*Corresponding author: padgo@mci.sdu.dk

***Abstract* — We review progress in quantum plasmonics and present analytical expressions for mesoscopic scattering coefficients of metallic cylinders, discussing how quantum nonlocal effects influence plasmon resonances and light–matter interactions. We then show that graphene plasmons can be leveraged to probe ultrafast thermoelectric phenomena and control donor–acceptor energy-transfer rates in nanoribbon structures.**

***Keywords*— quantum plasmonics, graphene plasmons, nonlocal effects, light–matter interactions.**

The optical response of metallic nanostructures can deviate strongly from classical predictions when their characteristic dimensions reach the nanometer scale ($\lesssim$10 nm) and/or when plasmon-mediated light–matter interactions processes involve near-fields characterized by large wavevector components [1–3]. The surface-response formalism based on Feibelman's *d*-parameters provides a practical and scalable framework for incorporating quantum nonlocal effects in nanoplasmonic systems [1–3]. After reviewing recent progress in this area, we present closed-form, analytical expressions for the *d*-parameter-corrected scattering coefficients of metallic cylinders, thereby completing the set of highly symmetric canonical geometries—the planar interface and the sphere having been derived previously in Refs. [3] and [1], respectively. We further analyze the impact of quantum surface response on plasmon resonances, plasmon-mediated Purcell enhancement, and electron energy-loss spectra for both single metallic cylinders and the dimer configuration.

In the second part, we present two applications of graphene plasmons. First, we show how plasmon-enhanced absorption in graphene can be used to probe ultrafast thermoelectric phenomena through the generation of transient electric fields on the picosecond timescale. Second, we demonstrate how plasmons in graphene nanoribbons can be exploited to control the energy-transfer rate between a donor–acceptor dipole pair.

***Abstract*—We have developed a frequency-dependent kinetic-energy functional for the Quantum Hydrodynamic Theory (QHT), which is non-empirical and can be implemented in a real-space framework. We show results for metallic nanoparticles and compare to full Time-Dependent Density Functional Theory (TD-DFT).**

***Keywords*— Quantum hydrodynamic theory, Density functional theory, plasmonic nanoparticles**

I. Introduction

The Quantum Hydrodynamic Theory (QHT), which can be considered a reformulation of the Time-Dependent Orbital-Free Density Functional Theory[1], [2], have been successfully applied to model optical properties of metallic nanoparticles[1]

The accuracy of the QHT absorption spectrum depends on the approximation of the kinetic energy (KE) functional. Conventional KE approximations are based on gradient-corrected KE functionals, such as the Thomas-Fermi-von Weiszäcker (TFvW), which can reproduce accurately the main plasmon peak or including higher-order corrections [3].

Most of the KE functionals for QHT are, however, static or defined within a different theoretical background[4] or in the reciprocal space[2]

II. Method and Results

The Lindhard response function has been fitted with the TFvW kinetic energy functional using complex-valued frequency-dependent coefficients. In this way the broadening is included in the functional without any empirical fit. As an example, in Fig. 1 we report the normalized absorption spectra for a jellium nanosphere comparing the reference Time-Dependent Density Functional Theory (TDDFT) and with our QHT theory. The position and the brodening of the main plasmon peak is well described, without any empirical input.

III. Conclusion

We have extended the QHT theory using complex-valued kinetic energy functionals. The method can be ready implemented in any real-space code, to model absorption spectra of plasmonic systems including the broadening without empirical inputs.

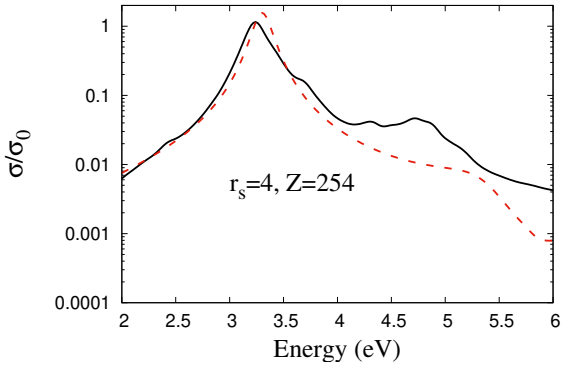

Fig. 1. Normalized absorption spectra for a jellium nanosphere with $r_s = 4$, i.e. sodium, with N=254 electrons. Black line is the reference TDDFT, dashed-red line is QHT.

***Abstract*—Non-perturbative multi-mode light–matter coupling modifies physical properties beyond those set by geometry. We demonstrate this across three platforms: resonant laser fields stabilize ionizing atomic transitions against continuum decay; cavity coupling suppresses photodissociation in molecular cations; and co-localized superstrong coupling in visible nanophotonic waveguides enables in-situ spatial control of electromagnetic field distributions.**

***Keywords*— polaritons, ultrastrong coupling, photostabilization, nanophotonics, photodissociation, super strong coupling.**

I. Introduction

Non-perturbative light–matter coupling involving multiple modes modifies intrinsic properties of both material and photonic systems beyond what geometry alone determines. We present three realizations spanning atomic, molecular, and solid-state platforms: (i) resonant laser driving stabilizes ionizing electronic transitions via AC Stark level repulsion [1]; (ii) multi-mode cavity coupling to the dissociative vibrational continuum suppresses photodissociation in diatomic molecular cations; and (iii) co-localized superstrong coupling (SSC) between an exciton and multiple photonic modes in visible nanophotonic waveguides gives real-space control over the electromagnetic field distribution [2].

II. Results and Discussion

Laser-stabilized ionizing transitions

Resonant pumping of an ionizing transition above a critical intensity creates a metastable discrete resonance via AC Stark level repulsion—a semiclassical counterpart of the photon-bound exciton (PBE) observed in microcavity-embedded doped quantum wells [3]. Unlike the Mollow triplet of a bound-to-bound transition, only two of the four emission channels survive, their spectral weights probing the hybridization with the continuum, and the state decays via two-photon (photon–polariton) ionization [1].

Multi-mode photostabilization of molecular photodissociation

Extending the Lee–Friedrichs framework to diatomic cations (H_2^+, K_2^+), multi-mode cavity coupling to the dissociative vibrational continuum reshapes polaritonic potential energy surfaces. Franck–Condon overlaps with continuum modes together with the coupling-strength dependence of the lower polariton energy define a threshold above which cavity-induced stabilization suppresses photodissociation, opening a route to optically controlled molecular reactivity.

Co-localized superstrong coupling in visible nanophotonic waveguides

Co-localized SSC is the photonic counterpart of multi-mode matter coupling: rather than one photon hybridizing with multiple matter excitations, one exciton hybridizes simultaneously with multiple photonic modes [2], whose distinct transverse field profiles make exciton-energy tuning a direct handle on the spatial electromagnetic energy distribution. Planar grating-coupled waveguides realize this in the visible range: restricting a 2D hybrid organic-inorganic perovskite active layer to 30% of the waveguide core yields a full modal overlap between TE_0 and TE_1, producing multi-mode polaritons. RCWA simulations fitted with a generalized Hopfield model [2] confirm a characteristic S-shaped dispersion; coupling the lowest-order modes yields up to 44% higher coupling strength than higher-order pairs, and exciton-energy tuning continuously switches the electromagnetic energy distribution between the bulk and surface of the waveguide.

III. Conclusion

Non-perturbative coupling to a structured continuum of modes opens degrees of freedom that geometry alone cannot provide: a coupling-induced threshold separating stabilized from ionizing or dissociating dynamics in atomic and molecular systems, and coherent mixing of spatially distinct field profiles in nanophotonic waveguides. Both directions point toward a unified design language for polaritonic devices, from decay-rate engineering to field-distribution control in integrated visible-wavelength photonics.

Geometric Phase Wavefront Shaping in Nonlinear Meta-Optics: From Tensor-Driven Phase to Nonlocal Metasurfaces

Luca Carletti[1,*]

[1] Department of Information Engineering, University of Brescia, Via Branze 38, 25123 Brescia, Italy
*Corresponding author: luca.carletti@unibs.it

Abstract—Nonlinear metasurfaces enable compact frequency conversion while shaping the generated wavefront. We outline two complementary routes: tensor driven phase control in AlGaAs metasurfaces for second-harmonic beam steering and structured light, and nonlocal resonant Silicon metasurfaces for third-harmonic generation that combine high quality factors with efficient beam steering.

Keywords— nonlinear metasurfaces, wavefront shaping, geometric phase, AlGaAs, silicon, nonlocal resonances.

I. INTRODUCTION

Metasurfaces provide subwavelength control of phase, polarization, and amplitude in ultrathin optical elements. Extending these concepts to nonlinear harmonic generation enables ultra-thin nonlinear light sources whose output can be structured without bulk optics [1]. Key challenges are simultaneously achieving strong nonlinear conversion and full wavefront control under realistic fabrication constraints.

II. METHODS

We consider two design paradigms, both based on geometric rotation of the unit elements of the metasurface to control the phase of the generated harmonic. First, in zincblende semiconductors the effective second-order susceptibility changes under in-plane rotations, introducing a nonlinear tensor-driven phase term that adds to the familiar rotation induced phase [2,3]. Rotated AlGaAs meta-atoms can therefore encode a desired phase profile directly onto the second-harmonic field. Second, nonlocal silicon metasurfaces are designed to support extended resonant modes with large quality-factors beyond single meta-atoms; by locally tailoring the unit-cell geometry or orientation, a spatially varying geometric phase can be imposed on the generated third-harmonic while benefiting from resonant enhancement [4].

III. RESULTS AND DISCUSSION

Both approaches are demonstrated experimentally:

- Second harmonic beam steering from AlGaAs metasurfaces that routes opposite circular polarizations into opposite diffraction orders.
- Generation of structured second harmonic light with unit topological charge by quadrant phase encoding, verified via fork-like interferograms and helical phase retrieval.
- Third harmonic beam steering in the visible from nonlinear nonlocal silicon metasurfaces combining high-Q resonances with spatially varying geometric phase.

IV. CONCLUSION

Tensor sensitive nonlinear phases and nonlocal resonant enhancement address complementary limitations of conventional nonlinear metasurfaces. Together they enable efficient harmonic generation with tailored wavefront control, supporting applications in compact beam steering, structured light sources, and nonlinear holography.

***Abstract*—We combine density functional and quantum hydrodynamic theories to study how molecular size and quantum tunnelling jointly affect the emitter-plasmon interaction in a plasmonic dimer. Compared with a point-dipole-based model, pronounced deviations arise at sub-nanometer separations, and the onset gap for tunnelling-induced quenching is over three times larger.**

***Keywords*— Quantum hydrodynamic theory, Density functional theory, Nonlocality, tunnelling, Plasmon-emitter interactions, emitter's spatial extent.**

I. Summary

The computationally demanding nature of purely quantum-mechanical methods to simulate fabrication-feasible plasmonic systems has made it indispensable to use either a semi-classical or a classical approximation to study emitter-plasmon coupling. Even though classical techniques, like the point dipole approximation (PDA), accurately predict long-range effects, they fail to account for important phenomena when the emitter-plasmon separation decreases to scales where the emitter size and plasmonic quantum effects become relevant. Semi-classical theories, including the Feibelman d-parameter scheme and the quantum hydrodynamic theory (QHT), have been advanced to address this issue by solving Maxwell's equations while systematically embedding the quantum effects. These extended classical models can be combined with quantum-mechanical treatment of the emitters, owing to their small size, offering a computationally feasible hybrid approach that addresses the emitter's finite-size effects as well as the critical quantum plasmonic effects.

In this talk, we present such a hybrid scheme by combining QHT [1] and time-dependent density functional theory (TDDFT) [2]. We utilize TDDFT to calculate the dipolar transition charge density of a p-nitroaniline (PNA) molecule, which then serves as a realistic excitation source for the QHT-treated plasmonic systems. We begin by examining how the emitter's finite spatial extent influences its interaction with a plasmonic nanoparticle within a classical framework. Emission rates of the molecule-based system are compared with those based on a point dipole (PD) [3] whose moment is determined from the same molecule. At large emitter-plasmon distances, the molecular and corresponding PD emission rates converge, as anticipated, confirming that they characterize the same underlying emitter response. However, at sub-nanometer distances, large differences appear in both the weak and strong coupling regimes.

Implementing the hybrid model in a plasmonic dimer and comparing it with its PD-based counterpart reveals substantial discrepancies for dimer gaps below 3.2 nm (i.e., sub-nanometer emitter-plasmon separations), affecting both the oscillator strength of the emission rates and the spectral positions of prominent modes. Interestingly, the maxima of the highest order mode analyzed in this work for the molecule-dimer system exhibit a non-monotonic dependence on the dimer gap, characterized by increasing and decreasing parts, where the quenching part is due to the effect of the tunneling electrons that start to emerge after a gap size of 1.64 nm. This exceeds the onset gap reported for the PD-based QHT-treated system in Ref. [4] by more than a factor of three.

We further analyse PD- and molecule-based emitter-plasmon coupling by progressively increasing the order of quantum effects, from local response approximation (LRA) to nonlocal Thomas-Fermi hydrodynamic theory (TFHT) up to full QHT. This hybrid approach interpolates between fully quantum and semi-classical methods, enabling systematic analysis of nanoscale emitter-plasmon interactions, with the potential to advance the design of quantum plasmonic devices.

***Abstract*—We employ first-principles simulations to investigate how localized plasmons in nanostructured 2D materials can be leveraged to drive strong nonlinear optical processes, spanning both perturbative frequency conversion and high-harmonic generation. We identify multiple pathways to enhance nonlinear light–matter interactions through either electrostatic doping, heterostructure engineering, or ultrafast photothermal activation.**

***Keywords*— nonlinear optics, nanophotonics, thermoplasmons, first-principles modelling.**

Nonlinear optics enables all-optical temporal and spectral control, central to future integrated photonic and quantum optical devices. [1], [2]. Extreme light–matter interactions under intense optical driving produce nonlinear electron dynamics that enable strong photon–photon coupling. A prime example is high-harmonic generation (HHG), in which radiation is emitted at integer multiples of the drive frequency, terminating at a sharp cutoff energy.

Using ab initio modelling and self-consistent perturbation theory, we have developed a framework based on Maximally Localized Wannier Functions (MLWFs) that captures both quantum finite-size effects and nonlocal electrodynamics in the nonlinear optical response of nanostructured 2D materials [3], [4]. Applying this framework, we characterize the highly adjustable plasmonic resonances in electrostatically doped in phosphorene nanoribbons (PNRs) that can be brought into resonance with the driving field to yield pronounced nonlinear emission and efficient HHG, see Figure 1 (a-b).

Beside the active control afforded by electrostatic doping, passive control of the nonlinearities can be achieved though heterostructuring. Our recent results demonstrate how the nonlinear response of graphene and phosphorene nanoribbon dimers, can be actively and passively tuned by independently controlling each constituent ribbon (geometry and carrier density) [5]. Notably, inter-ribbon coupling and symmetry breaking enable large, highly tunable even-order responses in these materials that would otherwise appear inversion-symmetric, see Figure 1 (c-d). Our finding additionally illustrated that the same design knobs extend into the extreme nonlinear regime to yield rich HHG spectra with tunable even-order harmonic content.

Finally, we address transient thermoplasmonics in narrow graphene nanoribbons (GNRs), where intense photoexcitation can convert absorbed energy into electronic heat on ultrafast timescales, producing hot-carrier distributions that support mid- and near-IR plasmonic features without requiring static doping. Because graphene's electronic heat capacity is low, modest absorbed energy densities accessible in ultrafast experiments can raise electron temperatures dramatically. Our simulations reveal how these induced thermoplasmons leads to pronounced changes in both linear absorption and third-order nonlinearities, including strong third-harmonic generation and Kerr-type responses, see Figure 2 [6]. This photothermal route offers a robust, non-invasive mechanism to switch on transient nonlinear plasmonic behaviour at infrared frequencies.

Excitation of Dark Modes and Multipole Plasmons via Surface-Response Function

Fan Yang[1,*]

[1]College of Physics, Sichuan University, Chengdu, Sichuan 610065, China
*Corresponding author: fyang@scu.edu.cn

***Abstract*—The dark mode can be excited by far-field illumination when surface electronic quantum effects are considered, which are modeled by the Feibelman d-parameter. On the other hand, multipole plasmons can be excited and engineered via surface nonlinearity.**

***Keywords*— dark mode, multipole plasmon, Feibelman d-parameter, surface nonlinearity**

I. Introduction

Dark modes are featured with a vanishing net dipole momentum, resulting minimum coupling with far-field illumination. It is conventionally believed that these modes cannot be excited by plane waves. However, we challenge this conventional view and propose that classical dark modes can be accessed by far-field illumination when surface electronic quantum effects are considered.

Multipole plasmons are characterized by high angular momentum. They cannot be accessed by the far field in strongly sub-wavelength nanoparticles and they are therefore dark. Localized sources, structured light, and electron beams have been proposed to excite these multipole plasmons. We find that these multipole plasmon can also be excited and engineered by surface nonlinearity, offering an alternative approach for their excitation.

II. Results and Discussion

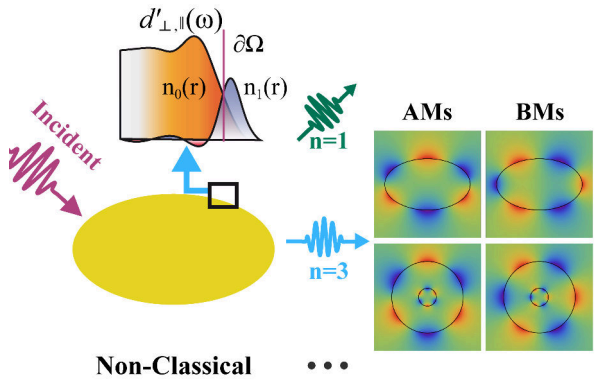

Fig. 1. Nonclassical effects at the metallic surface excite dark modes in an ellipical nanoparticle.

In Fig. 1, we present our result on dark mode excitation in an elliptical nanoparticle. The sub-wavelength elliptical nanoparticle features many non-degenerate eigenmodes with different angular quantum number m, where only dipolar mode with $m = 1$ can be excited by the plane wave according to the classical electrodynamics. However, we show in Fig. 1 that modes with higher quantum numbers can be excited if surface electronic quantum effects are taken into account.

To explore dark mode excitation, we employ the surface-response function—Feibelman d-parameter—to compute the dispersion of these dark modes. It is found the scattering matrix exhibits off-diagonal terms purely due to the non-zero d-parameter. These terms couple modes with different angular momenta, enabling dark modes to be excited via coupling with the dipolar mode.

Similarly, multipole plasmons can be excited by the nonlinear surface-response function, i.e. the nonlinear surface susceptibility. For an elliptical nanoparticle, the eigenfrequency can be engineered by varying the particle's elongation. By overlapping the dispersion lines of different harmonics, a desired multipole mode can be enhanced.

III. Conclusion

We have theoretically demonstrated that the classical dark mode becomes bright when electronic quantum effects are considered. Furthermore, the excitation and enhancement of multipole plasmons can be well controlled via surface nonlinearity.

***Abstract*— We report on local electro-optic sampling of phase-resolved phonon-polariton electrodynamics inside of cryogenically cooled, high-quality terahertz (THz) quartz cavities. With our novel detection scheme, we isolate the light and matter components of the polariton signal, thereby measuring the full eigenvector of the phonon-polariton, in contrast to conventional THz transmission measurements.**

***Keywords*— Terahertz Cavity Electrodynamics, Strong Light-Matter Coupling, Nonlinear Field Sensing**

I. Introduction

Terahertz cavity electrodynamics has received increasing attention recently, with much excitement focused on the renormalization of ground-state properties in correlated materials[1] and on modifications of phase transition temperatures. In the context of strong-field terahertz (THz) excitation, there is also significant interest in using cavities to modify the nonlinear excitation pathways by way of modification of the IR-active resonances, which mediate several nonlinear excitation routes.[2] It is within this context, where knowledge of the precise field structure inside the cavity is crucial to understanding field-driven effects, that we recently made the critical first step of applying the standard THz spectroscopic tool of electro-optic sampling[3] to trace electric-field dynamics inside a Fabry-Pérot cavity for the first time.[4]

Cavity electro-optic sampling is a powerful technique that enables measurement not only of the electric field inside the cavity but also of IR-active excitations that can be driven resonantly and selectively with a broadband THz pulse. We aim to take full advantage of this capability by measuring electro-optic sampling signals from z-cut α-Quartz embedded within a THz Fabry-Pérot cavity, which we demonstrate reaches strong coupling with the ~4 THz phonon at cryogenic temperatures and high cavity quality factors (Q>20). Furthermore, we take advantage of the sub-cycle, or phase-resolved, capabilities of THz spectroscopy to separate the light and matter components of the polariton signal. We note that this is only possible because of the phase-resolved spectral information, which allows the inclusion of effects such as the phonon inertial delay.

II. Methods

We measure electro-optic sampling traces by co-focusing a broadband, single-cycle THz pulse from a spintronic emitter along with a short near-IR probing pulse, accessing the electro-optic signal stroboscopically by employing a variable time delay for the probe pulse. The signal is generated nonlinearly using a $\chi^{(2)}$ process which is linear with respect to the probe field and THz field and read out using a balanced detection scheme. [4] The nonlinear susceptibility within our THz spectral bandwidth can be decomposed into a spectrally-flat, i.e. instantaneous, component, which responds instantaneously to the local electric field, and a Lorentzian component which reflects the signal corresponding to the local amplitude of the coherently-driven IR-active phonon within quartz. Therefore, the nonlinear susceptibility is written as follows:

$$\chi^{(2)} = \chi^{(2)}_{\text{light}} + \chi^{(2)}_{\text{matter}} = \chi^{(2)}_{\infty} + \frac{SR}{\omega_o^2 - \omega^2 - i\Gamma\omega}, \qquad (1)$$

where $\chi^{(2)}_{\infty}$ is the amplitude of the non-resonant susceptibility term, S is the phonon oscillator strength, and R is the Raman tensor for the mode in the near-IR, where the probe laser is spectroscopically situated.

III. Results and Discussion

We experimentally demonstrate the disentanglement of the light and matter components of the polariton signal, thereby retrieving the complex polariton eigenvector. This contrasts with conventional spectroscopic measurements, which measure transmitted light intensity and therefore the norm-squared of only the light character. Our novel method, in contrast, measures both the light and matter components and retains their true, complex nature, owing to the measurement of fields rather than intensities.

Furthermore, we utilize a wedged cavity structure to perform highly detailed investigations of light-matter interactions as a function of the resonant detuning between the participating cavity mode and the IR-active phonon, which can undergo

strong coupling at the highest cavity quality factors. This is enabled directly by the wedge structure, where translation of the wedge allows sampling of polariton propagation at variable thicknesses, thereby changing the cavity mode frequencies. In this way, we investigate the avoided crossing between the responsible cavity mode and the optical phonon, visualized for both the phonon and the electric-field components of the phonon polariton.

IV. Conclusion

We have demonstrated a novel experimental platform for measuring phonon-polaritons, enabling simultaneous measurement of the light and matter components of the polariton signal. We also implement a wedge cavity structure, which allows unprecedentedly detailed investigations of THz light-matter coupling as a function of resonance detuning, in conjunction with the light-matter decoupling principles.

Acknowledgments

We thank Sven Kubala for depositing the gold films, which serve as the cavity end mirrors of the quartz cavities.

***Abstract*— We report dramatic nonlocal optical effects in hexagonal boron nitride nanoparticles using electron energy-loss spectroscopy. Local dielectric theories fail to describe observed bulk modes and surface-mode splitting. Atomistic simulations incorporating long-range dipole-dipole interactions successfully reproduce experimental spectra, highlighting the critical role of nonlocality at the nanoscale.**

***Keywords*— phonon polaritons, hBN, nonlocality, EELS, atomistic simulations.**

I. Introduction

Mid-infrared phonon polaritons in polar van der Waals materials, such as hexagonal boron nitride (hBN), have attracted significant interest due to their ability to confine electromagnetic energy deep below the diffraction limit and their long lifetimes [1,2]. While the optical response of extended bulk hBN is well-described by local Drude-Lorentz models, these local approximations become insufficient for nanostructured materials. In the nanoscale regime, the optical response is often dominated by nonlocal effects, where the electric displacement depends on the field at other spatial locations.

In this work, we investigate these nonlocal effects in hBN nanoparticles using monochromated electron energy-loss spectroscopy (EELS). We observe spectral features, specifically bulk modes and surface-mode splitting, that cannot be explained by standard local dielectric theory. By employing atomistic calculations that account for long-range dipole-dipole interactions, we provide a microscopic explanation for the particle-size-dependent separation between longitudinal and transverse modes.

II. Methods

Experimental Setup: We prepared hBN nanoparticles via mechanical exfoliation and dry etching on silicon nitride membranes. The vibrational excitations were probed using a Nion high-energy-resolution monochromated EELS system in a scanning transmission electron microscope (STEM) at 30 kV. We focused on a representative semi-ellipsoidal nanoparticle with a radius R=33 nm and height H=64 nm, as attached Fig. 1 (a).

Theoretical Modeling: We compared two theoretical approaches. First, a continuum model using the finite-element method (FEM) where hBN is described by an anisotropic local dielectric tensor. The components are given by:

$$\epsilon_s(\omega) = \epsilon_{\infty,s}\left[1 - \frac{\omega_{\mathrm{LO},s}^2 - \omega_{\mathrm{TO},s}^2}{\omega(\omega + \mathrm{i}\gamma_s) - \omega_{\mathrm{TO},s}^2}\right]$$

where s denotes directions parallel or perpendicular to the atomic planes. Second, we performed atomistic simulations solving the equations of motion for atomic vibrations. This model utilizes dynamical matrices constructed from density functional theory (DFT) force constants and explicitly includes long-range dipole-dipole interactions.

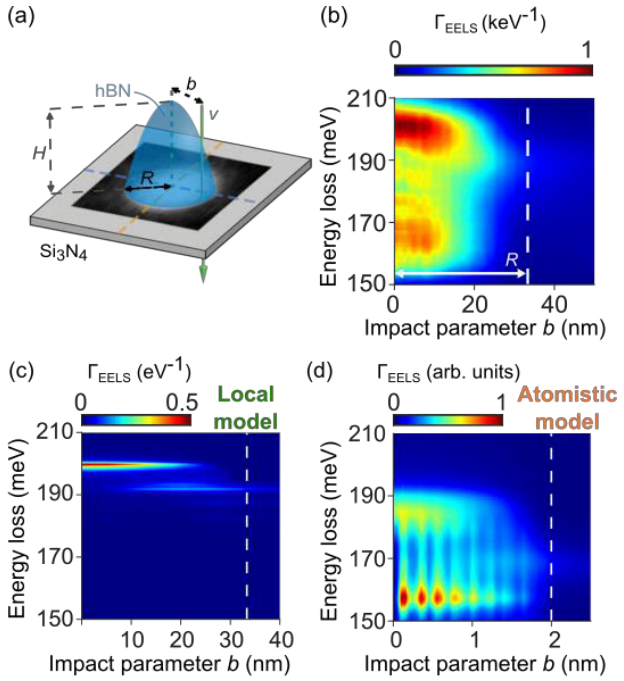

Fig. 1 (a) Schematic representation of an electron beam interacting with a hBN ellipsoid nanostructure positioned on a silicon nitride membrane. (b) Experimentally measured EELS probability distribution. (c) Simulated EELS probability using a local dielectric model via COMSOL. (d) DFT-based atomistic simulation of the EELS probability distribution incorporating dipole-dipole interactions.

III. Results and Discussion

The experimental EELS probability maps reveal two distinct spectral features: a low-energy mode near 158 meV and a high-energy mode near 200 meV (see Fig. 1 (b)). The intensity of these modes is strongest near the particle center and decays toward the edges.

Failure of Local Theory: The continuum FEM simulation based on the local permittivity reproduces the high-energy feature associated with longitudinal optical (LO) modes. However, it completely fails to capture the low-energy mode. This failure arises because the low-energy feature corresponds to transverse optical (TO) phonons, which require finite momentum transfers (a nonlocal effect) to be excited by the electron beam (see Fig. 1 (c)).

Success of Atomistic Theory: The atomistic simulations successfully reproduce both spectral features (see Fig. 1 (d)). Our analysis identifies the low-energy peak as a bulk-like TO mode, where atomic displacements are perpendicular to the propagation direction. This mode is insensitive to long-range dipole-dipole interactions. Conversely, the high-energy peak is identified as a surface-localized LO mode. Crucially, the spectral position of this LO mode is strongly dependent on dipole-dipole interactions.

IV. Conclusion

We have demonstrated that the optical response of sub-100 nm hBN particles is governed by nonlocal effects that escape conventional local dielectric descriptions. The excitation of bulk TO modes and the splitting of LO-TO modes are driven by finite momentum transfers and long-range Coulomb interactions, respectively. These findings establish that atomistic descriptions are essential for designing future phonon-polaritonic nanodevices.

