-frequency component at $f_1 =$

Fig. 1. Temporal spin-wave amplification near magnetic phase transitions. **(a,b)** Complex dispersion for the conservative case ($\alpha = 0$): instability ($\mathrm{Im}(\Omega) > 0$) occurs only for $H < H_{\mathrm{EP}}$ (red curves). **(c,d)** With finite damping ($\alpha = 0.01$), a new slow-instability regime emerges for $H_{\mathrm{EP}} < H < H_c$ (black curves): both $\mathrm{Re}(\Omega_+) < 0$ and $\mathrm{Im}(\Omega_+) > 0$, enabling amplification in a field window that would be stable without damping. For $H > H_c$ (green curves), conventional damped dynamics is recovered. **(e,f)** Adiabatic temporal interface: space-time evolution shows wavelength preservation with frequency conversion (one can see reversal of the direction of the phase velocity around $t \approx 10.5$ ns); spectral analysis confirms the incident wave at 4.09 GHz generates a time-refracted component at -0.42 GHz. **(g)** Amplification via temporal slab: background shading indicates the field profile—smooth 2-ns ramps between $\mu_0 H = 300$ mT and 225 mT (low-field plateau). Larger Gilbert damping produces stronger gain ($T = 36.4$ for $\alpha = 0.01$), demonstrating dissipation-enhanced amplification.

-0.42 GHz, corresponding to the time-refracted wave on the softened dispersion branch.

Giant amplification via temporal slabs. A temporal-slab protocol (high-field → low-field → high-field) exploits the slow-instability mechanism for frequency-preserving amplification. Figure 1(g) shows the time evolution of magnetization amplitude $m_z(t)$ during passage through an optimized temporal slab for three different damping values. The amplitude grows exponentially during the low-field plateau (light green region), while smooth transitions at the temporal interfaces confirm adiabatic behavior. Crucially, the amplification scales with Gilbert damping: larger α produces stronger gain, reaching $T = 36$ for $\alpha = 0.01$ compared to $T = 1.1$ for $\alpha = 0.0003$. For extended plateau durations and $\alpha = 0.002$, we achieve transmission coefficients up to $T = 175$ [7], substantially exceeding existing parametric schemes. The amplification is wavevector-selective, peaked at $k_{\mathrm{soft}} \approx 49$ rad/μm.

IV. Conclusion

We have demonstrated that temporal modulation of the bias magnetic field near phase transitions enables giant spin-wave amplification, achieving 175-fold gain without continuous pumping—substantially exceeding existing parametric and spin-torque schemes. The key insight is that Gilbert damping becomes the engine of amplification in the slow-instability regime between the exceptional point and critical field.

Unlike photonic non-Foster approaches requiring active electronic elements [9], our mechanism exploits the intrinsic interplay between damping and magnetic phase transitions. The framework is applicable to any PMA system with field-driven stripe-domain transitions, opening pathways toward reconfigurable magnonic devices where gain, frequency conversion, and wavevector filtering are programmed dynamically rather than fixed during fabrication.

Strong Coupling of Chiral Magnons in Altermagnets

Peng Yan
UESTC, China

***Abstract*— We show that the dipole-dipole interaction can induce the strong coupling between exchange magnons with opposite chiralities in altermagnets, manifesting as a significant level repulsion in the magnon spectrum. Crucially, the predicted magnon-magnon coupling is highly anisotropic, and observable in practical experiments. These exotic features are absent in conventional antiferromagnets.**

Relationship between Antiferromagnetic Spin Pumping and Magnetic Resonance

Masahiro Sato[1,*], and Hogara Watanabe[1]

[1]Department of Physics, Chiba University, Japan
*Corresponding author: sato.m.p2@gmail.com

***Abstract*— We develop a microscopic theory for spin pumping in antiferromagnets, by using the nonequilibrium Green's function and spin-wave theory. We find the relationship between the pumped spin current and the spin precession of magnetic resonance. It enables us to explain fundamental natures of spin pumping in different phases of antiferromagnets.**

***Keywords*—Spin pumping, spin current, THz electromagnetic wave, magnetic resonance.**

I. Introduction

Spin pumping [1,2] refers to the phenomenon that when an AC magnetic field is applied to a bilayer junction of a magnet and a metal, an DC spin current is injected from the magnet to the metal through the magnetic resonance in the magnet (see Fig. 1). In the last decades, the spintronics research has been extended from ferromagnets (or ferrimagnets) to antiferromagnets, whose resonance frequencies (typically 0.1-1.0 THz range) are generally higher compared to those (~10 GHz range) of ferromagnets. Therefore, the development and understanding of spin current generation in antiferromagnets are crucial for advancing ultrafast spintronics. Due to their low stray fields, antiferromagnets are also well-suited for integration. Furthermore, spintronic functions in more exotic magnets have been actively investigated. Despite various experimental studies of antiferromagnetic spintronics [6], the theoretical study has not progressed well. For instance, the microscopic theory for spin pumping in ferromagnets [7] has already been established, whereas such a theory for antiferromagnets has been less explored.

Given this situation, we have developed a microscopic theory [8] of spin pumping for typical three phases in antiferromagnets: The Néel and canted phases in easy-axis type antiferromagnets and the weak ferromagnetic phase accompanying another canted spin structure in antiferromagnets with a Dyzaloshinskii-Moriya (DM) interaction. Starting from a microscopic Hamiltonian, we apply the spin-wave approximation [9] and the nonequilibrium Green's function method [10] to formulate the tunneling spin current [11,12] injected from the magnetic material into the metal. We quantitatively estimate the dependence of the generated spin current on the external static magnetic field, the polarization direction of the AC magnetic field, and the AC-field frequency. From them, we show the qualitative differences among spin currents in the ferromagnetic phase, the Néel phase, the canted phase, and the weak ferromagnetic phase. From our microscopic approach, we also discover the relationship between the pumped spin current and the spin precession of magnetic resonance. Comparing our theory and recent experiments, we show that the predicted spin currents in different phases are at least qualitatively consistent with observed electric voltages driven by pumped spin currents in antiferromagnets.

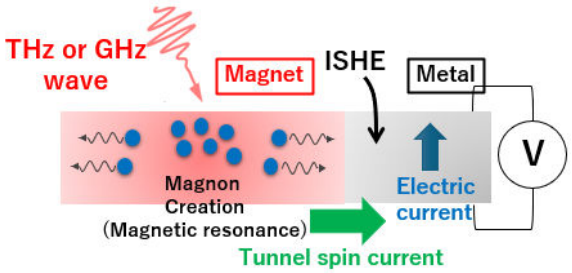

Fig. 1: Schematic image of spin pumping in an ordered magnet. When we apply frequency-tuned THz or GHz wave to a junction consisting of an ordered magnet and a normal metal with spin-orbit (SO) coupling, many magnons are resonantly created, i.e., a large spin precession occurs through magnetic resonance in the magnet. A part of the created magnons is transferred to spin current of conducting electrons in the metal through the interfacial exchange interaction and this means a spin current flows from the magnet to the metal. Finally, due to the SO coupling in metal, a part of spin current is changed into electric current via inverse spin Hall effect (ISHE) [3-5] and the current is detected as an electric voltage.

The relation between the spin current and the precession gives the fundamental insights into spin pumping in antiferromagnets: For instance, it tells us (i) the reason why the spin current in the Néel phase is generally much larger than those of the canted and weak ferromagnetic phases and (ii) that why the dependence of the AC-field polarization on pumped spin current is strong in the canted and weak ferromagnetic phases.

In the conference, we will report the essential parts of our theory, focusing on the relation between the spin current and the precession. In the remaining part of this short article, we

will explain our approach and result, focusing on the important part of our findings.

II. Theoretical Method

Our theory starts with the microscopic Hamiltonian for the junction systems of an antiferromagnet and a metal (see Fig. 1). The Hamiltonian consists of three parts:

$$H = H_{mag} + H_{metal} + H_{int} \qquad (1)$$

where H_{mag}, H_{metal}, and H_{int} are respectively the Hamiltonian of the magnet, the metal and the interfacial exchange interaction. When we consider the Néel, canted and weak ferromagnetic phases in antiferromagnets, the dominant part of H_{mag} is the Heisenberg exchange interaction between neighboring spins and the low-energy physics of H_{mag} is described by the spin-wave approximation [9]: The elementary excitations are magnons. The metal part H_{metal} can be approximated by a free electron model. By treating the interface interaction H_{int} and the external AC magnetic-field Zeeman interaction in H_{mag} as perturbations, we can derive the generic formula of AC-field driven spin current tunneling from the magnet to the metal. This calculation is based on the nonequilibrium Green's function method [10-12]. From the tunnel spin current formula, we can analytically obtain the dependence of the spin current on several parameters such as the AC-field frequency, a static magnetic field and magnetic anisotropies. The detailed calculation will be discussed in Ref. [8].

III. Results

Here, we briefly discuss three important results predicted from our theory [8] based on the model of Eq. (1). First, Fig. 2 shows the AC-field frequency and static-field dependence of computed spin currents in the Néel, canted, and weak ferromagnetic phases. We find that if we properly tune the frequency to a magnetic resonance point, spin pumping can occur. In Fig. 2, each peak position corresponds to a magnetic resonance frequency, and these peak structures are consistent with the experimental result of antiferromagnetic spin pumping. Antiferromagnets generally possess two magnon bands, and therefore two peaks of spin current exist in the Néel and weak ferromagnetic phases, which correspond to two magnon modes with wavevector $\boldsymbol{k} = \boldsymbol{0}$. However, one can also see from the panel (a) in Fig. 2 that there is only one peak in the canted phase. This is because another magnon band in the canted phase corresponds to the gapless Nambu-Goldstone mode and hence such a gapless mode cannot be excited by any AC field. These peak structures of pumped spin currents agree with the recent experiments (for example, see Refs. [13-16]) of spin pumping in antiferromagnets.

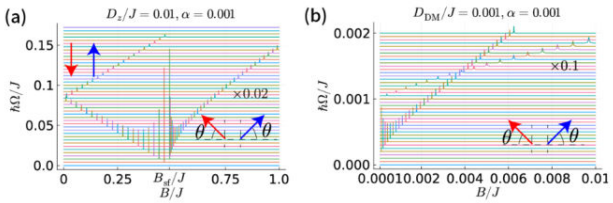

Fig. 2: AC-magnetic-field frequency (Ω) and static magnetic field (B) dependence of tunnel spin currents in (a) the Néel and canted phases and (b) weak ferromagnetic phases in spin pumping setup of Fig. 1. Peaks and their height, respectively, denotes the emergence of a finite spin current and its magnitude. In the easy-axis antiferromagnet of panel (a), weak- ($B < B_{sf}$) and strong-field ($B > B_{sf}$) regimes correspond to Néel and canted phases, respectively. In panel (b), the two spin current peaks correspond to quasi-ferromagnetic (q-FM) and quais-antiferromagnetic (q-AFM) modes of the weak ferromagnets, respectively.

Secondly, we compare the magnitudes of theoretically computed spin currents in different phases. Figure 3 shows the magnitude of pumped spin currents as a function of magnetic anisotropy (D_z) or staggered DM interaction (D_{DM}). We have

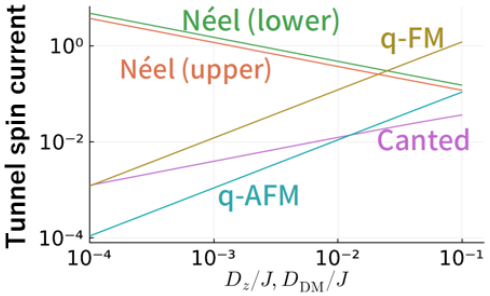

Fig. 3: Magnitudes of tunnel spin currents in spin pumping of different phases in a realistic parameter regime as a function of magnetic anisotropies (single-ion type D_z or DM interaction D_{DM}). The Hamiltonian of the magnet part H_{mag} has a magnetic single-ion anisotropy D_z, while that in the weak ferromagnets has DM interaction D_{DM} instead of D_z. Canted means the spin currents in a canted phase in easy-axis antiferromagnets. Néel (lower) and (upper) denotes two peaks of the Néel phase (see panel (a) of Fig. 2). q-FM and q-AFM means the pumped spin currents at the q-FM and q-AFM mode frequencies in the weak ferromagnets.

fixed other parameters (spin magnitude, exchange interaction, static magnetic field, etc.) at a realistic range. One sees that the spin current in the Néel phase is much larger than those of the canted and weak ferromagnetic phases in a typical range of $10^{-3}J < D_z, D_{DM} < 10^{-2}J$ (J is the strength of the Heisenberg exchange interaction). This size relationship is consistent with experimental results [13-16] of antiferromagnetic spin pumping at least in a qualitative level. These results indicate that our microscopic approach captures the essential aspects of spin pumping in antiferromagnets.

Finally, we discuss the relationship between computed pumped spin current and magnetic resonance. If we remove the attached metal in the spin pumping setup of Fig. 1, the system is equivalent to a typical experimental setup of magnetic resonance of antiferromagnets. Therefore, one can expect the

presence of a relationship between spin pumping and magnetic resonance. In fact, we can arrive at the fact that the computed spin current I_S can be described by using the language of magnetic resonance. When we apply an AC magnetic field along the α axis, whose frequency is chosen to the magnetic resonance frequency, we find that the resulting spin current satisfies the relation

$$I_S \propto A_m(\delta m^\alpha)^2 \qquad (2)$$

where A_m is the area drawn by uniform magnetic moment at the magnetic resonance, and δm^α is the amplitude of the magnetic moment oscillation driven by the AC field. The image of Eq. (2) is explained in Fig. 4. Ferromagnets have no sublattice

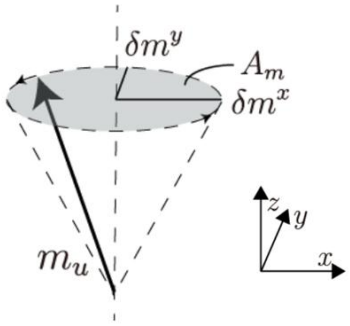

Fig. 4: Image of magnetic resonance under a static magnetic field along the z axis. The black arrow stands for macroscopic spin moment, and its precession motion is induced by an external AC magnetic field. The gray circle is the area given by the trajectory of spin precession.

structure, while antiferromagnets possess A and B sublattices. Therefore, correctly speaking, in the case of antiferromagnets, A_m and δm^α in Eq. (2) are, respectively, replaced with the mean value of areas drawn by A- and B-sublattice spins and that of A- and B-sublattice amplitude. The amplitude δm^α can be analytically estimated under the assumption that the magnon coherent state is realized for magnetic resonance.

Equation (2) gives new insights into spin pumping. For example, it tells us the reason why the pumped spin current in the Néel phase is much larger than those in the canted and weak ferromagnetic phases (see Fig. 3). The reason is as follows. It is well known that the area A_m are quite small in the canted and weak ferromagnetic phases in a weak magnetic field regime since the uniform magnetic moment is small. From this fact and Eq. (2) we can immediately see that the pumped spin current is small in these two phases. Moreover, it is also known that the precession trajectory at the magnetic resonance is an ellipse (NOT circle) in the canted and weak ferromagnetic phases. Therefore, we can predict that an AC-field polarization dependence of the pumped spin current happens in these two phases. In general, magnetic resonances in various magnetic phases have been well studied, and therefore we can extract various information about the spin pump from Eq. (2).

IV. Conclusion

In this short article, we briefly discussed our microscopic theory for spin pumping in antiferromagnets and a few important results [8]. From the theory, we can analytically obtain the dependence of the spin current on the AC-field frequency, a static magnetic field, magnetic anisotropies, etc. The results are consistent with recent experimental observations. Moreover, we discovered the relation between the spin current and magnetic resonance, which enables one to understand the spin pumping with well-established language of magnetic resonance. The detailed results will be explained in Ref. [8].

Spintronics functions of antiferromagnets have been actively investigated for more than ten years [6], whereas their microscopic theories have been less developed. Therefore, it is expected that the microscopic approach including our theory will continue to contribute to new predictions and the establishment of the foundations of antiferromagnetic spintronics.

***Abstract*— We herein demonstrate nanofabrication of chiral surface structures in azopolymers using optical skyrmions which manifest Möbius strip shaped polarization textures with a circular polarization point defect at a focal plane.**

***Keywords*— chiral structures, structured light, nanofabrication, topology.**

I. Introduction

Helix, spiral, and vortex shaped structures possess 'chirality' (an object or phenomenon cannot be superimposed onto its mirror image), and they play an important role in materials science.

Möbius strip shaped structured materials (referred to herein as 'topological structures') are an example of an unconventional chiral structure (twisted and connected to form a ring which possesses no defined front or back). They should possess exotic physical properties (for instance, magnetic monopole, etc.), and thus, they have long been of interest.

A quasiparticle is formed from a set of particles chosen from a single group within a physical system, and it exhibits topologically protected structures in 2-D and 3-D space. For instance, a magnetic skyrmion is a most remarkable quasiparticle, which encompasses all spin vector states mapped on a Bloch sphere, and it is finding the utility in new investigations, such as high-efficiency ultrahigh capacity data storage, information encoding, and magnetic memory.

Analogous optical quasiparticles (such as optical skyrmions) involve all polarization vector states (Stokes vectors of paraxial beams) represented on a Poincaré sphere (instead of all spin vector states mapped on a Bloch sphere), and they have been theoretically predicted and experimentally demonstrated. Also, they manifest topologically protected, Möbius strip shaped polarization (Stokes vector) textures with a circular polarization point defect (C-point defect) at a focal plane under a tightly focusing condition.

Thus, they will potentially allow the development of polarization-based manipulation of chirality and topology of materials at nano and submicron scales to fabricate topological structures on a nano scale; however, in contrast to more established optical vortices, optical skyrmions are still in their infancy as a research topic. There are few reports detailing the interaction between optical skyrmions and materials at a nano scale.

We herein address the nano-manipulation of chirality and topology of materials using optical skyrmions, towards advanced topological materials science and innovative topological structures fabrication.

In particular, we demonstrate the nanofabrication of topological structures in azopolymers with tightly focused optical skyrmions with nano scale C-point defect.