***Abstract*—We investigate phonon-driven exciton polariton transport in monolayer $MoSe_2$ at ambient temperatures. Three distinct regimes are identified: initial sub-ps ballistic-like expansion, few-ps transient superdiffusion, and a slow exciton-limited diffusion after thermalization. This work will help trigger and guide future experimental studies on phonon-mediated polariton transport in 2D semiconductors. *Keywords*— spatiotemporal dynamics, exciton polaritons, 2D materials, transition metal dichalcogenides**

I. Introduction

Exciton transport plays a key role in light-energy conversion technologies and has potential for ultrafast and energy-efficient excitonic circuits that bridge nano-scale electronics and micrometer-scale photonics. Particularly promising are transition metal dichalcogenides (TMD) monolayers, which support tightly bound Wannier excitons that are stable at room temperature and interact strongly with light [1]. At ambient temperatures and low excitation power, excitons propagate via phonon-driven diffusion, resulting in short propagation distances and small diffusion coefficients (on the order 1-10 cm^2/s in TMD monolayers [2]). The hybridization of excitons with cavity photons to form exciton polaritons enhances the propagation by orders of magnitude, enabling long-range ballistic transport suitable for quantum applications (Fig. 1(a)). The rich exciton landscape of TMDs provides intervalley scattering pathways via momentum-indirect excitons. These dark states have been extensively studied in the case of bare TMD monolayers, where they facilitate rapid energy relaxation on sub-ps timescales, and have recently been demonstrated to play a key role in both polariton absorption [3] and relaxation [4]. In the latter, it was shown that the KK' exciton reservoir can efficiently populate the polariton groundstate for certain detunings, circumventing the notorious polariton bottleneck effect. To date, the role of momentum-dark excitons in polariton transport has not been explored. This has become especially relevant, as recent experiments have reported a detuning-dependent crossover between ballistic and diffusive transport regimes [5]; however, the microscopic origins of this crossover are still not well understood. Focusing on a representative hBN-encapsulated $MoSe_2$ monolayer integrated within a Fabry-Pérot microcavity that is initialized with a localized non-resonant distribution, we provide a microscopic description of the phonon-driven spatiotemporal relaxation for different temperatures and detunings [6]. Crucially, we include momentum-resolved, real-space dynamics of polaritons and dark intra- and intervalley reservoir excitons.

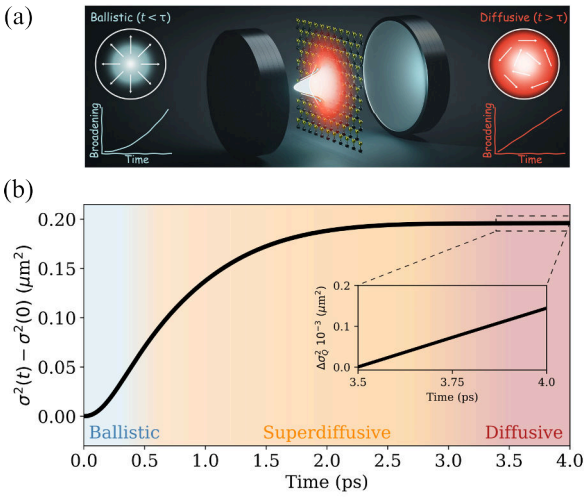

Fig. 1. (a) Schematic of a $MoSe_2$ monolayer integrated within a microcavity where the system is in the strong coupling regime. In this case, transport behavior is strongly modified because of the large group velocities of exciton-polaritons. Both the ballistic (left, blue) and diffusive (right, red) regimes are depicted, with the corresponding real-space broadening in time shown. The timescale τ represents a typical thermalization time that dictates the crossover from rapid ballistic-like expansion (quadratic) to a slower diffusive regime (linear). (b) Broadening of the momentum-integrated polariton density, illustrating a crossover from an ultrafast ballistic-like regime (blue shading), to a transient superdiffusive regime from $\sim 0.5 - 3$ ps (orange), and finally exciton-like diffusion (red) characterized by a linear slope.

II. Methods

The spatiotemporal dynamics are described by a Boltzmann transport equation within the polariton basis

$$\partial_t N_{n\mathbf{Q}}(\mathbf{R},t) = (-\mathbf{v}_{n\mathbf{Q}}\cdot\nabla - 2\Gamma_{n\mathbf{Q}} - 2\gamma_{n\mathbf{Q}})N_{n\mathbf{Q}}(\mathbf{R},t) + \sum_{m\mathbf{Q}'}\Gamma_{m\mathbf{Q}',n\mathbf{Q}}N_{m\mathbf{Q}'}(\mathbf{R},t) \quad (1)$$

where $N_{n\mathbf{Q}}(\mathbf{R},t)$ is the Wigner function, $v_{n\mathbf{Q}} = \partial_Q E_{n\mathbf{Q}}/\hbar$ is the group velocity, $\gamma_{n\mathbf{Q}}$ the radiative decay rate, $\Gamma_{n\mathbf{Q}}$ the exciton/polariton-phonon dephasing rate, and $\Gamma_{m\mathbf{Q}',n\mathbf{Q}}$ the in-scattering rate from the state $|m,\mathbf{Q}'\rangle$ into $|n,\mathbf{Q}\rangle$ via emission or absorption of phonons. The index n denotes both the polariton branch and the exciton valley, while $\mathbf{Q}$ is the centre-of-mass momentum and $\mathbf{R}$ the spatial coordinate. Our focus is re-

stricted to the low-excitation regime, where exciton/polariton-phonon scattering dominates. Exciton/polariton-phonon scattering is treated at the level of the second-order Born-Markov approximation [3], [4].

III. Results and Discussion

Figure 1(b) shows the time-dependent broadening of the momentum-integrated polariton cloud (i.e., $\sigma^2(t) - \sigma^2(0)$, where $\sigma^2(t) = \int N(\mathbf{R}, t) R^2 d^2R / \int N(\mathbf{R}, t) d^2R$ and $\sigma^2(0)$ is determined by the initial spatial profile). This is a directly extractable observable from time- and spatially resolved PL and pump-probe measurements commonly used in transport studies of excitons and polaritons [2]. Three distinct transport regimes can be identified:

- Below $\sim$ 300 fs, there is a rapid ballistic-like expansion characterized by a quadratic time dependence (blue shaded region). In this regime, the polariton occupation grows quickly as it is fed efficiently from the non-thermalized KK and KK' exciton reservoirs via intervalley phonon scattering. As a consequence, the polariton cloud expands rapidly as any radiative or scattering losses are compensated by the strong in-scattering.
- As the initial growth in the polariton occupation slows and the system approaches a characteristic timescale where the majority of polaritons will have radiatively decayed or scattered with a phonon, the rate of expansion drops and the system smoothly evolves into the transient superdiffusive regime (orange region). The time dependence of the broadening is now no longer quadratic but the polariton cloud still expands at a much larger rate than bare excitons (the peak diffusion coefficient is $\sim$ 1000 cm^2/s).
- Lastly, as the system tends toward the steady state, the expansion rate decreases by orders of magnitude and appears flat on the scale of Fig. 1(b) (red region). Closer inspection reveals a linear slope (see inset), characteristic of conventional Fickian diffusion. The rate of expansion is now about three orders of magnitude smaller than in the earlier transient ballistic-like and superdiffusive regimes, with an associated diffusion coefficient close (but still enhanced via the cavity) to typical excitonic values of around 1 cm^2/s. At these timescales, the polariton subsystem has reached thermal equilibrium with the exciton reservoir due to the strong scattering with phonons at room temperature.

In addition to the results shown in Fig. 1(b), we have also shown that in the ballistic regime there is a phonon-induced velocity renormalization. We also establish that polariton transport is strongly dependent on temperature, cavity detuning, and nonresonant excitation conditions [6]. These key experimental parameters act as effective levers to manipulate the transport dynamics of both polaritons and reservoir excitons, providing a framework for future experiments to probe the fundamental role of phonons.

IV. Conclusion

We have provided microscopic insights into ultrafast transport phenomena of exciton-polaritons in 2D semiconductors, crucially taking into account scattering with phonons and the full exciton energy landscape. The approach detailed here can be applied to a wide range of excitonic 2D materials, such as metal-halide perovskites, TMD bilayers, as well as to spatially structured cavities that host, for example, trapped and lattice polaritons.

Electrical excitation of surface plasmons and light

Elizabeth Boer-Duchemin

Institut des Sciences Moléculaires d'Orsay (ISMO),
Université Paris-Saclay, Orsay, France
Elizabeth.Boer-Duchemin@universite-paris-saclay.fr

***Abstract*— We use the inelastic tunneling current from a biased tunneling junction to locally and electrically excited surface plasmons on gold nanostructures.**

***Keywords*— surface plasmons, plasmonics, electrical excitation, scanning tunneling microscopy.**

I. Introduction

In today's information society, smaller, faster and more efficient devices with new functionalities for information transfer and storage are continually being sought after. In this context, we investigate the local, electrical excitation of surface plasmons on metallic nanostructures using a nanoscale tunneling junction. This tunneling junction may be the one found naturally between the tip of a scanning tunneling microscope (STM) and a conducting sample [1]; or, such a tunneling junction may also be intentionally engineered and incorporated into the sample [2].

II. Methods

Our main set-up consists of a commercial STM/AFM head operating in air, combined with an inverted optical microscope (see Fig. 1). When the biased STM tip is less than 1 nm from the metallic sample, tunneling current will flow. While most of this tunneling current is *elastic,* a small portion is *inelastic,* and may be used to excite the optical modes of the sample, including surface plasmons. The light emitted from the radiative decay of the excited optical modes is then collected through the transparent substrate by the oil immersion objective lens (NA=1.45). One of the main advantages of this technique is that wide-field images may be realized: when the *real plane* is projected on the CCD camera, information about the *spatial distribution* of the emitted light is obtained; when the *Fourier plane* or *back focal plane* is imaged on the CCD, we obtain information about the *angular distribution* of the emitted light. In particular, this information is key for the interpretation of the physical phenomena at play[3]. In order to further understand our results, we use simple models and sophisticated simulations (COMSOL Multiphysics) [4-5].

III. Results and Discussion

Using these techniques we have shown that:

- Propagating surface plasmon polaritons may be excited by inelastic tunneling current [1],
- The STM nanosource may be used to probe the radiative electromagnetic density of states of a sample[4],
- Near-field excitation of the plasmonic resonances of a nanoparticle will cause spectral shifts[5] and
- A biased cubic nanoantenna separated from a gold film by a thin insulating layer may be used to excite surface plasmons and to tailor the spectrum of the emitted light[2].

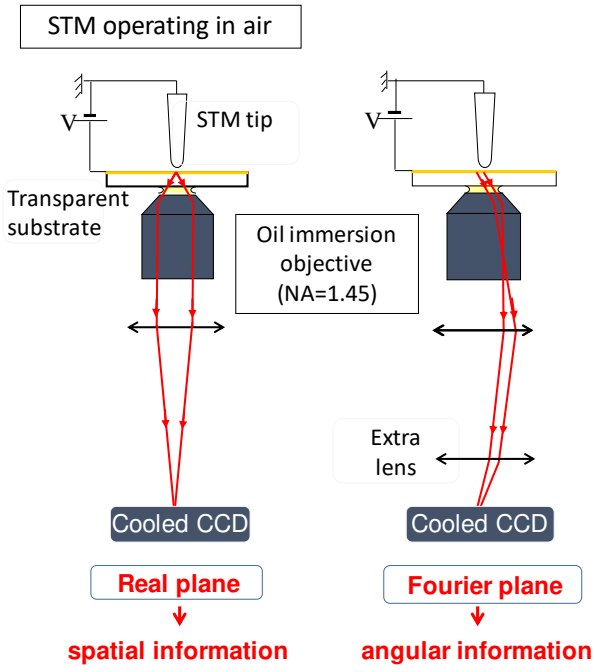

Fig. 1 Experimental set-up for the electrical excitation of surface plasmons and light.

IV. Conclusion

We have demonstrated that a scanning tunneling microscope coupled to an inverted optical microscope is a versatile tool for studying the local, electrical excitation of surface plasmons and light.

***Abstract*— We present all-organic excitonic nanostructures and hyperbolic metamaterials based on J-aggregates, enabling tunable permittivity, ENZ behaviour, and polaritonic coupling. These organic platforms and nanostructures can establish the playground for flexible, metal-free photonics and metamaterials.**

***Keywords*— organic metamaterials, organic photonics, exciton polaritons, J-aggregates**

Organic excitonic materials based on J-aggregates are emerging as versatile building blocks for next-generation photonics and nanophotonic metamaterials. Their delocalised Frenkel excitons and narrowband resonances enable optical responses that mimic plasmonic behaviour in selected spectral regions, including epsilon-near-zero (ENZ) conditions. [1] By tailoring molecular aggregation and supramolecular order, we achieve unprecedented refractive-index contrasts and tunable permittivity in fully organic systems. When integrated into photonic architectures, these properties unlock new optical modes and reshape absorption [2], emission, and dispersion [3], providing opportunities for enhanced nanoscale light–matter interaction, field confinement, and metamaterial-like dispersion engineering.

Our initial work in the area has shown that excitonic thin films composed of J-aggregates can exhibit metal-like reflectance and strong dispersive behaviour. By combining these films with distributed Bragg reflectors (DBRs), we demonstrated how compositional control and photonic design converge to modulate light–matter interactions in soft matter [3]. Building on this concept, we developed all-organic 1D-photonic crystals inspired by photosynthetic architectures [2]. These structures exploit near-zero refractive index properties to provoke slow-light effects to enhance absorption and tailor photoluminescence, achieving narrowband reflectance and directional emission without metals or complex nanofabrication. Such results highlight how tuning composition and supramolecular order enables new functionalities in organic photonic systems.

In this invited talk, I will present our latest advances toward exploiting the polaritonic properties of these organic platforms for all-organic metamaterials, following two complementary approaches:

(ii) **Organic Hyperbolic Metamaterials**. We demonstrate anisotropic multilayer architectures based on J-aggregates that achieve controlled dispersion regimes, including hyperbolic and epsilon-near-zero conditions. We further show that this hyperbolic dispersion can be achieved by a complete materials library from the visible to the infrared. Opening new routes to engineer polaritonic transport and directional optical states in ultrathin organic films. [5]

(i) **Colloidal nanoparticles.** We developed J-aggregate flakes that preserve supramolecular order in aqueous media and display robust colloidal stability. Optical characterization reveals sharp excitonic bands and angular-dependent reflectance consistent with plasmonic-like excitonic resonances at room temperature [4]. The flakes exhibit size-dependent scattering, which broadens extinction and induces photoluminescence redshifts, enabling tunable local photonic environments and controllable nanoscale field distributions.

Together, these two new approaches establish the transition from planar photonic stacks to nanostructured excitonic matter, enabling unprecedented control over morphology, anisotropy, and optical functionality. By creating materials composed by supramolecular structures as J-aggregates is possible to achieve ENZ regimes and engineered hyperbolic dispersion. These materials can define a roadmap toward an all-organic photonic metamaterial for light harvesting, emission control, and reconfigurable nanophotonic structures. Future work will extend these concepts to telecom wavelengths through molecular engineering and validate device-level gains via photonic integration.

***Abstract*— Bound states in the continuum (BICs) have attracted significant interest in nanophotonics for their ability to confine light with formally infinite quality factors. While traditional BICs are symmetry-protected at normal incidence, breaking out-of-plane symmetry by tilting meta-atoms gives rise to Brewster quasi-BICs (qBICs). Initially observed in the microwave regime using high-index ceramic disks, these states are characterized by large but finite Q-factors and a distinctive "dark" behavior at specific angles. In this work, we demonstrate that Brewster qBICs can be realized in the optical domain using Silicon metasurfaces. Using a coupled electric/magnetic dipole (CEMD) model, we reveal that these optical qBICs occur at modified Brewster angles that can deviate significantly from the physical tilt angle due to resonance hybridization [1].**
A key feature of these states is their profound mirror asymmetry. At one angle the qBIC is uncoupled and the metasurface is transparent. Conversely, at the symmetric angle the qBIC is strongly excited but remains cloaked, as symmetry forbids far-field reflection. The diverse phenomena associated with these asymmetric states offer a wide variety of applications in tunable/reconfigurable photonics.

***Keywords*— Bound states in the continuum, cloaking, Brewster q-BICS, symmetry breaking**

I. Introduction

Bound States in the Continuum (BICs) have transformed nanophotonics by enabling light confinement with theoretically infinite lifetimes. While traditional symmetry-protected BICs are well-understood, recent advances in out-of-plane symmetry breaking have revealed a richer landscape of "cloaked" and "uncoupled" quasi-BICs (qBICs). This work explores the emergence of cloaked qBICs in semiconductor metasurfaces composed of tilted nanostructures, where the spectral overlap of in-plane and out-of-plane dipolar resonances leads to a complex hybridization of the optical response.

II. Methods

We use silicon nanodisks with height h = 80 nm and diameter D = 200 nm, and Si nanopillars with height h = 250 nm and diameter D = 100 nm, both in a square array with a period a = 400 nm. Our methodology combines analytical modeling with advanced numerical simulations. We employ a Coupled Electric and Magnetic Dipole (CEMD) model to describe the metasurface response, accounting for the interaction between in-plane and out-of-plane dipoles. The effective polarizability and the condition for Brewster qBICs are validated using FDTD (Finite-Difference Time-Domain). For rigorous calculation of the electromagnetic coupling in periodic structures, we have used the T-matrix method (SMUTHI).

III. Results and Discussion

The results demonstrate that optical Brewster qBICs occur at specific angles ϕ_B that depend on the nanodisk tilt φ and the spectral overlap of resonances. Key findings include:

- Asymmetric Response: For an incident angle $\theta = \phi_B$, qBIC is uncoupled (transparency). For $\theta = -\phi_B$, the qBIC is excited but "cloaked" because the far-field reflection is cancelled by symmetry.
- Resonance Hybridization: Optical qBICs are driven by the interference of multiple dipolar modes, causing ϕ_B

to deviate from the geometric tilt φ.

- Near-Field Localization: Such asymmetric response is shown to have a strong impact in the case of the cloaked qBIC. Despite being undetected by the incoming plane wave, it exhibits largely enhanced near-field intensities.

IV. Conclusion

We have demonstrated that tilting the nanodisk meta-atom in a metasurfaces with out-of-plane symmetry breaking support dark asymmetric qBICs in the optical domain, either cloaked or uncoupled, resulting from various dipolar resonances of the meta-atoms that combine non-trivially. Moreover, the interplay between geometric tilt and tunable material properties offers a promising path toward high-efficiency devices where both the excitation state and the polarization of transmitted light can be precisely controlled.

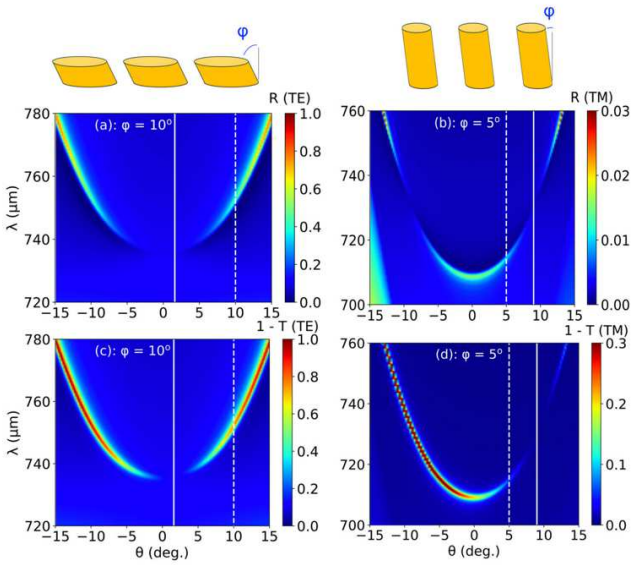

Fig. 1 Color maps of the reflectance and extinction calculated through FDTD for the two qBIC bands emerging in the two metasurfaces. Dashed lines represent again angles at which $\theta = \varphi$, whereas solid lines denote angles matching the uncoupled (dark) qBIC condition for the effective Brewster angles $\theta = \phi_B$.

***Abstract*—Advanced computational tools describing electron interactions with nanostructured materials are crucial for designing and interpreting experiments. Here, we report the extension of a generalized T-matrix scattering formalism to study observables in electron-beam spectroscopy. This method is implemented in the Python package *treams_ebeam*, and demonstrated while studying different nanophotonic materials of contemporary interest.**

***Keywords*— T-matrix method, cathodoluminescence, electron energy-loss spectroscopy.**

I. Introduction

In recent years, electron-beam spectroscopy has proven indispensable for exploring the optical properties of matter. Fast electrons passing by a sample transfer energy to the optical modes sustained therein, which can then be detected in two complementary techniques: cathodoluminescence (CL) and electron energy-loss spectroscopy (EELS) [1]. However, the systematic exploration of free-electron and matter interactions requires robust and versatile numerical tools.

The T-matrix method constitutes a highly efficient method for modeling such interactions [2], especially for systems comprising many scatterers, and for studies involving multiple length scales or requiring extensive parameter sweeps.

II. Methods

In a system consisting of one or more scatterers excited by an external illumination, the incident and scatterer field can be expressed on the basis of spherical or cylindrical waves. In a linear response theory these fields are related via a T-matrix as

$$\mathbf{p} = \mathbf{T}\mathbf{a}, \tag{1}$$

where $\mathbf{a}$ and $\mathbf{p}$ are vectors containing the expansion coefficients of the respective incident and scattered field in the chosen basis, and $\mathbf{T}$ is the T-matrix, which encodes all material and geometrical parameters of the entire structure, including interactions between scatterers.

Given the spherical or cylindrical T-matrix characterizing the system under study, the field of a fast electron can be readily expanded in the same basis, and then scattered field coefficients can be computed using Eq. (1). Once obtained, these coefficients are employed to simulate the CL and EELS spectra of the system.

Fig. 1. (a) Sketch of an infinite periodic array of amorphous silicon elliptical nanodisks excited by an electron beam. (b) Simulated EELS and (c) CL spectra per scatterer, considering a single nanodisk ($N = 1$), a finite cluster of equidinstant nanodisks of different sizes ($N = 3, 5, 9, 15$), and the infinite periodic array ($N = \infty$) shown in panel (a). Consecutive curves are vertically offset by $3 \cdot 10^{-3}$ eV^{-1} for readability.

The method is implemented as an extension of the in-house developed Python toolbox *treams*, designed for electromagnetic scattering computations [3]. The extended module *treams_ebeam* includes all functionalities of the original software, while adding electron beams as sources of illumination, and functions computing the relevant observable quantities [4]. The code is open-source and available online at https://github.com/tfp-photonics/treams_ebeam.

III. Results and Discussion

We demonstrate the capabilities of our approach and the *treams_ebeam* code through three representative examples: single scatterers of various shapes, a periodic chain of elliptical nanodisks (Fig. 1), and a finite cluster of nanospheres arranged in a two-dimensional (2D) lattice.

In all examples, we provide a detailed description of how to calculate the individual T-matrices for scatterers of different shapes, within *treams* or other numerical methods, as well as how to use the functions related to the electron-beam illumination provided in *treams_ebeam*. We show that the method can describe a wide range of optical modes, such as Mie resonances, and surface plasmon polaritons, as well as

collective phenomena, including lattice resonances and Smith-Purcell radiation.

IV. Conclusion

We have presented a T-matrix-based scattering formulation for modeling the interaction of fast electrons with single or multiple periodically and aperiodically arranged scatterers, and implemented it within the Python package *treams_ebeam*. To demonstrate both the method and the software, we have explored various representative examples. We envision this tool serving as a user-friendly resource for CL and EELS simulations.

***Abstract*— We present a mapping-to-manipulation framework for optical matter that couples fast 3D imaging with electrokinetic control. Using dielectrophoresis and tailored electrodes, we map particle trajectories, quantify flows, and then program selective assembly, transport, and sorting beyond the photon beam. The approach enables species-selective patterning, sequence writing, and reconfigurable colloidal devices.**

***Keywords*— metamaterials, optical matter, dielectrophoresis.**

I. Introduction

Optical matter sits at the crossroads of photonics, nanotechnology, and materials science: light not only traps single particles but also assembles, binds, and reconfigures them into ordered structures with emergent properties. From the early demonstrations of optical trapping and optical binding, the field has evolved to encompass complex nanoparticle assemblies, dynamically reconfigurable colloids, and light-induced forces in structured environments. These capabilities underpin advances in nanofabrication, sensing, optoelectronics, and reconfigurable materials, where sub-wavelength architectures yield functionalities unattainable in conventional matter.

One compelling frontier links optical matter to colloidal memory, where information is encoded as sequences of nanoparticles inside nano-/micro-capillaries. This vision demands sub-micrometer positional control and species selectivity, requirements naturally met by dielectrophoresis (DEP), which tunes particle attraction/repulsion through the frequency-dependent response of polarizable particles and the solvent. Equally crucial is fast 3D imaging (~100 fps over micrometer volumes) to visualize writing and diagnose limits. We present a multiplane microscopy toolbox that tracks 200-nm polystyrene particles over quadrupolar electrodes, resolving both positive and negative DEP, and quantifying electrokinetic flows in all three dimensions. By exposing regime-dependent dynamics and flow fields, this approach clarifies how to program spatiotemporal particle control, paving the way for selective sequence writing in colloidal memory and for chemically/optically reconfigurable optical-matter architectures.

II. Methods

Our methodology integrates theory and experiment. On the theoretical side, we collaborate with Profs. Delgado-Buscalioni and Marques (UAM, Madrid), Prof. Ishihara (Osaka University, Japan), and Prof. Hannah (University of Bristol, UK). Experimentally, we work with Prof. Hofkens (KU Leuven, Belgium) and Prof. Masuhara (NYCU, Hsinchu, Taiwan). When needed, we employ tailored nanoparticles prepared by Prof. Liz-Marzán (UVigo, Vigo; CIC biomaGUNE, San Sebastián, Spain) and Prof. Klymchenko (University of Strasbourg, France). This collaborative network emerged from the COODY research initiative, currently funded by the Flemish Government (FWO, W002221N).

III. Results and Discussion

We probed how surface-plasmon resonances govern swarming by tuning the trapping-laser wavelength with respect to the dipolar mode of gold nanoparticles of different sizes.[1] Swarming was maximized when the laser operated near the dipole resonance, which enlarged the active swarming region. We also found that the quadrupolar scattering mode supports optical binding, yet its scattered field remains confined to the focal volume and does not propagate efficiently beyond it.[2] This interpretation is consistent with single-particle simulations, scattering spectra and spatial light-scattering maps, showing that resonant matching of the first trapped particle to

the trapping beam is a key prerequisite for swarming to develop.

In a separate set of measurements, we demonstrated optical binding outside a single, tightly focused spot.[3] By trapping at an interface, up to three gold nanoparticles assembled linearly within the focus, in line with the state of the art. Crucially, light scattered by this in-focus chain seeded discrete, arc-shaped potential wells at half-wavelength intervals outside the focus. Particles entering these arcs moved in a correlated fashion with the in-focus chain and with each other, forming a dynamic binding network mediated by back-scattering and multichannel light scattering.

Finally, we linked these swarming architectures to optical matter, i.e., transient structures formed by light–object interactions at the micro/nanoscale. Using silica-shelled gold nanoparticles, we showed that the shell thickness tunes binding pathways and thus the resulting optical-matter phases.[4] For shells ≥50 nm, assemblies transitioned from linear chains to hexagonal lattices exhibiting circular motion, with the swarming morphology evolving from dumbbell-like to lobe-like patterns. A combined experimental–numerical model for metal–dielectric core–shell particles accounts for these behaviors; by incorporating non-optical interactions (e.g., electrostatic repulsion), the model provides a route to designing tunable optical matter.[5]

IV. Conclusion

We have established a mapping-to-manipulation framework for optical matter that couples fast 3D imaging with field- and resonance-guided control. By tuning the trapping wavelength to the dipolar plasmon of Au nanoparticles, we showed that resonance of the first trapped particle is a prerequisite for swarming, while quadrupolar scattering supports binding but remains localized at the focus. We further demonstrated optical binding outside the focal spot: a linear in-focus chain seeds half-wavelength, arc-shaped potential wells that recruit external particles into a correlated, many-body network via back- and multichannel scattering. Using silica-shelled Au nanoparticles, we mapped a shell-thickness–driven transition from linear chains to hexagonal, circulating lattices and rationalized these phases with an experiment-informed model that also incorporates non-optical interactions (e.g., electrostatics). Together, these results provide design rules for tunable, reconfigurable optical matter and, when combined with dielectrophoretic selectivity and multiplane microscopy, open a realistic route to species-selective sequence writing for colloidal memory and to adaptive photonic materials operating in fluid environments.

***Abstract* — We present an accurate analytical solution for the prolate spheroid model of the scattering-type scanning near-field optical microscopy in the quasi-electrostatic limit. The model is developed and experimentally validated for calculating near-field spectra of bulk and layered samples, and can be extended to more complex nanostructures.**

***Keywords* — field-enhanced spectroscopy; infrared nanospectroscopy; Laplace equation; prolate spheroidal coordinates.**

I. Introduction

Scattering-type scanning near-field optical microscopy (s-SNOM) is a versatile technique in nanooptics, enabling local probing of optical responses beyond the diffraction limit from vis to THz frequencies. Its theoretical modeling based on tip-sample interactions typically relies on computationally intensive numerical methods or phenomenological models with empirically fitted parameters, complicating spectral analysis and interpretation. Developing a rigorous quantitative analytical model remains a significant challenge in near-field microscopy. Here, we introduce an accurate analytical solution for the prolate spheroid model of s-SNOM in the quasi-electrostatic limit. We validate our solution through comparisons with numerical simulations and experimental spectra.

II. Methods

Our methodology integrates analytical approaches for electrostatic problems, finite-element numerical simulation, and s-SNOM measurements using a commercial nano-FTIR setup.

III. Results and Discussion

We analytically solve the electrostatic problem of charge distribution on the surface of a spheroid placed above the sample surface, as shown in Figure 1. This solution determines the dipole moment of the tip and, therefore, the expected near-field signal. As shown in Figure 1, the analytical solution matches the numerical simulation result perfectly.

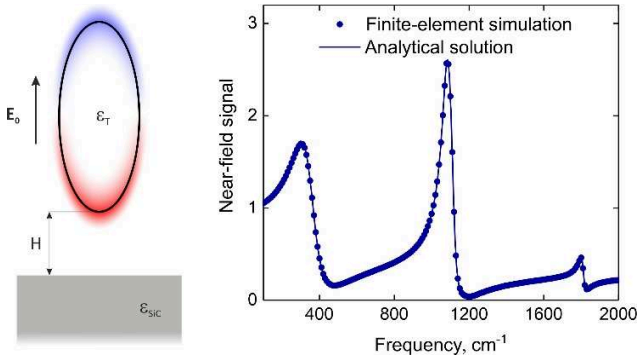

Fig. 1. Left: schematic of the spheroid over the sample surface in a uniform electric field. Right: Comparison of the numerically simulated and analytically calculated amplitude of the near-field signal second harmonic.

IV. Conclusion

We have developed a quantitative analytical model for scattering-type scanning near-field optical microscopy (s-SNOM). Due to its higher computational efficiency compared to numerical simulation and higher accuracy compared to phenomenological solutions, our solution for the spheroid model facilitates spectrum prediction and interpretation for bulk and layered samples. To promote further research and broader adoption, we have implemented the model in an open-source numerical tool available on GitHub [1].

***Abstract*—We demonstrate versatile light control using random metasurfaces modeled via the Coherent Scattering Model. By exploiting multipolar interference in disordered metallic and dielectric nanostructures, we achieve angle-independent structural colors, broadband reflection suppression, and phase-sensitive sensing. Our results establish random metasurfaces as robust, scalable alternatives to periodic systems.**

***Keywords* random metasurfaces, plasmonics, high-refractive index metasurfaces.**

I. Introduction

Metasurfaces have emerged as transformative platforms for photonic engineering due to their ability to manipulate light at subwavelength scales. Comprised of ultrathin layers of nanoscale elements—arranged in either periodic or disordered patterns—these planar, artificially structured materials circumvent the limitations of conventional bulk optics by providing tailored electromagnetic responses. While ordered metasurfaces have been extensively documented, random metasurfaces offer a unique paradigm for light-matter interaction, often providing advantages in fabrication scalability and spectral robustness. By precision-engineering these disordered subwavelength features, we have unlocked a diverse suite of applications: the generation of structural color via light transmission [1], the development of broadband antireflection coatings [2], the realization of the generalized Brewster effect for both polarizations [3], and the enhancement of light absorption through leaky lossy guided modes [4]. Furthermore, the high sensitivity of these disordered systems to environmental changes has positioned them as leading candidates for advanced sensing and biosensing technologies [5].

II. Methods

The description of the optical properties of disordered metasurfaces consisting of either dielectric or plasmonic nanospheres has been approached with effective medium theories (EMTs) such as the Bruggeman mixing formula, van der Hulst model, the erroneously used Maxwell-Garnett theory and the Dipolar Model. However, these models do not capture the complex light-matter interactions. Thus, we employ the Coherent Scattering Model (CSM), an approximate solution to Maxwell equations obtained by truncating the hierarchical LippmannSchwinger equations within the quasi-crystalline approximation [6]. This approach is particularly robust as it accounts for all multipolar orders induced within the nanospheres composing the metasurface and encompasses multiple-scattering effects, provided the system maintains a relatively low surface coverage and avoids grazing incidence angles.

As shown in Ref. [6], the reflection and transmission amplitude coefficients for a free-standing random monolayer are given by

$$r_{\mathrm{CSM}}(\theta_i) = \frac{-\alpha S_n(\pi - 2\theta_i)}{1 + \alpha S(0) + \frac{1}{4}\alpha^2\left[S^2(0) - S_{s,p}^2(\pi - 2\theta_i)\right]} \quad (1)$$

and

$$t_{\mathrm{CSM}}(\theta_i) = \frac{1 - \frac{1}{4}\alpha^2\left[S^2(0) - S_{s,p}^2(\pi - 2\theta_i)\right]}{1 + \alpha S(0) + \frac{1}{4}\alpha^2\left[S^2(0) - S_{s,p}^2(\pi - 2\theta_i)\right]}, \quad (2)$$

with

$$\alpha = \frac{2\Theta}{x_m^2 \cos\theta_i}, \quad (3)$$

where Θ represents the surface coverage, θ_i is the angle of incidence, and $x_m = ka$ is the size parameter (where k is the wavenumber in the matrix and a is the particle radius). The terms $S(0)$ and $S_{s,p}(\pi - 2\theta_i)$ denote the amplitude scattering coefficients at the scattering angles 0 and $\pi - 2\theta_i$, respectively, with subindices s and p specifying the incident polarization. These coefficients allow for the subsequent calculation of the reflectance and transmittance of a supported metasurface on a substrate.

In Fig. 1 we show a typically reflectance map for a metasurface made of identical gold spherical nanoparticles, as a function of the wavelength of the incident light λ_0 and the angle of incidence θ_i.

III. Results and Discussion

By employing all-dielectric random metasurfaces composed of polydisperse silicon nanoparticles onto a glass substrate, we demonstrate the generation of angle-independent transmission colors. As a proof of concept, we show that it is possible to generate a palette of colors with a combination of nanospheres with different radii and surface coverages. In this regard, we present a glimpse for a potential application that can be useful to design metasurfaces that display from warm to cold whites, as the typically emitted by light bulbs [1].

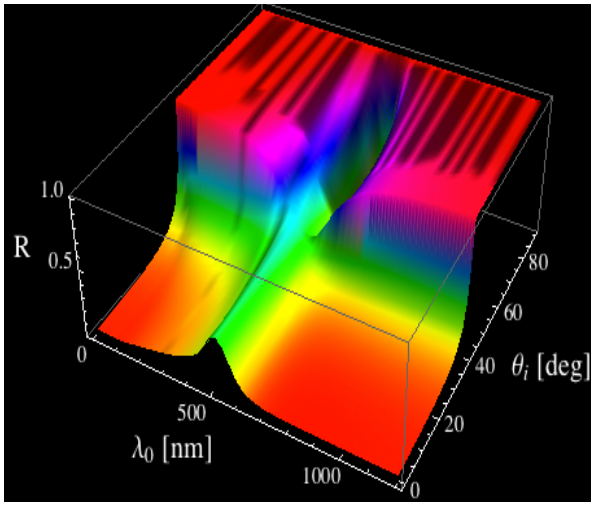

Fig. 1. Reflectance of a metasurface made of identical spherical gold nanoparticles of 5 nm radius and surface coverage of 5%, as a function of the wavelength of the incident light λ_0 and the angle of incidence θ_i .

The interplay between different multipolar contributions provides a powerful degree of freedom for controlling reflection. For metallic random metasurfaces, we observed a broadband suppression of reflection across a wide range of incident angles, independent of polarization. This phenomenon is rooted in the constructive interference between the radiation fields of the induced electric dipole and electric quadrupole within the subwavelength gold and bismuth spheres [2].

In contrast, high-refractive-index silicon metasurfaces exhibit a generalized Brewster effect for both s and p polarizations [3]. This behavior is dictated by the Kerker-like interference between induced electric and magnetic dipoles, which leads to total angle-selective scattering suppression.

Under internal reflection configurations, gold nanoparticle metasurfaces significantly enhance light absorption through the excitation of leaky lossy guided modes [4]. These modes arise from a balanced interplay between near-field coupling and the scattering properties of the individual particles.

Furthermore, we explored the application of these random metasurfaces in high-sensitivity sensing [5]. By operating at the near-zero reflectance point—a region characterized by a phase singularity in ellipsometric measurements—the system becomes hyper-sensitive to minute changes in the local refractive index. This topological feature in the phase response offers a significantly higher detection limit compared to traditional intensity-based plasmonic sensors.

IV. Conclusion

In conclusion, we have demonstrated that random metasurfaces, described by the Coherent Scattering Model, provide a versatile and robust platform for advanced light manipulation. By leveraging the interplay between electric and magnetic multipolar resonances in both plasmonic and dielectric nanospheres, we successfully engineered a diverse suite of optical responses, ranging from angle-independent structural colors and broadband reflection suppression to phase-sensitive sensing. These results highlight the advantages of random arrangements in achieving spectral stability and polarization independence, offering a scalable and efficient alternative to periodic photonic architectures for next-generation optoelectronic and biophotonic applications.

***Abstract*— By engineering a periodic non-uniform 1D array, we are able to steer the cathodoluminesce generated by a passing electron beam. We further demonstrate how to control such emission actively using disks of fluence-controlled phase-changing materials or electrostatically tunable graphene ribbons.**

***Keywords*— electron microscopy, 2D materials, Smith-Purcell.**

I. Introduction

Smith-Purcell (S-P) effect [1] consists of the constructive interference of cathodoluminescence (CL) arising from the interaction between moving charged particles and periodic structures, and it has traditionally been exploited for various applications, namely for the generation of broadband radiation sources.

In typical configurations, S-P effect is realized with perfectly periodic arrays where all elements are equivalent and thus are uniformly polarized up to a phase delay due to the finite velocity of the electron. Under such conditions, the resulting radiation at wavelength λ_0 follows a well-known geometric pattern resonating at angles obeying $\cos\theta_n = c/v - n\lambda_0/a$ [1], where n is an integer, a is the lattice period, and v is the electron velocity. Nevertheless, if the array is periodic but non-uniform, the induced dipole moment $\mathbf{p}_j$ in each array element j is in general different, and the far-field pattern is constructive according to the modified "generalized Smith-Purcell" (GSP) condition [2] $\cos\theta_n = c/v - [n - \ell/(N+1)]\,\lambda_0/a$, where $\ell = 0, \cdots, N-1$ denotes the normal modes of the dipole moment distribution according to the Fourier transform $\tilde{\mathbf{p}}_\ell = \sum_j \mathbf{p}_j e^{2\pi i j \ell/N}$.

II. Results and Discussion

In Fig. 1(a), we show the first few GSP channels for $n = 1$ and for parameters $v/c = 0.1$ and $a/\lambda = 0.09$. Although mode $\ell = 0$ is not viable (i.e., $\sin\theta_{1,0} < -1$) and therefore regular S-P emission is kinematically prohibited in a uniform array, modes $\ell = 1 - 9$ are viable channels for emission into the far-field that can be accessed through an adequate design of the array elements. To target such modes, we devise an induced dipole density with the harmonic form $\mathbf{p}_j(\xi)/p_0 = 1 + 2\sin(2\pi j\xi/N)$ whose Fourier transform directly yields modes $\ell = 0$ and $\ell = \pm\xi$. The far-field angular profile of GSP emission for a given modulation frequency ξ is shown in Fig. 1(b), with light emission accurately following the predicted GSP angles for each different ξ.

In practice, one can design the dipole moment imprinted in each element either passively (by controlling, for example, the

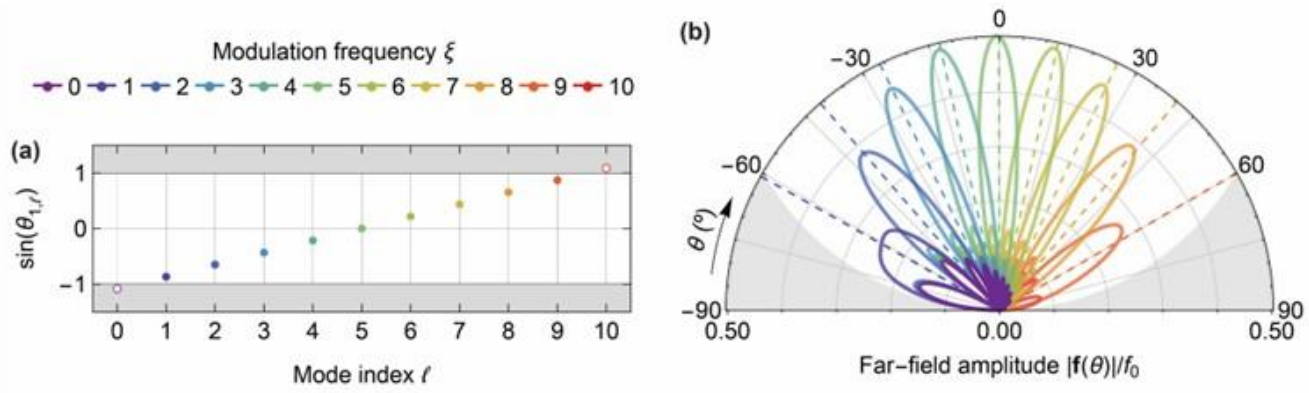

Fig. 1 (a) GSP channels emission angle for $n = 1$ and for an array/electron system with $v/c = 0.1$ and $a/\lambda = 0.09$. (b) Far-field emission angular profile of an array designed to target each modulation frequency ξ.

size and/or material of each array element), or actively (by controlling tunable physical or chemical properties of the individual array elements). We demonstrate this principle by exploring arrays composed by disks of VO_2 (a phase-change material) or graphene ribbons. In the former (latter) case, we inverse design the necessary fluence dosage (electrostatic gating) necessary to rigorously produce the designed dipole moment distribution $\mathbf{p}_j(\xi)$ (including intra-array interactions) and show that the reconstructed far-field profile matches perfectly the target angle for each ξ.

III. Conclusion

Our findings pave the way for the development of advanced S-P radiation sources with tailored and actively-controllable emission properties. By mapping a chosen angle to an implementable pattern on a compact finite array, the same device can be reprogrammed to steer, split, or modulate the beam without mechanical motion.

Abstract **- We predict and experimentally demonstrate Coulomb-driven crystallization in few-electron pulses and explore how discrete symmetry can emerge even in continuous beams. This reveals crystal-like ordering and enables new regimes for electron microscopy. We further study the quantum statistics of light emitted by such beams also modulated by an external laser field.**

Keywords **- electron microscopy, strong light-matter interaction, quantum-light generation, electron-electron correlations.**

I. Introduction

Under suitable conditions, particles with the same charge sign confined in a potential can form ordered structures stabilized by Coulomb repulsion, known as Coulomb crystals. This phase of matter has been extensively explored and observed in various systems, ranging from cooled ions in storage rings [1] to electrons in two-dimensional materials [2]. The formation of a Coulomb crystal is primarily determined by strong Coulomb coupling, i.e., a large ratio between the average interparticle Coulomb energy and the average kinetic energy associated with temperature in classical systems and with the energy level spacing in quantum systems.

In the context of electron microscopy, Coulomb repulsion between electrons in a high-current beam is typically regarded as detrimental. Known as the Boersch effect [3], intrabeam Coulomb scattering leads to an increase in emittance and, consequently, to a degradation of beam quality. Interestingly, it has recently been shown that electron-electron interactions can be exploited to generate a phase-space distribution with well-defined energy-time correlations, as observed in few-electron pulses photoemitted from a metallic nanotip and imaged in a transmission electron microscope [4].

In contrast to ions, whose spatial density can be measured via fluorescence, free electrons lack addressable internal energy transitions. Nevertheless, the electron phase-space density can be reconstructed using inelastic electron-light scattering (IELS) [5]. In this process, the electron couples to the evanescent fields generated by the scattering of a laser pulse at a material surface, resulting in the exchange of multiple light quanta that is imprinted onto the final electron spectrum. Since the strength

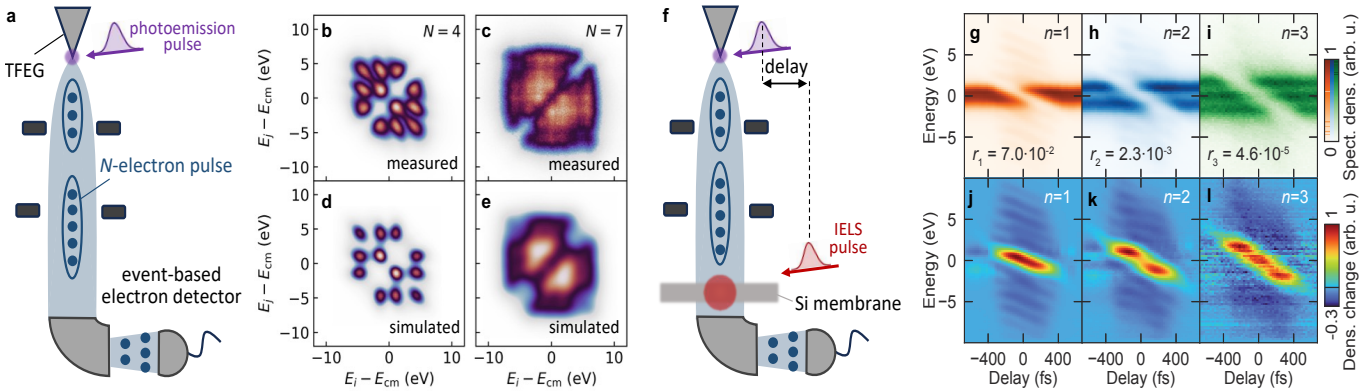

Figure 1. (a) Electron pulses are generated via photoemission from a thermal-field emission gun (TFEG) and then resolved in number and in energy using an event-based electron detector (Timepix3). Measured energy-energy correlations of expanded 4- (b) and 7-electron (c) Wigner crystallites, together with corresponding Monte-Carlo simulations (d,e) reproducing the data. (f) Coulomb-correlated electron pulses traverse a time-delayed optical near field at a silicon membrane, undergoing inelastic electron-light scattering. Figure 2. (a) A laser-modulated but uncompressed two-electron pulse interacts with a second structure; energy-time correlations still tailor CL emission via two-electron energy post-selection using an electron-resolved camera. (b) A multi-electron beam, laser-modulated and drifted over length *d*, forms density bunches; the CL two-photon correlation from a second sample is analyzed for various light modulations.

of this interaction depends on the light intensity, femtosecond laser pulses can be employed to capture snapshots of the electron density at a given time.

At the quantum level, due to the strong dependence between the input electron wave function and the output light state, IELS has been used for energy-time tailoring of free electrons, inspiring several works where electrons act not only as probes but as active elements capable of controlling the quantum state of light emitted into photonic structures [6].

II. Methods

We use Monte Carlo simulations, including charge-charge interaction between the electrons in the beam, to predict the phase-space evolution of the electrons in the column. We use quantum optics methods combined with the simulations to obtain the properties of the electron-triggered emission in cavities and in cathodoluminescence (CL) radiation.

Experiments were performed using the Göttingen Ultrafast Transmission Electron Microscope (UTEM), a platform based on a modified JEOL JEM-F200. Few-particle electron pulses have been generated via near-threshold photoemission from a W(100)/ZrO Schottky emitter.

III. Results and Discussion

In this work, we challenge the paradigm that associates Coulomb crystals exclusively with trapped particles by using Monte Carlo simulations to investigate the conditions under which Coulomb repulsion yields ordered one-dimensional chains of electrons, supported by experimental data. For finite particle numbers, we show how a photoemitted beam transitions from a stochastic state to a few-electron Coulomb crystal, enabled by the one-dimensional structure arising from the combined action of acceleration and time-dependent photoemission. Before expanding deterministically under Coulomb repulsion, thereby developing a phase space with well-defined energy and time peaks, the electron pulse evolves from a stochastic state to a transient state that is time-ordered but energy-disordered. Based on this observation, we interpret the well-defined energy-energy correlations measured in few-electron pulses photoemitted from a thermal-field emission gun in a transmission electron microscope (Fig. 1a), containing 4 to 8 particles (with only 4 and 7 shown in Fig. 1b,e), as evidence of transient ordered Coulomb crystallites formed during propagation in the column.

Furthermore, we report results from a related work [7], in which the energy-time distributions of two- and three-electron pulses are measured via an IELS interaction at a silicon membrane (see Fig. 1f). Delay scans, sorted according to the number of electrons in each pulse, are presented in Figs. 1g-i. At long time delays, distinct single-, double-, and triple-lobed spectral features appear. When the laser and electron pulses temporally overlap, the electrons undergo inelastic scattering to both higher and lower energy states, resulting in depletion of the zero-loss peak. This behavior becomes evident in the delay-dependent spectral difference plots (Fig. 1j-l), obtained by subtracting the large-delay spectra from those measured at varying delays. The electron pulse distributions are multimodal, with different regions exhibiting multiple-lobe structures arising from strong Coulomb-induced correlations.

Such two-electron Coulomb-IELS-modulated pulses can then be used to enhance or suppress the CL emission by post-selecting their energies alone, without the use of dispersive bunching (see Fig. 2a). Furthermore, by increasing the number of electrons and adjusting the IELS modulation parameters while allowing for free drift of the beam, the generated light can exhibit statistics ranging from thermal to Poissonian (see Fig. 2b).

IV. Conclusion

These results represent a fundamental step toward exploring correlated phases in free-electron systems and developing high-brightness beams for electron microscopy, as well as creating quantum light sources driven by correlated electron beams.

Acknowledgments

We acknowledge the continued support from the Göttingen UTEM team. We thank Thomas Rittmann for insightful discussions on phase-space density reconstruction. The

experiments were conducted at the Göttingen UTEM Lab, funded by the Deutsche Forschungsgemeinschaft (German Research Foundation) through Project-ID 432680300 (SFB 1456, project C01 to C.R.), the Gottfried Wilhelm Leibniz program (RO 3936/4-1 to C.R.) and the European Union's Horizon 2020 research and innovation programme under grant agreement no. 101017720 (FET-Proactive EBEAM), and we acknowledge fruitful discussions with the authors.

Free electrons shape light, light shapes free electrons

Álvaro Rodríguez Echarri

Center for Nanophotonics, NWO Institute AMOLF, 1098 XG Amsterdam, The Netherlands
*Corresponding author: a.rodriguezecharri@amolf.nl

***Abstract*— Swift electrons enable nanoscale light–matter interaction beyond optical diffraction. In electron energy-loss spectroscopy and cathodoluminescence, electrons generate optical excitations, whereas in photon-induced near-field electron microscopy incoming light reshapes electronic states. We present a wave-based perspective highlighting the reciprocal roles of light and free electrons in nanophotonic systems.**

***Keywords*— free electrons, nanophotonics, PINEM, near-field spectroscopy, light–matter interaction, electron microscopy.**

I. Introduction

Achieving control over light–matter interaction at the nanoscale is fundamentally limited by optical diffraction. Swift electrons provide nanometer spatial resolution and ultrafast temporal sensitivity, enabling access to electromagnetic excitations beyond the reach of conventional optical techniques. Electron-based approaches have therefore emerged as powerful tools for nanoscale nanophotonics.

II. Methods

We employ a semiclassical theoretical framework combining Maxwell's equations with quantum descriptions of free-electron wave packets. The approach captures electron-driven and light-driven processes, enabling the analysis of Smith-Purcell radiation, electron energy-loss spectroscopy, and photon-induced near-field electron microscopy. We further contextualize the theory by examining and comparing recent experimental and theoretical results in the field of swift electrons and near-field optics.

III. Results and Discussion

Electron–induced plasmonic excitations in spherical and cylindrical nanostructures:
We study electron–photon coupling in nanostructures with high symmetry, focusing on spherical and cylindrical geometries. For spherical particles, we revisit Mie theory with particular emphasis on penetrating electron trajectories, which access additional coupling channels to plasmonic modes that are forbidden for purely external trajectories. This perspective enables a complete modal decomposition of electron-induced electromagnetic excitations and clarifies the role of internal fields in plasmon excitation [1].
Extending these ideas to cylindrical geometries, we discuss recent analytical solutions for electron–photon interactions in systems with translational symmetry. These results go beyond numerical approaches, providing deeper physical insight into mode excitation, dispersion relations, and radiation processes, and highlighting both parallels and key differences with the spherical case [2].

Generalized Smith–Purcell radiation:
We present generalized Smith–Purcell frameworks that extend classical formulations to complex nanostructures and near-field regimes. This approach enables active, on-demand steering of Smith–Purcell radiation, providing full control over the emitted light [3]. The model applies to a diverse set of photonic devises.

Multiple PINEM interactions:
We analyze regimes of coherent photon-induced near-field electron microscopy interactions, where electrons undergo multiple energy exchanges with optical near fields. This leads to structured electron wave packets and highlights the active role of light in shaping electronic quantum states [4]. We also analyse the effect of the coherence in their interaction.

IV. Conclusion

The reciprocal interaction between light and free electrons establishes a unifying platform for nanoscale nanophotonics, where electrons act not only as high-resolution probes but also as controllable sources and manipulators of optical fields. By combining electron-driven light emission and light-driven electron-state engineering within a semiclassical framework, a physical playground emerges across EELS, Smith–Purcell radiation, and PINEM. This reciprocity enables unprecedented access to spatial, spectral, and temporal degrees of freedom, extending from classical near-field optics to coherent and quantum regimes. Such concepts point toward the development of hybrid electron–light devices, including electron-controlled light sources, optically shaped electron beams, and integrated platforms for ultrafast and quantum nanophotonics.

***Abstract*— Rapid advances in microscale-to-nanoscale light–matter interactions are redefining the limits of photonics, leading to a paradigm shift in photonic technologies. However, bridging the gap between laboratory breakthroughs and scalable real-world systems remains a central challenge. At AMO GmbH, we progress to address these challenges by developing fabrication processes that enable scalable realization of these emerging technologies.**

***Keywords* — photonic integrated circuits, PICs, nanofabrication, integrated photonics**

SUMMARY

Rapid advances in microscale-to-nanoscale light–matter interactions are continuously redefining the limits of photonics and leading to a paradigm shift in integrated photonic technologies. However, bridging the gap between laboratory breakthroughs and scalable, real-world systems remains a central fabrication challenge. Since their first conceptual demonstration in the early 1970s, photonic integrated circuits (PICs) have evolved into robust and scalable platforms that underpin increasingly sophisticated technologies, including terabit-scale data-center engines [1], programmable photonic processors [2], high-speed plasmonic modulators [3], ultra-low-loss waveguide platforms [4], and much more. Continuing the trend, we have now emerging challenges at hand like photonic designs that rely on extreme nanoscale light interactions at the expense of extremely tiny feature sizes and integration of diverse material platforms – such as 2D materials, polymers, plasmonic metals (eg: Ag, Au), etc - pushing the limits of fabrication capabilities. As a research foundry, AMO GmbH plays a critical role in developing fabrication processes to realize and scale up these next-generation technologies as illustrated by the examples highlighted in this summary.

Designing photonic components that push performance boundaries from ultralow-loss couplers to inverse design and machine-learning-inspired metasurfaces, inevitably tightens fabrication tolerances and drives process innovation. For eg: continuing advances in ultralow-loss silicon-nitride platforms have forced designers to trade waveguide loss for out-of-plane coupling strength - a trade that our grating-coupler work addresses by adding an amorphous-Si overlay and extremely controlled thickness/etch of the amorphous-Si and a 100 nm Si_3N_4 core. Such designs demand <10 nm nanometer film-thickness uniformity on a wafer scale, highly repeatable overlay deposition and etch recipes, and very low sidewall and surface roughness to avoid spoiling the platform's <0.1 dB/cm propagation loss. Overlay pattern alignment and lithography are also critical to achieve the coupling efficiency and directionality [4]. In parallel, chip-integrated inverse design and binary metasurfaces for beam-shaping and polarization control shift the burden to high-resolution pattern fidelity: such designs require lithographic feature sizes at, or below, the sub-100 nm scale, extremely low pattern placement error, and tight control of fabrication variability so that the simulated phase/amplitude response maps to the fabricated device performance across the chip (Figure *1*a,b) [5]. Such designs also add another layer complexity during SEM inspection to correlate and characterize the mismatch between the designed target vs on-wafer fabricated structures.

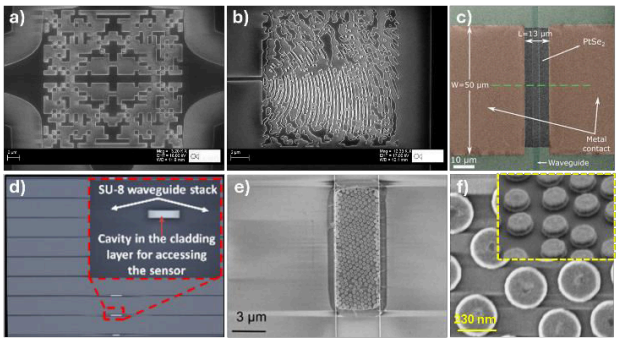

Figure 1: Photonic structures fabricated on advanced integrated platforms: a) and b) Advanced grating couplers for chip-Integrated quantum applications [5], c) Waveguide-integrated 2D $PtSe_2$ photodetectors [6], Bimodal plasmonic refractive index sensors [7], e) and f) Integrated plasmonic light sources [8].