Magnetoelectric effects in truly and falsely chiral media

Omar Jesus Franca Santiago[1,*] and Stefan Yoshi Buhmann[1]

[1] Institut für Physik, Universität Kassel, Germany

*Corresponding author: uk081688@uni-kassel.de

***Abstract*—Three magnetoelectric effects are presented here. Purcell effect is studied in chiral media, quantum friction in chiral media and topological insulators, and Vavilov-Cherenkov radiation in topological insulators. How parity and time-reversal symmetry breaking allow to understand their differences in the context of true and false chirality is investigated.**

***Keywords*— Chiral media, nonreciprocal media, topological insulators, Purcell effect, quantum friction, Vavilov-Cherenkov radiation**

I. Introduction

There are different kind of materials that present a coupled electric and magnetic response. Among them, there are two important classes: chiral and nonreciprocal media. The first class breaks parity symmetry, so it is considered truly chiral and they allow to distinguish left- from right-handedness. The second class breaks time-reversal symmetry, e.g. topological insulators, so it is falsely chiral because the handedness of the medium may be inverted by either space inversion or time reversal. Although they have very similar constitutive relations, their behaviour and physical consequences are rather different.

II. Methods

Our analysis of the Purcell effect and quantum friction is based on macroscopic quantum electrodynamics [1], which allows to express the fields $\hat{\mathbf{E}}$ and $\hat{\mathbf{B}}$ through the Green's tensor and the bosonic creation $\hat{\boldsymbol{f}}^\dagger$ and annihilation operators $\hat{\boldsymbol{f}}$ as follows:

$$\hat{\mathbf{E}}(\mathbf{r}) = \int_0^\infty \mathrm{d}\omega \sum_{\lambda=e,m} \int \mathrm{d}^3 r' \mathbb{G}_\lambda(\mathbf{r},\mathbf{r}';\omega)\cdot\hat{\boldsymbol{f}}_\lambda(\mathbf{r}';\omega) + \text{ H.c.}, \tag{1}$$

$$\hat{\mathbf{B}}(\mathbf{r}) = \int_0^\infty \frac{\mathrm{d}\omega}{\mathrm{i}\omega} \sum_{\lambda=e,m} \int \mathrm{d}^3 r' \nabla\times\mathbb{G}_\lambda(\mathbf{r},\mathbf{r}';\omega)\cdot\hat{\boldsymbol{f}}_\lambda(\mathbf{r}';\omega) + \text{ H.c.}\,, \tag{2}$$

where λ denotes the polarizations and the Green's tensor $\mathbb{G}$ satisfies the corresponding Helmholtz equation. Then, by considering for the Purcell effect the interaction Hamiltonian [2] $\hat{H}_{AF} = -\hat{\mathbf{d}}\cdot\hat{\mathbf{E}}(\mathbf{r}) - \hat{\mathbf{m}}\cdot\hat{\mathbf{B}}(\mathbf{r})$, and for quantum friction the following one [3] $\hat{H}_{AF} = -\hat{\mathbf{d}}\cdot\hat{\mathbf{E}}(\mathbf{r}) + \dot{\mathbf{r}}\cdot\hat{\mathbf{d}}\times\hat{\mathbf{B}}(\mathbf{r})$, we are able to find in the weak atom-field coupling regime the decay rate for the Purcell effect in chiral environments, and the decay rate and frequency shift for the quantum friction.

On the other hand, our analysis of the Vavilov-Cherenkov radiation generated by a charged particle moving parallel to the interface of a topological insulator is purely classical. By solving the corresponding Helmholtz equation, we obtain the electric field [4]

$$\mathbf{E}(\mathbf{r};\omega) = \mathrm{i}\omega\mu_0 \int d^3 r'\, \mathbb{G}(\mathbf{r},\mathbf{r}';\omega)\cdot\mathbf{j}(\mathbf{r}';\omega)\,. \tag{3}$$

where $\mathbf{j}$ is the external current. Then, in the far-field approximation of Eq. (3) we analyse the angular distribution of the radiated energy per unit frequency at both sides of the interface given by [4]

$$\frac{d^2\mathcal{E}}{d\omega d\Omega} = \sqrt{\frac{\varepsilon_0\varepsilon}{\mu_0\mu}}\frac{r^2}{\pi}\mathbf{E}^*(\mathbf{r};\omega)\cdot\mathbf{E}(\mathbf{r};\omega)\,. \tag{4}$$

III. Results and Discussion

Our results show:

- The Purcell decay rate is enantiosensitive.
- The spectroscopical quantities of quantum friction provide two bridges between chirality and nonreciprocity.
- The radiation along the Vavilov-Cherenkov cone is inhomogeneous and asymmetric.

IV. Conclusion

We studied and fully characterized three different magnetoelectric effects gaining insight on how parity and time-reversal symmetry breaking dictamines their main properties.

Resonances and reversal in local and global chirality responses

Itamar Kimchi[1,*]

[1]Department of Physics, Georgia Institute of Technology, Atlanta, GA, USA
*Corresponding author: ikimchi3@gatech.edu

***Abstract*—We theoretically study local chirality responses and discuss several surprising results. These include a chirality reversal generated by isolated chiral or magnetic defects. We also discuss diagnosis of local chirality through extensions of local marker and relation to spectral localizer, loop current patterns, orbital magnetization, and subspace chirality.**

***Keywords*— chirality reversal, magnetic impurities, orbital magnetization, loop currents, spectral localizer, subspace chiral phases, half chiral phases, disorder, local topological markers, chiral orbital currents, resonance, defects.**

I. Introduction

In the remainder of this abstract we focus on just the first result highlighted above [1], without discussing the additional related results [2], [3], [4], [5], [6], [7] , in order to be concrete while keeping this abstract brief.

The quantum Hall effect with its topologically protected chiral edge modes has analogues in insulators with Chern bands as exemplified by Haldane's honeycomb model. The model begins with spinless fermions hopping on the honeycomb (graphene) lattice with chemical potential tuned to the two 2D Dirac cones. Time reversal breaking (TRB) is then incorporated by adding imaginary hopping on next-nearest-neighbor (NNN) bonds of the honeycomb lattice. Microscopically the imaginary hopping term is quite general and could describe orbital magnetic fields or arise via superexchange in the presence of any magnetic background. The interesting effects of the TRB term can be seen by considering its action on the gapless Dirac cones: it opens a topological gap and generates a Chern number set by the sign of the imaginary hopping. As in the Quantum Hall effect, the bulk band with nonzero Chern number has a corresponding chiral edge state whose circulating current reflects the bulk topology.

What happens to the spectral structure if time reversal is broken only by a dilute density of magnetic or chiral defects? The effects of defects on orbital magnetization, arising from the electronic bands even in the absence of spin magnetization, and therefore arising more generally for various quasiparticles in metamaterials, have not been as well explored.

II. Methods

The spinless Haldane model offers an avenue for accessing this limit. Each magnetic scatterer can be modeled as a defect hexagon. The imaginary NNN bonds are then added only within these isolated defect hexagons. Such Haldane hexagon defects provide the effective description of a magnetic impurity or any other TRB scattering, with no spin degree of freedom explicitly involved.

Thus we analyze lattice models with Dirac fermion excitations perturbed by a localized magnetic impurity that generates a Haldane type next nearest neighbor hopping pattern on a single plaquette. This perturbation produces a local topological mass and breaks time reversal symmetry in a confined region of the lattice.

To characterize the resulting chirality we compute two complementary observables. First, we evaluate orbital magnetization through real space implementations of the local Chern marker, which provides a bulk sensitive probe constructed from the occupied states of the system. Second, we calculate electronic current distributions associated with low energy states near the impurity.

In addition to these diagnostics we discuss broader real space approaches for characterizing topology in inhomogeneous systems, including spectral localizer methods and generalizations of local markers for chirality.

III. Results and Discussion

Our analysis reveals a chirality reversal as the local defect strength is tuned. For weak impurity strength the induced orbital magnetization matches the defect, while beyond a critical strength the induced magnetization flips sign. Both orbital magnetization computed from the local Chern marker and the current patterns of low energy states show a consistent reversal near the same critical impurity strength.

IV. Conclusion

Experimental implications of these results are clear: an inhomogenous TRB mass term can change its effective sign as a function of its bare TRB strength. For example, adding positive chirality defects would produce positive orbital magnetization for weak impurity scattering strength, as usually expected, but increasing the impurity scattering strength could suddenly reverse the orbital magnetization and the associated chiral currents — producing negative orbital magnetization even while the impurity chirality remains positive.

Topological polarization textures and emergent chirality in ferroelectric materials

Svitlana Kondovych[1,*]

[1]Institute for Theoretical Solid State Physics, Leibniz Institute for Solid State and Materials Research Dresden
Helmholzstr. 20, D-01069 Dresden, Germany
*s.kondovych@ifw-dresden.de

***Abstract*—Ferroelectric materials can host complex patterns of electric polarization, which arise from electrostatic interactions and nanoscale confinement and can exhibit switchable chirality. Understanding how these topological polar textures form and can be controlled opens new possibilities for designing functional materials and next-generation electronic devices.**

***Keywords*—ferroelectrics, polarization, chirality, topology.**

Chirality is a fundamental manifestation of broken symmetry and plays a central role in many physical phenomena. In condensed matter systems, chiral ordering of vector fields often emerges from specific microscopic interactions. For example, in magnetic materials the antisymmetric exchange known as the Dzyaloshinskii-Moriya interaction selects a preferred rotational sense of the magnetization and stabilizes chiral spin textures such as skyrmions. In contrast, ferroelectric materials provide a conceptually different platform for chirality [1]: here it can arise spontaneously from long-range electrostatic interactions and geometrical constraints, without any intrinsic microscopic interaction favoring a particular handedness.

Ferroelectrics are characterized by a vector order parameter, the electric polarization $\boldsymbol{P}$, whose spatial distribution can form complex textures resulting from the interplay of electrostatic, elastic, and anisotropy energies. In confined geometries such as nanodots, nanowires, thin films, or multilayer heterostructures, the strong depolarization fields associated with bound charges impose stringent constraints on the polarization field. To minimize electrostatic energy, the system tends to form configurations that suppress bound charges $\rho_P = -\boldsymbol{\nabla} \cdot \boldsymbol{P}$, effectively enforcing a divergence-free condition on the polarization, $\boldsymbol{\nabla} \cdot \boldsymbol{P} = 0$. Under such conditions, the polarization field behaves similarly to incompressible vector fields studied in hydrodynamics. This analogy allows one to apply mathematical concepts developed in fluid dynamics [2] to classify and understand polarization textures in ferroelectrics [3].

Within this framework, confined ferroelectrics support two main classes of topological states. Two-dimensional vortex configurations represent the simplest solutions of a divergence-free polarization field, while three-dimensional structures include knotted polarization states – hopfions [4]. The latter are topologically nontrivial and exhibit chirality arising from the twisting and linking of polarization field streamlines. In contrast to magnetic systems, where chirality is usually fixed by microscopic interactions, the handedness of chiral ferroelectric textures results from electrostatic and geometrical effects and therefore does not have a predefined orientation. Consequently, their chirality can be modified or switched by external stimuli such as electric fields [5] or mechanical strain [6], providing a platform for controlled topological polarization states in ferroic materials.

Beyond their fundamental interest, chiral polarization textures hold considerable promise for technological applications. Topological states are inherently robust against perturbations due to their global structure, which makes them appealing for information storage and processing. Ferroelectric systems further provide advantages such as low energy dissipation, electric-field control, and strong coupling to mechanical and optical degrees of freedom. These properties open prospects for novel device concepts, including high-density non-volatile memories, neuromorphic architectures, and nanoscale functional elements operating in the terahertz regime.

***Abstract*—Topology provides a unifying language for structured fields across optics, magnetism, and metamaterials. We demonstrate that homotopy-based classifications are incomplete when backgrounds are non-uniform, and introduce a flux-tube linking framework that captures mixed and fractional topology. The approach enables systematic classification of three-dimensional textures across physical platforms.**

***Keywords*— topology, Skyrmions, Hopfions, Twistons, screw dislocations, linking number**

Fig. 1: Topological textures in a normalized orientation field $\mathbf{v}(\mathbf{r})$: (a) Skyrmion (b) a Skyrmion string with isolines of $\mathbf{v}$ (preimages of $\mathbf{v}$) and fieldlines of emergent field $\mathbf{F}$ parallel along the z-direction, (c) a Skyrmion string with a twist along the vertical direction, (d) a Hopfion that can be imagined as a Skyrmion tube twisted and its ends connected (e) fieldlines of $\mathbf{F}$ for the Hopfion (f) any pair of fieldlines of $\mathbf{F}$ is a pair of oriented curves with Gauss linking number -1.

I. Topology Across Physical Platforms

Topological concepts play a central role in modern optics, where structured light fields host vortices, knots, and linked optical fields. Optical Skyrmions, polarization singularities, and optical Hopfions have been experimentally demonstrated and actively explored for robust information encoding and wave control [1], [2], [3]. Similar topological structures arise in magnetic systems [4], [5], liquid crystals, and acoustic or mechanical metamaterials, motivating a platform-independent topological description.

Fig. 2: (a) Skyrmion (b) meron (c) Hopfion (d) Twiston respectively with $(Q, H) = (-1, 0)$, $(-1/2, 0)$, $(0, -1)$ and $(1/2, -3/4)$. The S^2 sphere is shown as a grey sphere with the background overlayed as a black line. The degree of mapping of textures in $\mathbb{R}^2$ (a-b) or $\mathbb{R}^3$ (c-d) to an S^2 sphere can be measured in terms of topological indices Q and H. These become non-integer when the background is non-collinear, i.e., an S^1 line on the S^2 sphere [6], as in (b) and (d).

II. Skyrmions and $\pi_2(S^2)$ Topology

In two-dimensional (2D) systems with a fixed and uniform background, Skyrmions are classified by the homotopy group $\pi_2(S^2) = \mathbb{Z}$. The corresponding topological invariant, the Skyrmion number, is defined as

$$Q = \frac{1}{4\pi} \int \mathbf{F} \cdot d\mathbf{S}, \tag{1}$$

where the emergent field $\mathbf{F}$ is constructed from a normalized orientation field $\mathbf{v}(\mathbf{r}) \in S^2$ as

$$F_i = \frac{1}{2} \epsilon_{ijk}\, \mathbf{v} \cdot (\partial_j \mathbf{v} \times \partial_k \mathbf{v}) \,. \tag{2}$$

This invariant counts how many times physical space wraps around the order-parameter sphere and remains quantized under smooth deformations as long as the background at infinity ($\mathbf{r} \to \infty$) is fixed.

In magnetic systems, $\mathbf{v}$ corresponds to the local magnetization direction. In optics, analogous constructions arise when $\mathbf{v}$

Fig. 3: (a) to (f) show a continuous transformation from Hopfion to Skyrmion tube, through a change of the background [6].

represents the normalized Stokes vector, the normalized Poynting vector, or the direction of the electric or magnetic field vectors [1], [2], [3]. While Skyrmions arise from mappings of 2D space into the sphere, three-dimensional textures admit fundamentally different topology.

III. Hopfions and $\pi_3(S^2)$ Classification

In three dimensions (3D), textures such as Hopfions are classified by the homotopy group $\pi_3(S^2) = \mathbb{Z}$. The corresponding invariant is the Hopf index, traditionally computed using the Whitehead integral formula,

$$H = \int \mathbf{A} \cdot \mathbf{F}\, d^3r, \tag{3}$$

where $\mathbf{F} = \nabla \times \mathbf{A}$. This expression is gauge invariant only for compact, uniform backgrounds [7]. In systems with non-uniform backgrounds or extended textures with flux crossing the boundaries, such as $S^2 \times S^1$ configurations (shown in Fig. 1(b-c), Fig. 2(b,d) and Fig. 3(b-e)), additional boundary terms appear in H and explicit gauge fixing is required [6], limiting the practical applicability of this formula.

IV. Flux-Tube Linking Framework

To circumvent these issues, we reformulate the Hopf index in terms of linking numbers of flux tubes of $\mathbf{F}$ [6]. Decomposing the field $\mathbf{F}$ into N_Φ flux tubes yields

$$H = \sum_{i=1}^{N_\Phi} L_{ii}\Phi_i^2 + \sum_{\substack{i=1 \\ j\neq i}}^{N_\Phi} L_{ij}\Phi_i\Phi_j, \tag{4}$$

where Φ_i is the flux of tube i, L_{ii} its self-linking, and L_{ij} the mutual linking between tubes. Both linking numbers are computed using the Gauss integral formula. This formulation is gauge independent, analytically tractable, and naturally captures mixed and fractional topology: in non-collinear backgrounds, flux tubes may intersect the boundary, allowing partial flux redistribution through the boundaries and yielding continuously tunable values of Q and H. It is particularly well suited to textures such as the Twiston–that is stabilized by a screw dislocation background winding [5]–that interpolate continuously between 2D and 3D topological character (see Fig. 3).

V. Tunable Topological Textures

Distinct topological textures such as Skyrmions and Hopfions (see Fig. 1) are commonly classified by different homotopy groups under the assumption of a fixed and uniform (ferromagnetic) background. However, if the background configuration is allowed to become non-collinear (see Fig. 2), and to vary continuously, these textures can smoothly deform into one another without singularities (see Fig. 3). In this extended configuration space, the distinction between integer-valued invariants becomes less rigid and intermediate states with mixed topology naturally emerge [6].

The transformation illustrated in Fig. 3 demonstrates such a pathway: a Hopfion continuously evolves into a Skyrmion tube through intermediate configurations (screw dislocations [6], [5]) where both the Skyrmion number and Hopf index take non-integer values. Topology therefore evolves smoothly rather than changing abruptly.

This behavior reflects the dependence of topological invariants on global boundary conditions (see Fig. 2). When the constraint of a collinear background is relaxed [8], the configuration space expands, allowing continuous interpolation between textures traditionally assigned to distinct homotopy classes. Engineering the background thus provides a direct route to controlled switching between 3D particle-like states across physical platforms.

VI. Outlook and Realizations

The flux-tube picture reveals that 3D topology is far richer than suggested by conventional classification schemes using homotopy groups of spheres. Rather than isolated, discrete objects, Skyrmions, Twistons, and Hopfions form a connected landscape of textures that can continuously transform into one another when the background is allowed to vary.

Because this mechanism relies only on the geometry of oriented fields, it is not restricted to magnetism. The same principles apply to structured optical fields, liquid crystals, and engineered metamaterials.