The integration of emerging materials introduces additional fabrication challenges centered on heterogeneous processing and interface control. Our $PtSe_2$ photodetector (Figure *1*c) work highlights the need for scalable, low-temperature synthesis or transfer methods that provide precise layer-thickness control, uniform crystallinity, and clean interfaces compatible with photonic substrates. Reliable performance further depends on optimized contact engineering and encapsulation to suppress

dark current and enable reproducible integration of 2D materials into scalable photonic platforms [6]. Polymer-based bimodal plasmonic sensors (Figure *1*d) and plasmonic and nanopatch devices that enhance emitter radiation (disc-on-disc (DoD) nanoantennas with controlled openings) (Figure *1*e,f) introduce a second class of challenges: nanometer-scale gap control, reproducible antenna geometry, and deterministic placement/encapsulation of colloidal quantum dots into hotspots without degrading their emission. Achieving the emission enhancements and accessible hotspots reported requires lithography with tight critical-dimension control, robust lift-off or etch processes for very small gaps, and surface/chemical treatments that maintain QD optical properties during assembly and encapsulation [8]. For the polymer-clad bimodal plasmo-photonic sensors, integrating an aluminum plasmonic stripe with a bilayer SU-8 waveguide and a specialized optical cladding poses additional issues: metal patterning on polymer (adhesion, thermal budget, edge roughness), achieving high refractive-index contrast while avoiding scattering from rough interfaces, and encapsulation to provide opto-mechanical isolation and long-term stability - all of which addressed tailored process flows that emphasize CMOS-compatible steps, polymer curing control, and careful metal/polymer interface engineering. Collectively, these examples highlight both the addressed and ongoing challenges faced in cleanroom fabrication environments striving to realize exotic light–matter interactions within scalable technological platforms.

***Abstract*— The rational control of nanoscale heat transport is essential for advancing photothermal therapies. We introduced the Iris-Gated Core–Double–Shell (ICDS) nanoparticle as a minimalistic strategy to induce thermal asymmetry while preserving geometric symmetry. By introducing a conical aperture into a spherical glass/gold/polymer overshell, we enable directional heat redistribution without perturbing the underlying plasmonic response. We identified an optimal configuration resonant within the first biological window that redirects up to 67% of the conductive heat flux and enhances local surface power density by 50% ($\Delta T \approx 20-23$ °C). Transient analysis under pulsed excitation confirms that this thermal asymmetry persists during the considered pulse intervals. The ICDS framework provides an efficient route for tailoring anisotropic heat transport, offering a promising platform for controlled photothermal therapies.**

***Keywords*— Thermoplasmonics, Plasmonics, Nanophotonics.**

I. Introduction

Plasmonic nanoparticles have revolutionized photothermal applications by acting as efficient light-to-heat converters. However, most conventional designs generate isotropic thermal envelopes, limiting their effectiveness in therapies requiring precise spatial control [1]. While Janus-like particles can break this symmetry, they often require complex fabrication or sacrifice optical efficiency [2,3]. We propose the ICDS architecture, which utilizes a strategic "iris" aperture in a dielectric overshell. This design allows for "thermal gating," where the gold core provides the heat source via Localized Surface Plasmon Resonance (LSPR), and the modified shell dictates the direction of the resulting heat flux [4]. This study explores the trade-offs between optical absorption and thermal anisotropy in both stationary and transient regimes.

II. Methods

To evaluate the ICDS architecture, we employed a hybrid analytical–numerical approach combining electromagnetic absorption and heat diffusion. Optical properties were characterized using generalized Mie theory to optimize the nanoparticle geometry for maximum absorption within the first biological window. Heat transport was modeled through the stationary heat diffusion equation to quantify the steady-state thermal bias. For transient regimes under pulsed excitation, we implemented a generalized heat-source formulation accounting for electron–phonon relaxation and pulse duration. Finally, a thermal focusing gain parameter was introduced to quantify the performance of the iris gate relative to a symmetric counterpart

III. Results and Discussion

Our optimization yields an ideal configuration at $(r_c, \delta_{Au}, \delta_p, \theta) = (36\,nm, 5\,nm, 40\,nm, 70°)$. In the steady state, the ICDS redirects 67% of the conductive heat flux toward the aperture-side hemispace, achieving temperature rises of 20–23 °C under reference illumination. This directional redistribution corresponds to a 50% increase in local surface power density, effectively "focusing" the heat. Under pulsed excitation, while the directional effect is most efficient in the stationary regime, the ICDS architecture retains measurable thermal asymmetry during the pulse interval. This confirms that the thermal bias is fundamentally rooted in the structural design and persists even under fast transient dynamics.

IV. Conclusion

The ICDS nanoparticle represents a significant step towards "programmable" nanothermal sources. By using a symmetric core-shell structure with a conical aperture, we achieve high-impact directional heat delivery without compromising the stability of the optical resonance. This framework is not only computationally efficient but also offers a scalable design rule for the next generation of anisotropic photothermal agents and advanced thermoplasmonic applications.

***Abstract*—Chiral cavities are required to harness light–matter interactions for the optical control of chirality, especially in molecular processes. We computationally study chiral cavities assembled from metasurface mirrors featuring optimized electromagnetically-chiral scatterers. Our aim is to provide the necessary environment for applications such as maximizing enantioselective effects for chiral molecules.**

***Keywords*—chiral cavities, electromagnetic chirality, light–matter interaction, metasurfaces, transition matrix formalism.**

I. Introduction

Chirality – the geometric property of an object that cannot be brought to coincide with its mirror image through translations and rotations – is ubiquitous in nature, and its detection and control are crucial. For instance, most biologically relevant molecules are chiral, and organic processes are vitally sensitive to the handedness of the enantiomers involved. Therefore, advancing our abilities to detect and manipulate chemicals in a handedness-selective manner is an extremely relevant task, not least for drug synthesis.

Light promises to be a useful tool for this purpose, as it can interact with matter in a handedness-selective manner. The exemplary system to capitalize on the interaction of light and matter is an optical cavity due to the resonant enhancement it provides. Importantly, application in a chiral context requires the cavity to be selective with regards to the light's circular polarization handedness, i.e., more generally, helicity-selective [1]. This is not the case with ordinary Fabry–Perot cavities, for instance, since each reflection from a typical mirror or surface at normal incidence results in a reversal of the circular polarization handedness.

In our work [2], we approach the design of chiral cavities, focusing on metasurfaces consisting of periodic arrangements of optimized electromagnetically-chiral scatterers.

II. Methods

The proposed design of the chiral cavity follows a bottom-up scheme, starting from the optimization of a chiral unit and its assembly into a periodic structure yielding a collective chiral optical response. In the optimization, we make use of the electromagnetic chirality (em-chirality) [3] which quantifies the chirality of an object's response to light. Similar to Garcia-Santiago et al. [4], we use em-chirality as an objective function to optimize the response of nanohelical metallic scatterers.

We use the transition matrix (T-matrix) formalism to represent the scatterers' linear optical response. The in-house developed open-source code *treams* [5] allows us to efficiently study the optical properties of single as well as periodically arranged scatterers.

III. Results and Discussion

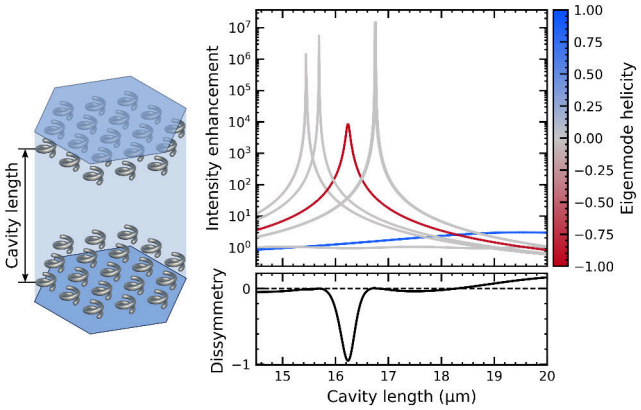

Fig. 1. Internal intensity enhancement of cavity eigenmodes colored according to their helicity content (top), and total dissymmetry (bottom). By varying the cavity length, different eigenmodes are brought into and out of resonance. On resonance, the contrast in the intensity enhancement between the negative helicity and positive helicity modes is nearly four orders of magnitude. Taking all modes into account, negative helicity dominates the cavity with a total dissymmetry reaching $95.3\,\%$ of its absolute bound at a cavity length of $16.23\,\mu\mathrm{m}$.

We consider a chiral cavity formed by two facing planar mirrors featuring hexagonal lattices of optimized em-chiral scatterers, schematically shown on the left of Fig. 1. The lattice spacing is chosen to be barely diffracting in the embedding material at the considered operating frequency of $44.21\,\mathrm{THz}$. This follows a similar approach to the one used by Feis et al. [6]. Consequently, we consider not only normally incident modes but also modes with large in-plane, or transverse, momenta, constituted by the six first diffraction orders. Our approach combines the high degree of helicity preservation exhibited by grazing angle reflection with the strong helicity selectivity introduced by the optimized em-chiral scatterers. As a result, the cavity supports modes of nearly pure helicity

(98.8 %). Figure 1 shows the internal intensity enhancements of the eigenmodes of the cavity for a varied cavity length. Importantly, the cavity exhibits a contrast of almost four orders of magnitude between the maximal (on resonance) intensity enhancement of the negative helicity eigenmode and its positive helicity counterpart. Expressed as a dissymmetry by normalizing the helicity-weighted sum of all intensity enhancements to the total sum of all intensity enhancements, this contrast reaches 95.3 % of its upper bound (corresponding to a cavity with a modal landscape of pure helicity).

IV. Conclusion

We have demonstrated a chiral optical cavity featuring eigenmodes with nearly pure helicity and a strong dissymmetry between the resonant intensity enhancements of modes of opposite helicity. On resonance, the enhancement of the negative helicity eigenmode exceeds that of its positive helicity counterpart by nearly four orders of magnitude. These values signify the cavity's ability to provide the strongly helicity-selective electromagnetic environment for potential applications such as the enhancement of enantioselectivity in cavity-aided chiral molecular chemistry.

I. Introduction

The electronic degrees of freedom of organic molecules can interact with internal vibrational modes, as well as with phonon modes of the surrounding environment. As a consequence, when a laser is used to excite the molecules, they can emit photons inelastically due to energy exchange between light and vibrations, a process known as Raman scattering. For example, photons that are red-shifted with respect to the excitation laser are emitted when the final vibrational state has a higher energy than the initial one; these lower-energy photons are referred to as Stokes photons. In the opposite case, when the emitted photons have a higher energy than the excitation laser, they are called anti-Stokes photons. Here, we discuss recent advances in Raman scattering obtained by using quantum-mechanical models and that contrast with often-invoked assumptions. We first consider the Stokes-shifted emission from two molecules embedded in a solid-state matrix that interact electromagnetically with each other due to their short separation distance [1], [2]. In this case, we analyze the correlation of Stokes photons and show that it can be affected by quantum coherence [3]. Next, we consider Surface-Enhanced Raman Scattering (SERS) from many molecules in a plasmonic nanocavity, showing that the cavity optical modes can mediate molecular interactions and give rise to collective effects in the Raman signal [4]. Moreover, we explore the possible connection between Raman scattering and time-varying media, which are material whose electromagnetic properties are modulated on time [5].

II. Methods

We describe the molecular dynamics using a master-equation formalism, with the corresponding numerical simulations performed using the QuTiP Python package [6]. Further, to describe the interaction between molecules and the plasmonic nanocavity, we use a molecular optomechanics framework [7], [8], where the molecular vibrations play the role of the mechanical degrees of freedom in standard cavity optomechanics. The finite element method solver COMSOL Multiphysics [9] is used to characterize the electromagnetic response of the nanocavity.

III. Results and Discussion

We first consider the Stokes-shifted emission from organic molecules embedded in a solid-state matrix at cryogenic temperatures, in the absence of any plasmonic cavity. The molecules are excited by a laser resonantly tuned to the electronic transition. In this context, recent experiments have been able to analyze the optical response of pairs of molecules

at sufficiently short separation distances such that they can interact electromagnetically [1], [2], leading to the formation of hybrid superradiant and subradiant states [10]. In these experiments, the molecules are resonantly driven to the electronic excited state, and the detected light is spectrally filtered to eliminate the laser contribution, so that only Stokes photons (i.e., the Raman signal) are collected.

We develop a master-equation framework to describe the intensity correlations of the Stokes photons emitted from these interacting molecules. Importantly, we show that the resulting expression for the Stokes correlation can be decomposed into a contribution that is unaffected by quantum coherence (neither molecular coherence nor electromagnetic-field coherence) and additional contributions that explicitly depend on coherence effects. By comparing the different contributions with experimental observations, we demonstrate that quantum coherence can indeed play a significant role in the correlation of Stokes photons, in contrast to the often assumption that Raman scattering is an incoherent process.

Next, we consider many molecules at room temperature in an extreme plasmonic nanocavity known as a Nanoparticle-on-a-Mirror (NPoM). The NPoM nanocavity consists of an Au nanosphere and an Au substrate, which are separated by a $\sim$1 nm gap, in which the molecules are located. We use a molecular optomechanics framework that accounts for the intermolecular interactions mediated by the NPoM nanocavity [11], [12]. In this way, we study the dependence on the laser intensity of the Stokes signal, of the anti-Stokes signal (corresponding to the emission of higher-energy photons due to the exchange of energy between light and a molecular vibration), as well as of the anti-Stokes-to-Stokes ratio. By varying the separation distance between the molecules in the nanogap, which modifies the strength of the nanocavity-mediated interaction between the molecules, we show that the behavior of the anti-Stokes-to-Stokes ratio is modified, constituting a strong signature of many-molecule collective effects in SERS. These results are in good agreement with experiments, challenging the typical assumptions that collective effects can be ignored in SERS and thus that the Raman signal scales with the number of molecules.

Finally, we address effective macroscopic quantities of optically driven molecules, with the aim of exploring possible connections between the fields of molecular optomechanics and time-varying media.

IV. Conclusion

We show that quantum coherence can affect the Stokes-shifted emission from two interacting molecules, and that collective effects can impact the SERS signal from many molecules in a plasmonic nanocavity. These results challenge typical assumptions in classical models of Raman scattering, thus unveiling new quantum effects in molecular Raman scattering.

***Abstract*—Photonic time crystals generally require a high modulation amplitude of the time-varying permittivity to show detectable momentum bandgaps. We demonstrate that by efficiently trapping light in time-varying metasurfaces using their high-Q resonances, even with weak permittivity modulation, noticeable bandgaps can be achieved.**

***Keywords*— photonic time crystals, bound states in the continuum, Mie theory.**

I. Introduction

Photonic time crystals (PTCs) are formed by rapidly modulating the permittivity of the underlying medium as a function of time in a periodic fashion. The frequency of such a modulation compares with the oscillation frequency of light. PTCs exhibit momentum bandgaps as their characteristic feature. Inside these gaps, complex frequency modes exist that can amplify light that couples to them (see Fig. 1). However, to show detectable momentum bandgaps, bulk PTCs generally require relative permittivity changes of the order of unity. To overcome this limitation, we utilize the high-Q resonances of the time-varying metasurfaces. In particular, we show that by using Mie and quasi-bound states in the continuum (qBIC) resonances, the large modulation amplitude requirement of the PTCs to open detectable momentum bandgaps can be considerably relaxed [1–3].

II. Methods

The proposed metasurface-based PTC is made from a periodic arrangement of finite nanoresonators in two dimensions (2D) (see Fig. 1). The permittivity $\Delta\varepsilon(t)$ of each nanoresonator varies as a function of time as

$$\Delta\varepsilon(t) = \varepsilon_\infty \left[1 + m\cos(\omega_\mathrm{m} t)\right] , \tag{1}$$

where ε_∞ denotes the background permittivity of the underlying static medium, m is the modulation amplitude, and ω_m is the modulation frequency. We use the Mie theory-based T-matrix method to computationally model the metasurfaces [1].

III. Results and Discussion

Our numerical simulations show:

- Noticeable momentum bandgaps corresponding to an incident angle range of $\Delta\theta = 4^\circ$ for modulation amplitudes as small as $m = 10^{-4}$ can be achieved using the resonant metasurface-based PTCs [3].
- Four orders of magnitude reduction in the required modulation amplitude is theoretically realized as compared to the bulk PTCs while simultaneously expanding the momentum bandgap approximately 60 times [3].

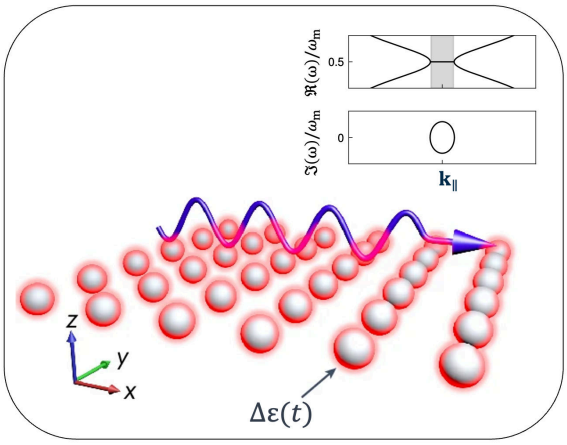

Fig. 1. A metasurface-based photonic time crystal (PTC). The PTC is formed by a periodic arrangement of nanoresonators in two dimensions (2D). The momentum bandgap is shown in the inset. Here, ω is the eigenfrequency, and $\mathbf{k}_\parallel$ is the in-plane wave vector of an eigenmode.

IV. Conclusion

We have discussed that using the high-Q resonances such as the Mie and qBIC resonances of metasurfaces, the modulation amplitudes required to attain noticeable momentum bandgaps can be considerably reduced. Future theoretical work will involve investigating the designs made from multilayered time-varying metasurfaces.

Abstract: Nanoscale photon sources exhibit a dipole-like emission pattern, limiting their incorporation into on-chip devices. Nanoantennas can control their radiation pattern, but often involve lossy plasmonic nanoparticles. Here, we show that a single dielectric nanoparticle can direct the emitted light of a nearby nanoemitter, allowing for geometrical and spectral light routing.

Summary: Nanoscale photon sources such as fluorescent molecules exhibit a dipole-like emission pattern, significantly limiting the amount of light that can be collected and hampering their incorporation into flat photonic devices. Developing nanophotonic structures capable of directing photon emission with tunable angular distributions in the visible spectrum has been pursued for applications ranging from integrated optical systems to discrimination of molecular species. To date, such directional control has been achieved using optical antennas whose overall footprint is larger than the emission wavelength and often rely on lossy plasmonic components. Researches attempts to design compact directional plasmonic antennas rely on achieving unidirectional emission through interference between electric multipoles. Alternatively, interference between electric and magnetic resonances have recently been explored as an alternative to enhance nanoantenna directivity based on the Kerker condition. Although metal-based multiparticle geometries can deliver high directivity following this effect, their performance is often narrow band and sensitive to small variations in element size or emitter position.

Individual low-loss high-index dielectric nanoparticles (HID NPs) offer a low-loss alternative that supports strong electric and magnetic Mie resonances and flexible scattering-pattern engineering in the visible range.[1] Numerical studies indicate that a single HRID NP can effectively direct emission from a nearby dipolar emitter,[2,3] drastically reducing the footprint of previous demonstrations. Moreover, a single HID NP promises to have more advantages, as it has been proposed to be able to reverse this directionality depending on the emission wavelength,[2] and to be able to either collect or reflect the emitted light by tuning the particle-emitter distance.[3] However, those effects have never been demonstrated experimentally, mainly due to the difficulties of placing an individual dipole emitter in the proximity of the NPs with high accuracy.

Here, we experimentally demonstrate that a single SiNP with a footprint $< 0.05\ \lambda^2$ can serve not only as an optical antenna capable of directing light from a nearby emitter, but also as a versatile element for color routing and beam-steering. Using DNA origami assembly, we position single emitters adjacent to one SiNP with

nanometric accuracy and map the resulting far-field emission patterns. Using a 120 nm SiNP, we achieve robust broadband directionality in the visible range, with F/B values as high as 7 dB, for emitter-NP separations ranging from 8 to 85 nm. Furthermore, the emission direction follows the displacement of the emitter around the NP, realizing a beam-steering effect previously predicted theoretically.[4]

For 170 nm SiNPs and specific emitter positions, the emission direction becomes wavelength-dependent, routing green and red emission into nearly opposite directions, i.e., color routing,[2] (see shematic figure below). These results are in good agreement with previous theoretical works. Moreover, specific simulations of the experiments elucidate the underlying modal interference mechanisms responsible for directionality, beam steering, and color routing, opening the way for further designs of HRID nanophotonic directional devices.

***Abstract*— We present an in-operando controllable platform for vibrational upconversion using tip-enhanced nanoparticle-on-mirror nanocavities. Simulations and experiments show that combining a s-SNOM tip with a visible-resonant NPoM form a cascaded nanolens system that enables the enhancement of sum-frequency generation signals from molecule-filled nanogaps up to 14 orders of magnitude.**

***Keywords*— Infrared spectroscopy, Nanocavities, Nonlinear optics, Vibrational Upconversion.**

I. Introduction

Vibrationally-assisted sum-frequency generation (SFG) in plasmonic nanoantennas enables the coherent upconversion of near- and mid-infrared photons into visible light [1]. This upconversion happens via molecular vibrations acting as optomechanical transducers placed nearby nanogaps formed by dually IR- and VIS-resonant plasmonic nanostructures [2]. While recent dual nanoantenna designs have demonstrated to be useful for SFG, yet they often lack the flexibility to selectively target different molecular vibrational modes [3, 4]. Efficient upconversion further requires precise spatial overlap of strong infrared and visible near fields inside the plasmonic nanogaps, as well as an efficient far field radiation from plasmonic nanocavities in the IR. These challenges prevent previously presented approaches from reaching the upconversion efficiencies of other optomechanical devices operating in different frequency ranges [5].

II. Methods

We present an innovative approach for vibrational upconversion based on scattering-type Scanning Near-field Optical Microscopy (s-SNOM) coupled to individual visible-resonant gold nanoparticle-on-mirror (NPoM) cavities filled with BPT molecules (Fig 1a). The metallic s-SNOM tip acts as a broadband infrared and visible antenna, locally illuminating the NPoM cavity forming a cascaded nanolens (Fig 1b). Finite-element electromagnetic simulations (COMSOL) are used to model the optical response of the multiscale system, which consists of a micron-sized metallic tip positioned above a faceted gold nanoparticle separated from a gold substrate by a thin dielectric spacer, forming a nanometer-sized gap. Field enhancement distributions are calculated as a function of the lateral and vertical tip position relative to the nanoparticle, enabling for quantitative evaluation of the enhancement on linear (SERS) and nonlinear (SFG, DFG) vibrational upconversion mechanisms.

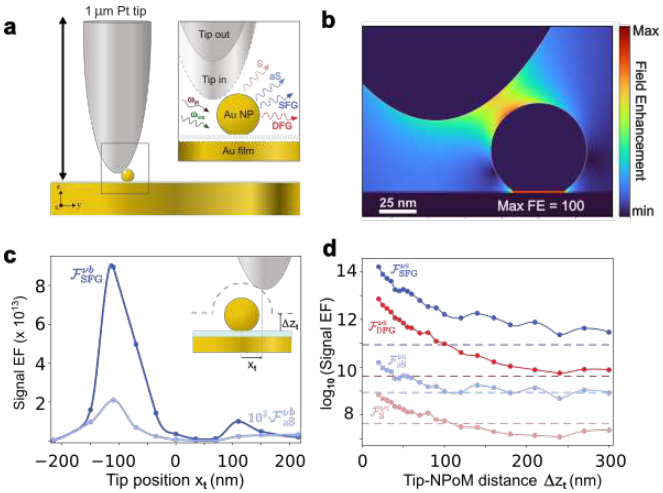

Fig. 1 **a** Illustration of the simulated tip-enhanced nanocavity. A 1 µm Pt ellipsoid is placed nearby an Au NPoM, in whose nanogap SFG, DFG, and SERS processes take place. **b** Near Field Enhancement (FE) distribution for a tip-enhanced NPoM in the IR. **c** Simulated SFG and anti-Stokes SERS signals Enhancement Factor (EF) for different tip-NPoM lateral distances. **f** Simulated SFG, DFG, anti-Stokes and Stokes SERS signals EF for different tip-NPoM vertical distances.

III. Results and Discussion

Numerical simulations reveal that the s-SNOM tip plays a critical role in activating and modulating the NPoM plasmonic resonances, resulting in cascaded near-field enhancement across both the IR and VIS spectral ranges. As a consequence, SFG signals are enhanced by up to 14 orders of magnitude (Fig 1c). The tip concentrates non-resonant infrared fields at its apex, which subsequently drive intense localized fields within the NPoM gap, enabling efficient coherent IR to VIS light upconversion. We experimentally demonstrate the efficient generation of SFG and DFG signals from individual molecule-filled NPoM cavities upon continuous wave illumination. The enhancement of SFG and DFG signals is actively controlled by the 3D nanopositioning of the tip. Numerical simulations reproduce the experimentally observed spatial dependence of SFG signals on the tip position (Fig 1c,d), confirming in-operando control of linear and nonlinear vibrational signals.

IV. Conclusion

We present tip-enhanced NPoM nanocavities as a versatile and efficient platform for vibrational upconversion under low-power continuous-wave excitation. Our approach circumvents limitations of previous approaches, such as the need for pulsed lasers and complex doubly resonant nanostructures. We demonstrate sensitivity down to individual molecule-filled nanocavities and active control of nonlinear signals. These capabilities open new opportunities for nanoscale vibrational spectroscopy, nonlinear nanoimaging, and the study of molecular dynamics at deeply subwavelength length scales.

***Abstract*—An iterative deconvolution algorithm is used to resolve, beyond the diffraction limit of light, the spatial distribution of radiatively recombining excitons excited in a transition metal dichalcogenide monolayer by current tunneling under the tip of a scanning tunneling microscope.**

***Keywords*— 2D materials, excitons, scanning probe microscopy, superresolution.**

I. Introduction

Two-dimensional (2D) semiconductors such as transition metal dichalcogenide monolayers are the building blocks of a future generation of optoelectronic devices, and in particular, of ultrathin electroluminescent devices. The diffusion of charge carriers and excitons (bound electron-hole pairs) and their interactions with defects play a key role in the electroluminescence properties of these materials. Understanding and controlling these processes is crucial for the performance of future devices based on these materials. Unfortunately, exciton diffusion occurs at scales (20 - 200 nm) that are smaller than the spatial resolution of far-field optical microscopes (200 - 500 nm), which are limited by the diffraction of light. There are nanoscopy techniques coupling light and scanning near-field probes that overcome this diffraction limit. Recently, the electroluminescence properties of 2D semiconductors have been mapped at the nanoscale by recording light induced by tunneling current under the tip of a scanning tunneling microscope (STM) scanned over the sample [1], [2], [3], [4]. However, such techniques provide no information on the diffusion of charge carriers and excitons, as they are not sensitive to the spatial distribution of emission around the excitation source. At each tip position, the signal emitted by the entire sample, regardless of its source, is integrated. In this work, we demonstrate a solution to this problem: we combine tunneling-current excitation under the tip of an STM (for extremely local excitation), wide-field optical microscopy (to image the spatial distribution of the emission), and deconvolution of optical microscopy images using an iterative Richardson-Lucy algorithm (to achieve spatial resolution beyond the diffraction limit) [5].

II. Methods

The excitonic luminescence of monolayer tungsten diselenide (WSe_2) and tungsten disulfide (WS_2) is locally and electrically excited using the tunneling current of a scanning tunneling microscope (STM). The spatial distribution of emitters is resolved beyond the diffraction limit of light by deconvolving real-space optical microscopy images of the emitted light using an iterative algorithm, i.e., Richardson-Lucy (RL) deconvolution. The point spread function of the optical microscope is calculated using an analytical dipole model, where the polarization and spectral dependence of the emitted light are taken into account.

III. Results and Discussion

In this way, we reconstruct spatial emission distributions around the excitation point that have full widths at half maximum as small as $\lambda_0/(9.4 \pm 0.7)$ (λ_0 is the emission wavelength), where the resolution of the optical microscope is at best $\lambda_0/2.98$ (Abbe criterion) or $\lambda_0/2.44$ (Rayleigh criterion). This result corresponds to an improvement in spatial resolution of at least a factor of 3. One reason why this has never been done before is that this type of deconvolution requires knowledge of the point spread function (PSF), which is generally very difficult to define for this type of combination of optical microscopy and scanning probes. Here, we overcome this difficulty by using known exciton properties to simulate the PSF as the image of an emitting exciton.

IV. Conclusion

We show that the information extracted from the deconvolved images about the spatial distribution of emitters around and away from the excitation source is valuable for understanding the mechanisms of STM-induced luminescence and, more broadly, the elementary electronic and excitonic processes involved in the operation of TMD-based electroluminescent devices. We anticipate that this type of information will be used in future studies for the development of models that better integrate the spatial aspect of these mechanisms and elementary processes.

***Abstract*— Cathodoluminescence (CL) spectroscopy in a scanning electron microscope enables optical characterization of nanostructures with nanometer spatial resolution. Here we investigate optical Mie resonances in individual crystalline silicon nanospheres using hyperspectral CL mapping and time-resolved pump-probe CL spectroscopy. By coupling a laser into the SEM, we locally heat single nanoparticles and observe thermo-optic spectral shifts of the Mie modes. Synchronizing pulsed laser excitation with nanosecond electron pulses allows us to probe the temporal evolution of these shifts and monitor nanoscale heating dynamics. These results demonstrate that dielectric Mie resonances can serve as sensitive probes for nanoscale thermometry and highlight the potential of pump–probe CL for studying ultrafast electron–light–matter interactions.**

***Keywords*— cathodoluminescence, Mie resonance, dielectric nanoparticles, pump-probe spectroscopy.**

I. Introduction

Cathodoluminescence (CL) spectroscopy in a scanning electron microscope enables optical characterization of nanostructures with nanometer spatial resolution. Dielectric nanoparticles such as silicon nanospheres[1] support well-defined optical Mie resonances that can be efficiently excited by fast electrons[2]. In addition to mapping these modes, understanding thermal effects in nanostructures is important for nanophotonic applications. Here we combine CL spectroscopy with optical excitation inside the SEM to study thermo-optic shifts of Mie resonances and implement pump–probe CL spectroscopy to probe nanoscale heating dynamics.

II. Results and Discussion

Hyperspectral cathodoluminescence (CL) measurements of individual silicon nanospheres reveal distinct spectral signatures of their optical Mie resonances. The excitation efficiency of these modes varies with the electron beam position, reflecting the spatial distribution of the associated optical near fields[3].

By coupling a continuous-wave laser (λ = 442 nm) into the SEM, we locally heat individual nanoparticles and observe thermo-optic red-shifts of the Mie resonances[4]. As shown in Fig. 1, the electric quadrupole (EQ) mode exhibits spectral shifts of up to ~100 meV under optical excitation, demonstrating its sensitivity to temperature changes. Complementary heat-flow simulations show that the temperature rise strongly depends on the thermal contact between the nanoparticle and the supporting SiN membrane, with contact areas ranging from 3 nm^2 at low laser power to ~100 nm^2 at highest applied power.

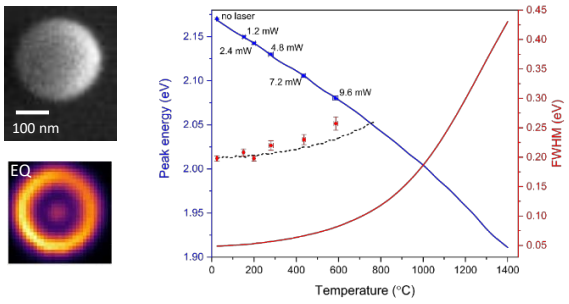

Fig. 1 Left: SEM image of 250 nm-sized Si nanosphere (top) and corresponding 30 keV-CL map of electric quadrupolar (EQ) Mie mode (bottom). Right: Peak energy (blue) and linewidth (red) of EQ Mie mode in Si nanosphere vs. temperature calculated using Mie model with temperature-dependent optical constants (solid lines). Experimental data for all laser powers are displayed at squares.

Finally, pump–probe CL spectroscopy is implemented by synchronizing nanosecond electron pulses with pulsed laser excitation. By varying the delay between laser and electron pulses, we probe the transient spectral response of the Mie

resonances and monitor the heating dynamics of a single silicon nanoparticle.

III. Conclusion

Experimental results show:

- Hyperspectral cathodoluminescence spectroscopy enables nanoscale mapping of optical Mie resonances in individual silicon nanospheres and their directional far-field emission.
- Optical heating inside the SEM induces thermo-optic red-shifts of the resonances, allowing the electric quadrupole mode to be used as a sensitive nanoscale temperature probe.
- Heat-flow simulations reveal that the temperature rise strongly depends on the thermal contact between the nanoparticle and the supporting SiN membrane.
- Pump–probe cathodoluminescence with synchronized laser and electron pulses enables time-resolved measurements of heating dynamics in a single nanoparticle.
- These results demonstrate the potential of pump–probe CL for studying nanoscale thermometry and electron–light–matter interactions in nanophotonic systems.

Infrared Magnetoplasmonics in Transparent Conductive Oxide Nanocrystals

Alessio Gabbani[1,*]

[1]Department of Chemistry and Industrial Chemistry, University of Pisa, Italy

*Corresponding author: alessio.gabbani@unipi.it

***Abstract*— Magnetoplasmonics is a promising strategy for active nanophotonics. Here, we demonstrate that transparent conductive oxide nanocrystals (NCs) enable superior tunability of carrier parameters through defect engineering. Exploiting these NCs, we achieve enhanced magnetic circular dichroism and Faraday rotation in the near infrared, and further demonstrate their photochemical modulation.**

***Keywords*— magnetoplasmonics; magneto-optics; nanocrystals; active plasmonics.**

I. Introduction

Infrared (IR) light is attractive for nano-optics, as the low loss windows of optical fibers for telecommunications fall in the near IR, and vibrational modes of molecules have absorption fingerprints in the medium IR. Transparent Conductive Oxide (TCO) nanocrystals (NCs) represent a unique platform for infrared plasmonics, as they provide tuneable carrier density, covering a wide spectral range, from 1.5 to 10 μm.[1,2] Magnetic tunability of surface plasmon is also extremely interesting for nanophotonics, enabling to remotely tune the plasmonic response for optical isolators or improving the sensitivity of plasmon resonance tracking.[3] Here, we demonstrate how TCO NCs can provide a promising platform for infrared magnetoplasmonics.

II. Methods

We exploit colloidal chemistry synthetic approaches to prepare different TCO NCs with different dopants type and content. Their plasmonic response was studied through UV-vis-NIR spectroscopy. Magnetoplasmonic response was measured on colloidal dispersion of such NCs in transmission geometry through Magnetic Circular Dichroism and Faraday rotation at room temperature. Post synthetic photo-chemical simulation was performed in situ through illumination with a 365 nm light emitting diode, while measuring the optical and magneto-optical response. Optical and magneto-optical spectra were fitted with an analytical model to extract carrier parameters, namely carrier density and mass.

III. Results and Discussion

Our results demonstrate that:

- Magneto-optical response of TCO in the infrared challenges state-of-the-art metallic nanostructures;
- Magneto-optical spectroscopy can be used to extract carrier parameters in TCO NCs, and in particular carrier density and mass;
- Large post-synthetic modulation of Faraday rotation and Magnetic Circular Dichroism is achievable.

IV. Conclusion

We demonstrated the outstanding magnetoplasmonic response of TCO NCs, challenging state-of-the-art metallic nanostructures. We further demonstrate the possibility of switching the sign of Faraday rotation at fixed wavelength through photo-chemical post synthetic modulation of the plasmonic response.

SERS Chemosensing of Metal Ions: Transduction Strategies and Interface Design

Luca Guerrini[1,*]

[1] Department of Physical and Inorganic Chemistry. Universitat Rovira i Virgili, Spain.
*Corresponding author: luca.guerrini@urv.cat

***Abstract*—Due to the intrinsic Raman silence of monoatomic species, SERS-based detection of metal ions necessarily relies on indirect strategies that translate coordination chemistry into a measurable spectroscopic response. This contribution presents a concise overview of key transduction mechanisms and interface design principles enabling effective SERS chemosensing of metal ions.**

***Keywords*—plasmonic, metal ions, sensing, SERS**

Transition metal contamination represents a major environmental and public health concern. Although many transition metals are naturally occurring and biologically essential, anthropogenic activities have significantly increased human exposure [1]. Their toxicity depends critically on chemical identity, oxidation state, speciation, dose, and exposure time, making selective and ultrasensitive detection a central analytical challenge [1]. Over the past decades, SERS has evolved into a powerful strategy for metal ion sensing in aqueous environments [2]. Because monoatomic ions are intrinsically Raman silent, detection relies on indirect approaches in which molecular receptors immobilized on plasmonic substrates selectively bind the target ion. Measurable metal-dependent SERS read-outs commonly originate from: (i) conformational changes of surface-bound receptors, such as DNA-based systems [3]; (ii) electronic modifications of molecular chemosensors upon metal coordination [2,4–7]; and (iii) specific chemical reactions between receptor and analyte [2,8]. In the latter two cases, receptors act simultaneously as recognition elements and SERS transducers, enabling speciation analysis and ratiometric quantification. More recently, we addressed a central bottleneck in SERS metal-ion sensing: the limited availability of surface receptors capable of translating selective binding of vibrationless analytes into measurable spectroscopic signals. To overcome this constraint, we developed hybrid substrates combining highly SERS-active plasmonic cores with ZIF-8 metal–organic framework (MOF) shells (Fig. 1) [6,7]. The MOF layer captures aromatic ion-selective receptors in close proximity to the plasmonic surface regardless of their intrinsic metal affinity, while preserving their coordination chemistry. At the same time, the porous framework provides molecular sieving and preconcentration effects, enabling direct operation in complex media. Using different classes of chromogenic ligands, this architecture allowed ultrasensitive detection of transition and alkaline earth metal ions, including Cu^{2+} quantification in untreated biological fluids. These multifunctional MOF–plasmon platforms significantly expand the practical applicability of SERS in real-life environmental and biomedical metal-ion analysis.

***Abstract*— We present a time-dependent theoretical approach to simulate plasmon-enhanced Raman spectra. By propagating the vibronic wave function of a molecule coupled to a plasmonic nanoparticle, we capture the real-time Raman response and field interactions, enabling quantitative modeling aligned with experimental setups.** ***Keywords*— SERS, time-dependent, theory**

I. Introduction

Surface-enhanced Raman scattering (SERS) is a powerful spectroscopic technique that provides detailed insight into the vibrational and electronic (vibronic) properties of molecules.[1] SERS relies on the enhancement of the local electromagnetic field induced by surface plasmon resonances on metal nanoparticles (NPs), resulting in a stronger Raman response. The scientific community widely agrees that the enhancement of the molecular signal arises from two primary mechanisms: electromagnetic and chemical interactions. In particular, the electromagnetic contribution is generally assumed to dominate the SERS signal, especially when electric fields resonant with the plasmonic peak are used. Theoretical modeling of the Raman signal has greatly advanced our understanding of the underlying mechanisms. Our work focuses on developing a new theoretical strategy to simulate plasmon-enhanced Raman spectra in the time domain,[2] inspired by the pioneering theory of Lee and Heller.[3] This approach uniquely provides insights into the time evolution of the molecular Raman signal, capturing the dynamics of the incident electric field and its interaction with a plasmonic nanoparticle. Its flexibility allows the use of various incident electric field shapes, enabling closer alignment with experimental setups.[4]

II. Methods

Time-dependent SERS simulations are based on the real-time propagation of the system wave function, mutually with the polarization charges on the NP surface. The electronic properties of the molecule are equilibrated with the electromagnetic field of a nearby NP. The vibronic wave function is then constructed by dressing the electronic states with vibrational levels computed at the TDDFT level, incorporating the Franck–Condon and Herzberg–Teller expansions of the transition dipole moments.[5] During the real-time dynamics, coupling with the plasmonic NP is treated within a multiscale framework that combines a quantum mechanical description of the molecule with a polarizable continuum model for the NP.[6,7] Propagation of the vibronic wave function under a light pulse yields the time evolution of the vibronic coefficients, from which the Raman signal is obtained via an inverse Fourier transform of these dynamics.

III. Results and Discussion

We present numerical examples on a realistic organic molecule to demonstrate the approach. Calculations have been performed on Porphine molecule close to a gold nanoellipsoid considering different polarization for the incident electric field. Time-dependent raman scattering is computed providing insight into the timescale and the dynamics involved into the Raman scattering process.

IV. Conclusion

We have proposed a method able to compute the time-dependent surface-enhanced Raman scattering of molecules, which gives information on the Raman signal accumulated during the molecule-NP electrodynamics. This method combines multiscale approach for molecule-NP interaction in time-domain with a time-dependent approach for Raman scattering, which paves the way for simulation of time-resolved plasmon enhanced Raman scattering.

Operando SERS: From Molecular Spectroscopy to Plasmon-Driven Photochemistry

Shashank K. Gahlaut*, Ilko Bald, Radwan M.Sarhan, Biswajit Bhattacharyya

[1] Institute of Chemistry, University of Potsdam, Germany
*Corresponding author: gahlaut@uni-potsdam.de

***Abstract*— Light-driven chemical transformations on plasmonic metal nanostructures offer promising opportunities for sustainable synthesis and photocatalysis. The interaction of light with plasmonic nanoparticles generates enhanced electromagnetic fields, energetic charge carriers, and localized heating, which collectively drive chemical reactions at the nanoscale. Surface-enhanced Raman spectroscopy (SERS), enabled by near-field enhancement at plasmonic interfaces, provides a unique platform to both initiate and monitor these reactions in real time.**

We employ operando SERS to investigate bond cleavage and bond formation processes occurring on plasmonic nanostructures. Time-resolved SERS measurements are used to follow model plasmon-driven reactions, including the dehalogenation of 8-Bromoadenine, the dimerization of 4-nitrothiophenol to 4,4′-dimercaptoazobenzene (DMAB). These reactions serve as well-established probes for understanding plasmon-mediated chemistry. More recently, plasmon-assisted cross-coupling reactions have also emerged as an exciting class of transformations, demonstrating the potential of plasmonic nanostructures to drive complex catalytic processes under light excitation.

We further explore how the geometry and composition of plasmonic nanostructures influence reaction dynamics. Hybrid nanostructures based on noble metals such as Ag and Au are investigated to reveal structure-dependent catalytic behavior. In particular, chiral plasmonic gold helicoids allow efficient control of reaction rates using circularly polarized light. The generation of chiral hot carriers in these structures amplifies the photochemical g-factor, which can be reconfigured through nanoparticle assembly on substrates.

Beyond noble metals, the development of earth-abundant alternative plasmonic materials is essential for scalable photocatalysis. In this context, $CuFeS_2$ nanocrystal exhibiting plasmon-like resonances in the visible region is investigated as emerging plasmonic photocatalyst. Using operando SERS, we demonstrate previously unexplored plasmon-driven chemical transformations on this material system.

These results highlight the power of operando SERS as a versatile tool for understanding and controlling plasmon-driven chemistry, opening new opportunities for designing light-driven catalytic processes and chiral photochemistry at the nanoscale.

We investigate the influence of plasmonic nanopores geometry on flow-through single-molecule SERS during electrophoretic molecular delivery. Using microsecond-resolved SPAD detection, we compare circular, slit, and V-shaped nanopores. Experiments and simulations show enhanced SERS efficiency for the slit and V-shaped pores, highlighting geometry as a key parameter for SERS-based molecular sensing.

Keywords: **Single-molecule SERS, plasmonic membrane, nanopores, electrical translocations.**

I. Introduction

Surface-Enhanced Raman Spectroscopy (SERS) is a powerful technique for biosensing due to its single-molecule sensitivity, molecular specificity, and rapid response. Despite significant progress in recent years, reliable high-throughput detection and sequencing of biopolymers remain major challenges [1]. Fast and accurate identification of DNA and proteins would enable transformative diagnostic, therapeutic, and analytical applications.

In our previous works, we established an approach combining SERS with a solid-state nanopore for identification and sequencing, and demonstrated the feasibility of discriminating individual nucleotides and amino acids during their translocation through plasmonic nanopores [2,3]. However, further progress toward robust SERS-based sequencing requires nanopore geometries capable of providing stronger and more reproducible electromagnetic enhancement. Here, we systematically investigate the influence of nanopore geometry on SERS signal strength and detection efficiency in a flow-through translocation regime, which defines **the central novelty of the current research**.

II. Methods

We employ our previously developed approach for single-molecule identification and sequencing based on permeable plasmonic membranes combined with real-time microsecond SERS detection [2]. This platform enables an ultrafast acquisition of spectral data during molecular translocation with high spatial and temporal resolution.

To evaluate the impact of different nanopore geometries on SERS signal strength and detection efficiency, we fabricated nanopores with different geometries fabricated on 5 nm thick HfO membranes. We studied three pore types: Circular (O), slit-shaped (I), and V-shaped (V), all with characteristic lateral dimensions of approximately 15 nm. To further reduce the effective pore size and enable plasmonic enhancement, we sputtered a 20 nm Ag layer on top of the HfO membranes, preceded by a 2 nm Ti adhesion layer.

We validated the SERS behavior of these pores using poly-L-arginine (polyArg) molecules with an average length of approximately 100 amino acids. The molecules were prepared at a concentration of 1 nM in a 150 mM NaCl buffer, diluted in deionized water (>18.2 MΩ·cm, Milli-Q system), and additionally filtered through a 0.22 µm membrane before use. Molecular translocation was driven by an applied bias voltage of 50 mV across a single nanopore in a membrane. These conditions are close to physiological and are commonly used in related nanopore studies.

SERS spectra were collected in a flow-through geometry using a Single-Photon Avalanche Diode (SPAD) camera set to 100 µs temporal resolution for a single-event detection.

III. Results and Discussion

Our results demonstrate that nanopore geometry plays a critical role in determining the efficiency of SERS signal enhancement during molecular translocation.

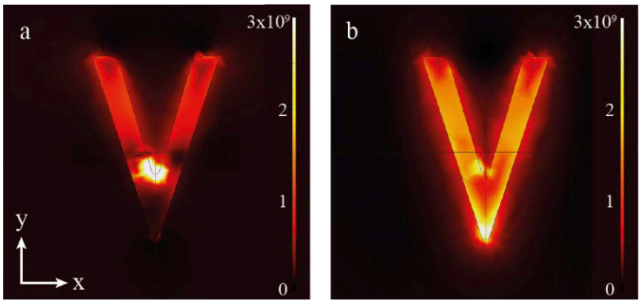

Fig. 1 Simulated electromagnetic field intensity distribution in a V-shaped nanopore excited at 532 nm with incident polarization along the y-axis (a) and x-axis (b).

Figure 1 shows simulated electromagnetic field distributions for a V-shaped nanopore excited at 532 nm with different polarizations, oriented parallel and perpendicular to the pore axis. The simulations show the hot spot distribution inside the pore and reveal a strong dependence of the local field enhancement on the incident polarization. These results indicate that both pore geometry and excitation conditions critically affect the SERS performance.

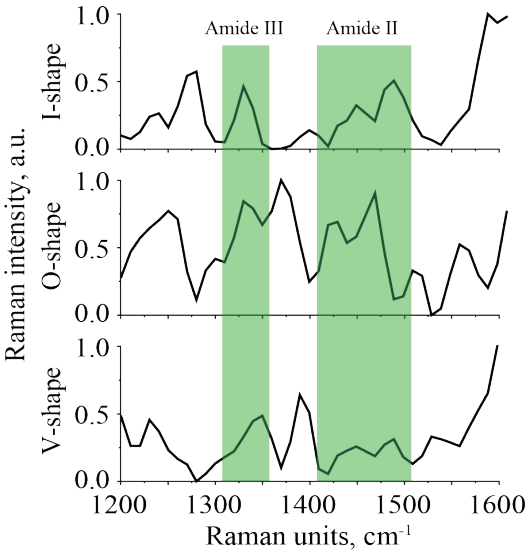

Fig. 2 Averaged SERS spectra of polyArg molecules acquired during single-molecule translocation through V-, I-, and O-shaped plasmonic nanopores for 532 nm laser excitation with laser polarization oriented perpendicular to the pore (x-axis, Fig. 1a).

We further analyzed experimentally acquired SERS spectra of polyArg molecules by averaging ~100 individual single-molecule translocation events. The resulting spectra for V-, I-, and O-shaped pores are shown in Figure 2. While the relative peak intensities may vary between pore types, the spectral peak positions are consistent with minimal fluctuations, normal for single-molecule SERS. This demonstrates a reliable molecular identification across different nanopore geometries.

To quantitatively assess nanopore performance, we analyzed photons detected for each individual translocation. Event selection was performed using a threshold based on the total number of detected photons per frame. The threshold was defined as a 3σ deviation of the distribution of photons per acquired frame during the experiment, corresponding to a 99% confidence level. The resulting histograms of photon counts are shown in Figure 3, highlighting differences in overall detection efficiency for the three different pore geometries.

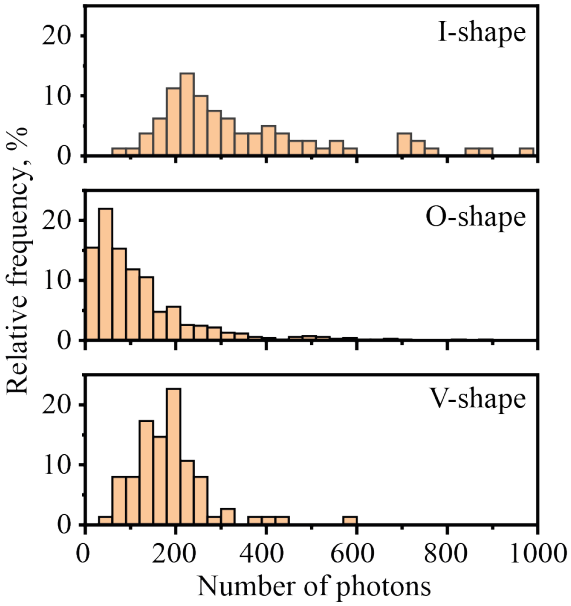

Fig. 3 Histograms of detected photons per each individual molecular translocation for each nanopore geometry, excited with 532 nm laser and polarization oriented perpendicular to the pore (x-axis, Fig. 1a).

Owing to the enhanced performance of the non-circular nanopores, these plasmonic nanopores represent a promising platform for high-throughput SERS-based molecular sensing.

IV. Conclusion

We demonstrated a strong dependence of a flow-through SERS enhancement on nanopore geometry and excitation polarization during single-molecule translocation, using polyArg molecules as a model system. Regular circular pores exhibited the weakest enhancement, limiting their applicability for SERS-based translocation studies. In contrast, I-shaped and V-shaped nanopores provided significantly stronger enhancement due to their geometry, with additional sensitivity to excitation polarization. These results show the importance of nanopore design for emerging SERS sequencing and single-molecule sensing applications.

***Abstract*— Rapid identification of PFAS in complex mixtures is critical for environmental monitoring and remediation. We use concave cubic gold nanoparticles for SERS detection of six MassDEP-regulated PFAS at ppm levels. The platform enables quantitative analysis, chain-length differentiation, and identification in real AFFFs, validated by mass spectrometry for field-deployable screening applications.**

***Keywords*— SERS, PFAS, AFFFs, gold nanoparticles**

I. Introduction

Per- and polyfluoroalkyl substances (PFAS) comprise a large class of synthetic fluorinated compounds widely used in industrial processes and consumer products due to their thermal stability and surfactant properties. Their environmental persistence, resistance to degradation, and documented associations with adverse human health outcomes have driven increasingly stringent regulatory limits, often at parts-per-trillion levels. Analytical detection is complicated by the extensive structural diversity of PFAS, their occurrence in complex multicomponent matrices such as aqueous film-forming foams (AFFFs), and interference from coexisting surfactants, organic constituents, and variable pH conditions.

Liquid chromatography–tandem mass spectrometry (LC-MS/MS) remains the gold standard for PFAS quantification due to its sensitivity and specificity; however, it requires laboratory-based instrumentation, extensive sample preparation, and still captures only a fraction of the thousands of PFAS in commercial use. These limitations motivate the development of rapid, field-deployable screening tools capable of selective detection in chemically complex environments.

Surface-enhanced Raman spectroscopy (SERS) offers a promising alternative by leveraging plasmonic nanostructures to amplify Raman scattering signals and enable trace-level detection. With rationally designed nanoparticle substrates, SERS has demonstrated the potential for sensitive and selective PFAS identification across environmentally relevant concentration ranges, providing a pathway toward portable, high-throughput monitoring of contaminated water sources and AFFF-impacted sites.

II. Methods

Concave Cubic Gold Nanoparticle Synthesis

Synthesis of Au seeds: 0.250 mL of 10 mM $HAuCl_4$ and 0.02 mL of 1 M HCl were added sequentially to 10.0 mL of 100 mM CTAC with vigorous stirring, resulting in a light-yellow solution. Next, 0.60 mL of freshly prepared 10 mM $NaBH_4$ was rapidly injected into the vigorously stirring solution, which led to the formation of an orange-brown seed solution. The seed solution was allowed to stir for an additional minute to ensure uniform dispersion of the reducing agent. The solution was allowed to age at room temperature for 2 h. Next, 0.20 mL of 1 M HCl, 0.50 mL of 10 mM $HAuCl_4$, and 100 µL of 10 mM $AgNO_3$ were added sequentially into 10.0 mL of 100 mM CTAC with gentle swirling. Then 0.10 mL of 100 mM ascorbic acid was introduced, causing a noticeable color change from light yellow to clear. 0.10 mL of an aliquot of seeds, which had been diluted 1000× in 100 mM CTAC, was then added to initiate the growth of particles.

SERS Scan of PFAS

SERS data were collected from a Bruker Senterra Dispersive Raman microscope, Serial number R200.0238, Detector model DU420A-OE-152, at a laser 785 nm. To avoid damage due to laser-induced heating, all measurements were performed at a low laser power of 50 mW. The integration time was set to 10 s, with an averaging of 4 scans to improve the signal-to-noise ratio. Concave cube Au nanoparticles were synthesized by following the method above, transferred to a 2 mL centrifuge tube, and concentrated to 50 µL. The concentrated nanoparticle solution was drop-cast onto a silicon wafer and dried at room temperature. SERS PFAS samples were prepared by diluting 6-MA-regulated PFAS stock solutions to different low concentrations down to 0.1 ppm. A silicon wafer with a concave cube Au nanoparticle was placed on a glass slide, a drop-cast-diluted PFAS solution was placed on the silicon wafer surface, and dried at room temperature.

The frequency gap (Δ) was calculated from Raman spectra as the difference between the C–C alkyl chain stretching, located near 250 cm^{-1}, and the C–C symmetric stretching modes, located near 1150 cm^{-1}, referenced to an internal silicon standard, located at 520 cm^{-1}, and normalized to the characteristic C–F stretching vibration, located near 750 cm^{-1}.

III. Results and Discussion

Concave cubic nanoparticles clearly result in enhanced SERS of PFAS down to ppm concentrations. The talk will detail how this was performed for 6 PFAS relevant for environmental regulation, in addition to comparing with bulk and calculated spectra.

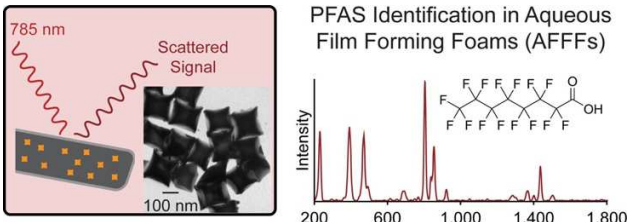

Fig 1. Scheme and typical SERS result.

Separately, experimental results highlight the ability to detect PFAS, specifically PFOS and PFOA, in real firefighting foams. This is supported by ^{19}F nuclear magnetic resonance (NMR) spectroscopy).

IV. Conclusion

We demonstrate that concave cubic gold nanoparticle SERS substrates (785 nm excitation) enable rapid, nondestructive identification of the six MassDEP-regulated PFAS at ppm levels and detect PFOS directly within complex commercial AFFF mixtures, with key spectral assignments supported by spontaneous Raman, DFT calculations, 19F NMR, and LC-MS/MS. Ongoing efforts focus on improving substrate durability, lowering detection limits, and expanding analysis to structurally diverse PFAS analogues to strengthen quantitative capability and real-world applicability in complex environmental matrices.

***Abstract*— Here, we present our recent results concerning the investigation and exploitation of metal film over nanosphere (MFoN) SERS substrates, spanning from rational, AI-driven plasmonic design to fundamental studies on spectral shaping induced by focusing / defocusing, and issues related to real-world analytical applications in nanoplastic detection.**

***Keywords*— localized plasmons, colloidal-based SERS substrates, machine learning, nanoplastics.**

The first part of this work discusses our approach to combine finite-difference time-domain (FDTD) simulations with artificial neural networks (ANN) to achieve rational optimization of metal film over nanosphere (MFoN) SERS substrates. FDTD simulations are used to systematically map the influence of key geometrical parameters on the localized surface plasmon resonance (LSPR) properties and the electromagnetic SERS enhancement [1]. The resulting dataset trains an ANN capable of accurately predicting the average electromagnetic field at the substrate surface. This predictive model is subsequently employed as a surrogate for optimization, identifying substrate geometries that maximize electric field intensity at 785 nm. The excellent agreement between ANN predictions and FDTD-calculated values validates the reliability and efficiency of this machine learning-guided design framework.