***Abstract*—The shape of a ferromagnet maps its geometric parameters (locally defined principal curvatures) and topologic features (connectivity and number of holes) to its magnetic state. The resulting phenomena include topological patterning and states with multiple chiral characteristics. We discuss reflections of local and nonlocal geometric features on global magnetic state.**

***Keywords*— 3D magnetism, geometry, curvature, topology, magnetostatics.**

I. Introduction

Being motivated by a potential scalability and dense packaging of electronic components beyond planar architectures, curvilinear and 3D magnetism explores the role of complex geometry in static and dynamic properties of ferro- and antiferromagnetic textures [1], [2], [3], [4]. Its theoretical foundation is based on differential geometry and topology. The language of covariant derivatives allows us to map a curvilinear magnetic shell on an effectively planar sample with the spatially varying magnetic parameters modified by such intrinsic geometric invariants as principal curvatures and reflect its chiral and anisotropic properties. The topology of a sample accounts for the number of holes and compactness of its surface. It constrains the number and type of topological solitons that can or should be available in the sample. Recent advances in fabrication provide various techniques, such as multiphoton lithography, focused electron beam induced deposition (FEBID) or glancing angle deposition, that are capable of high-quality complex-shaped nanoarchitectures and bring us an opportunity for direct verification of theoretical predictions.

The non-local phenomena in ferromagnets are under active development [5], [6], [7]. Here, we review the recent progress in understanding the role of magnetostatics and topology of the sample's geometry in equilibrium magnetic states.

II. Topological patterning

Topology of the sample with a compact (i.e., finite) surface ς is characterized by its genus, giving the number of holes. On one hand, genus determines the fixed difference between sources and drains of any vector field $\vec{m}$ defined on ς. On the other hand, it provides the degree of the normal map of $\vec{m}$. In this way, the sample's topology provides (i) an information about the balance between vortices and antivortices in soft ferromagnets [8] and (ii) a shift of the topological charge for the hard magnets with the normal easy axis [9].

The effects of topological patterning can be demonstrated with FEBID-fabricated wireframes [8]. Topologically, a magnetically soft tetrapod is equivalent to a sphere, implying that the total vorticity counted at its surface equal two. The shape anisotropy leads to the formation of four vortices at the tetrapod ends. These vortices are the surface textures similar to the flower states in nanowires. Their total vorticity is compensated with two antivortices at the junction. Depending on the asymmetry between the top and bottom "V"-shaped parts of the tetrapod, the antivortices could be either connected by a common Bloch line or also represent the textures localized in the vicinity of the surface. In a sample topologically equivalent to a torus with one hole, the number of vortices and antivortices is the same, giving zero total vorticity. With multiple holes in the geometry, it is possible to construct the topologically protected states with only antivortices.

III. Coupling between volume and surface magnetostatic charges

The leading-order contribution of surface magnetostatic charges in thin films is given by the easy-surface shape anisotropy [10]. In thick enough or highly asymmetric samples, the next-order interaction between surface and volume magnetostatic charges can lead to sizable phenomena [11].

In a wide range of radii and thicknesses, Permalloy planar nanodisks and caps support the vortex ground state. The deposition procedure commonly leads to a high asymmetry between the top and bottom surfaces in hemispherical caps. Lowering of the sample's symmetry lifts degeneracy between the opposite magnetization circulations and can even link circulation with vortex polarization. Non-planar geometry acts on the vortex Bloch line in a two-fold way. The exchange boundary conditions force it to be perpendicular to the surface, while the balance between the surface and volume magnetostatic charges at the vortex core is decisive for the vortex placement and Bloch line shape. For a low enough sample's symmetry, the Bloch line acquires a helical shape with the torsion linked to the circulation of the vortex [12].

Continuous extended films with a regular geometric pattern can be designed on the top anode aluminum oxide (AAO) templates. They can provide a hierarchy of geometric and magnetic scales from hundreds of micrometers to dozens

of nanometers within the same sample. In a squared array of nanoflowers separated by hemispherical valleys, large needle-like domains are formed by the locally uniform valley magnetization. Nanoflowers support the formation of highly asymmetric textures, including flower states and asymmetric vortices [13]. An energy landscape formed by the spatially inhomogeneous shape anisotropy assists the formation of magnonic crystals in such geometries [14].

Emergent Magnetoelectricity in Stacked Van der Waals (vdW) Magnets

Yong P. Chen[1,2,*]

[1]Institute for Materials Research and WPI-Advanced Institute for Materials Research, Tohoku University, Japan

[2]Institute for Physics and Astronomy, Aarhus University, Denmark

*Corresponding author: yongchen@tohoku.ac.jp

***Abstract*— We discuss our recent magneto-optical (MOKE) and magneto-transport (tunneling) experiments on stacked and/or twisted (Moire) structures (both homo and hetero) between vdW/2D layered antiferromagnets such as CrI_3 and $CrCl_3$, revealing novel magnetoelectric behaviors in new regimes of magnetism (e.g. non-collinear Moire magnetism), with potential spintronic/magnetic and optical/optoelectronic device applications.**

***Keywords*— 2D materials, 2D magnets, vdW heterostructures, twistronics, Moire, magnetism, magnetoelectric.**

I. Introduction

The past few years has witnessed the rise of a variety of van der Waals (vdW) layered magnetic "2D materials". These materials have challenged our fundamental understanding of magnetism, where the very existence of 2D magnetism has been somewhat surprising. Meanwhile, these magnetic 2D materials, which can be made down to atomic thickness, are relatively easy to transfer, deform and tune their properties, have presented exciting new opportunities for realizing novel physics and functionalities, and potential applications ranging from spintronics to quantum technologies. Recent experimental work on such magnetic 2D materials and related heterostructures and electrically gated devices have yielded many intriguing findings. In particular, as to be discussed in this talk, stacking two antiferromagnets (each with zero measured magnetization) can produce a ferromagnet-like state [1,2] or (magnetic) meta-materials-like state [2,3] (through various mechanisms such as an effective interlayer exchange bias [1] or "Moire magnetism" [2,3]), where rich behaviors tunable by a voltage and a relative "twisting" angle are observed, uncovering novel forms of magnetism and magnetoelectricity.

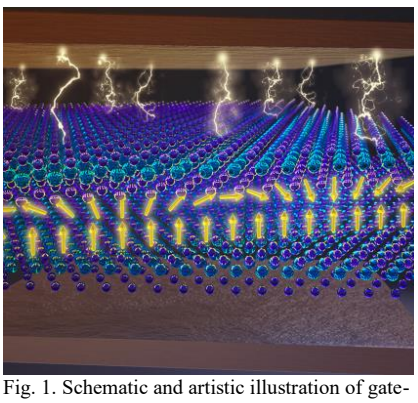

Fig. 1. Schematic and artistic illustration of gate-tunable Moire magnetism (with alternating interlayer ferromagnetic and antiferromagnetic domains) formed in twisted double bilayer CrI_3 (a layered antiferromagnet).

II. Methods

Our methodology integrates fabrication of homo/hetero vdW stacked structures (involving CrI_3 and $CrCl_3$, insulating layered antiferromagnets with out-of-plane and in-plane anisotropies respectively, and electrically gated devices and magnetic-tunnel-junctions (MTJs), magneto-optical-Kerr-effect (MOKE) measurements and electrical transport (tunneling) measurements under variable magnetic fields, temperatures and applied electrical biases, other supplemental characterizations (such as transmission electron microscopy), and DFT and micromagnetics simulations.

III. Results and Discussion

Experimental results have revealed several new forms emergent magnetism, all of which are tunable electrically:

- an out-of-plane (OP) interfacial ferromagnetism in stacked $CrCl_3/CrI_3$ (even when neither have any OP magnetizations), via an exchange-bias-like mechanism [1];
- a Moire magnetism, a metamaterial-like state for magnetism, with alternating ferromagnetic and antiferromagnetic regions, in twisted double-bilayer CrI_3, exhibiting emergent OP ferromagnetic-like behavior over a broad range of twist angles [2];
- Another Moire magnetism featuring a "twisted-S" phase with 90 degree domain walls, in twisted n-layer/n-layer (up to n=9 studied) $CrCl_3$, an in-plane XY magnet [3]

IV. Conclusion

We have demonstrated several different types of emergent magnetism in stacked vdW magnets with novel magnetoelectric couplings.

***Abstract*—We present a theoretical framework for molecular light–matter interactions in chiral resonators and few-emitter nanolasing. Using analytical and first-principles approaches, we reveal how strong coupling, vibrational structure, and emitter number govern enantiomer discrimination and laser performance, providing design principles for chiral control and molecular-scale photonic devices.**

***Keywords*— chirality, polaritonics, strong coupling, lasing**

I. Introduction

Fueled by an ever expanding set of metamaterials and nanocavities, new regimes have been reached for the interplay between light and matter. Here, we demonstrate the fascinating opportunities for two specific examples. First, we demonstrate that the confinement of chiral standing waves in adequately designed cavities allows to couple strongly, and especially selectively, to only one enantiomer in a racemic.[1] We discuss the current challenges of this approach and illustrate a potential path forward.[2] Second, we demonstrate that a few molecules confined in nanocavities give rise to unexpected lasing phenomena, breaking with the current paradigm for the description of molecular lasing.[3]

II. Methods

We perform analytical and numerical simulations. Our predictions for chiral polaritonics are based on the Tavis-Cummings and Hopfield model, both simplifications of the quantum electrodynamic approach to the microscopic light-matter interaction in magnetic dipolar limit

$$\hat{H}_{LM} = -\frac{1}{\varepsilon_0}\sum_n \hat{\mu}_n \cdot \hat{D}_\perp(r_n) - \sum_n \hat{m}_n \cdot \hat{B}_\perp(r_n) + \frac{1}{2\varepsilon_0}\int d^3r \hat{P}_\perp^2 + \frac{1}{8m}\sum_{n,i}(q_{ni}\hat{r}_{ni} \times \hat{B}(r_n))^2 + \mathcal{O}(\nabla D)$$

III. Results and Discussion

Our theoretical results demonstrate

- Enantiomer selective coupling with sqrt-N$_{mol}$ scaling
- A linear dependence on the molecular chirality
- Lasing for molecular few-emitter systems that shows resonant features related to vibrational structure (Fig. 1)
- The vibrational features in few-emitter lasing break the current paradigm for the description of molecular lasing

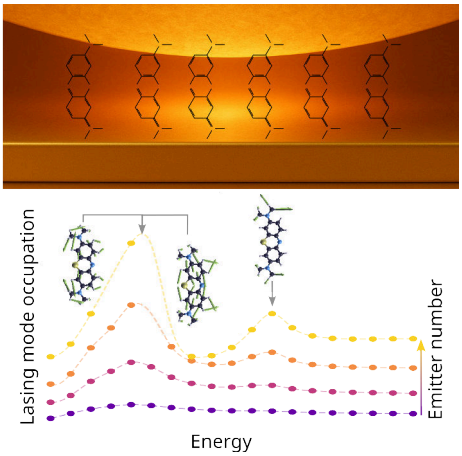

Fig. 1. Vibrational features in molecular few-emitter lasing.

IV. Conclusion

We have demonstrated that metamaterials and nanocavities promise a path to novel applications, including enantiomer selective coupling and molecular lasers. A consistent and detailed theoretical description is required. Future work will be extending the theoretical methodology as well as linking it to experimentally accessible observables and regimes.

Persistent Energy Fluxes and Angular momentum in Non-reciprocal Electromagnetic Systems

Ivan Latella[1,*]

[1]Department of Condensed Matter Physics, University of Barcelona, Martí i Franquès 1, 08028 Barcelona, Spain
*Corresponding author: ilatella@ub.edu

***Abstract*—We investigate persistent energy fluxes and electromagnetic angular momentum in non-reciprocal systems at thermal equilibrium. We show that a divergence-free mean Poynting vector arises from thermal and vacuum fluctuations, with vacuum contributions dominating. This flux persists even at zero temperature, so it does not necessarily represent flow of heat.**

***Keywords*— nonreciprocal systems, electromagnetic fluctuations, angular momentum, persistent energy fluxes.**

Electromagnetic field fluctuations play a fundamental role in the transfer of energy and momentum at the nanoscale, shaping a wide spectrum of light-matter interaction phenomena. When materials exhibit non-reciprocal electromagnetic properties, such as magneto-optical media or Weyl semimetals, these fluctuations lead to behaviors that have no counterpart in reciprocal systems. In addition to enabling directional radiative heat transport in non-equilibrium conditions [1], non-reciprocity remarkably gives rise to persistent energy fluxes [2] in thermal equilibrium, where electromagnetic energy continuously flows in closed paths without net dissipation.

In this work, we examine the mean Poynting vector in thermal equilibrium and the nature of energy circulation in electromagnetic systems that are not constrained by time-reversal symmetry. Employing a theoretical framework based on Green's functions and the fluctuation-dissipation theorem, we demonstrate that the equilibrium energy flow in non-reciprocal system is inherently divergence-free [3]. This proves that the observed circulation corresponds to local redistribution of energy rather than creation or loss, thereby providing a general thermodynamic foundation for persistent fluxes in non-reciprocal systems. In close connection, we argue that persistent heat currents, while present in equilibrium, cannot be detected through conventional out-of-equilibrium heat transfer measurements.

Our results further show that equilibrium energy circulation, characterized by a non-zero mean Poynting vector, originates not only from thermal fluctuations, but also from vacuum fluctuations of the electromagnetic field. Around a single neutral non-reciprocal particle, these fluctuations generate a non-vanishing energy flux and an associated electromagnetic angular momentum. A notable finding is that the contribution of vacuum fluctuations dominate the equilibrium energy flux and angular momentum at finite temperature, implying that the effect persists even as temperature approaches zero. Importantly, such persistent flows can also exist in lossless materials, indicating that dissipation is not a necessary ingredient for their existence. This allows us to conclude that a non-vanishing mean Poynting vector can exist even in the absence of thermal fluctuations, and therefore is not necessarily a flow of heat.

Taken together, these findings establish persistent energy fluxes as a fundamental manifestation of non-reciprocal electromagnetic fluctuations. These fluxes and the associated electromagnetic angular momentum emerge as a universal equilibrium property rooted in broken time-reversal symmetry. This perspective not only advances the conceptual understanding of thermal radiation and fluctuation-induced phenomena but also suggests new opportunities for manipulating energy flow and electromagnetic angular momentum at the nanoscale through the engineering of non-reciprocal materials and structures.

***Abstract*— We report nonreciprocal second harmonic generation in a-Si/Ce:YIG based all-dielectric magneto-optical metasurfaces. Despite of negligible nonreciprocity at the fundamental frequency, large SHG intensity contrast up to 3.6 times was observed for forward and backward propagation, attributed to the nonreciprocal magneto-optical second order susceptibility of the Ce:YIG material boosted by guided mode resonance (GMR).**

***Keywords*— nonreciprocal, metasurface, magneto-optical, second harmonic generation.**

I. Introduction

Nonreciprocal metasurfaces allow on-demand bidirectional electromagnetic wave propagation can enable a variety of functionalities such as free-space electromagnetic wave isolation, circulation, nonreciprocal antennas and radomes and full-duplex communication. Despite of successful demonstration in the microwave frequency range[1,2], realizing nonreciprocal metasurfaces in the optical frequency has been challenging.[3,4] In particular, a magneto-optical nonreciprocal metasurface has not been demonstrated so far, due to the limited MO effects at optical frequencies. In this report, we show that clear optical nonreciprocity can be achieved in all-dielectric nonlinear magneto-optical metasurfaces. Up to 3.6 times intensity difference has been observed for forward and backward excitation of SHG in a magnetized a-Si/Ce:YIG all-dielectric metasurface, which can be explained by the nonreciprocal magneto-optical second order susceptibility of Ce:YIG films.

II. Methods

200 nm thick epitaxial Ce:YIG thin films were grown on gadolinium gallium garnet (GGG(111)) substrates by pulsed laser deposition. The magnetic second order susceptibility was characterized by measuring the SHG of the sample magnetized along the surface normal at 750 nm wavelength using a femtosecond pump laser at 1500 nm. The $\chi^{(2)}$ of Ce:YIG can be expressed as follows

$$\chi_{\pm}^{(2)} = \chi^{Cr} \pm \chi^{magn} \cdot M \quad (1)$$

where $\chi_{\pm}^{(2)}$ denotes the second order susceptibility, χ^{Cr} is the second order susceptibility from crystal asymmetry, $\chi^{magn} \cdot M$ is the second order susceptibility from material magnetization, and ±M stands for the magnetization of Ce:YIG. An a-Si disk on Ce:YIG all-dielectric metasurface was fabricated by chemical vapor deposition, e-beam lithography and reactive ion etch. Nonreciprocal SHG of the metasurface was measured by pumping the magnetized device along the surface normal at the GMR wavelength at 1415 nm using circular polarized light.

III. Results and Discussion

We first measured the $\chi_{\pm}^{(2)}$ of epitaxial Ce:YIG films grown on GGG. Figure 1a shows the sketch of the measurement process. Right circular polarized light at 1500 nm wavelength was incident along the surface normal direction to the sample. The sample was magnetized with 0.2 T applied magnetic field along the up or down directions, indicated as +M and -M respectively. SHG was measured at the transmission port. Figure 1b shows the measured SHG power versus the square of fundamental wavelength (FW) intensity. A linear relationship can be observed for samples at +M, -M or demagnetized states. The inset shows the fitted slope of 1.99, indicating a SHG process. A clear difference of SHG power can be observed for the two magnetization directions according to Eq. (1). By comparing the SHG intensity with a 3R-MoS_2 sample, we calculated the $\chi_{\pm}^{(2)}$ of Ce:YIG to be 4.42 pm/V and 2.49 pm/V. Correspondingly, $\chi^{magn} \cdot M = 0.96\ pm/V$ and $\chi^{Cr} = 3.46\ \ pm/V$.

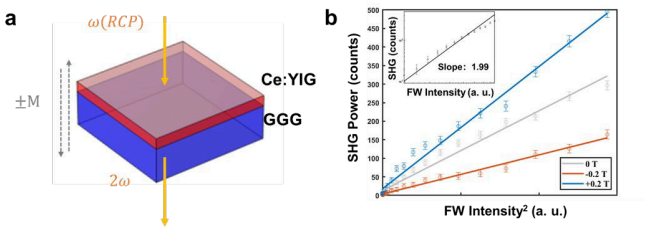

Fig. 1 (a) Sketch of the SHG measurement process on Ce:YIG films. (b) The measured SHG power versus the square of FW intensity.