Next, we address a subtle yet critical factor affecting SERS measurements on solid planar nanostructured SERS substrates: the role of laser focus positioning along the optical axis (Z direction) [2]. Axial scans reveal that the SERS signal intensity follows a Lorentzian profile, with the maximum consistently occurring above the physical substrate surface. More significantly, the intensity ratios between different spectral features, including SERS bands and the broad background, vary non-monotonically along the Z axis. FDTD simulations attribute these spectral shape variations to the plasmonic near-field response of the substrate under focused and defocused illumination conditions. These findings underscore the importance of precise focus control in quantitative SERS analyses, particularly in band-ratio-based assays performed on nanostructured solid substrates.

Finally, we extend the investigation of MFoN substrates to the analytically challenging problem of nanoplastic detection. Using wavelength-scanned SERS in the near-infrared range, we first characterize the performance of various substrates with benzenethiol as a molecular probe analyte. We then assess the same substrates for the detection of individual polystyrene nanoplastic particles. The results reveal an important insight: while a substrate optimized for molecular detection may exhibit excellent sensitivity towards small-molecule analytes, separate and distinct optimization is required for effective detection of nanoscale particulate matter such as nanoplastics [3].

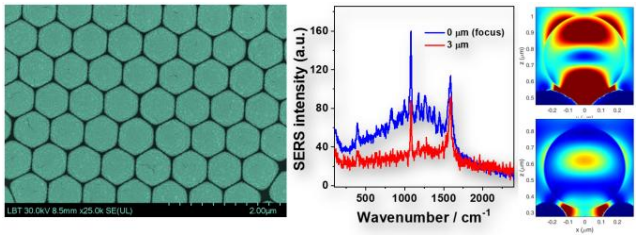

Fig. 1 (left) SEM image of metal film over nanosphere; (centre) SERS spectra of 4-aminobenzenethiol upon focusing/ defocusing; (right) FDTD simulations of spherical nanoplastic on the SERS substrate.

Taken together, these interconnected studies on the MFoN platform provide a unified perspective spanning computational substrate design, fundamental understanding of SERS spectral shape, and emerging environmental sensing applications, contribution to the rational development and application of SERS substrates.

***Abstract*— We present a multiscale quantum and classical framework for simulating surface enhanced spectroscopies of molecules near plasmonic substrates. The method combines quantum molecular response with an atomistic classical electromagnetic description of metals. We demonstrate accurate and efficient prediction of surface enhanced Raman signals of molecules on realistic plasmonic substrates.**

***Keywords*— QM/MM, SERS, plasmonics, atomistic.**

I. Introduction

Surface-enhanced spectroscopies arise from the coupled response of a molecule and a plasmonic substrate, requiring a balanced description of (i) the substrate electromagnetic response and (ii) molecule–substrate coupling. We address this problem with an atomistic, frequency-dependent classical model for the metal response and its coupling to a quantum description of the molecule, enabling realistic simulations at low computational cost.

II. Methods

The plasmonic substrate is modeled through the frequency-dependent Fluctuating Charges and Fluctuating Dipoles (ωFQFμ) approach, which provides a fully atomistic description of the metal electromagnetic response. Under a monochromatic external field at frequency ω, the ωFQFμ unknowns q and μ are obtained from the linear system:

$$\begin{pmatrix} \mathbf{A}^{qq} & \mathbf{A}^{q\mu} \\ \mathbf{T}^{\mu q} & \mathbf{T}^{\mu\mu} \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ \boldsymbol{\mu} \end{pmatrix} = \begin{pmatrix} \mathbf{f}^{q} \\ \mathbf{f}^{\mu} \end{pmatrix} \qquad (1)$$

where $\mathbf{A}^{qq}$ and $\mathbf{A}^{q\mu}$ collect charge–charge and charge–dipole couplings (including Drude-like terms), $\mathbf{T}^{\mu\mu}$ and $\mathbf{T}^{\mu q}$ are the dipole–dipole and dipole–charge interaction kernels, and $\mathbf{f}^{q}$ and $\mathbf{f}^{\mu}$ account for the driving electric potential and field at the atomic positions. Molecular properties are computed with TDDFT, while the ωFQFμ environment enters as a frequency-dependent embedding contribution. From the coupled response we obtain the frequency-dependent polarizability and compute SERS intensities within Placzek's approximation.

III. Results and Discussion

Figure 1 compares computed SERS spectra of pyridine adsorbed at distinct sites (vertex, edge, and face) on an icosahedral gold nanoparticle (10 179 atoms) with the corresponding experimental spectrum. The simulations reproduce the main experimental features, and the average over site-resolved signals provides a practical estimate of the measured response, indicating that realistic nanoparticle sizes and heterogeneous adsorption environments can be treated within a fully atomistic framework at a computational cost compatible with routine simulations.

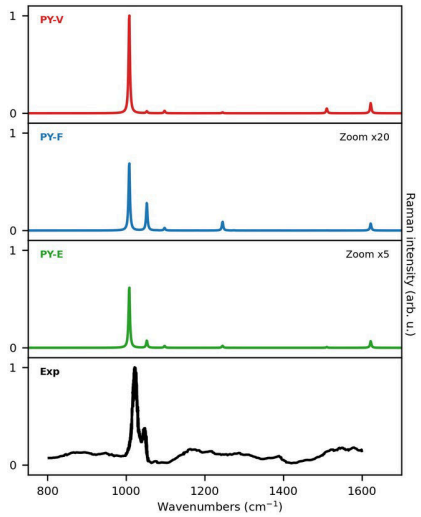

Fig. 1 QM/ωFQFμ SERS spectra of pyridine at different adsorption sites on an icosahedral gold nanoparticle (10 179 atoms), compared with experiment.

IV. Conclusion

We have presented the multiscale QM/ωFQFμ framework for the efficient simulation of SERS signals of molecules adsorbed on plasmonic substrates (e.g., silver, gold, graphene). The approach combines a quantum-mechanical description of the molecule with an atomistic electromagnetic model of the substrate, delivering results in good agreement with experimental benchmarks at a substantially reduced computational cost. We also introduced further developments aimed at improving the overall efficiency of the method, and extended the same multiscale strategy to access additional surface-enhanced spectroscopies, including SEIRA and SEF.

***Abstract*— We developed a theoretical framework for visualizing vibrational modes in tip-enhanced Raman scattering based on resonance Raman processes. In particular, by exploiting electronically forbidden excitations, we showed that the resulting spatial distribution of vibrational signals can differ fundamentally from that obtained via conventional allowed transitions.**

***Keywords*— Raman scattering, nonlocal response theory, quantum electrodynamics, plasmon.**

I. Introduction

Raman scattering enables access to vibrational information intrinsic to matter. Recent advances in tip-enhanced microscopy, both experimentally [1–3] and theoretically [4–8], now enable visualization of vibrational states at the single-molecule level. Although Raman scattering originating from electronically forbidden excitations has been reported [9], its observation in tip-enhanced Raman scattering (TERS) has not yet been demonstrated.

In this work, we develop a theoretical framework for single-molecule TERS imaging in which not only the incident field but also scattering processes are treated self-consistently with the optical near field generated by the metallic tip–substrate nanostructure. Furthermore, by incorporating a spatially distributed molecular dipole response, we construct a nonlocal description of light–matter interaction. Using this formulation, we investigate how Raman processes mediated by electronically allowed and forbidden excitations give rise to distinct mode-resolved TERS imaging patterns, revealing that forbidden pathways can enhance Herzberg–Teller (HT)–related symmetry components in the spatial contrast, thereby enabling discrimination of vibrational modes with similar energies.

II. Methods

We formulate tip-enhanced Raman scattering (TERS) within a nonlocal quantum–electrodynamical framework. The total Hamiltonian is written as,

$$\hat{H} = \hat{H}_{\mathrm{mol}} + \hat{H}_{\mathrm{rad}} + \hat{V}, \tag{1}$$

where $\hat{H}_{\mathrm{mol}}$ describes the electronic and vibrational states of the molecule and $\hat{H}_{\mathrm{rad}}$ represents the quantized electromagnetic field in the plasmonic nanostructure. The light–matter interaction is given by,

$$\hat{V} = -\int d\boldsymbol{r}\, \hat{\boldsymbol{P}}(\boldsymbol{r}) \cdot \hat{\boldsymbol{E}}(\boldsymbol{r}), \tag{2}$$

with the polarization operator expressed in terms of transition dipole densities $\boldsymbol{\mathcal{P}}_{nm}(\boldsymbol{r})$, expanded into Franck–Condon (FC) and HT components, allowing us to evaluate their interference.

Starting from the quantum master equation under the Born–Markov approximation, we evaluate the expectation value of the polarization to first order in the interaction. This yields a spatially nonlocal response of the form [10-12],

$$\boldsymbol{P}(\boldsymbol{r},\omega) = \varepsilon_0 \int d\boldsymbol{r}'\, \boldsymbol{\chi}(\boldsymbol{r},\boldsymbol{r}',\omega)\boldsymbol{E}(\boldsymbol{r}',\omega), \tag{3}$$

where, in the present TERS formulation, the nonlocal susceptibility is derived as,

$$\boldsymbol{\chi}(\boldsymbol{r},\boldsymbol{r}',\omega) = \frac{1}{\varepsilon_0}\sum_{n,m}(\langle\hat{\sigma}_{nn}(0)\rangle - \langle\hat{\sigma}_{mm}(0)\rangle) g_{mn}(\omega)\boldsymbol{\mathcal{P}}_{nm}(\boldsymbol{r})\boldsymbol{\mathcal{P}}_{mn}(\boldsymbol{r}'). \tag{4}$$

Here $g_{mn}(\omega)$ denotes the molecular energy denominator including relaxation. Because the transition dipole density is spatially distributed, the response is intrinsically nonlocal and naturally incorporates multipolar coupling to spatially varying near fields. The plasmonic environment is incorporated through a renormalized Green's function obtained from Maxwell's equations including the metal dielectric response. This Green's function incorporates the full set of plasmonic modes and consistently modifies both excitation and the subsequent spontaneous emission.

The Raman scattering intensity is evaluated from the time derivative of the photon number operator. After solving the coupled operator equations under steady-state conditions, the scattered intensity at frequency ω_s can be written in the form,

$$S(\omega_s) = \frac{1}{\pi}\sum_{n,m} \mathrm{Re}\left[\sum_{p=1}^{4} D_{n,m}^{(p)}(\omega_i, \omega_s)\, Y_{n,m}^{(p)}(\omega_s)\, I_{n,m}^{(p)}(\omega_i)\right]. \quad (5)$$

Here $I_{n,m}^{(p)}$ contains the near-field–dependent excitation process, $Y_{n,m}^{(p)}$ represents the Green-function–mediated spontaneous emission process, and $D_{n,m}^{(p)}$ corresponds to molecular energy denominators. Under appropriate approximations, and in the absence of metallic structures, the four terms reduce to the conventional Kramers–Heisenberg–Dirac dispersion formula. This formulation enables mode-resolved analysis of electronically forbidden Raman processes under tip-enhanced conditions.

The simulation model is shown in Fig. 1(a) and (b). For computational simplicity, the gold tip is modeled as a sphere with an atomically small protrusion at its apex. A pentacene molecule is placed between the tip and a gold substrate, oriented parallel to the substrate surface.

III. Results and Discussion

The electronic structure and vibrational modes of the pentacene molecule were calculated using Gaussian. The spatial distributions of the vibrational mode corresponding to the Raman shift at 1027 cm^{-1}, visualized via electronically allowed and forbidden transitions, are shown in Fig. 2. When mediated by an allowed excitation, the signal appears at the upper and lower regions along the short molecular axis of pentacene. In contrast, excitation via a forbidden transition yields four spatially separated signal regions.

For the allowed transition, the HT–induced contribution produces a transition dipole at both molecular termini oriented along the same direction of the short axis, resulting in the distribution shown in Fig. 2(a). By contrast, in the electronically forbidden case, the transition dipole densities at the two molecular ends are oppositely oriented, leading to the four-lobed distribution shown in Fig. 2(b). This contrast can be understood as arising from a phase reversal of the HT-related polarization between the two termini in the forbidden pathway, which makes the intrinsic two-end character of the HT distribution more explicit in the spatial imaging pattern.

IV. Conclusion

In conclusion, we have developed a nonlocal quantum–electrodynamical framework for single-molecule TERS imaging that consistently incorporates plasmonic renormalization and spatially distributed molecular dipole responses. The formulation enables mode-resolved analysis of FC and HT contributions, including electronically forbidden excitations. Our results demonstrate that vibrational imaging patterns can differ qualitatively depending on whether the Raman process is mediated by electronically allowed or forbidden transitions. In particular, the reversal of transition dipole moment densities at the molecular termini in the forbidden case gives rise to a distinct four-lobed spatial distribution. These results suggest that electronically forbidden excitations provide a symmetry-sensitive pathway for contrast formation, enabling discrimination of vibrational modes with similar energies.

***Abstract*— We develop zwitterionic polymeric coacervates as antifouling plasmonic boxes for one-pot SERS sensing in complex biofluids. Local enrichment of selected targets and Raman-active gold nanoparticles increase signal to noise ratio of at least 10-fold compared with free gold nanoparticles in solution, enabling limits of detection below nM range in plasma and cerebrospinal fluid, as demonstrated here with the amyloid beta 1-42.**

***Keywords*— zwitterionic coacervates, Raman-SERS spectroscopy, biofluids, plasmonic boxes, amyloid beta.**

I. Introduction

Direct biomarker detection in plasma and cerebrospinal fluid is hindered by low analyte abundance, matrix interference, and biofouling on sensing interfaces. While surface enhanced Raman spectroscopy (SERS) can provide chemically specific readout, its use in complex biofluids is often limited by uncontrolled hotspot formation, nonspecific adsorption, and poor signal to background. Liquid-liquid phase separated associative coacervates offer a complementary route to preconcentrate targets under mild conditions. Zwitterionic coacervates are characterized by interesting antifouling features suppressing nonspecific binding, engineered to uptake specific biomolecules in complex biofluids [1,2]. When integrated with biophotonics technologies such as SERS-active nanostructures [3], these engineered droplets create confined plasmonic systems that enhance molecular signatures. Here we combine antifouling zwitterionic coacervates with programmed affinity capture and Raman active plasmonic probes to create tunable liquid plasmonic boxes for one pot sensing in biofluids.

II. Methods

A zwitterionic copolymer was prepared starting from sulfobetaine based monomers and further functionalized via EDC NHS coupling with capturing probes to increase selectivity. Phase separation into polymer rich droplets was induced by reducing ionic strength to 100 mM NaCl across a broad pH window. Gold nanoparticles were synthesized as multilayer core shell structures embedding a Raman reporter with a 2235 cm^{-1} band in the biological silent region. Droplet recruitment was quantified by fluorescence microscopy and SERS spectra were acquired by confocal micro-Raman microscopy.

III. Results and Discussion

Engineered zwitterionic coacervates form stable, liquid-like droplets that act as confined microenvironments and intrinsically enrich molecular clients. The droplets show robust phase behavior under mild conditions and provide a low-fouling compartment where biomolecules can be concentrated without extensive sample processing. By programming the droplet phase with affinity ligands, we achieve selective uptake of biomolecules and concomitant recruitment of plasmonic probes. Plasmonic multilayer gold nanoparticles provide a strong Raman band in the biologically silent region and once compartmentalized inside droplets, generate confined hotspots that markedly improve signal to background compared with bulk measurements. Streptavidin is first used as a model system to validate specific and controllable partitioning: biotin-based affinity drives droplet loading, while the zwitterionic matrix minimizes nonspecific adsorption, demonstrating effective discrimination against background components, with sensitivity down to 0.8 pM (Fig.1 a-c). Building on this modular strategy, antibody functionalization enables selective capture of amyloid beta 1-42 and its enrichment in complex media. This plasmonic box configuration enables one-pot quantification of amyloid beta 1-42 with a 0.1 to 10 nM working range and a 0.24 nM limit of detection. Importantly, the assay maintains performance in clinically relevant matrices, allowing direct

readout in plasma and cerebrospinal fluid (CSF) with good reproducibility and low coefficient of variation (Fig. d-f).

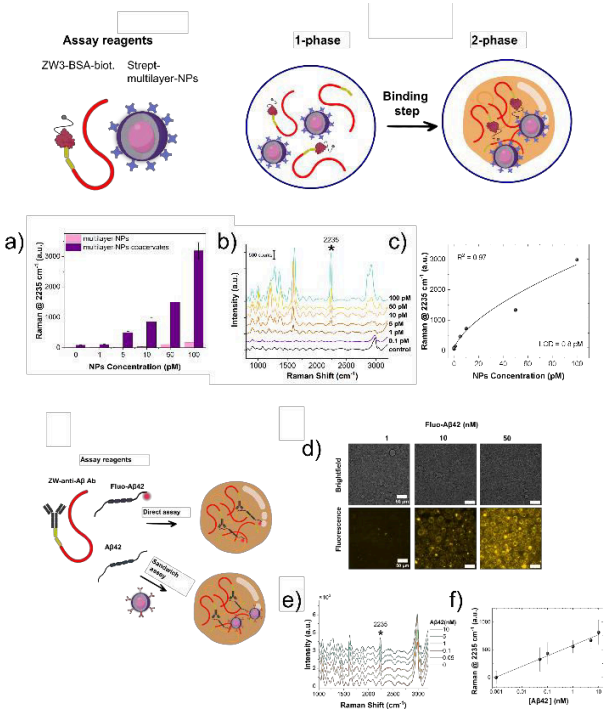

Fig. 1 Zwitterionic coacervate “plasmonic box” for one pot SERS in biofluids: selective recruitment of reporter encoded gold nanoparticles into liquid droplets creates confined hotspots in the silent region. Plots and images show nanoparticle enrichment, Raman spectra, for streptavidin as gold-standard and amyloid beta 1-42 quantification in plasma and CSF.

IV. Conclusion

Zwitterionic coacervates act as programmable, antifouling liquid compartments that concentrate biomarkers and plasmonic probes to generate confined hotspots for Raman readout. This plasmonic box strategy enables streamlined, one pot quantification of amyloid beta 1-42 directly in clinically relevant biofluids and can be adapted to other targets by changing the affinity ligands.

***Abstract*—Surface-Enhanced Raman Spectroscopy (SERS) is a sensitive technique that has the potential to be implemented in Therapeutic Drug Monitoring protocols for anti-epileptic drugs, reducing the time and cost of High-Performance Liquid Chromatography (HPLC) methods.**

***Keywords*— Raman, Cenobamate, gold nanoparticles.**

I. Introduction

Epilepsy is a neurological disease affecting 1% of the population worldwide. Nowadays, antiepileptic drugs can help people suffering from epilepsy to guarantee up to 100% seizure control. To do so, it is important to monitor the concentration of these types of drugs in blood to ensure they are below a certain threshold, which can lead to toxicity, especially in children, the elderly, and people suffering from other pathologies. It is also important to ensure that drug concentrations are high enough to control seizures. Therapeutic Drug Monitoring (TDM) is the process of assessing drug concentrations in body fluids for medical purposes [1]. In this context, HPLC coupled with mass spectrometry is a powerful detection method for quantifying drug concentrations in human plasma and is currently used in hospitals [2]. The possibility of complementing this costly and time-consuming technique with a quicker and sensitive spectroscopic technique, such as SERS, is of interest to speed up the analyses and improve the quality of life of patients, reducing the blood sample volumes used for the analyses [3]. SERS is a sensing technique based on Raman spectroscopy in which, thanks to the interaction of the analyte molecule with a nanostructured metal substrate, Raman signals can be intensified by several orders of magnitude. Here, we investigate the SERS behavior of the recently approved anti-epileptic drug Cenobamate [2], for which, to the best of our knowledge, such spectroscopic data are lacking in the literature. To this end, we use both gold nanoparticles obtained from colloidal phases and gold thin films prepared by Pulsed Laser Deposition (PLD), which have demonstrated appealing SERS capabilities [4] and tunable plasmon resonances [5,6].

II. Methods

Cenobamate (CNB) has been purchased by Alsachim®. It appears as a white powder, poorly soluble in pure water. A stock solution of CNB (10^{-3} M) has been prepared by dissolving 1 mg of CNB in 0.3 ml of methanol and adding 1.2 ml of water. Successive dilutions of this stock solution (down to 10^{-6} M) were prepared to study the SERS behavior as a function of drug concentration.

Gold nanoparticle colloids have been prepared following the Turkevich approach [7], which involves preparing a 10^{-3} M solution of $HAuCl_4$ in water (75 ml), and mixing it under stirring with a 1 wt% water solution (7.5 ml) of trisodium citrate (TSC) after both solutions have reached the boiling point. In about 20 minutes, the mixed solution reaches a stable, red wine-like color, indicating the formation of gold nanoparticles about 20 nm in diameter. After cooling, the colloidal suspension is ready for use. SERS samples were prepared by mixing 200 µl of CNB solution with 50 µl of Au colloidal solution, then centrifuging for 10 minutes at 10000 RPM. After removing the supernatant, the concentrated colloidal mixture was drop-cast onto an aluminum foil and dried, forming a film of aggregated nanoparticles suitable for SERS measurements.

Thin-layer gold substrates produced by the PLD technique [5], with a plasmon resonance peak around 720 nm, were tested by directly depositing on the films a 10 µl drop of the CNB aqueous solution (5×10^{-5} M).

Micro-Raman spectra were recorded using a 785 nm excitation wavelength, with a laser power of 1 mW focused through a 50× objective. The spectra were acquired with a 30-second exposure time, averaging 2 accumulations. To obtain clear SERS signals from colloids, five spectra were recorded on the edge of each dried drop, where the nanoparticle film is denser. For each of the five repeats, we selected the spectrum with the best-resolved and intense spectral features. The spectra were compared with both a blank spectrum (the dried colloid without the drug) and a reference Raman spectrum of the CNB molecule in aqueous solution (10^{-3} M).

III. Results and Discussion

The plasmon resonance of the gold colloids shown in Fig. 1 matches the expected optical properties of the Turkevich colloid [7]. Upon aggregation, the original plasmon resonance broadens and red-shifts, and additional light absorption in the 700–850 nm region arises from interactions among the

nanoparticles. This feature enables the use of 785 nm excitation for SERS experiments with both aggregated Au colloids and SERS substrates produced by PLD, which are known to exhibit tunable plasmon resonances in the 650–800 nm range [5,6].

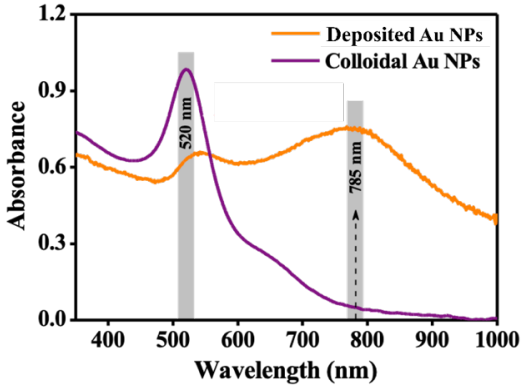

Fig. 1. UV-Vis extinction of the as-prepared gold colloids and a film formed by aggregated colloids deposited on glass.

Fig. 2 compares the reference Raman spectrum of CNB in aqueous solution and representative SERS spectra of CNB collected using the gold colloids and the PLD gold substrates. We observe a good match between the SERS spectra and the reference Raman spectrum of CNB. In the context of TDM, such correspondence supports the use of the strongest SERS peaks (424, 1040, 1212 cm^{-1}) as markers of the drug's presence. Interestingly, by comparing the SERS signal obtained from the colloids with that from the PLD gold substrates, we observe that the latter show lower band intensities. This is due to the shift of the plasmon resonance peak of the PLD substrates relative to the laser excitation wavelength (720 nm *vs*. 785 nm). This point highlights the importance of carefully tuning the optical properties of PLD-produced films, which will be addressed in future work.

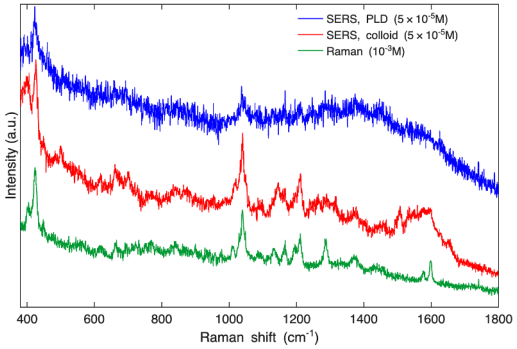

Fig. 2. Raman and SERS spectra of CNB (see text). For clarity, the SERS intensity from PLD has been doubled.

Fig. 3 shows the SERS spectra recorded with gold colloids exposed to decreasing concentrations of CNB, ranging from 5×10^{-5} to 5×10^{-6} M. Notably, this range of concentrations overlaps with the one considered in the HPLC investigation of CNB [2]. Due to the uneven distribution of hotspots in the dried film formed by gold colloids, a robust linear correlation between band intensity and concentration has not yet been established. However, we observe good reproducibility in the overall shape of the SERS spectra across different spots on a single sample and a monotonic increase in SERS intensity with CNB concentration. This is appealing for setups in which the SERS signal is spatially averaged using a spinning device [8].

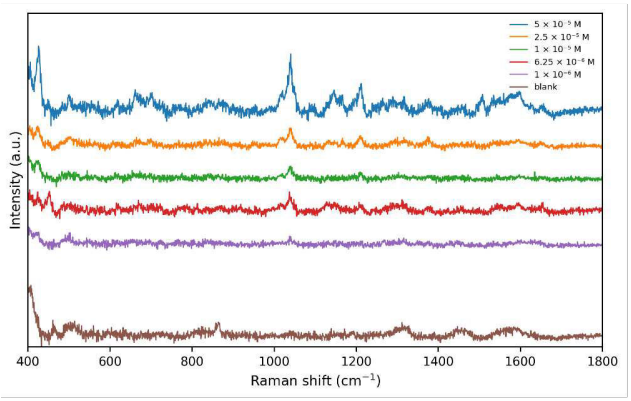

Fig. 3. Baseline-corrected SERS spectra of CNB from gold colloids (see text).

IV. Conclusion

The results presented here show that SERS is a promising sensing technique for the antiepileptic drug Cenobamate. Being quick and sensitive, SERS might speed up procedures, reduce clinic workload, and improve the quality of life for people with neurological diseases.

Inelastic light scattering by metallic nanocrystals: symmetry, shape and chirality

Lucien Saviot[1,*]

[1]Université Bourgogne Europe, CNRS, Laboratoire Interdisciplinaire Carnot de Bourgogne ICB UMR 6303, 21000 Dijon, France

[*]Corresponding author: lucien.saviot@cnrs.fr

***Abstract*—Inelastic light scattering spectra of metallic nanocrystals depend strongly on shape, elasticity, and environment. To assign the observed features, numerical approaches are presented to calculate the vibrations by taking advantage of the symmetries including for core-shell nanocrystals and to calculate the spectra with application to chiral shapes.**

***Keywords*— metallic nanocrystals, inelastic light scattering, Rayleigh-Ritz approximation, finite element method**

I. Introduction

Acoustic vibrations of nano-objects can be observed using inelastic light scattering (ILS) measurements and provide information about the size, the shape, the material the nano-objects are made of and also their environment[1]. Complex Brillouin or low-frequency Raman spectra have been obtained recently for core-shell nanocrystals[2]. Numerical approaches to interpret such spectra are presented. The first one improves the convergence of the Rayleigh-Ritz (RR) method to calculate the vibrations of core-shell nanocrystals. The second one relies on the finite element method (FEM) to calculate the scattered intensities for nanocrystals having arbitrary shapes. They are validated by comparison with analytic calculations obtained for spherically symmetric systems.

II. Methods, Results and Discussion

The shape of the nanocrystals considered in this work are shown in Fig. 1.

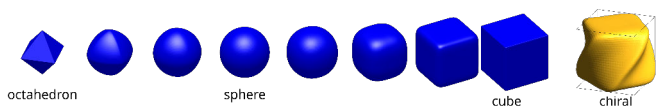

Fig. 1. Shapes modeled with superellipsoids allow variations from a tetrahedron to a sphere and to a cube. A twisted rounded cube is used as a model for a chiral gold nanocrystal (right).

Vibrations are calculated using the RR method by expanding the displacement on the $x^l y^m z^n$ basis of functions. It is very efficient provided volume integrals of the basis functions have analytic expressions and enables to take into account the symmetry of the nanocrystals and classify the vibrations according to their irreducible representations[3]. The convergence is poor for core-shell objects because the slope of the displacement changes at the inner interface. This is challenging to approximate with the power functions basis. To overcome this issue, functions suitable for the vibrations of the clamped core were added to the basis. Such functions vanish at the core-shell interface and in the shell. Calculations using this extended basis for a simple isotropic core-shell sphere for which an analytic solution exists show a significantly improved convergence[4].

ILS spectra were calculated using FEM by adapting an analytic approach developed for isotropic gold spheres[5]. We first reproduced these results with FEM. Then the shape of the gold nanocrystal was varied and revealed that nanospheres are very particular in this context. In the quasistatic approximation, the electric field inside the spherical gold nanocrystal is constant resulting in a vanishing ILS intensity. The non-zero intensity is due to deviations from the quasistatic approximation coming from the retardation effect[5]. For non-spherical shapes, the electric field inside the nanocrystal is not constant anymore even in the quasistatic approximation resulting in a quick increase of the ILS intensity as the shape deviate from a sphere[6]. Calculations for chiral shapes reveal a significant difference in the scattered intensities for right versus left incident circular polarizations.

Driving giant monochromatic THz strain waves in metal heterostructures by electronic pressure

Matias Bargheer [1,2]

[1] Institute of Physics and Astronomy, University of Potsdam, Potsdam, Germany
[2] Helmholtz-Zentrum Berlin, HZB, Berlin, Germany
*Corresponding author: bargheer@uni-potsdam.de

***Abstract*— Nanolayered metal superlattices are thermoacoustic metamaterials, in which we drive giant THz strain waves by ultrafast optical excitation across the visible spectrum. Electronic stress at metal-metal interfaces actuates the coherent phonons faster than the electron-phonon coupling time. Ultrafast x-ray diffraction probes the phonons beyond the optical skin depth.**

***Keywords*— metamaterials, terahertz strain, ultrafast x-ray diffraction, metal heterostructures.**

I. Introduction

High-frequency strain engineering is a central challenge for phononics at the nanoscale with broad application potential. Coherent strain control at terahertz (THz) frequencies in metal heterostructures has remained elusive because free electrons are expected to delocalize energy beyond the optical penetration depth, preventing rapid and efficient stress generation.

This presentation discusses robust and cost-effective metal–metal superlattices (SLs), where periodic repetitions of bilayers — each layer a few atoms thick — are deposited by sputtering, as thermoacoustic metamaterials that overcome this limitation.

II. Methods

Ultrafast x-ray diffraction (UXRD) is our key to material-specific nanoscale sensing of strain even in optically opaque metal heterostructures.[1-3]

For modeling we rely on density-functional theory for electron-phonon coupling within each material and two-temperature modelling (2TM) [4] coupled to the elastic wave equation for the spatio-temporal dynamics. We utilize the modular Python library udkm1Dsim that supports N-temperature models in layered structures - coupled to the one-dimensional wave equation. [5] Optical excitation is included via a matrix formalism and dynamical X-ray diffraction models include a temperature-dependent structure factor (Debye-Waller factor) to simulate the UXRD experiments.

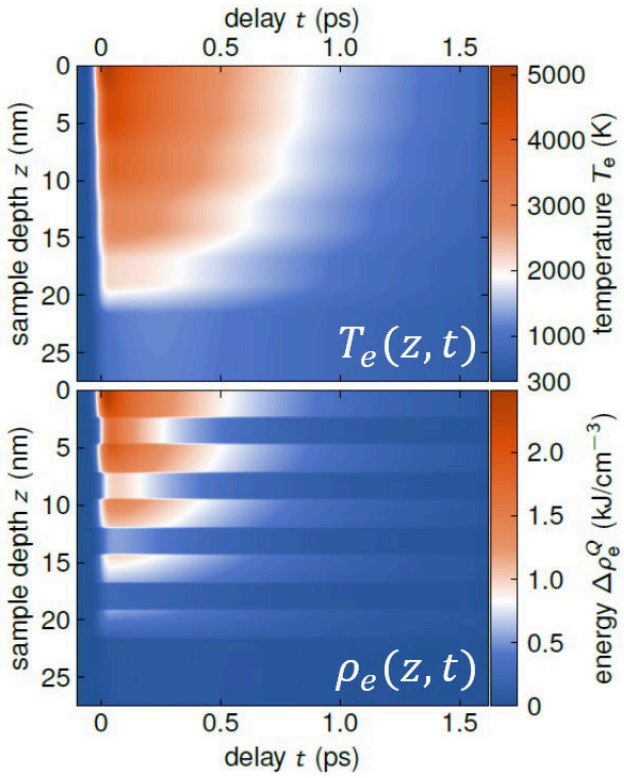

Fig. 1 Spatiotemporal temperature and energy density in a Pt/Cu superlattice with about 5 nm period. The electron temperature essentially shows rapid thermalization which leads to sharp localized features of the energy density in the electron system.

III. Results and Discussion

Our model fits UXRD data on various metal-metal superlattices (PtAu, FeAu and PtCu) at different pump wavelengths and fluences. The 2TM shows that after a nearly homogenous optical excitation, the energy deposited in the electron system spontaneously localizes in thin layers with a periodicity significantly below the skin depth (Fig. 1). While the electrons are significantly hotter than the phonons, electronic pressure acts on metal-metal interfaces, although the latter are transparent to electronic energy transport. Once

electron-phonon coupling sets in, very large temperature gradients can persist across the metallic interface for several tens of picoseconds.[6] Within the 2TM we rationalize heat transport without heating [2] and dominant energy transport via phonons at the nanoscale in noble metals [3].

The main ingredient for these observations is that metals with d-orbitals at the Fermi level (Pt, Pd, Ni, Fe, Co…) have a significantly larger thermally accessible electronic density of states, which increases the electronic heat capacity and the electron phonon coupling. It is the combination of such materials with nobler metals such as Au and Cu, which leads to the counterintuitive phenomena, which we uniquely cross-check via the material specific ultrafast X-ray diffraction.

We explain how monochromatic THz phonons can be actuated by electronic pressure, although the electron-phonon coupling time is longer than the period of the generated THz phonon. The presentation reports 1 THz strain waves with a 1% strain amplitude.

IV. Conclusion

We establish electron pressure as an engineerable, dominant actuation mechanism in metallic metamaterials, in which THz strain can be tailored by the pitch and the constituent materials of the superlattice structure. This will enable new applications such as ultrafast strain-mediated control of functional materials.

Modeling the Acousto-Plasmonic Coupling: Raman Energy Density Framework

Nicolas Large[1,*]

[1]Department of Physics and Astronomy, University of Texas at San Antonio, United States

*Corresponding author: nicolas.large@utsa.edu

***Abstract*— We present a theoretical study of the interactions between confined acoustic vibrations and localized surface plasmons in metallic nanoparticles. We introduce a new physical quantity, the Raman energy density, which is a local quantity that serves as a tool for the study of Raman scattering mediated by plasmons in nanoparticles.**

***Keywords*— plasmonic nanoparticles, localized surface plasmons, acoustic vibrations, acoustic Raman scattering, Raman energy density, computational modeling.**

I. Introduction

Multifunctional nanomaterials are of high interest to a wide range of technological applications in optoelectronics, biomedicine, energy, sustainability, optics, photonic devices, quantum sensing, quantum computing, and applied chemistry. The development of such materials relies critically on a deep understanding of the relationships between structure, interfaces, and physical properties at the nanoscale, where collective excitations, confinement, and non-equilibrium effects dominate the response of matter. The interesting properties of LSPs and their coupling to phonons also offer a unique platform for unconventional light manipulation pathways. LSPs can be temporally modulated by acoustic phonons naturally present in nanomaterials and their environment [1]. Such modulation can be used to increase detection and sensing accuracy of plasmonic-based nanosensors. Acoustic Raman scattering, which directly probes acoustic phonons in nanomaterials, is a very effective, high precision, non-invasive technique for nanometrology.

II. Methods

Here, the transition rate associated with the Raman scattering by acoustic phonons is calculated using a Fermi golden rule where we introduce a new physical quantity: the Raman energy density (RED; Fig. 1) [2]:

$$U_R(r,\omega_i,k_i,\omega_f,k_f) = -\varepsilon_0\chi(r)\left[\frac{V_{DP}}{\hbar\omega_{ex}-\hbar\omega_{ib}}\nabla\cdot u(r)\right] \times E_f(r)\cdot E_i(r) - \varepsilon_0\chi(r)E_f(r)\cdot\left[E_f(r)\cdot E_i(r)\right] \quad (1)$$

where $E_i(r)$ and $E_f(r)$ are the local electric fields associated to the LSP before and after the interaction with the acoustic phonons, respectively. $\chi(r)$ is the electric susceptibility of the metallic NP and is defined using a size-corrected Drude model, $\hbar\omega_{ib}$ is the interband transition threshold, V_{DP} is the deformation potential, and $\nabla\cdot u$ is the divergence of the displacement field obtained from elastodynamic simulations.

The first term in eq. (1) is called the deformation potential coupling mechanism or volume mechanism. It describes the modulation of the electric susceptibility by the acoustic phonons. A change in a NP volume results in a change in the electronic band structure *via* the deformation potential. The effect of the electric susceptibility modulation on the intraband transitions is negligible in the visible range because their excitations are in the infrared range. Nevertheless, the interband transition modulation contributes to the volume mechanism because the interband transitions lay in the UV range, close to the LSP. Therefore, this term could be negligible in metals but not in semiconductors. The second term in eq. (1) is the surface orientation coupling mechanism. Contrary to the volume mechanism, the surface mechanism is the dominant contribution to the Raman scattering in metals [1].

This framework allows for rigorously calculate the acoustic Raman scattering spectra of any nanostructured material:

$$\sum_{vib}\frac{2\pi}{\hbar^2}\left|\int U_R^{vib}(r)\,dV\right|^2\frac{\Gamma_{vib}}{\left(\hbar\omega_{ex}-\hbar\omega_{vib}\right)^2+\left(\Gamma_{vib}/2\right)^2}\cdot\frac{1}{e^{\left(\hbar\omega_{ex}/k_BT\right)}} \quad (2)$$

III. Results and Discussion

Here, we present a theoretical investigation of the interactions between confined acoustic vibrations and LSPs (Fig. 1, left) in the framework of resonant acoustic Raman scattering. We express the Raman scattering process in the framework of the Raman energy density (Fig. 1, center). Similarly to the Raman-Brillouin electronic density (RBED) introduced for semiconductors [3–4], this new physical quantity is used as a theoretical tool for the interpretation of resonant Raman scattering mediated by LSPs in metallic nanoparticles. The RED represents the electromagnetic energy density excited by the Raman probe and modulated by the acoustic vibrations of the nanoparticle. We show that,

similarly to the local density of optical states (LDOS) and the RBED, the RED is a local physical quantity that can be mapped in the near-field region. It provides a clear picture of the interaction between LSPs and acoustic vibrations which give rise to inelastic Raman scattering measurable in the far-field. Here, we use the newly introduced RED concept to investigate elastic (an)isotropy effects and calculate the Raman selection rules of spherical nanoparticles in a dielectric environment (Fig. 1, right).

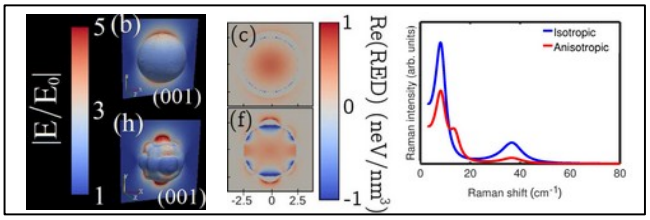

Fig. 1 Left: Isotropic (l=0) and Anisotropic (A1g) breathing acoustic mode of a AuNP modulating the near electric field induced par the dipolar localized surface plasmon (LSP). Center: Raman energy density (RED) resulting from the interaction of the l=0 and A1g vibration mode with the dipole LSP. Right: Calculated acoustic Raman spectra for the isotropic and anisotropic nanoparticles.

Lastly, the RED formalism is applied to nanoparticle-on-mirror (NPoM) nanocavities, which represent extreme cases of electromagnetic confinement [5]. In these systems, molecules confined within sub-nanometer gaps experience enormous field enhancement and strong optomechanical coupling. Using combined electrodynamic and elastodynamic simulations in the RED framework, we demonstrated that the dominant low-frequency Raman background arises from Lamb-type shear modes confined within the molecular layer (Fig. 2). These terahertz vibrational modes were previously unidentified and are comparable in strength to conventional molecular SERS peaks.

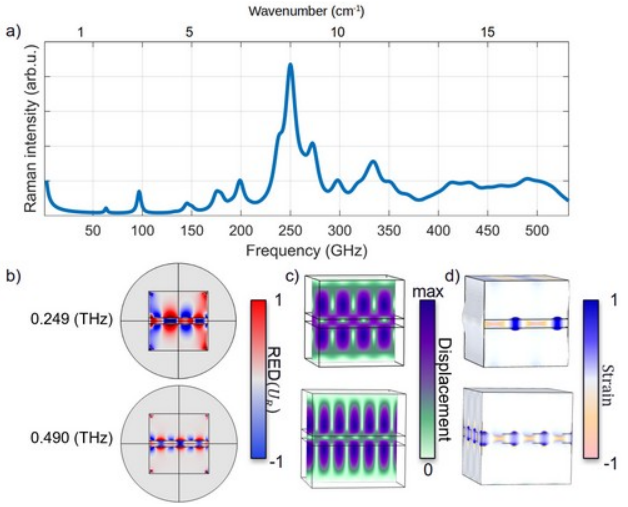

Fig. 1 Modelling of surface acoustic waves in nanogaps. (a) Raman spectrum computed from over 800 vibrational modes in the Au-BPT-Au system. (b) RED calculated for the two Lamb modes at 0.249 and 0.490 THz . Normalized displacement fields and strain are shown in (c,d) respectively. In (d) FEM model consists of a 1.1 nm BPT layer sandwiched between two gold slabs, each of side 5nm.

IV. Conclusion

Similar to the RBED previously introduced for semiconductors, the RED is used as a theoretical tool for the interpretation of resonant Raman scattering mediated by LSPs in metallic nanostructures. Analogous to the LDOS, it represents the electromagnetic energy density excited by the Raman probe and modulated by acoustic phonons. It is a local quantity mapped in the near-field which provides a clear picture of the acousto-plasmonic interaction involved in the far-field Raman scattering. It can predict the Raman (in)active modes, thus providing the Raman selection rules and open the door to study effects such as vibrational transfer, acouto-plasmonic hot-spots, acoustic SERS, and symmetry breaking will be investigated.

***Abstract*— We present our recent collaborative work on coupled hole and phonon dynamics in photoexcited germanium, which was studied by time-resolved Raman spectroscopy as well as by DFT calculations. Our time-dependent model based on DFT data can describe the observed changes in temperature of Raman-active optical modes on picosecond time scale.**

***Keywords*— electron-phonon interaction, DFT, Raman, semiconductors, phonon-phonon interaction, ultrafast**

I. Introduction

In recent years, progress in time-dependent computational approaches which couple density functional theory (DFT) – based description of the electron-phonon and phonon-phonon scattering rates with the time-dependent Boltzmann transport equations (t-BTEs) as well as progress in time-resolved spectroscopy experiments allowed unprecedented insight into coupled dynamics of hot carriers and phonons [1]. In this paper, we discuss our recent collaborative work on coupled hole and phonon dynamics in photoexcited germanium, which was studied by time-resolved Raman spectroscopy as well as by DFT calculations coupled with t-BTEs in two-temperature approximation.

II. Methods

From the experimental side, novel developments by the team of University of Basel [2] allowed to observe the temperature dynamics of Raman-active optical phonon modes in photoexcited Ge with unprecedented accuracy, and to quantitatively describe the phonon temperature rise due to the transfer of energy from photoexcited carriers, as well as subsequent temperature decay. From the theoretical side, in order to explain the observed dynamics, we have coupled DFT-based description of the carrier-phonon and phonon-phonon interactions with the t-BTEs for carriers and phonons [2].

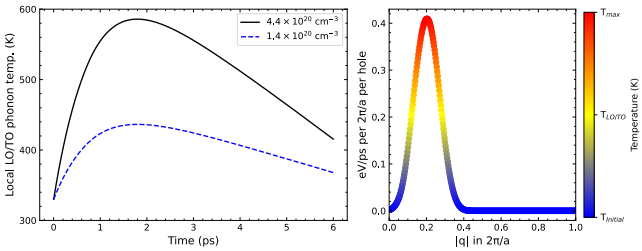

Fig. 1 From [2]. Dynamics of temperature rise of TO/LO modes calculated with time-dependent two-temperature model for carriers and phonons, coupled with DFT-based description of the hole-phonon and phonon-phonon coupling in Ge. Right: Hole-phonon energy transfer rate calculated with DFT as a function of phonon wavevector, which illustrates the localization in the Brillouin zone of the overheated optical modes. Left: Calculated local temperature rise of Raman optical modes due to hole-phonon interaction, for two values of hole densities. Subsequent decay into acoustical phonons is modeled with a calculated phonon-phonon decay rate of 2.5 ps.

III. Results and Discussion

According to the results of our calculations, the temperature rise of Raman optical phonons is attributed to the photoexcited hole dynamics: the dominant scattering process for photoexcited holes is intravalley scattering with optical phonons, that leads to the heating of Raman-active optical modes. In contrast, the dynamics of photoexcited electrons are mostly determined by the intervalley scattering [1], which explains why photoexcited electrons do not influence the dynamics of Raman-active optical modes. As seen in the right panel of Fig. 1, photoexcited holes transfer their energy only to phonons localized close to the Brillouin zone center, producing a strong rise in the local phonon temperature. The left panel of Fig. 1 shows our calculated phonon temperature dynamics. The calculated rise is found to occur on ps scale in agreement with experiments. The subsequent temperature decay with 2.5 ps rate is due to the decay of optical phonons into acoustic ones, also in very good agreement with experiments.

Keywords -acoustic phonons, nanophononic platform, Brillouin scattering

Abstract: The growing interest in acoustic phonon engineering in microstructures is driven by applications in optoelectronics, solid-state simulations, and quantum technologies [1]. In these platforms, the physical properties are governed by the coupled dynamics of charge and heat carriers. Therefore, for the manipulation of confined sub-THz acoustic phonons, it is crucial to understand the mechanisms governing the energy relaxation of photoexcited charge carriers. Brillouin spectroscopy is a powerful tool for probing acoustic phonon dynamics; however, it faces significant experimental challenges in ultrafast pump–probe configurations. In particular, detecting scattered signals spectrally close to the excitation laser is limited by the finite spectral bandwidth of ultrafast laser pulses, while the measurable signal corresponds to minute variations at extremely low photon fluxes.

In this work, we present advancements in an experimental scheme for time-resolved Brillouin spectroscopy in GaAs/AlAs-based Fabry–Perot optophononic resonators using single-photon detectors (SPDs). Our approach exploits a double optical resonance condition [2,3] in semiconductor planar cavities to simultaneously enhance Brillouin scattering excited by two pulsed laser sources. This scheme enables efficient spectral filtering of both Brillouin signals, making it compatible with single-photon detection experiments. The proposed setup provides a versatile platform for exploring the dynamics of confined phonons in engineered optophononic microresonators.

Plasmon-Enhanced Brillouin Light Scattering Investigations of Acoustoplasmonic Metasurfaces

Thomas Vasileiadis

Faculty of Physics and Astronomy, Adam Mickiewicz University,
Uniwersytetu Poznańskiego 2, Poznan, 61-614, Poland.
thomas.vasileiadis@amu.edu.pl

***Abstract*— Acoustoplasmonic metasurfaces (APMs) combine plasmonic and phononic resonances to enhance optomechanical interactions. This talk will present APMs offering plasmon-enhanced Brillouin light scattering (BLS) and optomechanics for propagating surface acoustic waves. Plasmon-enhanced BLS can result from plasmonic coupling between adjacent nanostructures or colocalization of plasmonic and acoustic fields on nanostructured surfaces.**

***Keywords*— metasurfaces, plasmonics, phononics, Brillouin light scattering.**

I. Introduction

Plasmons enhance Raman scattering by molecular vibrations, and enable molecular optomechanics in nanocavities. However, less emphasis has been given to plasmon-enhanced optomechanics for GHz acoustic phonons. For confined GHz vibrations, plasmon-enhanced Brillouin light scattering (BLS) and optomechanics can arise from plasmonic coupling between metallic nanoparticles [1]. Plasmon-enhanced BLS from surface acoustic waves (SAWs) requires nanostructured surfaces with plasmonic and phononic resonances, *i.e.*, acoustoplasmonic metasurfaces (APMs).

II. Methods

Plasmons, SAWs, and optomechanics were studied with finite element method calculations. The measured BLS intensity (I) depends on the optomechanical coupling constant, g_{OM}, according to $I \propto |g_{\mathrm{OM}}|^2$. The momentum-resolved, backscattering BLS spectra were recorded on- and off-resonance with the plasmons, using 660 and 532 nm wavelength of light (λ), respectively. The probed phonon wavenumber parallel to the APM surface ($k_{||}$) was $k_{||} = 4\pi \sin\theta/\lambda$, where θ is the angle of incidence.

III. Results and Discussion

Bottom-up synthesized APMs consisted of self-assembled Au nanoparticles (**Fig. 1a**, Ref. [2]). Top-down synthesized APMs consisted of 30 nm-thick Au, grown on a thermal SiO_2-on-Si wafer, and patterned with a square lattice of holes (**Fig. 1b**, Ref. [3]). The phonon-mode specific enhancement was captured with momentum-resolved BLS on- and off-resonance with the plasmons. Plasmonic coupling of nanoparticles enhanced low-frequency vibrational coupling modes, while colocalization of plasmons and SAWs near nanohole edges enhanced high-frequency modes (**Fig. 1c**) due to the moving interface effect.

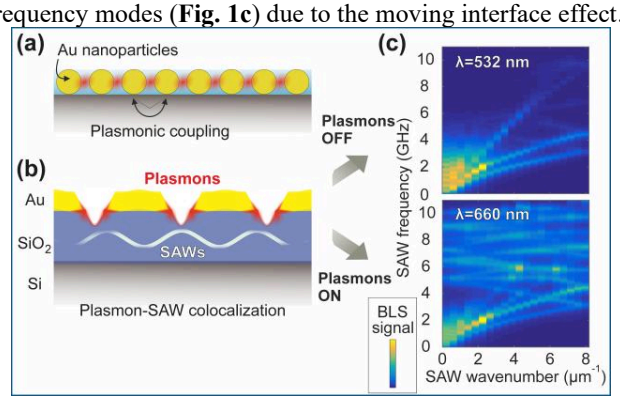

Fig. 1 Metasurfaces were synthesized with self-assembled plasmonic nanoparticles (a) or by perforating a Au/SiO_2/Si surface with nanoholes (b). In the latter case, the mode-resolved BLS (c) revealed enhanced optomechanical coupling of high-frequency SAWs.

IV. Conclusion

Electromagnetic field confinement on APMs enables the control of optical beams with mechanical vibrations [2],[3]. Our work paves the way for developing plasmon-enhanced optomechanical sensors and modulators operating at GHz frequencies.

Nanostructuration for Ultra-High Frequency Acoustic Wave Emission and Detection using Femtosecond Laser Pulses

Arnaud Devos*

1IEMN, UMR 8520 CNRS, Avenue Poincaré BP 69, 59652 Villeneuve d'Ascq, France

***Abstract*— Picosecond acoustics uses ultrafast lasers to generate and detect ultra-high-frequency acoustic waves, which are ideal for thin-film characterization, but is inherently limited to longitudinal modes. To overcome this limitation, we have developed two distinct nano-structuring approaches that enable transverse wave generation, along with adapted optical detection schemes.**

***Keywords*—picosecond acoustics, transverse waves, phononic crystals.**

I. Introduction

Picosecond acoustics has been widely used to study thin film elasticity, hypersound attenuation, and adhesion of thin films to substrates[1-3]. A major limitation of the technique is its restriction to only longitudinal waves. And this is a problem for accessing to elasticity since it is governed by several constants that require the measurement of speed of sound of several types of waves. Previous work has shown that it is sometimes possible to get around this limitation[4], but always in specific sample configurations. In particular, it was impossible to generalize to thin-film samples on silicon, the basic geometry for applications.

In recent years, we have explored two approaches to overcoming this difficulty. One approach involves using a 2D phononic crystal deposited on top of the sample to be characterized, which acts as a surface acoustic wave (SAW) transducer[5]. The other approach is based on using a thin, nanostructured metal film made of tilted columns, which allow for the direct emission of bulk transverse waves[6]. We examine both approaches in the following, discussing the particular optical detection needed in each case.

II. 2D Phononic Crystals as SAW Transducers

Our initial motivation was to study the elastic properties of artificial crystals made of 2D ensemble of nanocubes. When illuminated by a laser pulse, two types of acoustic mode are expected: individual modes of the cubes which originate from the eigenmodes of the isolated cube. As the cubes are organized in a lattice, each of these modes becomes a band that is more or less flat depending on the coupling between dots [7]. A second class of modes is also expected, with a much more lower frequency. We elaborated such crystals made with 200 nm cubes with different lattice symmetries and parameters (see Fig. 1), and studied the acoustic modes in the time-domain. In particular, we demonstrated that these phononic crystals act as SAW transducers: the low-frequency or collective modes are SAWs emitted in various directions, as determined by the crystal symmetry. In the time domain, several frequencies are detected and we show that they correspond to the same SAW mode but propagating in different directions. This is illustrated in Fig. 1, in which we plot the measured frequencies for several lattice parameters a. As these frequencies correspond to the same mode, but are emitted in different directions, remarkable ratios exist between them. By measuring the response of the sample for different lattice parameters, it is possible to build the dispersion curve from which the speed of sound of the Rayleigh mode can be deduced in case of an infinitely extended lattice, in other words, the Rayleigh of the sample without cubes. By performing an usual longitudinal measurements on the same layer, we obtain two sound velocities from which we deduce the Young modulus and Poisson ratio of the film[5].

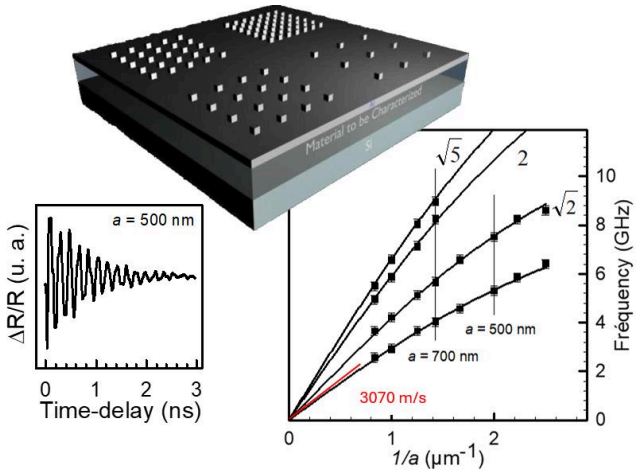

Fig. 1 Artificial crystals made of 200 nm Al nanocubes with various lattice parameters a deposited on top of a silica layer. Such a nanostructuration allows the emission/detection of very high

frequency surface acoustic waves.

This protocol requires extensive and costly sample preparation, as it uses electronic beam lithography. Indeed, the lattice parameter must be as small as possible in order to confine the SAW in the layer to be characterized, thus avoiding the need for simulation to eliminate the substrate contribution. Despite this, the technique has known quite a great success as measuring the Young modulus and Poisson ratio on layer as thin as 150 nm is very challenging.

To extend the process to thinner and thinner films, crystals with smaller and smaller lattice parameters are required. If the same technology can be used to prepare smaller dots (typically 50 nm) and arranged in a more denser lattice (typically spaced by 100 nm), the usual optical setup cannot detect a signal. Indeed, optical detection of SAWs is limited by the probe wavelength, which must be smaller than or comparable to the lattice step. One way to characterize thinner films is therefore to use shorter wavelengths. This is what we did by exploring the capabilities of picosecond acoustics in the middle UV using a probe beam obtained by tripling the femtosecond laser source (around 266 nm)[8]. Then, we demonstrated that it is possible to overcome the limitation related to the diffraction of the probe light by the lattice, by using an interferometric detection[9]. In that case, SAW as high as 25 GHz have been measured in a 50 nm AlN film.

III. Nanostructured Metal Transducer

In a second approach, a thin, nano-structured metal film consisting of tilted columns is deposited on top of the layer to be characterized. Originally, our goal was to focus on the characterization of a thin, transparent film deposited on silicon.

Thanks to its columnar geometry, the laser light excites longitudinal and bulk transverse waves in the metal film. Both types of wave are detected in the transparent layer using the Brillouin oscillation mechanism. Several conditions are required for this to happen. Firstly, the nanostructured metal film must be thin enough to allow the probe light to penetrate the sample. Secondly, in order to detect transverse wave, an optical setup must be modified to be sensitive to any change in the probe polarization. Fig. 2 illustrates this in the case of a 3 µm thick SiC layer grown on Si(100).

After t=0, acoustic waves are emitted from the top metal film and penetrate the transparent layer. As the metal film is sufficiently thin, the propagation can be detected by the probe light through an acousto-optic mechanism, known as the Brillouin oscillation. At around 300 ps, the longitudinal pulse reaches the Si substrate and the typical Si signature is detected[9]. The Fourier transform of the signal between 0 and 300 ps reveals two peaks: the peak around 150 GHz corresponds to the longitudinal mode and the one below 120 GHz corresponds to the transverse frequency.