Figure 2a shows the sketch of the a-Si/Ce:YIG metasurface. The magnetization was along the surface normal. The pump light was circular polarized. The nonreciprocity of SHG was measured by switching the magnetization direction. Figure 1b shows the SEM image of the fabricated sample. Figure 1c shows the reflectance of the sample near the GMR wavelength of 1415 nm. Clear reflection peak indicates the excitation of GMR mode. Notice there was almost no contrast of the reflectance for films magnetized along different directions, indicating negligible nonreciprocity at the fundamental frequency. Figure 1d shows the SHG spectrum of the metasurface. The SHG was originated from the second order susceptibility of Ce:YIG . First, the SHG was clearly boosted by over one order of magnitude at the half of the GMR mode wavelength. Second, clear nonreciprocity of the SHG is observed at the GMR resonance. The peak SHG intensity for +M magnetization is 3.6 times compared to -M magnetization. When fixing the magnetization direction and changing the chirality of the incident light, the SHG intensity also showed comparable contrast, demonstrating the nonreciprocity of the SHG process.

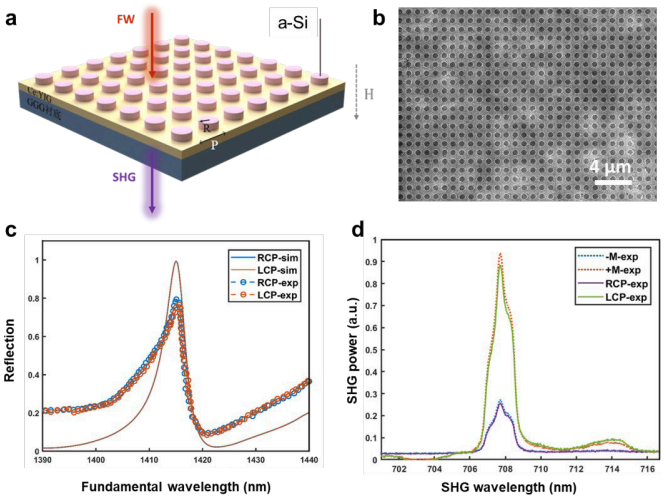

Fig. 2 Nonreciprocal SHG in nonlinear all dielectric MO metasurfaces (a) Sketch of the measurement process. (b) The sample SEM image (c) The simulated and measured reflection spectrum at the fundamental wavelength. (d) SHG power vs. SHG wavelength of the MO all dielectric metasurface

IV. Conclusion

In conclusion, we demonstrate clear optical nonreciprocity in nonlinear magneto-optical metasurfaces by utilizing the nonreciprocal $\chi^{(2)}$ of Ce:YIG thin film and GMR of a-Si/Ce:YIG metasurfaces. Our work paves the way for nonreciprocal metasurfaces in the optical frequencies for nonlinear light source, optical communication and quantum photonic applications.

***Abstract*—I will present analytical estimates for sorting time, throughput, and achievable purity in all-optical enantiomer separation driven by chiral dipolar forces near waveguides. By combining a symmetry-based force decomposition with drift–diffusion dynamics in liquids, I obtain closed-form performance limits applicable to arbitrary dipolar molecules and nanoparticles under realistic experimental conditions.**

***Keywords*—chirality, enantiomer separation, optical forces, evanescent waves, waveguides.**

I. Introduction

Optical forces offer a contact-free route to enantiomer separation, yet many proposals based on propagating or evanescent waves [1, 2, 3, 4] focus primarily on demonstrating the existence of a non-zero chiral force. For applications, however, the relevant questions are: *How long does separation take? At what purity? And what throughput is physically achievable?*

In this invited contribution to the Chiral Symposium at META 2026, I address these questions analytically for dipolar chiral particles in liquids near nanophotonic waveguides, where Brownian diffusion competes directly with enantioselective drift.

II. Optical Force Framework

Within the dipolar approximation, each enantiomer labelled by the sign ($\pm$) experiences a force

$$\boldsymbol{F}_{\pm} = \boldsymbol{F}^{\pm}_{\text{gra}} + \boldsymbol{F}^{\pm}_{\text{pre}} + \boldsymbol{F}^{\pm}_{\text{rec}}. \tag{1}$$

The three contributions correspond respectively to gradient forces, which localise particles in regions of high field intensity; radiation-pressure forces, which transfer linear momentum from the optical field; and recoil forces, which arise from asymmetries in the scattered field and can generate lateral motion. Each of these contributions will have chiral and achiral parts discussed in [1].

III. Drift–Diffusion Model

In liquids, inertia is negligible and the motion of each enantiomer is overdamped. Its dynamics are therefore governed by the Langevin equation

$$\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t} = \boldsymbol{v}_{\pm}(\boldsymbol{r}) + \sqrt{2D}\,\boldsymbol{\xi}(t), \qquad D = \frac{k_{\mathrm{B}}T}{\gamma}, \tag{2}$$

where $\boldsymbol{v}_{\pm} = \boldsymbol{F}_{\pm}/\gamma$ is the drift velocity set by the optical force, γ is the viscous damping coefficient, T the temperature, and k_{B} the Boltzmann constant. The corresponding concentration fields $C_{\pm}$ evolve according to the drift–diffusion (Fokker–Planck) equation

$$\frac{\partial C_{\pm}}{\partial t} = -\boldsymbol{\nabla}\cdot(C_{\pm}\boldsymbol{v}_{\pm} - D\boldsymbol{\nabla}C_{\pm}), \tag{3}$$

which captures the competition between enantioselective drift and thermal diffusion. As a result, the mean positions of the two concentration profiles separate in time due to their different drift velocities, while thermal diffusion increases their variance (Fig. 1). For a chosen target enantiomeric excess, we define the separation time as the time at which the degree of separation between the two distributions reaches the corresponding threshold.

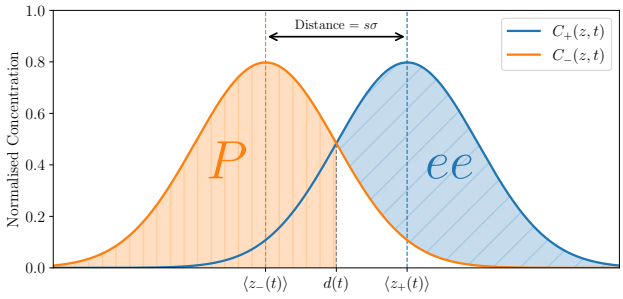

Fig. 1. Enantiomer distributions after some time t. They collectively travel a distance $d(t)$, and the separation between the peaks is $s(t)\sigma(t)$. Shaded regions represent two different measures of enantiopurity: enantiomeric fraction of the dominant enantiomer P (orange) and enantiomeric excess ee (blue). These can be related to the degree of separation $s(t) = \Delta z(t)/\sigma_z(t)$.

IV. Scope of the Talk

Using this framework, the talk will present fully analytical estimates for separation time, throughput, and achievable enantiomeric excess under realistic experimental conditions. In particular, I will compare:

- Longitudinal sorting driven by chiral radiation pressure.
- Transverse sorting arising from chiral lateral recoil forces in evanescent tails of guided modes.
- The role of trapping and confinement in modifying separation efficiency.
- The impact of the initial distribution on the separation time.

***Abstract*—We experimentally demonstrate and theoretically verify bottom-up engineered hybrid plasmonic broken L-shaped metamaterial platforms exhibiting broadband enhanced optical chirality. Two-step glancing angle deposition enables robust control of structural handedness. The resulting hybrid Si-Ag nanocolumnar architectures support strong spin-dependent plasmonic coupling and enhanced chiral near fields spanning the near-infrared to ultraviolet.**

***Keywords*— metamaterials, ellipsometry, plasmonic chirality.**

I. Introduction

Chiral light–matter interactions underpin a wide range of phenomena spanning biomolecular imaging and spectroscopy, enantioselective chemistry, spin-controlled integrated photonics, and emerging quantum optical technologies [1–3]. Chirality originates from broken mirror symmetry, whereby a structure cannot be superimposed onto its mirror image. Optically, this symmetry breaking manifests when a material interacts differently with left- and right-circularly polarized light, giving rise to circular dichroism (CD) and circular birefringence. While chirality in nature is indeed present at all scales from macro-molecules to the galaxies, the natural materials exhibit intrinsically weak chiroptical responses, typically limited to narrow spectral windows and small dissymmetry factors. This limitation arises from the intrinsic dominance of electric-dipole over magnetic-dipole interactions in natural materials, as well as the large mismatch between molecular dimensions and optical wavelengths, which suppresses higher-order multipolar contributions and results in small dissymmetry factors and narrow spectral bandwidths [4]. With the rapid development of quantum communication, spin-based information processing, and polarization-encoded photonic technologies, there is growing demand for artificial platforms capable of enhancing and controlling optical chirality across broad spectral ranges. Engineering broadband and enhanced optical chirality therefore remains a fundamental challenge in nanophotonics. Metamaterials provide a powerful route to overcome these limitations by introducing subwavelength structural asymmetry that amplifies chiral electromagnetic mode coupling [5–8]. While top-down lithographic techniques have enabled precise planar chiral geometries, scalable fabrication of ultrathin, large-area, and broadband chiral platforms at nanoscale remains difficult [9].

II. Methods

Glancing angle deposition (GLAD) offers a versatile bottom-up alternative for fabricating three-dimensional nanocolumnar architectures through oblique-angle physical vapor deposition. Under highly oblique flux conditions, self-shadowing and limited adatom surface diffusion dynamics drive the formation of self-organized spatially coherent tilted columnar structures. By dynamically controlling substrate rotation during growth, deterministic structural asymmetry and handedness can be introduced without masks or templates [8-11]. This approach enables scalable, large-area fabrication of complex chiral nanomorphologies with tunable geometric parameters. Here, we demonstrate bottom-up engineered hybrid plasmonic broken L-shaped metamaterials fabricated via a two-step GLAD process. Prior to the deposition of second segment in the proposed structure by rotating the substrate between sequential oblique depositions, hybrid Si–Ag nanocolumn architectures with controllable handedness are realized. The plasmonic–dielectric hybridization supports spin-dependent electro-magnetic mode coupling, leading to broadband enhanced optical chirality spanning the near-infrared to ultraviolet spectral range. Full-wave simulations reveal pronounced asymmetries in electric and magnetic near-field distributions under opposite circular polarizations, elucidating the physical origin of the large dissymmetry factors.

III. Results and Discussion

Figure 1*Spectrally controlled broadband enhanced chirality from Si–Ag hybrid broken L-shape twisted nanocolumnar structure design. (a) Circular dichroism (CD=$A_{LCP}-A_{RCP}$) spectra demonstrating handedness-dependent optical response of the hybrid Si–Ag nanocolumn array (blue/red correspond to opposite circular polarizations). (b) CD spectrum of a reference all-dielectric Si nanoboomerang (twisted L-shaped) structure for comparison, highlighting differences in spectral bandwidth and CD magnitude. (c–d) Finite-element simulated electric field distributions under left- and right-circularly polarized (LCP/RCP) excitation, illustrating spin-dependent near-field localization within the tilted nanocolumn geometry. (e) Polar plot of polarization-resolved far-field scattering intensity, confirming asymmetric spin-dependent radiation. (f) 3D schematic of the tilted GLAD-grown hybrid nanocolumn architecture on the substrate. (g) Differential near-field maps ($\Delta E/E_0$ and $\Delta B/B_0$) showing handedness-induced electric and magnetic field contrast above the substrate interface. (h) Cross-sectional and (i) top-view high-resolution SEM images revealing spatially coherent, axially modulated hybrid Si–Ag nanocolumn arrays (scale bar: 200 nm).*

Figure 1 summarizes the structural, spectral, and electromagnetic characteristics of the bottom-up engineered hybrid Si–Ag broken L-shaped nanocolumn metamaterials. The spectral evolution of circular dichroism shown in Fig. 1(a) clearly reveals a pronounced handedness-dependent optical response, with opposite rotation directions during the two-step GLAD process producing mirrored CD spectra. Compared to the reference silicon nanoboomerang structure, the hybrid architecture exhibits broader spectral features and enhanced CD amplitude, highlighting the role of plasmonic–dielectric coupling in strengthening the chiral response. With the visualization of near field and far field characteristics via finite element simulations (Fig. 1(c–g)) provide insight into the underlying physical mechanism. Under opposite circularly polarized excitations, the hybrid nanocolumns support asymmetric electric field localization and spin-dependent plasmonic mode coupling. The differential near-field (electric (E) and magnetic (B)) maps demonstrate pronounced field magnitude contrast ($\Delta E=E_{LCP}-E_{RCP}$) and $\Delta E=E_{LCP}-E_{RCP}$) above the substrate, indicating enhanced local optical chirality density. This asymmetric near-field distribution directly correlates with the experimentally observed broadband CD response. Cross-sectional and top-view SEM images (Fig. 1(h,i)) confirm the formation of tilted nanocolumn arrays with uniform morphology over large area. As follow up to this, ongoing experimental optical characterization using Mueller matrix generalized spectroscopic ellipsometry will further quantify the full polarization-resolved chiroptical response.

IV. Conclusion

We demonstrate a template-free and scalable approach for engineering a new class of metamaterial platform with spin-selective broadband chiral light–matter interactions. Precise control of substrate stage and particle flux dynamics enable deterministic structural handedness without lithographic patterning. The observed broadband enhanced optical chirality originates from engineered 3D plasmonic–dielectric hybridization of electromagnetic modes. This versatile platform opens new opportunities for polarization-selective photonics, chiral sensing, and integrated nanophotonic technologies.

***Abstract*—We study the polarization in a crystal induced by a perturbation linear in the coordinates. We establish the quantum transport equation for insulators with slow modulations in space and time, and calculate the current and charge densities. From this result, we obtain the formula for the electric polarization and orbital magnetization, and compare the results with previous works.**

***Keywords*- polarization, quantum transport equation, orbital magnetization.**

I. Introduction

A formulation using Berry connections has been established for electric polarization in spatially homogeneous crystals. As an extension, an expression based on semiclassical theory has been proposed for electric polarization induced in inhomogeneous crystals [1]. This result is related to the formulation of electric quadrupoles in crystals. Meanwhile, it has been pointed out that these results are inconsistent with the expression for the electric quadrupole introduced from thermodynamic arguments [2].

II. Main Results

We point out that the previous results differ from the expression for electric polarization based on linear response theory [3], [4]. Furthermore, the topological term called the Chern-Simons 3-form, predicted by the semiclassical theory, cannot be derived from linear response theory [4]. Thus a different approach has been desired to perform a comprehensive verification.

In this talk, we address this problem from the perspective of quantum transport equations. Our focus is on the solution of the one-particle density matrix that deviates from the local equilibrium distribution due to inhomogeneity in a non-dissipative insulator. We obtain this solution up to second order in perturbation theory with respect to time and spatial gradients [5]. Furthermore, we analytically derive the expectation values of the polarization charge, polarization current, and magnetization current from the obtained density matrix solution, thereby determining the electric polarization and orbital magnetization [5]. The obtained electric polarization and orbital magnetization reproduce the known results from the modern theory. In this presentation, we also obtain the expressions for the higher-order contributions: the electric polarization induced by spatial modulation and the orbital magnetization induced by temporal modulation, and compare them with previous studies. From this result we can obtain various formulas such as charge polarizability and magnetoelectric susceptibility, and compare with the results in the previous works.

III. Conclusion

We establish the quantum transport equation for insulators with slow modulations in space and those in time, and calculate the current and charge densities due to the modulations. From this result we obtain the formula for the electric polarization and orbital magnetization.

***Abstract*—Magnetic helicity, stored in static matter, is the counterpart to the electromagnetic helicity of free radiation fields. Here, we study the magnetic helicity of different chiral molecules. We extend the current formalism, which deals with the magnetization coming from electron spin, to include the stationary currents in the system.**

***Keywords*— magnetic helicity, chirality, chiral molecules, magnetization, stationary currents, light-matter interaction**

I. Introduction

Electromagnetic helicity is the property of a free radiation field describing the sense of its twistedness. For example, for plane waves, it relates to circular polarization handedness, and the helicity is given by the difference between left- and right-handed circularly polarized parts of the field. Helicity is typically studied in dynamic fields, which are characterized by a positive frequency. However, static fields can also contain a type of helicity – magnetic helicity. The magnetic helicity is a quantity most frequently considered in scientific domains such as solar physics, astrophysics, and cosmology. Much like its electromagnetic counterpart, magnetic helicity is related to field twistedness. Namely, it can be stored in chiral magnetic field configurations.

It is natural to pose the question if these two types of helicity are actually two embodiments of the same fundamental quantity [1]. In fact, it turns out that we can use the same scalar product to describe both free fields and static matter [2], and get the correct formulas for both corresponding types of helicity. The magnetic helicity is obtained in [1] from the magnetization density of the system.

To put this framework in a more practical context, here we study the magnetic helicity of stationary chiral molecules, whose electron configurations break inversion symmetry. Chiral molecules interact differently with light of opposite helicity, as seen in their circular dichroism spectra [3], and the analysis of their magnetic helicity may help furthering our understanding these mechanisms.

II. Theoretical Results

Typically, the magnetic helicity in a spatial region D is defined as [4]

$$\int_D \mathrm{d}^3\mathbf{r}\, \mathbf{A}(\mathbf{r}) \cdot \mathrm{curl}\mathbf{A}(\mathbf{r})\,, \tag{1}$$

where $\mathbf{A}(\mathbf{r})$ is the vector potential with the magnetic field $\mathbf{B}(\mathbf{r}) = \mathrm{curl}\mathbf{A}(\mathbf{r})$. The magnetic helicity content $\langle \Lambda_{\mathrm{mag}} \rangle$ in static matter, described by an electric charge density and a magnetization distribution, can be expressed as [2]

$$\langle \Lambda_{\mathrm{mag}} \rangle = \frac{\mathrm{i}\mu_0}{c} \int_{\mathbb{R}^3} \frac{\mathrm{d}^3\,\mathbf{k}}{|\mathbf{k}|} \mathbf{M}(\mathbf{k}) \cdot \big(\mathbf{k} \times \mathbf{M}(\mathbf{k})\big)\,. \tag{2}$$

Here, μ_0 is the vacuum permeability, c the speed of light, $\mathbf{k}$ the momentum vector, and $\mathbf{M}(\mathbf{k})$ the 3-dimensional Fourier transform of the spatial distribution of the magnetization, $\mathbf{M}(\mathbf{r})$. Note that the static charge distribution has no contribution to the magnetic helicity as it produces no magnetic field. Equation (2) is proportional to expression (1) [1].

In our analysis, we extend the setting in [1], [2] by allowing for stationary currents in the system. Such currents can exist in the systems we consider as they do not change with time. We find that with the substitution

$$\mathbf{M}(\mathbf{k}) \to \mathbf{M}(\mathbf{k}) + \mathrm{i}\frac{\hat{\mathbf{k}}}{|\mathbf{k}|} \times \mathbf{J}(\mathbf{k})\,, \tag{3}$$

we can achieve the desired inclusion of the current, where $\mathbf{J}(\mathbf{k})$ the 3-dimensional Fourier transform of the spatial distribution of the current, $\mathbf{J}(\mathbf{r})$. Applying the above substitution to Eq. (2) yields different terms contributing to the magnetic helicity of a system with both a magnetization and stationary currents – pure $\mathbf{M}-\mathbf{M}$ and $\mathbf{J}-\mathbf{J}$ terms and mixed $\mathbf{M}-\mathbf{J}$ terms.

III. Numerics

We use non-collinear spin density functional theory to simulate chiral molecules and calculate the magnetization density arising from electron spin and the stationary currents arising from spin-orbit coupling [5]. Closed-shell molecules have a trivially zero magnetization in this treatment, while open-shell ones can have a non-zero $\mathbf{M}(\mathbf{r})$. As a first example, we compute $\mathbf{M}(\mathbf{r})$ and $\mathbf{J}(\mathbf{r})$ for an open-shell chiral lanthanide compound. Furthermore, we consider both 1,1'-binaphthyl-2,2'-diol (BINOL) chiral variants as well as a forced achiral configuration. BINOL is diamagnetic and has negligible spin-orbit coupling due to being composed only of light atoms, so it would have neither $\mathbf{M}(\mathbf{r})$ nor $\mathbf{J}(\mathbf{r})$ on its own. We therefore place all configurations in a static homogeneous magnetic field to induce currents. Then the magnetic field is orders of magnitude more important than the spin-orbit coupling. We vary the field strength, which changes the currents and even results in a non-zero magnetization when BINOL goes into a

triplet state. We study the variation of the different magnetic helicity contributions depending on the molecule and setting in question. Details will be presented at the conference.

IV. Discussion

Studying if and how much magnetic helicity is stored in molecules under different conditions is important for understanding this quantity in the context of the interaction of molecules with electromagnetic radiation, and in particular its helicity. The analysis has the potential to be extended to dynamical processes to investigate the possibility of helicity transfer between matter and the free field.

Hot-Electron Generation and Photoinduced Chirality in Plasmonic Nanocrystals

Alexander Govorov

Ohio University, Athens, USA
govorov@ohio.edu

Abstract— This talk will cover the following phenomena:

1. Plasmonic hot spots efficiently generate energetic ("hot") electrons, which can be utilized in photochemistry and photodetection.

2. Nanostructures with small interparticle gaps enhance optical heat generation and can confine high photoinduced temperatures to nanoscale volumes.

3. Colloidal nanocrystal assemblies and metastructures with plasmonic resonances significantly amplify the chiroptical responses of biomolecules (e.g., circular dichroism) and can induce chiral morphologies through surface photochemical processes.

Tailoring Smith-Purcell radiation using moiré photonic crystals and chiral materials

***Abstract*—Dielectric gratings provide interesting opportunities to shape Smith-Purcell radiation, which is emitted when an electron passes close by a periodic structure. We describe various designs that influence the direction, efficiency and wavelength of the emission, amongst others via moiré photonic crystals and the inclusion of chiral materials.**

***Keywords*— Smith-Purcell radiation, photonic crystals, moiré gratings, chiral materials.**

I. Introduction

When an electron beam passes in the near-field zone of a grating, the optical Bloch modes of the device can be excited and couple the evanescent electron field into far-field radiation, which is called Smith-Purcell (SP) emission [1]. Traditionally, metallic gratings, with potentially plasmonic modes, were analyzed and employed for emission into air. However, dielectric high-index gratings also offer resonances, with even higher quality factors, that can be tailored via numerous interference-based phenomena. Therefore, current research examines new types of SP-like radiation effects [2], and optimizes the dielectric resonances for increased efficiency, directionality and emission wavelength, amongst others.

In this work, we numerically evaluate a variety of high-contrast photonic crystal devices, leading to rich SP emission patterns. First, we employ longitudinal symmetry breaking, a glide translation, between two adjacent gratings, with the electron beam in-between, to direct the radiation into the upper or lower half-space, respectively [3]. Second, we employ the concept of moiré photonic crystals to position multiple resonances at desired wavelengths. Third, we introduce a chiral, Pasteur medium into the gratings, in order to couple with modes that would otherwise not be excited by the polarization of the electron source.

II. Methods

The SP phenomena can be efficiently simulated by employing only a single (super)period of the structure. We use the finite-element commercial software COMSOL, with the appropriate source term and boundary conditions, see e.g. [4]. The chiral constitutive relations for a Pasteur medium can be conveniently implemented, as explained in [5]. For physical insight, we use Coupled-Mode Theory, starting with information from the calculated Bloch dispersion relations.

III. Results and Discussion

By adjusting the glide shift between two opposing gratings, it is possible to nearly-completely direct the radiation into the upper or lower direction, respectively. With this design, no extra Bragg mirror is thus required. By coupling two gratings with a different, but commensurate, period, the resulting superperiod moiré grating leads to strong interaction between the upper and lower resonances, leading to tailored emission peaks. Finally, the chiral effects couple the transverse-magnetic electron excitation with a transverse-electric mode, which would not show up in SP spectra with only achiral materials.

IV. Conclusion

High-index-contrast coupled gratings form a versatile platform to provide new SP functionalities. Moreover, probing these dielectric structures with electron beams is a novel way to exploit advanced electromagnetic concepts, such as bound-states-in-the-continuum, moiré or twisted photonic crystals and chiral materials.

[*]Corresponding author: cbdag@iu.edu

***Abstract*—I review the recent advances in the field of *chiral* cavity quantum materials and present a perspective on the future prospects. Chiral cavities, that is the cavities that break time-reversal symmetry of the photonic cavity field, have recently been fabricated, opening the doors to test theoretical predictions given in the past years, including the chiral-vacuum-induced Quantum Anomalous Hall Effect. This perspective elaborates on some of the current challenges in the field with a focus on theory, and proposes a route to address some of those challenges.**

***Keywords*— cavity quantum electrodynamics, chiral cavities, light-matter interaction, two-dimensional quantum materials, graphene, topological edge states, quantum many-body physics.**

I. Introduction: A brief review

Engineering topological phases with light has emerged as a central theme in quantum materials research in the last decade [1]. Conventional approaches rely on periodic driving to generate Berry curvature and nontrivial band topology, but intense driving fields can introduce heating. Cavity quantum electrodynamics, on the other hand, offers an alternative route in which enhanced vacuum fluctuations of confined electromagnetic modes modify electronic structure in equilibrium [2]. Recent developments in chiral cavity architectures enable the realization of circularly polarized vacuum fields capable of breaking time–reversal (T) symmetry [3].

T symmetry is a key symmetry in graphene, as it protects the Dirac nodes, and breaking it opens a topological band gap in graphene. Inspired by the insights that are arrived in Floquet engineering of graphene with circularly polarized light, the first theoretical predictions of chiral cavities were given for graphene embedded inside a chiral cavity [4], [5]. Recently, theories on other two-dimensional quantum materials, i.e., transition metal dichalcogenides, kagome lattices, graphene stacks, 2DEG, subject to chiral vacuum fields have been developed [6].

II. Methods of the field

Quantum field theory, Schrieffer-Wolff transformation, Hartree-Fock mean field theory and exact diagonalization have been the most common techniques applied in this field to reveal the cavity mediated electronic interactions and to perturbatively solve the many-body problem of all electrons coupled to a single cavity mode [4], [6]. In the larger field of cavity-QED engineering, density matrix renormalization group has been applied to solve for the many-body ground state of one-dimensional many-body systems coupled to a single cavity mode [7].

Additionally, the problem of graphene in a chiral cavity has been solved in the single electron limit revealing topological photo-electronic, i.e., cavity polaronic, bands where photon exchange processes can introduce Berry phase to the photo-electronic wave function [5]. Recently, a transfer matrix method was developed to find the photo-electronic topological edge mode dispersions of graphene ribbons in a chiral cavity, and analytical results on these edge modes were derived, e.g., localization length in terms of light-matter coupling strength, by recognizing the connection between the Hamiltonian in single electron picture and the cornerstone model of quantum optics, the Jaynes-Cummings model [5].

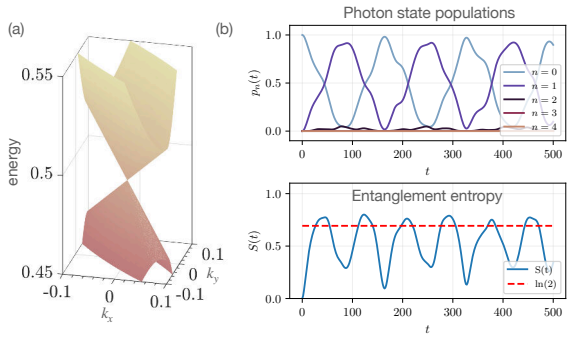

Fig. 1. (a) The band structure of a monolayer nodal superconductor minimally coupled to a chiral cavity: the nodal points are intact. (b) Photon populations (upper) and electronic entanglement entropy (lower) of edge modes in graphene ribbons after suddenly turning on light-matter coupling in a dark cavity, periodically forming bright modes. Adapted from [5].

III. Discussion

Can the T-symmetry breaking of chiral vacuum fields be imprinted in *any* 2D material embedded inside such cavities? This turns out to be not true. In particular, a $d-$wave nodal superconductor remains time-reversal symmetric even when it is subject to a chiral vacuum field that minimally couples to the electrons, shown in Fig. 1(a). This reveals that the form of electron-photon coupling, originating from minimal substitution, is significant to imprint the symmetry properties of enhanced vacuum fluctuations on the solid-state materials.

All existing chiral cavities require an external magnetic field to make the vacuum chiral, and even in the case of tHz photonic crystal cavities where the magnetic field needed is relatively low, it is not sufficiently low not to induce Landau levels in graphene [3]. This suggests that novel chiral cavity designs are in demand, where either no external magnetic field

will be needed or, the material under study will be shielded from the applied field.

Solving for the many-body ground state of strongly correlated two-dimensional systems is itself an active area of research. Here, we have even a more complicated problem of such systems coupled to a single photonic mode. We understand that in the perturbative regime where we can integrate over the photonic mode, photon mediated long-range interactions arise, i.e., all-to-all for a homogeneous field, and might compete with the intrinsic electronic interactions of the material to determine the ground state ordering. If such a competition exists, it only becomes more significant in the ultra-strong coupling regime where one cannot integrate out the photon field. These expectations are yet to be tested, and various tensor network algorithms can in fact rise to occasion. Developing tensor network methods geared particularly towards cavity quantum materials —a type of fermion-boson mixture— in higher than one dimension will be useful to answer the question whether the strong hybridization between electrons and photons, as observed in any material coupled to cavity photons, can lead to quasiparticle formation. The latter will likely be helpful to also better understand the nature of ultrastrong light-matter coupling in quantum materials, as well as deeper coupling regimes.

Ref. [5] demonstrated the presence of unidirectional edge currents carrying finite photon occupation in graphene ribbons embedded in chiral vacuum. Fig. 1(b) shows how the topological edge mode formed in graphene due to chiral cavity also acquires a photonic character and gives rise to a bright mode, i.e., 1-photon state, $n = 1$, populated, periodically in a dynamical setup. We observe that the electronic entanglement entropy maximizes at times where $n = 0$ and $n = 1$ states are equally populated, pointing to the strong hybridization between electron and photon modes. While these results constitute being a modest first step toward cavity-tunable unidirectional and hybrid channels in photonic solid-state devices, the effect of dissipation, e.g., cavity photon loss, on the hybrid edge modes needs to be understood. In fact, dissipation out of cavity can also be the way to detect such hybrid modes in the first place.

Geometric Phase Modulation in Circularly Birefringent Plasmonic Structures

Pasha Goz[1], Akash Das[1,2] Andre Yaroshevsky[1], Yuri Gorodetski[1,2,*]

***Abstract*—Geometric phase in metasurfaces is conventionally realized using spatially rotated linearly birefringent meta-atoms under circularly polarized illumination. Here we demonstrate that full $\sim 2\pi$ geometric phase modulation can be achieved through circular birefringence and observed under linear polarization excitation. We introduce a plasmonic metasurface composed of spatially rotated chiral spiral unit cells designed to produce space-variant circular retardance. This generates a geometric phase ramp equivalent to a blazed grating, leading to ± 1 diffraction orders in momentum space. Using leakage radiation microscopy, we directly resolve these orders and show how their intensities depend upon the input linear polarization confirming the geometric origin of the phase. We theoretically analyze the phenomenon using a rotated Poincaré space and confirm our results by direct Stokes parameters measurement. These results establish basis-independent approach to geometric phase accumulation in circularly birefringent plasmonic metasurfaces.**

***Keywords*— metamaterials, spatio-temporal measurement, weak measurements, plasmonics, spin-orbit interaction.**

I. Introduction

Geometric phase, originating from the seminal works of Pancharatnam and Berry [1], [2], constitutes one of the most profound manifestations of gauge structure in wave physics. In optics, it arises when the polarization state undergoes cyclic evolution on the Poincaré sphere, leading to a phase shift determined solely by the geometry (enclosed solid angle) rather than optical path length [1], [2], [3], [4], [5]. This Pancharatnam-Berry (PB) phase has evolved from a conceptual curiosity into a central design principle for flat optics, singular optics, and metasurfaces [6], [7], [8], [9], [10], [11].

Conventional PB metasurfaces rely on spatially rotated linearly birefringent meta-atoms [12], [13], [6], [14]. Under circularly polarized illumination, the local optical axis orientation $\theta(x)$ imparts a helicity-dependent phase shift $\pm 2\theta$, enabling wavefront shaping via geometric phase gradients [7], [9], [10], [15]. In this widely adopted framework, geometric phase is typically described in the circular polarization basis and is intrinsically associated with spin conversion. However, geometric phase is fundamentally basis-independent: it depends only on the trajectory of the polarization state on the Poincaré sphere [2], [5], [16], [17], [18]. This raises a critical question that remains insufficiently explored [19]: can full 2π geometric phase modulation be achieved through circular birefringence instead of the conventional linear birefringence ? Establishing such complementarity would extend geometric-phase optics beyond the conventional PB paradigm and clarify the underlying gauge structure governing metasurface phase engineering.

Chiral metastructures provide a natural platform for addressing this question [19], [20]. Subwavelength spiral and twisted meta-atoms can exhibit strong circular birefringence and optical activity [21], [22], [23], with circular polarization eigenmodes as the natural basis. However, no direct experimental demonstration of spatially varying geometric phase induced by circular birefringence and its quantitative verification via solid-angle reconstruction has been reported. In such systems, spatial variation of the structural orientation induces a position-dependent geometric phase. When implemented in plasmonic platforms, the resulting phase gradient modifies the in-plane momentum of excited surface plasmon (SP) polaritons [24], [25], leading to controlled diffraction into discrete k-space channels [19]. Because SPs exhibit transverse spin and spin-momentum locking [26], [27], [28], they provide a sensitive probe of polarization-dependent geometric effects at subwavelength scales.

Here we introduce a plasmonic metasurface composed of spatially rotated chiral spiral unit cells arranged with supercell periodicity $N = 3$, engineered to produce controlled circular retardance. By rotating the effective coordinate frame on the Poincaré sphere, we formulate the transformation into a linear-eigenmode basis and show that spatial rotation of the spiral induces a geometric phase ramp analogous to a blazed grating. Crucially, this phase modulation persists for linear polarization inputs, revealing the basis independence of geometric phase accumulation.

A *leakage radiation microscopy* (LRM) [29], [30] followed by a Fourier lens is used to map the in-plane SP momentum distribution in the far field and directly resolve the geometric diffraction orders (satellites) in k-space. These orders intensities are found to be strongly dependent on the rotation of the incident linear polarization. By measuring the local Stokes parameters of the emerged field, we confirm a space-variant field ellipticity induced by the structure. This effect exemplifies the basis transformation of the Poincaré space.

Finally, we demonstrate an example of a plasmonic device based on the space-variant chirality. We fabricate a rotating spiral array with a period of $\Lambda = 1020$ nm and with $N = 3$.

Fig. 1. Optical setup for real- and k-space imaging. The beam was expanded using a beam expander (BE) and then passed through the LRM system comprising of illumination objective (O1) and the imaging oil-immersion objective (O2) attached to the substrate of the sample with an index matching oil. The imaging system included a tube lens (TL) a couple of relay lenses (L1,L2) and a camera (Cam). An aperture (A) was used to control the beam size and the wave plate (WP1) controlled the input polarization. The Stokes parameters were determined using the classical four-measurement scheme with a quarter-wave plate (WP2) followed by a linear polarizer (LP). A Fourier lens (FL) was used to image the k-space Insets show the scanning electron microscope image of the spiral array fabricated by the FIB and the schematic geometry of a single spiral slit.

Fig. 2. Plasmonic distribution measured from a rotating spiral array in the real space - (a,b) and in the k-space - (c,d) with $|\nearrow\rangle$ and $|\searrow\rangle$ input states, respectively. The yellow arrow guides the eye to the dominant satellite/plasmonic beam. The white dashed line shows the SP momentum and the k-space cross-section , taken along the blue dashed line is shown in the inset.

These parameters were chosen such that the satellites of the first diffraction order overlap with the plasmonic momentum, $k_{SP} = \frac{2\pi}{\Lambda} + \frac{2\pi}{N\Lambda}$. The inspection of the k-space (see Fig. 2a,b) reveals that a left-hand/right-hand satellite maximize for $|\nearrow\rangle$/$|\searrow\rangle$ state and provide a perfect coupling to a plasmonic unidirectional beam. This surface wave can be clearly seen in Fig. 2c,d. The yellow arrow marks the relevant geometric orders in the k-space and the resulting plasmonic beams in the real space. The white dashed line depicts the plasmonic momentum at our wavelength. The cross-section of the measured k-space along the central line is also shown, and the satellites intensity variation can be clearly observed. Similar device has been previously demonstrated with rotating rectangular plasmonic nanoapertures under circular state illumination[31]. Nevertheless, in the current system a space-variant chiral polarizer leads to the geometric phase from the linear states.

In general, our results establish a circular-birefringent analogue of PB metasurfaces and demonstrate that geometric phase modulation does not require linear birefringence nor circular polarization excitation. Our findings reveal a deeper complementarity between polarization basis and geometric phase accumulation, expanding the design space of metasurface-based phase engineering and opening opportunities for polarization-sensitive platforms in chiroptical spectroscopy and biophysical sensing. More broadly, our findings clarify the fundamental equivalence between spin-dependent and basis-independent geometric phase accumulation in structured chiral media.

***Abstract*—We provide the overview of the state of art on development of magnetic wires with high Giant Magnetoimpedance (GMI) effect. Excellent soft magnetic properties and GMI ratio up to 750% have been observed in as-prepared low magnetostrictive amorphous Co-rich microwires. Appropriate processing, such as annealing, allows to increase further the GMI ratio value. Although less expensive Fe-rich microwires exhibit rather high magnetostriction coefficient and consequently quite low GMI effect, magnetic softness and GMI effect can be substantially improved by appropriate processing. In both Fe and Co-rich microwires the maximum GMI ratio is observed for frequencies above 100 MHz.**

***Keywords*—Giant Magnetoimpedance, Magnetoelastic anisotropy, Magnetostriction, Amorphous microwires.**

I. Introduction

Studies of Giant magnetoimpedance, GMI, effect have attracted considerable attention in the last few years owing to its suitability for technological applications [1,2]. The main features of the GMI effect have been successfully explained in terms of classical electrodynamics that consider the influence of a magnetic field on the penetration depth of AC current (MHz-GHz frequency range) flowing through the magnetically soft conductor.

The most common quantity for the characterization of the GMI effect is the GMI ratio, ΔZ/Z, defined as:

$$\Delta Z/Z = [Z(H) - Z(H_{max})] / Z(H_{max}), \quad (1)$$

where H_{max} is the axial DC-field with maximum value up to few kA/m.

Extremely high sensitivity of the GMI effect to even low magnetic field attracted great interest in the field of applied magnetism, basically for applications in magnetic sensors and smart composites. Cylindrical shape and high circumferential permeability observed in amorphous wires are quite favorable for achievement of high GMI effect [1-4].

One of the tendencies in modern GMI sensors is the size reduction [3-5]. Recently developed magnetic sensors using the GMI effect allow achieving nT and pT magnetic field sensitivity with low noise [1,3,4]

The aim of this report is to provide recent results on the optimization of soft magnetic properties and the GMI effect in magnetic microwires.

II. Methods

We measured magnetic field dependences of impedance, Z, and GMI ratio, $\Delta Z/Z$, of magnetic microwires using a specially designed micro-strip sample holder. The sample holder was placed inside a sufficiently long solenoid that creates a homogeneous magnetic field, H. The sample impedance Z was measured using vector network analyzer from reflection coefficient S_{11}, reported elsewhere [3,6].

III. Results and Discussion

As discussed elsewhere [1-4], for amorphous materials characterized by the absence of magneto-crystalline anisotropy the main sources of magnetic anisotropy are the shape and magnetoelastic anisotropy, K_{me}. The latter is determined by the magnetostriction coefficient, λ_s, and the internal stresses, σ_i, by the relation [3]:

$$K_{me} = 3/2\ \lambda_s \sigma_i, \quad (2)$$

Nearly-zero λ_s –values can be achieved in $Co_{1-x}Fe_x$ alloys at x about 0,03 – 0,08 [3]. Accordingly, Co-rich microwires can present high GMI ratio. $\Delta Z/Z(H)$ dependencies measured at different frequencies in $Co_{67}Fe_{3.9}Ni_{1.4}B_{11.5}Si_{14.5}Mo_{1.6}$ (d=10.8 μm, D= 13.8 μm) microwire are shown in Fig. 1a. This microwire presents high maximum GMI ratio, $\Delta Z/Z_m$, (~530%) at optimal frequency of about 700 MHz (see Fig. 1b).

However, from $\Delta Z/Z_m(f)$ dependence for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ microwires with d=10.8 μm

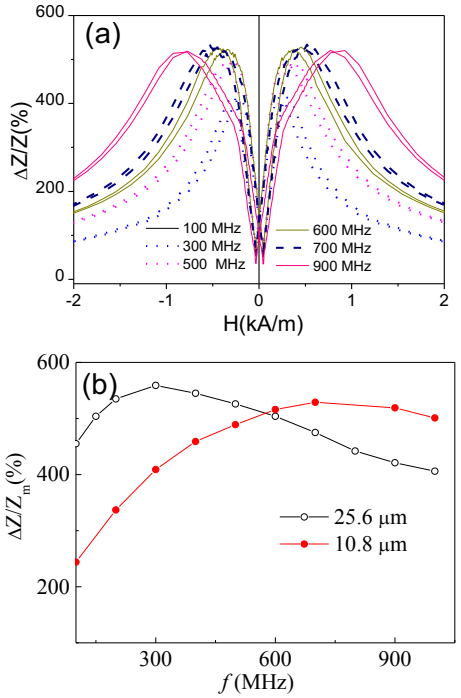

Fig. 1. *ΔZ/Z(H)* dependencies measured in $Co_{67}Fe_{3.9}Ni_{1.4}B_{11.5}Si_{14.5}Mo_{1.6}$ (d=25.6 μm, D= 26.6 μm) microwires (a) and $\Delta Z/Z_m(f)$ dependence for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ with d=10.8μm, D=13.8μm and d=25.6 μm, D= 26.6 μm microwires.

and d=25.6 μm we can appreciate that for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ microwires with d=25.6 μm the optimal frequency is about 300 MHz at which $\Delta Z/Z_m \approx 560\%$ can be achieved. The observed behaviour reflects the relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required [5]. The diameter reduction must be associated with the increasing of the optimal GMI frequency range [3,5].

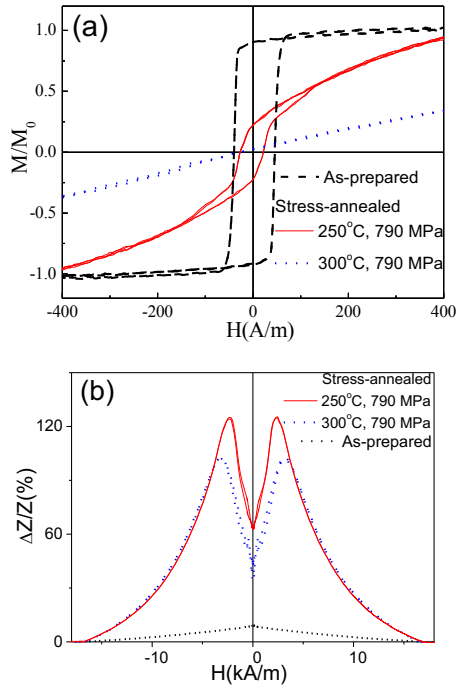

Fig. 2. Hysteresis loops (a) and *ΔZ/Z(H)* dependences measured at 300 MHz (b) of as-prepared and stress-annealed $Fe_{75}B_9Si_{12}C_4$ microwires.

Usually, highly magnetostrictive Fe-rich microwires present poor GMI effect. However, from the viewpoint of the cost Fe-rich microwires are preferable. Recently, we identified that the magnetic softness and GMI effect of Fe-rich microwires can be substantially improved by stress-annealing (see Fig. 2): an order of magnitude $\Delta Z/Z_m$ improvement (see Fig. 2b) is explained by transverse character of induced by stress-annealing magnetic anisotropy (see Fig .2a).

It is worth noting that annealing can also improve the GMI effect of Co-rich microwires. Thus, recently we reported $\Delta Z/Z_m$ up to 900% in annealed Co-rich microwires [6].

IV. Conclusion

We studied the factors allowing optimization of GMI effect of magnetic microwires. Generally, low coercivity and high GMI effect have been observed in as-prepared Co-rich microwires. We identified a relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required. GMI ratio of Fe-rich microwires can be substantially improved by the adequate postprocessing.

***Abstract*— Nano-engineered capsules for targeted drug delivery represent an essential milestone on the path to advancing precision medicine concepts. As most phenomena occur in a liquid environment in vivo, understanding cargo-fluid interaction mechanisms in vitro is an important factor that can control release rates. In this contribution, we introduce metamaterial drug-delivery capsules based on golden, gilded, and magnetized vaterite and demonstrate how electromagnetic control enables a unified light- and magnetic-based theranostic paradigm. We will demonstrate optomechanical delivery, one-photon and two-photon bioimaging, controlled release, and optothermal therapy enabled by vaterite metamaterials. Beyond optical activation, we add magnetic targeting and field-guided propulsion to address the long-standing bottleneck of precise accumulation at the site of interest. Magnetized capsules can be steered along programmed magnetic field landscapes to drive transport toward tumors or other targets, improving localization while reducing reliance on passive circulation.**

***Keywords*— Metamaterials, Biophotonics, Drug Delivery.**

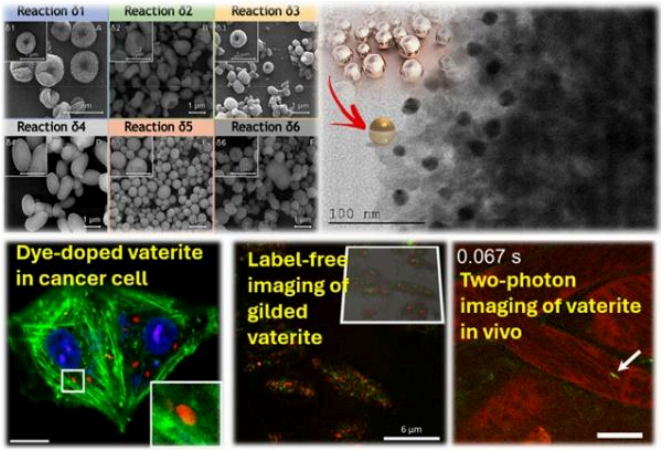
I. Introduction

The presentation is based on our recent works [1], [2], [3], [4], [6], [7], [8] and on a large set of new data. In addition to our published results, we will demonstrate novel light-driven functions, including release, uptake acceleration, and cell treatment, that underline the golden', gilded', and magnetized' vaterite advantages. W*e present results from joint collaborations with leading hospitals in which our particles are under evaluation. We show that magnetic metamaterials overcome the long-standing challenge of nanoparticle targeting by propelling drug-loaded carriers toward tumors via deliberate shaping of the magnetic field landscape, thereby breaking current limitations and enabling effective delivery.*

II. Results and Discussion

The fast-changing landscape of biomedical challenges motivates the ongoing development of new functional platforms. Implantable devices made from biocompatible materials that respond to optical signals and tailor the propagation of light waves can be employed in health monitoring applications and therapeutics. The incorporation of such elements into living organisms can boost light-tissue interactions and shift conventional approaches toward precision medicine by opening new opportunities in sensing, photothermal therapy, photoacoustic tomography, and bioimaging. One of the grand challenges along those pathways is the miniaturization of biocompatible photonic structures that provide multiple functionalities, such as monitoring vital biological processes, light-responsive drug release, and local nanoscale heating with simultaneous temperature measurement.

The vaterite polymorph of calcium carbonate has a wide scope of potential applications in biology and medicine due to its outstanding combination of chemical, morphological, and physical properties. As a fully biocompatible, FDA-approved material, it possesses a sponge-like morphology that effectively entails a wide range of functional materials. As cargo release from vaterite particles is associated with structural transformations, an understanding of particle−fluid interactions is required to advance this material platform toward targeted drug delivery needs. Figure 1 is our executive summary. The panels on the left demonstrate the different shapes of fabricated particles. The shapes are not only responsible for optical properties but have a crucial impact on particle-cell interaction dynamics, as we will demonstrate. The right panel shows 'golden' vaterite – small 3nm gold nanoparticles are diffused into the mesoporous matrix, creating a new metamaterial. This structure exhibits an artificial localized plasmon resonance in the infrared spectral range, which matches the biological transparency window. The bottom part is the imaging.



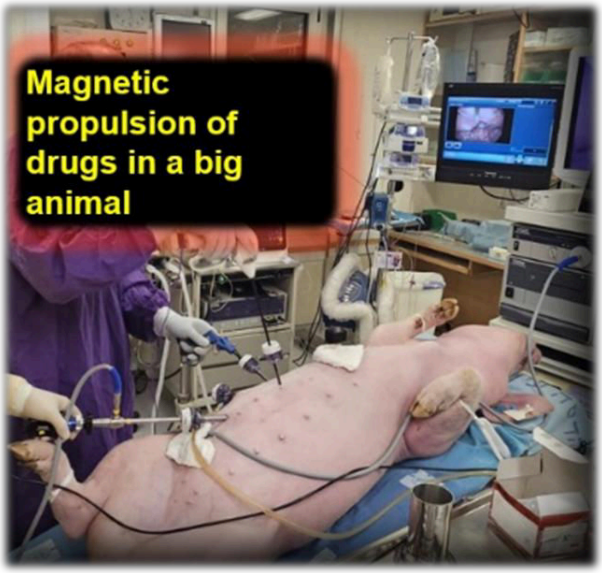


Fig. 1 Vaterite. (up) Particles of different shapes to tailor both optical properties and particle-cell interaction dynamics. (Right) 'Golden' Vaterite – TEM image of CaCO3 matrix, loaded with gold nanoparticles. Bottom: Imaging capsules in vitro and in vivo.

***Abstract*— Effective heat mitigation remains a central challenge for photovoltaic (PV) technologies, directly influencing conversion efficiency, operational stability, and device lifetime. In this work, by exploiting radiative cooling and spectrally engineered optical responses, we demonstrate cooling coating structures providing significant temperature reductions and measurable efficiency gains across different PV architectures.**

***Keywords*— radiative cooling, photovoltaics, solar cells**

I. Introduction

Temperature elevation in photovoltaics (PVs) constitutes a serious limiting factor for their performance and life-time. Even moderate heating degrades electrical output and accelerates material aging. Passive radiative cooling (PRC) has recently emerged as an attractive solution, capable of dissipating excess heat through engineered thermal emission, reducing thus the PV temperature. Unlike active cooling strategies, PRC operates without external power input, making it particularly appealing for scalable solar technologies.

Our work focuses on the design and demonstration of photonic structures/coatings that enhance radiative cooling in PVs and tailor spectral reflection and transmission properties, in order to reduce PV operating temperatures while preserving, or even enhancing, optical absorption in the useful spectral range.

II. Design Strategies and Key Results

Our cooling coating structures are designed as to exploit several complementary photonic mechanisms:

a) Enhancement of PRC, i.e. of thermal emission within the atmospheric transparency window (8–13 μm) and beyond ; this enables efficient heat rejection to outer space.

b) Increase of reflection of sub-bandgap radiation ; this minimizes parasitic heating.

c) Control of ultraviolet reflection (enabling reflection up to a critical wavelength, dependend on the active material); this protects sensitive photovoltaic materials (e.g. adhesion layers).

d) Preservation or even enhancement of the optical transparency (to avoid photocurrent loss).

To quantitatively evaluate these mechanisms on different PV architectures, we developed a comprehensive opto-electro-thermal simulation framework capable of predicting photovoltaic temperature and efficiency given the transmission/reflection/absorption-emission charcateristics of a cell, under realistic environmental conditions. This modeling platform allows systematic assessment of any designed cooling structure.

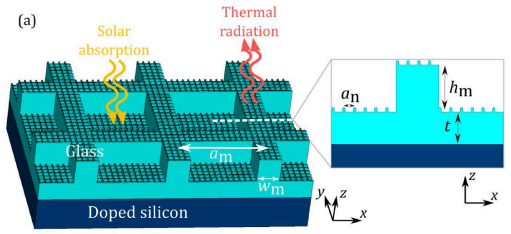

Fig. 1: A double-periodic nano-micro-structured glass coating (light-blue), able to provide a close to 6° C temperature reduction and a 3.1% solar cell efficiency increase if placed on top of Si solar cell. Inset shows a vertical cross-section of the structure

Fig. 1 shows a cooling structure that we have proposed that exploits almost all the above mechanisms. It is a double-periodic- (micro/nano) structured glass slab of micrometer thickness. This slab was placed atop a silicon solar cell, resulting to a numerical démonstration of a temperature decrease of ~ 6°C (compared to the structure without coating) and an efficiency improvement exceeding 3%. These results, among others, highlight the effectiveness of hierarchical (micro-nano) structuring in optimizing radiative heat exchange in solar cells without compromising electrical output.

The benefits of photonic cooling are even more pronounced for emerging thin-film technologies, such as organic and perovskite solar cells, which exhibit strong thermal and UV sensitivity. By incorporating ultrathin hybrid organic–inorganic radiative cooling layers in organic and perovskite cells, we demonstrated temperature reductions beyond 7°C while maintaining high photovoltaic performance.

Alternative promising approaches for “cooling” include the incorporation of cooling layers or structures in essential PV components, such as electrodes. In the framework of this work we also designed and demonstrated numerically an efficient “cooling” electrode for perovskite PV structures, resulting to ~7°C temperature reduction and more than 1.3% efficiency increase. This is a clear demostration of the high potential of smart cooling strategies for lightweight and flexible solar platforms.

III. Conclusions

This work demonstrates that carefully engineered photonic structures can substantially improve photovoltaic thermal regulation and operational efficiency. By integrating radiative cooling with spectral management techniques, it is possible to enhance device durability and performance across both conventional and next-generation PV technologies.

Our results establish a pathway toward scalable, passive thermal management solutions and provide a foundation for further developments of advanced photonic cooling architectures.

***Abstract*— We report experimental progress on the design, fabrication, and characterization of high-performance confocal Fabry–Pérot cavities formed by dielectric metasurfaces. These metasurfaces stabilize the cavity, optimize the mode volume, and introduce polarization birefringence, with particular emphasis on single-spin chiral cavities enabled by dielectric metasurface mirrors.**

***Keywords*— Chiral Cavities, Metasurfaces, Fabry-Perot**

I. Introduction

Free-space Fabry–Pérot cavities are powerful platforms for enhancing light–matter interactions in systems such as cold atoms and single quantum emitters. However, integrated confocal cavities with stable free-space modes have not yet been experimentally realized [1,2]. We present new design strategies and preliminary results for confocal cavities formed by (i) Pancharatnam–Berry phase reflecting metasurfaces [3] that focus a single helicity, and (ii) multilayer polarization-birefringent metasurfaces that reflect one linear polarization while transmitting the orthogonal one. The metasurface mirrors are vertically mounted with lithographically defined spacing

(I) Self-polarizing Chiral Cavity: The chiral metasurface consists of a subwavelength array of 500-nm-tall round-corner rectangular nanofins placed on a 50-nm silver back-mirror. A focusing phase profile is implemented by rotating each nanofin according to the geometric-phase relation by an angle $\theta(x,y)=2\varphi(x,y)$ where φ is the desired phase . Because subwavelength periodicity can excite lossy plasmonic modes, a thin SiO spacer is added to suppress field buildup on the silver surface, reducing depolarization and loss and enabling higher-Q performance. The design is further optimized to maintain polarization purity across all rotation angles. A second fabrication challenge is the formation of nanoislands in the silver layer during PECVD deposition of amorphous silicon, driven by thermally induced dewetting. To prevent this, the silver is magnetron-sputtered and capped with a thin SiO film before PECVD. SEM images confirm that this approach avoids dewetting compared with conventional e-beam-evaporated silver. The SiO layer therefore plays a dual role: suppressing plasmonic loss and protecting the silver film during high-temperature processing.

(II) Polarization-dichroic Fabry–Pérot cavity: A second cavity uses vertically mounted birefringent metasurfaces operating in confocal mode. Each consists of a phase-imparting layer and a dimerized high-contrast grating (DHCG) [5] providing near-unity polarization discrimination. Independent phase profiles are designed via ray tracing to ensure mode overlap. This cavity is used to implement a single-photon gate with cold Cs atoms. Figure 1 illustrates the PB-phase metasurface (a–c) and the bilayer polarization-dichroic metasurface (d–f).

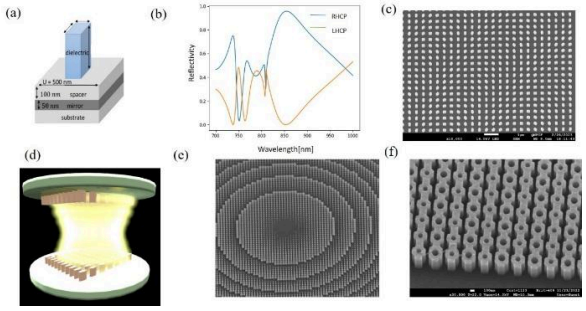

Figure 1 (a–c) depict a Pancharatnam–Berry phase reflecting metasurface made of PECVD-grown α-Si nanofins on a multilayer stack. Panels (d–f) bilayer polarization-dichroic metasurface, where one layer imparts the phase profile and the second—a dimerized HCG.

Microscopic Hopfield Theory of Hyperbolic Phonon Polaritons in Layered Materials

Yu Zhang[1,*]
[1]Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM, 87545, USA.
*Corresponding author: zhy@lanl.gov

***Abstract*—Hyperbolic phonon polaritons in biaxial van der Waals crystals (e.g., α-MoO_3) are extremely confined and anisotropic, yet usually modeled with fitted Lorentz permittivities. We present a gauge-consistent microscopic Hopfield theory linking DFPT lattice inputs to LO–TO splitting, dielectric response, slab dispersion, and twist-controlled inter-slab hybridization via Green-function coupling.**

I. Introduction

Polaritons—hybrid excitations of light and matter—enable extreme electromagnetic confinement and dispersion engineering via material resonances. In polar dielectrics, infrared-active optical phonons couple strongly to mid-IR fields, forming phonon polaritons with long lifetimes and strong near-field enhancement [1]. A particularly rich regime occurs when the dielectric response is *indefinite* (principal components of $\boldsymbol{\epsilon}(\omega)$ have opposite signs), producing hyperbolic isofrequency contours and highly directional energy flow. The biaxial van der Waals crystal α-MoO_3 hosts multiple hyperbolic Reststrahlen bands with pronounced in-plane anisotropy, making it a model platform for natural hyperbolic nanophotonics [2]. However, most existing descriptions rely on phenomenological Lorentz fits of $\epsilon_i(\omega)$, which mask the microscopic origins of oscillator strength, LO–TO splitting, and anisotropic screening and complicate extensions to multi-slab and twisted structures. This work develops a unified, gauge-consistent microscopic theory that connects *ab initio* inputs directly to macroscopic hyperbolic phonon polaritons (HPhPs) in bulk and confined geometries.

II. Methods

We construct a microscopic lattice-electrodynamics framework that bridges DFPT quantities (Born effective charges, $\boldsymbol{\epsilon}_\infty$, and phonon eigenvectors) to polariton eigenmodes. Starting from the harmonic phonon Hamiltonian, optical phonons are expressed in normal coordinates $\hat{Q}_{\mathbf{q}\nu}$, and the macroscopic polarization is written as a phonon-coordinate operator using *mode effective charges*:

$$\hat{P}_i(\mathbf{q}) = \sum_\nu Z_i^{(\nu\mathbf{q})} \hat{Q}_{\mathbf{q}\nu}, \tag{1}$$

where $Z_i^{(\nu\mathbf{q})}$ is obtained by projecting atomic Born charge tensors onto phonon eigenvectors, fixing oscillator strengths microscopically.

Long-range Coulomb interactions generate a nonanalytic correction to the dynamical matrix that produces LO–TO splitting in the $\mathbf{q}\to 0$ limit for biaxial screening:

$$D^{\mathrm{NA}}_{a\alpha,b\beta}(\mathbf{q}) = \frac{e^2}{\Omega} W_c(\mathbf{q}) \frac{\left(\mathbf{q}\cdot\mathbf{Z}^*_a\right)_\alpha \left(\mathbf{q}\cdot\mathbf{Z}^*_b\right)_\beta}{\sqrt{M_a M_b}}. \tag{2}$$

This explicitly shows that LO–TO splitting depends on propagation direction, anisotropic $\boldsymbol{\epsilon}_\infty$, and Born charges—key ingredients for hyperbolicity in biaxial crystals.

To couple phonons to photons in a gauge-consistent manner, we quantize the transverse electromagnetic field and use the multipolar Power–Zienau–Woolley (PZW) Hamiltonian, including the essential polarization self-energy term:

$$\hat{H}_{\mathrm{int}} = -\int d^3r\, \hat{\mathbf{P}}_\perp(\mathbf{r}) \cdot \hat{\mathbf{E}}_\perp(\mathbf{r}), \tag{3}$$

$$\hat{H}_{\mathrm{self}} = \frac{1}{2\epsilon_0} \int d^3r \left|\hat{\mathbf{P}}_\perp(\mathbf{r})\right|^2. \tag{4}$$

The resulting quadratic Hopfield model is diagonalized via a bosonic Bogoliubov transformation, yielding polariton eigenfrequencies and eigenmodes.

III. Results and Discussion

The theory delivers a unified microscopic explanation of hyperbolic phonon polaritons and enables predictive modeling beyond Lorentz fitting [3]: 1) Polariton eigenmodes from a gauge-consistent Hamiltonian: Including polarization self-energy ensures stability and consistency, and the Bogoliubov diagonalization yields polariton dispersions that match Maxwell-based approaches while retaining microscopic interpretability. 2) Twisted bi-slabs and controlled inter-slab hybridization: Interlayer coupling is derived from the dyadic Green function in a quasi-static limit, producing a coupled-mode splitting

$$\omega_\pm(\mathbf{q}) = \frac{\omega_1(\mathbf{q}) + \omega_2(\mathbf{q})}{2} \pm \sqrt{\left(\frac{\omega_1(\mathbf{q}) - \omega_2(\mathbf{q})}{2}\right)^2 + \kappa^2(\mathbf{q},\theta)}, \tag{5}$$

where $\kappa(\mathbf{q},\theta)$ encodes twist- and gap-dependent overlap of polarization fields and decays approximately as e^{-qg}. This provides a microscopic justification for effective block-matrix coupling models and enables predictive twist-engineered polaritonic band design.

IV. Conclusion

We develop a gauge-consistent microscopic Hopfield theory for biaxial hyperbolic phonon polaritons that directly connects DFPT quantities to polariton eigenmodes. Applied to α-MoO_3, the framework explains hyperbolic transport as a microscopic consequence of direction-dependent LO renormalization and resonant lattice polarization, and it predicts slab dispersion and thickness trends without phenomenological oscillator refitting beyond damping. By deriving inter-slab hybridization from the dyadic Green function, the approach further enables predictive modeling of twisted polaritonic heterostructures and lays a foundation for engineered hyperbolic and moiré-like phonon-polaritonic metamaterials.

Photoelectron chiral dichroism from tailored light: symmetry and helicity

Ofer Neufeld*

[1]Technion – Israel Institute of Technology, Faculty of Chemistry, Haifa, Israel.
*Corresponding author: ofern@technion.ac.il

***Abstract*— Symmetry plays a key role in light-matter interactions, including in chiral systems. Still, a group theory for photoelectron chiral dichroism (PECD) has not been developed prior. Here I will present the first such theory, also leading to novel selection rules in PECD from tailored-light, and PECD geometries without helical driving.**

***Keywords*— chirality, PECD, ultrafast spectroscopy, optical chirality.**

Photoelectron chiral dichroism (PECD) is one of the most well-established approaches for studying gas-phase and ultrafast chirality. It provides huge chiral signals that arise from purely electric-dipolar interactions (contrarily to standard chiroptical schemes where magnetic-dipoar interactions play a role in chiral signal generation, leading to weak signals) [1] [2] [3]. Recently, PECD has been driven from polarization-tailored geometries in the strong-field regime, employing bichromatic lasers [4] [5]. The chiral signals were shown to persist even when both carrier waves were linearly-polarized, and comprised forward/backwards and up/down asymmetric spectra. Notably, it remains unclear why non-vanishing PECD can be obtained with linearly-polarized lasers (that do not carry angular momentum and have a vanishing time-average optical chirality). The fundamental origin of the PECD asymmetries are also largely unknown and have only been explained on an ad-hoc basis.

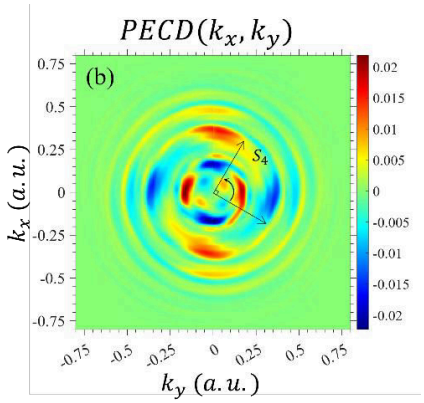

Fig. 1 Novel PECD selection rule that gives rise to 4-fold asymmetry in PECD due to a 4-fold improper rotational driving laser (comprised of three tailored laser colors).

In a related avenue, all PECD to date has been generated by helical laser beams with non-vanishing optical chirality [6]. In this mechanism the ionized photoelectron interacts with the chiral potential of the molecule left behind, and the helical laser field, as it is driven to the detector. This dual interaction permits strong chiral signals. However, chirality can also manifest in laser fields in a non-instantaneous manner [7], in which case there are no helical components in the drive on an instantaneous timescale. It remain unclear if such sources also drive a dichroic response (analytical work has proposed this to be possible for non-CEP stable longer pulses, but it has never been tested in experiments or numerically [8]).

Here we address these two issues directly. First, we develop a group theory for PECD capable of handling tailored laser fields with multiple frequency components [9]. From this theory we explain all known PECD selection rules (e.g. forwards/backwards or up/down asymmetries/symmetries), as well as predict novel selection rules in new geometries (see exemplary Fig. 1). All novel selection rules are numerically validated with *ab-initio* simulations.

Next, we directly simulate PECD driven by a train of linearly-polarized pulses, which is a non-helical light source (see Fig. 2). We show that this still leads to PECD signals that are as large as in the helical light case [10] (see Fig. 3), but the mechanism differs compared to the standard case and involves a chiral hole wave packet evolving in the molecular ensemble.

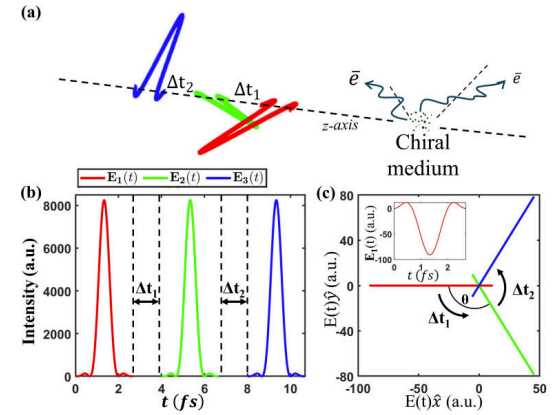

Fig. 2 PECD from non-helical light set-up. (a) pulse train comprised of three few-cycle linearly-polarized pulses, with a polarization axis rotating from pulse to pulse, drives PECD. (b) description of pulse train in time-domain. (c) description of pulse train in polarization space showing non-instantaneous chirality.

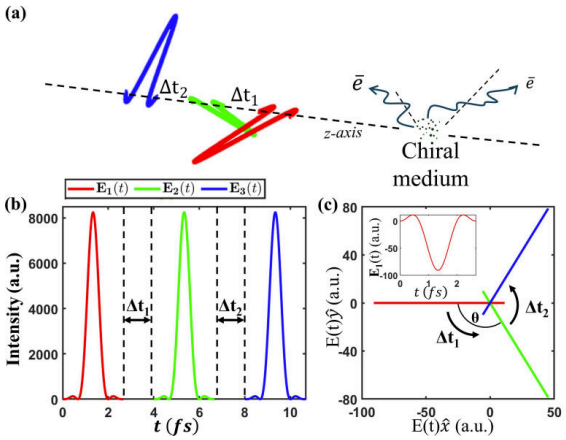

Fig. 2 PECD from non-helical light set-up. (a) pulse train comprised of three few-cycle linearly-polarized pulses, with a polarization axis rotating from pulse to pulse, drives PECD. (b) description of pulse train in time-domain. (c) description of pulse train in polarization space showing non-instantaneous chirality.

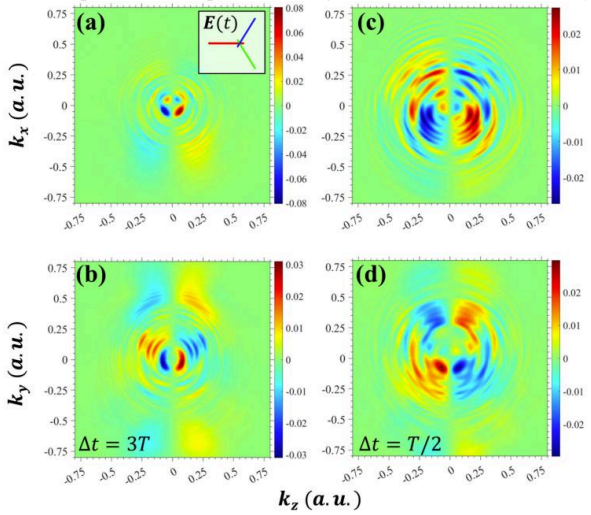

Fig. 3 PECD simulations calculated with the pulse train configuration in Fig. 2 for different inter-pulse delays (in units of T, the period of the carrier wave.

Overall, our work paves way for novel PECD geometries and analysis of PECD in unique tailored-light conditions, which could be utilized for ultrafast chirality spectroscopy.

Evaluating Surface-Enhanced Chiroptical Spectroscopy on Nanostructured Aluminum Substrates in the Deep-UV

Björn M. Reinhard[1]

[1]Department of Chemistry and The Photonics Center, Boston University, Boston, Massachusetts, United States
*Corresponding author: bmr@bu.edu

***Abstract*— Scalable fabrication of aluminum nanostructures with tunable resonances in the UV provides opportunities for surface enhanced spectroscopies in which electronic transitions of molecular systems and plasmon resonances overlap. This presentation provides an overview of fabrication strategies and discusses advantages and challenges in applications for chiral molecular sensing.**

***Keywords*— nanomaterials, nanoplasmonics, nanofabrication, field-enhanced spectroscopy.**

I. Introduction

Nanostructured materials from gold and silver can provide plasmon resonances in the visible and infrared range of the electromagnetic spectrum and are widely used in sensing and surface-enhanced spectroscopy applications. The absorption lines of many molecular quantum emitters lie, however in the ultraviolet (UV) and thus outside of the range accessible with localized plasmon resonances of gold and silver. Aluminum (Al) nanostructures provide resonances in the UV and can thus extend the range for plasmon-enhanced interactions with molecular systems into a range where plasmon and molecular resonances overlap. Harnessing these interactions for the detection and characterization of chiral molecules is of great interest.

II. Methods

Our approach combines scalable fabrication of nano-structured Al surfaces with optical spectroscopy. Large areas of nanostructured Al are generated using nanosphere lithography. Choice of the NP size, etching of the NPs, and thickness of deposited Al provides control over the morphology of the array and allows for a systematic tuning of its spectral response. Alternatively, hole mask colloidal lithography was applied to generate discrete Al nanoparticles or small clusters of nanoparticles. This strategy was used to generate random arrays of Al NPs distributed over a large area. Choice of the NP size and shape as well as the aggregation state of the NPs facilitates tuning of the plasmon resonance. We chose fabrication strategies that yielded achiral plasmonic structures and arrays and then deposited chiral analyte molecules. Deep UV-Raman spectroscopy with excitation wavelengths at 266 nm and 227 nm was performed in a homebuilt microscope to characterize the substrates. Finally, circular dichroism (CD) spectra of the analyte molecules in the presence and absence of the Al nanostructures were obtained. The CD spectra were collected in a commercial CD spectrometer without adjustments.

III. Results and Discussion

Reflection measurements confirmed that Al substrates generated by scalable NP-based lithography sustain plasmon resonances throughout the deep UV down to 200 nm, the limit of our spectrometer. We also validated that the generated substrates provide electromagnetic hot-spots by Raman spectroscopy of test molecules performed at 227 and 266 nm. Although the optical response of the materials in the UV was generally broad, variation of the assembly conditions made it possible to achieve especially strong resonances at the excitation wavelengths.

The CD spectra of selected probe molecules with absorption band in the spectral range of the Al plasmons were measured and categorized. Overlap of electronic molecular resonances with plasmonic resonances resulted in an increase of the detected CD signal. The origin of the chiral CD signal enhancement through the achiral substrate are discussed and strategies for further improvements developed.

IV. Conclusion

We have implemented and tested scalable fabrication strategies for nanostructured Al substrates with plasmon resonances throughout the deep-UV. These substrates supported electromagnetic hot-spots in spectral ranges that overlap with the absorption bands of target molecules. The materials provide a rational platform to investigate resonant molecule – plasmon interactions and allows a systematic evaluation of their effect on chiroptical spectroscopy.

Nonreciprocal Neural Networks for Decoupled Bidirectional Computing via Magneto-Optical SSPP Transmission Lines

Xiaomeng Li[1,2], Enzong Wu[1,2], Hongsheng Chen[1,2], Zuojia Wang[1,2,*]

[1]International Joint Innovation Center, Zhejiang Key Laboratory of Intelligent Electromagnetic Control and Advanced Electronic Integration, Zhejiang University, China

***Abstract*—We demonstrate nonreciprocal neural networks inspired by biological directionality, to achieve compact decoupled bidirectional computing. Enhanced magneto-optical effects are leveraged in TE mode spoof surface plasmon polariton (SSPP) transmission lines, providing independent forward global perception and backward localized response. We also discuss how this nonreciprocal framework enables miniaturization and reconfiguration.**

To address the burgeoning demand for computing capacity in artificial intelligence, optical neural networks have been explored for their ultrafast speed and high parallelism. However, most existing networks are restricted by Lorentz reciprocity, where forward and backward propagations are intrinsically coupled [1]. This constraint leaves the backward pathway largely unexplored and poses a critical challenge for integrated perception-response systems, which typically require bulky directional modules to prevent signal interference. Biological neural systems, which inherently exhibit nonreciprocity, offer a compelling model to address this limitation.

Here, to introduce nonreciprocity into neural networks, we first establish the physical foundation: a TE-polarized SSPP nonreciprocal phase shifter based on the transverse Faraday effect. Unlike conventional devices based on TM modes, which require scarce gyroelectric materials, our design capitalizes on the inherent magnetic transverse spin of TE surface plasmons. We show that this transverse spin enables robust resonant coupling with the Larmor precession in gyromagnetic materials. To realize this, we synthesize the required TE mode through a meticulously designed meandering SSPP structure. Our experimental results demonstrate a substantial differential phase shift of 114.07° at 10 GHz, marking a 52-fold improvement in nonreciprocal performance over conventional microstrip lines. This confirms the efficacy of the 'spin-precession' coupling mechanism for compact nonreciprocal integrated circuits.

Building upon this high-performance nonreciprocal unit, we introduce a nonreciprocal neural network to realize compact, decoupled bidirectional computing. By leveraging enhanced magneto-optical effects in SSPP transmission lines, we successfully decouple the forward and backward paths [2]. This architecture effectively emulates the unidirectional transmission of biological networks, achieving independent control within a single structure. We demonstrate broadband bidirectional decoupled image processing with tailored operator configurations: the forward propagation performs regional integration to emulate global perception, while the backward propagation executes edge detection to simulate localized response. The bidirectional functionality within a single structure eliminates the need for external directional modules and reduces the complexity of the system. As a result, this simplified design can improve resource efficiency and integration density, especially for large-scale, densely connected networks. Furthermore, matrix-solving operations can be facilitated by incorporating feedback waveguides for desired recursion paths.

Finally, extending the nonreciprocal framework, we realize physical path compression within symmetric or chiral topological structures. By exploiting the splitting of forward and backward propagation constants induced by symmetry breaking, signal pathways are effectively "folded" within a compact footprint, enabling significant miniaturization. We demonstrate that by rotating the external bias state, the system can be dynamically reconfigured to execute diverse signal processing functions.

Resonator Cascades in a 3D Lattice as a Broadband Acoustic Metamaterial

Frieder Lucklum

Centre for Acoustic-Mechanical Microsystems (CAMM), DTU Electrical and Photonics Engineering, Technical University of Denmark (DTU), 2800 Kgs. Lyngby, Denmark
Corresponding author: fluc@dtu.dk

***Abstract*— Cascading coupled resonators allows multiple frequency splitting, a common concept in electronic filters. Translating this idea to acoustic metamaterials leads to connected Helmholtz resonators in a 3D lattice, similar to elastic 3D mass-spring metamaterials. Analytical, numerical, and early experimental results demonstrate broadband sound absorption and sound insulation potential.**

***Keywords*— acoustic metamaterial, Helmholtz resonator, resonator cascade, 3D lattice, sound absorption, sound insulation.**

I. Introduction

The concept of coupled resonators is well understood in physics, e.g. for electrical or mechanical systems, leading to splitting of the original resonance into lower and higher frequencies. Cascading coupled resonators repeats this frequency split into more separate resonances and lowers the first common resonance further below the original frequency. Applying this concept to acoustic resonators offers a new design tool to optimize sound absorption and sound insulation.

Helmholtz resonators (HRs) in metamaterials allow fine tuning of resonance frequency and absorption [1]. To overcome their narrow-band limitation, one popular approach is to combine multiple differently tuned resonators that overlap their frequency response [2, 3]. In this approach, individually tuned resonators are typically treated as separate elements (Fig. 1.a). Conversely, resonance coupling has been demonstrated by near field interference of adjacent resonators [4-6]. Directly connected resonator cascades only rarely and very recently appear in literature [7-10]. In all cases, angle dependence is often ignored but this diminishes the suitability for random or diffuse wave incidence, unless explicitly optimized [3]. Multidimensional resonator cascades appear to be unexplored. This work proposes directly connecting HRs in 3D cascades, as illustrated for a cubic lattice in Fig. 1.b, similar to elastic 3D mass-spring metamaterials [11].

II. Concept and Methods

Two coupled single degree-of-freedom (DOF) resonators form a 2-DOF system with two resonances and one anti-resonance. In acoustic systems, connecting the neck (mass) of a Helmholtz resonator to another cavity (spring) effectively cascades a second acoustic mass-spring resonator to the first.

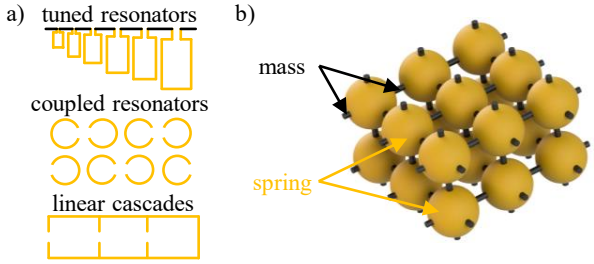

Fig. 1: a) Typical broadband approaches using multiple differently tuned resonators, coupled resonators, or simple connected cascades; b) proposed cubic lattice of connected Helmholtz resonator cascades.

The acoustic 2-DOF system exhibits two local impedance minima and one local maximum: coupled resonances below and above the original resonance frequency and an anti-resonance in between (Fig. 2). The lower resonance appears when the connected resonators are in-phase, the higher resonance when out-of-phase (see insets). The connected resonators form a resonance cascade, where the in-phase resonance does not correspond to a single resonator with twice the mass and compliance, and the out-of-phase resonance is not at twice the frequency. The neck of every layer, acting as acoustic mass, connects to the cavity of the prior layer, acting as acoustic compliance. Dampers represent primarily viscous losses in the neck due to high tangential velocities, and primarily thermal losses in the cavity. The acoustic input impedance Z_{in} at the surface cascades with the impedance of the next layer $Z_{\mathrm{i-1}}$ and the number of layers, i.e. $Z_{\mathrm{in}} = Z_{\mathrm{neck}} + Z_{\mathrm{cav}} || Z_{\mathrm{i-1}}$.

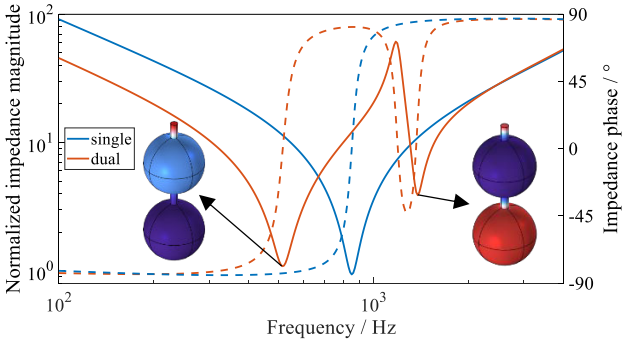

Fig. 2: Normalized input impedance of a single HR (blue) and two connected resonators (red) that show two resonances (in-phase and out-of-phase pressure, see insets) and one anti-resonance.

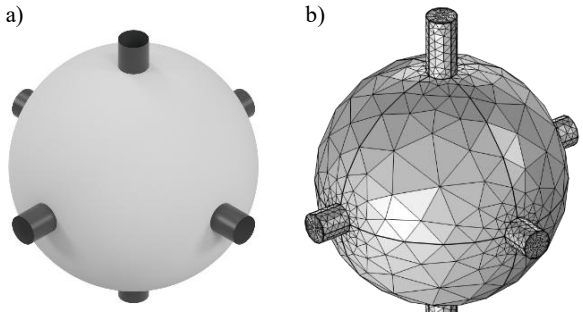

Fig. 3: a) Basic simple cubic unit cell with necks (black) of adjacent resonators connecting to cavity (gray); b) exemplary finite element boundary layer mesh for full Navier-Stokes solution.

The main studies utilized numerical finite element models built in *COMSOL Multiphysics 6.4*. Multiple layers of unit cells (Fig. 3.a) are modelled in the surface-normal direction. The infinite half-space in front (for absorption studies) and the back (for transmission) of the structure is modelled through periodic plane-wave port conditions. Lateral periodicity is achieved through Floquet boundary conditions. The boundary layer impedance (BLI) condition applies viscous and thermal losses to all solid surfaces. Reference studies with the fully linearized Navier-Stokes solution indicate very good agreement for the dimensions investigated here. The mesh for the latter is visualized in Fig. 3.b to illustrate the boundary layer thickness in the frequency range of interest compared to the neck width. The main mesh size is limited to a fifth of the wavelength in air at the highest frequency of interest. Additionally, eigen-frequency study is conducted on the unit cell to determine the dispersion relation.

III. Results and Discussion

Results are shown for a unit cell of spherical cavity and cylindrical neck with a lattice constant of 20 mm, neck diameter of 2 mm, and sphere diameter of 16 mm. These arbitrary dimensions target a single HR frequency around 1 kHz and are not optimized for any specific performance or bandwidth.

Sound absorption: A periodic 3D lattice of identical HRs is connected to a surface. Each coupled resonance leads to a maximum in absorption due to a maximum in velocity through the neck and therefore a maximum of viscous boundary losses. Figure 4 shows the absorption coefficient for a single resonator (black) as well as a cascade of two, five, ten, and twenty layers.

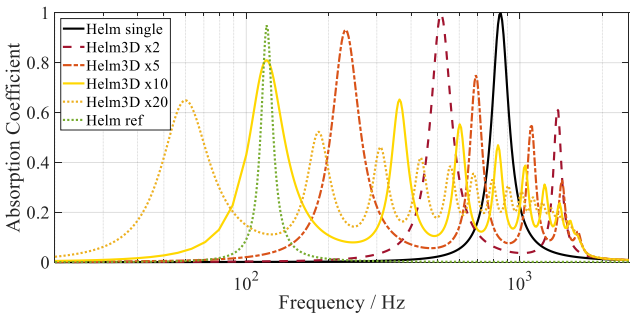

Fig. 4: Absorption coefficient for a metasurface consisting of different resonator cascades (orange colors) compared to original single Helmholtz resonator (black) and scaled single HR (green).

The first absorption peak continuously decreases in frequency for each layer, for ten layers (gold) from 850 Hz down to 120 Hz. For reference, the figure also includes a single resonator scaled to match the 10-layer cascade (dotted green). A similar first absorption peak appears, but the cascade offers larger peak bandwidths and higher order resonances.

Besides the broadband response due to multiple resonances, the cascade also displays a notably different incidence angle dependence. Figure 5 illustrates the frequency response of the single, scaled Helmholtz resonator (green) at normal incidence and near-grazing incidence in addition to a generic porous material layer (blue). In both cases, the absorption coefficient decreases drastically towards grazing incidence. On the contrary, the 10-layer cascade (gold) achieves maximum absorption around 80° incidence for multiple resonance peaks. The higher order resonances are more strongly dependent on the incidence angle. Notably, cascading does not have to extend into the depth of the surface but utilize lateral or coiling arrangements. In this case, the single HR, porous layer, and a spiraled 10-layer cascade all have similar total thickness. But only the Helmholtz resonators achieve high absorption as low as around 100 Hz and only the 10-layer cascade offers broadband absorption through multiple resonances from 100 Hz to 1.5 kHz, especially at near-grazing incidence.

Combining different cascades by connecting them to the same surface results in a similar effect as combining differently tuned single resonators. The different individual absorption peaks add up to a broadband and wide-angle absorption envelope. Considering the examples in Fig. 4 and starting with a 20-layer cascade, such an absorption envelope would extend from 50 Hz to 1.7 kHz. On top of the cascading illustrated here, each cascade and each individual resonator could also be optimized to target a specific overall absorption profile.

For validation, round cylindrical sample cascades were 3D-printed (*Epsilon W27*, BCN3D, Spain) and measured in an impedance tube with 100 mm diameter and a valid frequency range from 50 – 2000 Hz (*AcoustiTube Type II*, Acoustic Engineering Dresden, Germany) following the two-microphone method of ISO 10534-2. The printed sample as illustrated in Fig. 6 is placed at the termination and sealed to avoid leakage effects. Through the measurement of direct and flipped transfer functions, the complex reflection coefficient and subsequently the surface impedance and absorption coefficient are determined. The experimental results are in good agreement to a finite element model adapted to the actual printed dimensions.

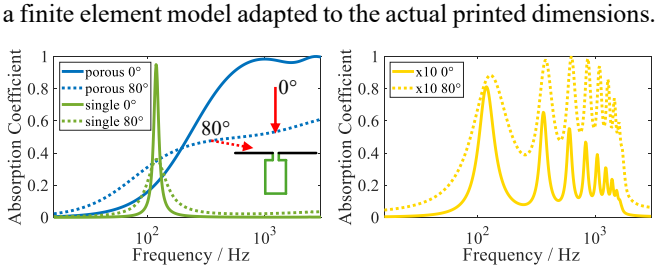

Fig. 5: Dependence of absorption on incidence angle for porous absorber and single Helmholtz resonator (left), as well as 10-layer cascade (right), all with similar total thickness around 10 cm.

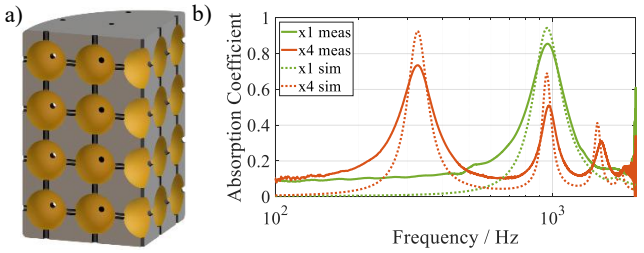

Fig. 6: a) Rendered quarter-cut of 3D-printed cascade (inverse of HR lattice with gold indicating cavities and black for necks); b) measured and simulated absorption curves for single HR and 4-layer cascade.

Sound insulation: Connecting the 3D lattice to the other side of a metamaterial slab also forms an insulator that combines the effects of a sonic or phononic crystal with local resonances. This is visualized in the full dispersion diagram shown in Fig. 7.a. The low frequency limit is determined by local resonances, including the fundamental Helmholtz resonances. Bragg scattering results in a complete band gap centered around half-wavelength in respect to the lattice constant, here at 8.6 kHz (wavelength in air 40 mm), while for the normal incidence ΓX direction the local resonances extend the gap down to 1/10th of the wavelength at 1.7 kHz (wavelength 200 mm). Further gaps form at higher frequencies (second gap at 15 – 21 kHz).

Within these gaps the transmission loss is extremely high, as high as 160 dB for a 4-layer cascade (Fig. 7.b). For comparison, a perforated plate (MPP) with the same hole dimensions as the neck of the HR and the same lattice constant and thickness offers no band gap and only limited transmission loss. The periodic pattern in the MPP response corresponds to a Fabry-Perot resonator (half-wavelength resonances starting at 2 kHz in the individual tubes). At these resonances, transmission loss is decreased but absorption increased.

Lastly, the angle dependence of power reflection, transmission, and absorption coefficients is illustrated in Fig. 8 for normal incidence and near-grazing incidence. Prior to the band gap opening frequency, transmission and absorption is increased at the cascaded resonances, with higher values for 80° incidence. Inside the first band gap, absorption also increases for grazing incidence, while transmission stays effectively zero. Transmission loss at 80° incidence decreases by approximately 10 – 15 dB, which in the case of the MPP results in up to 20% transmission at the Fabry-Perot resonance peaks.

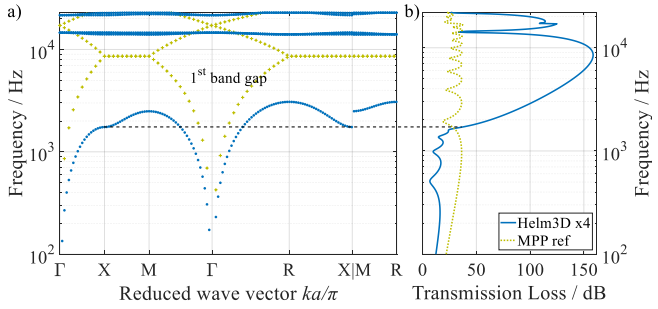

Fig. 7: a) Dispersion diagram for 3D HR unit cell (blue) with first band gap from 3 – 14 kHz (1.7 – 14 kHz for normal incidence ΓX) compared to perforated plate (beige); b) transmission loss through 4-layer cascade (blue) compared to similar perforated plate (beige).

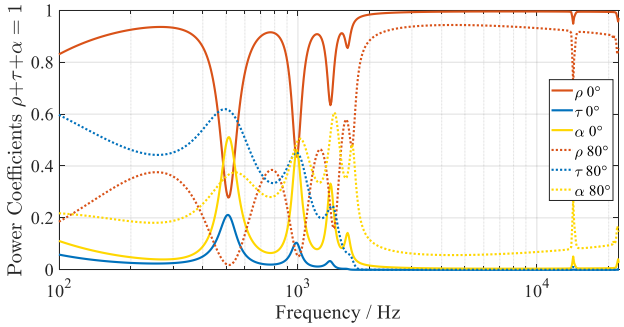

Fig. 8: Angle dependence of power reflection (ρ, red), transmission (τ, blue), and absorption (α, gold) coefficients through 4-layer 3D cascade at Helmholtz resonances (<2 kHz) and inside band gap.

IV. Conclusion

Cascading connected acoustic resonators in a metamaterial lattice leads to frequency splitting into multiple resonances with high absorption. Studies also show superior incidence angle dependence for the 3D cascades. Utilizing the coupled lattice as an insulation panel yields wide band gaps with high transmission loss superior to comparable perforated plates. Initial impedance tube experiments validate this novel conceptual design approach. In future work, the configuration and 3D lattice connections of each resonator can be optimized to achieve a desired sound absorption and sound insulation.