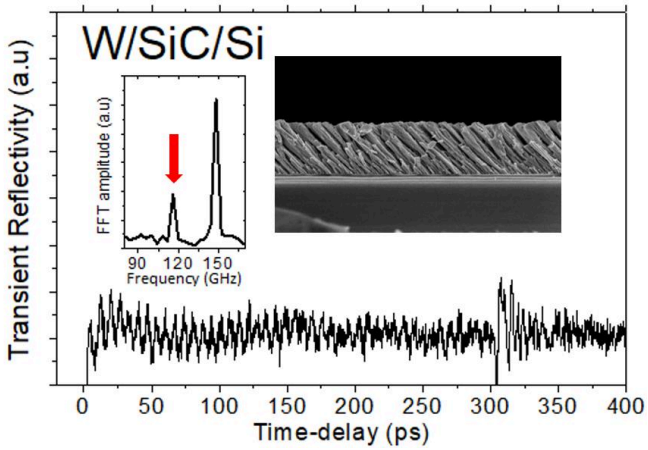

Fig. 2 Time-resolved reflectivity measured on a W/SiC/Si sample, where W is a thin nano-structured Tungsten film The texture of such a metal film is illustrated in the SEM image (400 nm thick W).

We have demonstrated this capability in a wide variety of transparent materials, using different metals, such as Ti, Mo, and W. One major advantage of this approach is that the sample preparation can be made using a standard deposition tool. Although the protocol was originally developed for thin transparent film, it can be easily extended to opaque films, in which no Brillouin oscillation can be detected. In that case, the transverse time of flight in the layer is measured by detecting a returning transverse echo in the nanostructured film itself.

IV. Conclusion

We have developed two approaches to extend picosecond acoustic characterization to transverse waves, combining specific sample preparations with modifications of the optical detection. Using 2D artificial crystals as SAW transducers. Optical detection in this case requires a short wavelength or an interferometric detection. Using a nanostructured metal film composed of tilted columns, which is capable of emitting both longitudinal and transverse bulk waves. Detection must be adapted to be sensitive to change in light polarization.

Thermal Metamaterial Design for Phonon Heat Management at Low Temperature

Boris Brisuda[1], Jon Canosa Diaz[2], Thierry Crozes[1], Jean-François Robillard[2], Olivier Bourgeois[1,*]

[1]Institut NEEL, CNRS and UGA, 25 avenue des Martyrs, 38042 Grenoble, France

Abstract **This study explores nanoscale phonon (heat) flux control—critical for quantum tech and thermal management. Using a nanostructured SiN ribbon with staggered triangles, we demonstrated thermal rectification at 900 mK; the heat flow being favored toward triangle tips which seems to be related to ballistic phonon flow in anisotropic structures.**

Keywords**- thermal metamaterials, phonons, thermal bridge method, nanostructuration, phononic crystal, thermal rectification.**

I. Introduction

The manipulation of phonon fluxes (or heat management) is becoming essential in many important situations like energy harvesting using thermoelectric materials, evacuation of heat flows, thermal balance in qubits etc… In all these cases, controlling the flux heat through phonon flow is mandatory, especially at the nanoscale. Here, we will illustrate this through many experiments where the transport of phonons is measured at the nanoscale. Indeed, using advanced nanostructuration, thermal transport is studied in nanowires, nanomembranes, 2D materials or thermal metamaterials, one of the major challenges of the current nanoscale energy management from room temperature to very low temperature (down to 50 mK).

II. Sample design

The studied systems are designed in such a way that temperature gradients can be applied across a nanostructured sample in both directions. The idea of the thermal bridge experiment is to allow establishing temperature differences across a nanostructured sample. As shown in the Fig. 1, the suspended thermal bridge is shown with the sample connecting the two platforms. The major advantage of the two symmetric platforms is to ensure the ability to establish identical temperature difference across the sample but with an opposite sign to probe thermal rectification [1]. The sample is an array of staggered triangles of the following edge dimension of 300 nm.

In order to perform very sensitive measurement of temperature, highly sensitive niobium nitride thermometry is used with two NbN transducers installed on each membrane [2]; this will help to precisely control the temperature profile over each platform [3].

III. Thermal bridge methods

Our methodology for measuring the heat rectification consists in comparing the two heat fluxes in forward (a->b) and reverse (b->a) directions for identical amplitude of temperature difference across the sample (see Fig. 2). The rectification ratio is given by this equation:

$$\eta = \frac{\Phi_{sample}^{a\to b} - \Phi_{sample}^{b\to a}}{\Phi_{sample}^{a\to b}}$$

Where $\Phi_{sample}^{a\to b}$ the larger flux and $\Phi_{sample}^{b\to a}$ the smaller flux to ensure that η will be between 0 and 1. The determination of the heat flux through the nanostructured sample requires precise measurement of the thermal conductance to heat bath.

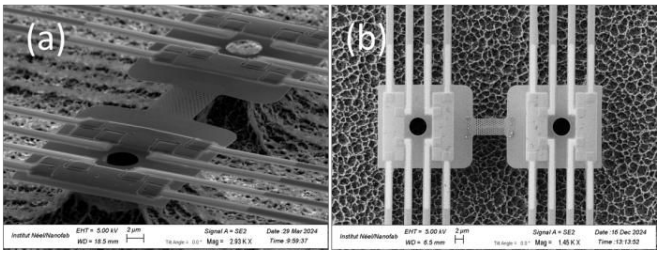

Fig. 1 Suspended double platform and nanostructured sample. On each platform two transducers allow the fine control of temperature over a broad temperature range from 50 mK to 5 K.

These measurements have been done at very low temperature where thermal properties of (nano)materials become of significant interest [3,4]. The ratio between the thermal flux flowing through the sample and the one flowing to the heat bath

is on the same order of magnitude, the ideal range for optimized sensitivity.

IV. Results and Discussion

The experimental results obtained at 900 mK are presented in Fig. 2 where the heat flux is represented as a function of the temperature difference between the two membrane temperatures T_1 and T_2. In the case of the red squares, the temperature gradient has been established from a to b. As for the measurement of black dots the temperature gradient has been reversed for b to a. When comparing the two heat fluxes with opposite directions, we can clearly see the differences; the flux in the a to b direction being much larger than the one from b to a direction. The flux pointing to the tip of the triangle is favored, demonstrating thermal rectification in such dissymmetric phononic crystal. The rectification factor η is between 0.1 and 0.2.

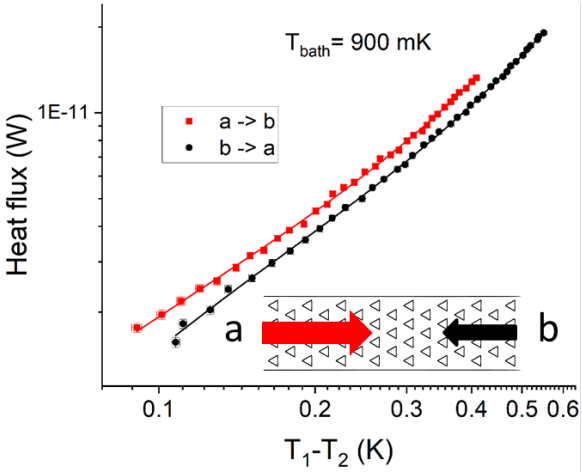

Fig. 2 Heat flux measured as a function of the direction of temperature difference at 900 mK bath temperature.

The rectification effect may arise not only from the asymmetry of the sample but also from inherent non-linearities in the systems, like the temperature variation of all the thermal properties of the sample (heat capacity and thermal conductance).

V. Conclusion

We have set-up a thermal bridge experiment to probe potential thermal rectification effect in nanostructured ribbons of SiN. We have demonstrated thermal rectification at 900 mK in a thermal metamaterial in the limit of phonon ballistic limit. The sample is a nanostructured SiN ribbon with an array of staggered triangles. The phonon flow is favored in the a to b direction pointing to the tip of the triangles. More investigations are required to clearly demonstrate the origin of the phenomena, especially by measuring over a broader temperature range. We also plan to investigate theoretically this effect by modelling the phonon transport is such nanostructure at very low temperature in the ballistic regime.

Mastering thermal management at the nanoscale and at cryogenic temperature is of major importance for all the enabling quantum technologies to ensure proper thermalization process [5-7].

Acoustic Phonons, Vibronic Coupling, and Room-Temperature Super-Radiance in Engineered, Icosahedral Virus Capsids

Bogdan Dragnea[1,*]

[1]Department of Chemistry, Indiana University – Bloomington, USA
*Corresponding author: dragnea@iu.edu

***Abstract*—Molecular dyes covalently bonded to the confines of a symmetric viral capsid can spontaneously synchronize after simultaneous excitation, producing a burst of super-radiant fluorescence, at room temperature, in solution. The underlying mechanisms enabling the accelerated, collective emission at room temperature—despite the presence of collisional dephasing and inhomogeneous broadening—remains unresolved. In other low-dimensional condensed matter systems where room-temperature superradiance has been observed, vibronic coupling between phonons and electronic states is thought to be crucial. Guided by this observation, we investigated experimentally the presence of underdamped phonon modes in virus capsids. Our results suggest that the electronic state responsible for super-radiant emission is coupled to long-lived, acoustic modes of the capsid. The frequencies of these global modes suggest significantly greater stiffness at high frequencies than one might expect from quasi-static mechanical measurements. Building on these insights, we propose a vibronic coupling model that outlines key design parameters for future implementations of super-radiant bioengineered nanoparticles in applications.**

***Abstract*—Silicon carbide (SiC) is an outstanding platform for high-quality nanomechanical resonators, combining intrinsic material quality with the possibility of dissipation dilution engineering. We compare resonators made of 4H-SiC and 3C-SiC, demonstrating routes to ultrahigh Q-factors, suitable for spin-mechanics and spin-cavity optomechanics applications.**

***Keywords*— nanomechanical resonators, silicon carbide, quality factor, dissipation dilution.**

I. Introduction

Nanomechanical resonators with ultrahigh quality factor (Q) are at the forefront of quantum sensing, quantum transduction, and hybrid quantum systems. The quality factor, a dimensionless measure of energy storage relative to dissipation, determines both the coherence time and the force sensitivity of a mechanical oscillator. Silicon carbide (SiC) is an exceptionally attractive material for such resonators, combining extraordinary mechanical stiffness and low intrinsic damping with a rich set of functionalities including integrated spin defects. SiC exists in multiple polytypes, most notably the hexagonal 4H-SiC and the cubic 3C-SiC, each offering distinct pathways towards high quality factors.

II. Intrinsic Quality Factors in 4H-SIC

Hexagonal 4H-SiC is a well-established material in nanophotonics and power electronics, and is considered an emerging material platform for nanomechanical systems. This is a consequence of its large Young's modulus (~450 GPa) and its high intrinsic quality factor. Nanomechanical resonators monolithically fabricated from high-purity semi-insulating 4H-SiC wafers yield intrinsic quality factors exceeding 10^5 at room temperature. Crucially, 4H-SiC hosts highly coherent spin defects, such as the silicon vacancy and the divacancy, whose spin states can be initialized and read out optically. The co-integration of these atomic-scale qubits with high-Q mechanical resonators in a monolithic platform is a key asset for realizing spin-mechanics experiments and spin-cavity optomechanics [1].

III. Dissipation Dilution Engineering in 3C-SIC

Cubic 3C-SiC, grown epitaxially as a thin film on silicon substrates, offers a complementary route to ultrahigh Q-factors through the mechanism of dissipation dilution [2]. Epitaxial growth of 3C-SiC on Si(111) substrates naturally incorporates strong biaxial tensile pre-stress, in the SiC film. Nanomechanical string resonators fabricated from this material exhibit a tensile stress of several GPa [3,4]. This results in significant dissipation dilution, boosting the measured Q-factor beyond its intrinsic value [5,6] and enabling Q x frequency products approaching 10^{13} Hz at room temperature. The thin-film geometry is furthermore amenable to hierarchical clamping designs and soft-clamped phononic crystal patterning, techniques that have proven highly successful in silicon nitride membranes [6] and which we now translate to the SiC material platform.

IV. Results and Discussion

We present a systematic comparison of nanomechanical resonators fabricated from both 4H-SiC and 3C-SiC, with device geometries ranging from singly-clamped cantilevers over doubly-clamped nanobeam and -strings to optomechanical crystals, a combined photonic and phononic crystal slab with a co-localized defect cavity. We perform a thorough material characterization, enabled by the high-throughput characterization and statistical analysis of many modes. For both materials, we discuss the Young's modulus, residual tensile stress and intrinsic quality factor, and identify the limiting dissipation mechanisms. For 3C-SiC, we experimentally determine the dissipation dilution factor. This comprehensive analysis allows to point out pathways towards the mitigation of the dominant loss channels, paving the way towards further enhanced quality factors.

V. Conclusion

Silicon carbide represents a uniquely versatile material platform for approaching ultimate quality factors in nanomechanical resonators. The hexagonal 4H polytype enables monolithic, defect-integrated devices with high intrinsic Q, while the cubic 3C polytype harnesses dissipation dilution from epitaxial tensile stress to surpass intrinsic limits. Together, these two material routes

establish SiC as a leading contender for the realization of macroscopic quantum states of mechanical motion and for next-generation hybrid quantum devices combining mechanical, spin, and photonic degrees of freedom.

***Abstract*—We examine how disorder and localization shape vibrational energy transport in finite networks. A multiterminal conductance framework reveals sparse communication backbones whose reorganization under small perturbations produces switch like responses without thermodynamic criticality. The same physical picture connects disordered solids, metamaterials, and allosteric proteins.**

***Keywords*— phonons, localization, disorder, energy transport, allostery.**

I. Introduction

Wave transport in disordered matter is intrinsically heterogeneous. Disorder, interference, and mode mixing generate broad distributions of amplitudes, relaxation times, and mean free paths, blurring the distinction between propagating, diffusive, and localized vibrations [1], [2]. The central issue is therefore not only how much transport survives disorder, but how the surviving transport is organized in space.

This question is especially acute in finite systems. Macroscopic switch-like responses are usually associated with symmetry breaking or critical thresholds, yet finite heterogeneous networks cannot access such singular limits. Still, many display abrupt and cooperative behavior. We argue that this regime can be understood by viewing transport not as a bulk coefficient, but as a structured network process.

II. Multiterminal transport and sparse vibrational backbones

A natural description is provided by a multiterminal framework, in which transport is resolved into pairwise energy-exchange channels between nodes or functional units. In the harmonic or near-equilibrium regime, this leads to effective couplings

$$Q_{ij} = \int_0^\infty \frac{g_i(\omega)\, g_j(\omega)}{\sum_k g_k(\omega)}\, d\omega, \qquad . \tag{1}$$

where $g_i(\omega) = \sum_\mu |\psi_\mu(i)|^2\, \delta(\omega - \omega_\mu)$ is the power spectral density of of atomic sites at i and j. Rather than a single effective conductivity, one obtains a transport map that reveals where energy exchange concentrates and which links dominate communication. Recent work showed that this mode-resolved quantum–Langevin formalism provides a transparent multiterminal theory of coherent phonon transport in complex networks [3].

Its main implication is conceptual: in heterogeneous structures, transport is typically sparse and anisotropic. A small subset of channels carries a disproportionate fraction of the total flux, much as force chains dominate granular load transmission or marginal backbones dominate response near connectivity thresholds. Localization should therefore not be viewed only as transport suppression, but as a mechanism that organizes transport into a structured backbone.

III. Switching without thermodynamic criticality

Once transport is backbone-dominated, weak local perturbations can produce large system-level effects. It is not necessary to modify the whole network uniformly; altering a bottleneck or bridge is sufficient to reroute energy flow globally. Finite switch-like behavior can then emerge without singularity, diverging correlation length, or genuine phase transition. The mechanism is instead a finite-size crossover sharpened by heterogeneity and by the sparsity of dominant transport paths.

This viewpoint suggests an alternative strategy for wave-based metamaterials: rather than relying solely on global spectral gaps or resonant selection, one may engineer architectures whose function is controlled by selective rewiring of internal energy routes.

IV. From disordered solids to proteins

Biological macromolecules offer a striking realization of this physics. Proteins are finite, anisotropic, and disordered elastic networks with broad vibrational spectra, making them natural candidates for backbone-dominated transport [4], [5]. In this language, allostery becomes a transport problem: the relevant question is how a local perturbation reorganizes the network of vibrational exchange linking distant functional sites.

Hemoglobin provides a paradigmatic example. Successive ligation events do not merely populate effective conformational states [6]; they also reweight intersubunit communication pathways. The resulting cooperative response can be interpreted as the cumulative rewiring of a sparse vibrational backbone, producing a marked yet rounded switch in a system far too small to exhibit conventional criticality.

V. Conclusion

Disorder does more than degrade transport. By generating heterogeneous vibrational landscapes, it creates sparse communication backbones that can be exploited for control. A

multiterminal description makes these backbones visible and provides a general framework for understanding strong switch-like responses in finite disordered networks, from phononic structures to biological macromolecules.

***Abstract*— Heat transport at the nanoscale and in nanoscale materials can differ from conventional, diffusive heat transport. Here we use spatiotemporal microscopy to follow heat in space and time and observe highly viscous heat transport in two-dimensional semiconductors toward the monolayer limit, which we attribute to combined hydrodynamic and thermoelastic effects.**

***Keywords*— 2D materials, heat transport, nanoscale, hydrodynamic, thermoelastic.**

I. Introduction

Understanding and – ideally – controlling heat transport in materials is important both from a fundamental and an applied standpoint. This is particularly true at the nanoscale, where novel fundamental heat transport phenomena can occur and where hotspots can emerge that can lead to device failure.

Two-dimensional (2D) semiconducting materials, such as MoS_2, are also interesting both from a fundamental and an applied standpoint. They have several fundamentally different properties compared two their three-dimensional counterparts, such as extremely high exciton binding energies, which dictate many of their optical properties. And for applications, there are several leading roadmaps that project that they will be used in transistors for future logic.

We studied heat transport in $MoSe_2$ and MoS_2 and observed highly non-diffusive transport. We identified the origin of this non-diffusive behavior as a combination of hydrodynamic and thermoelastic effects, thus unravelling a novel "hydro-thermoelastic" heat transport regime [1]. Whereas hydrodynamic transport in MoS_2 had been predicted [2], this had so far not been observed. Moreover the interplay between hydrodynamic and thermoelastic effects had so far not been addressed in any material. Importantly, the observed non-diffusive "hydro-thermoelastic" heat transport regime is controllable via material thickness and heating mode – pulsed *vs.* continuous.

II. Methods

The technique that we used to observe heat transport is spatiotemporal pump-probe microscopy [3,4], which makes it possible to follow heat spreading directly in space and time with ~100 femtosecond temporal and ~10 nanometer spatial accuracy. In particular, we probed near the exciton absorption peak, whose linewidth depends on temperature [5], thus giving us a high temperature sensitivity with a thermoreflectance coefficient on the order of 10^{-4} K^{-1}, which means that we can observe sub-Kelvin changes in temperature [6].

We used suspended single-crystalline flakes of $MoSe_2$ and MoS_2 of varying thickness, prepared via exfoliation and PDMS-assisted transfer, following Ref. [7]. The suspended region had a diameter of 15 μm.

III. Results and Discussion

The experimental results showed that upon decreasing the thickness of the 2D semiconducting materials, the effective diffusivity decreased by an order of magnitude. This only occurs under pulsed heating, as probed using spatiotemporal pump-probe microscopy, and not under continuous heating, as probed using Raman thermometry. Indeed, our earlier Raman thermometry study showed very little change in the thermal conductivity of $MoSe_2$ even in the monolayer limit [8].

In order to understand these results, we developed a mesoscopic model that extends the Guyer-Krumhansl description of hydrodynamic heat transport [9] to include out-of-equilibrium thermoelastic effects. As input parameters for the model, we used values from *ab initio* calculations. This model accurately predicts the observed experimental results without any freely adjustable fit parameters.

IV. Conclusion

We have demonstrated a novel non-diffusive "hydro-thermoelastic" heat transport regime, where hydrodynamic and thermoelastic effects jointly lead to highly viscous heat transport, which is controllable via material thickness and heating mode. These results pave the way for unprecedented control over heat transport pathways in the industrially promising material platform of 2D semiconductors and beyond.

We report the investigation of phonon dynamics in nanophononic membranes with square and rectangular lattices of holes, at phonons wavelengths comparable with the nanostructure lengthscale. We unveil the signature of lattice anisotropy both on phonon energies and lifetimes, and identify its microscopic origin at the light of finite element simulations.

***Keywords*— nanophononic materials, extreme ultraviolet transient grating, phonon lifetime, phonon coherence**

I. Introduction

Nanophononic materials are characterized by a periodic nanostructuration,which may lead to coherent scattering of phonons, enabling interference and resulting in modified phonon dispersions. Recently, we have invetsigated phonon frequencies and lifetimes in a low-roughness nanoporous phononic membrane of SiN at wavelengths between 50 and 100 nm, comparable to the nanostructure lengthscale. We have revealed a drastic phonon lifetime reduction upon nanostructuration, which has been explained as due to a strong interference of the phonon with its own reflections at periodic interfaces. This mechanism becomes dominant for phonon wavelengths comparable to the holes lattice period and neck (inter-holes distance) [1]. In this work, we pursue our understanding of interference effects on phonon dynamics by investigating the orientation dependence of phonon energy and lifetime in SiN membranes with a square and a rectangular lattice of holes.

II. Methods

The study has been performed on commercially available suspended membranes of LPCVD amorphous SiN, provided by Norcada Inc. (Edmonton, Canada). The membranes were 55nm thick. For the square lattice, the period was 377 nm, and the hole diameter 124 nm, averaged along the thickness. For the rectangular lattice, the long period was 377 nm, the short one 179.6 nm, and the average hole diameter 105 nm. We used the extreme ultraviolet transient grating (EUV TG) technique at the TIMER beamline of the FERMI free electron laser (Trieste, Italy).

III. Results and Discussion

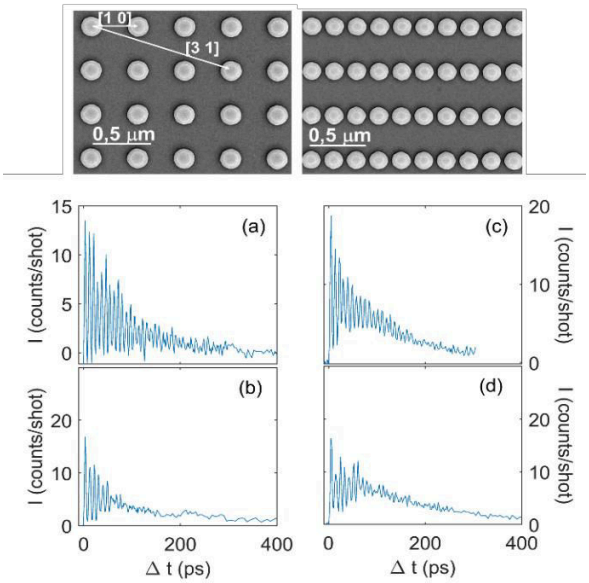

Fig. 1 Transient grating signal for a phonon wavelength 84 nm in the two nanostructures on the top. Left column: square lattice. (a): [1 0] direction; (b): [3 1] direction. Right column: rectangular lattice. (a): long period direction; (b): short period direction

We have measured phonon dynamics in the two membranes, as a function of orientation, including low symmetry directions, such as the [3 1] in the square lattice (see Figure). We observe a strong dependence of both phonon energy and lifetime on the orientation in both lattices. This anisotropy may be understood in terms of a modification of coherent phonon interference with the geometry.

***Abstract*—We investigate surface acoustic wave–induced ferromagnetic resonance in magnetic thin films. By measuring the magnetic-field and angular dependence of Rayleigh SAW velocity variations, extract the magnetoelastic coupling. A non-reciprocal acoustic response is also observed at resonance, highlighting the potential of tunable magnetoelastic devices.**

***Keywords*— magnetoacoustic, magnonic.**

I. Introduction

Magnon straintronics enables voltage control of spin-wave (SW) amplitude and phase through strain-mediated magnon–phonon coupling, offering promising perspectives for beyond-CMOS technologies. Surface acoustic wave–induced ferromagnetic resonance (SAW-FMR) provides a powerful platform to probe this interaction.

II. Methods

We investigate SAW-FMR in epitaxial Fe thin films grown on GaAs(001) [1,2], forming a magnetoelastic/piezoelectric heterostructure compatible with spintronic and magnonic devices (Fig. 1). We introduce an original method to tune and quantitatively determine the magnetoelastic coupling constant in pristine and nitrogen-implanted Fe films. After determining the magnetocrystalline anisotropy by standard magnetic characterization, we extract the magnetoelastic constant from the magnetic-field and angular dependence of Rayleigh SAW velocity variations.

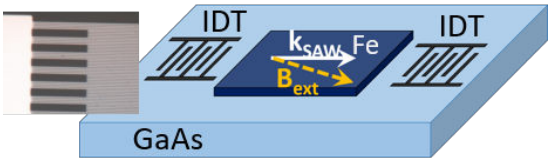

Fig. 1 Sketch of the sample: The Fe mesa is 54 nm thick on GaAs(001). The wave vector $\mathbf{k}_{SAW}$ is parallel to [110], the Fe magnetic hard axis, $\mathbf{B}_{ext}$ is the in-plane applied magnetic field.

III. Results and Discussion

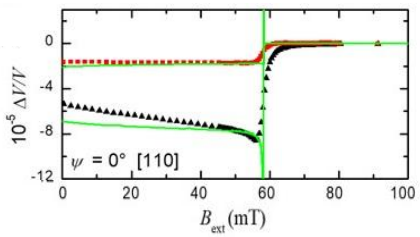

Fig. 2 Relative variation of the SAW velocity V measured versus decreasing amplitude of the external field. The magnetic field $\mathbf{B}_{ext}$ is applied in the film plane, parallel to the [110] direction (hard axis, ψ = 0◦)

Experimental results show: resonant coupling, SAW-FMR for a particular configuration when the magnetic field $\mathbf{B}_{ext}$ is applied in the film plane, parallel to the [110] direction and $\mathbf{k}_{SAW}$ propagation (Fig. 2). A phenomenological model derived from the Landau–Lifshitz–Gilbert formalism, including calculated SW dispersion relations, accurately reproduces the field dependence of SAW velocity vs angles between SAW propagation direction and $\mathbf{B}_{ext}$ in both pristine and implanted samples. From this calculation the magnetoelastic constant B_2 was extracted (Fig. 3) [3].

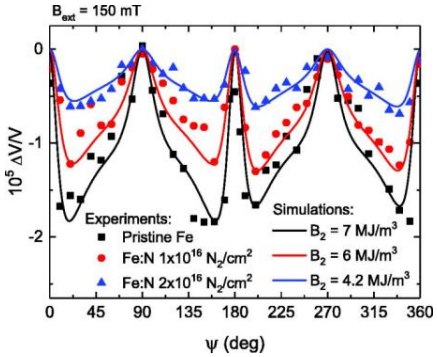

Fig. 3 SAW relative velocity variation as function of the angle between $\mathbf{k}_{SAW}$ and $\mathbf{B}_{ext}$ for pristine Fe, intermediate and highest doped Fe:N at = 150 mT.

IV. Conclusion

We have observed an almost twofold reduction of the magnetoelastic coupling constant at a nitrogen dose of 2×10^{16} N_2/cm^2, as well as a non-reciprocal acoustic response at resonance, highlighting the potential for tunable and non-reciprocal magnetoelastic devices.

***Abstract*— Nanophononic metamaterials are key components for controlling acoustic signals in nanotechnology. Here, we present automated, algorithm-driven strategies for realizing phononic metasurfaces based on inverse-design and hyperuniform architectures. The resulting designs are fabricated and experimentally characterized, validating the predicted phononic properties and demonstrating the effectiveness of algorithm-designed metastructures.**

***Keywords*— metamaterials, nanophononics, inverse design, phononic crystals**

I. Introduction

Controlling acoustic properties at the nanoscale is crucial across a wide range of fields, from thermal transport and mechanical resonators to nanosensing and quantum technologies. In this context, phononic crystals have emerged as efficient metamaterials for tailoring the propagation of acoustic waves [1]. These structures are typically implemented by patterning a membrane or depositing pillars on the surface of a substrate. However, the design of such structures still largely relies on conventional geometries and simple rules guided by human intuition. To overcome this limitation, algorithm-based design strategies have been proposed and explored theoretically [2]. To translate these approaches into real-world devices, the fabrication feasibility must be explicitly incorporated into the optimization process. Here, we present the results of two studies investigating nanophononic metasurfaces for controlling acoustic wave propagation designed using different algorithmic approaches. The resulting designs are fabricated into experimental devices, whose characterization demonstrates the effectiveness of algorithm-designed phononic structures.

II. Methods

The design algorithms presented in this talk are based on two strategies. First, we employ a genetic algorithm that mimics Darwinian evolution to optimize a quasi–two-dimensional silicon phononic metasurface over successive generations (Fig.1) [3]. The optimization follows the principle of survival of the fittest with respect to a selected property – in this work, the chosen property corresponds to the anisotropy of acoustic wave propagation. At each generation of phononic structures, only those that maximize the acoustic anisotropy are allowed to transmit their genes, i.e., their design parameters, to the next generation.

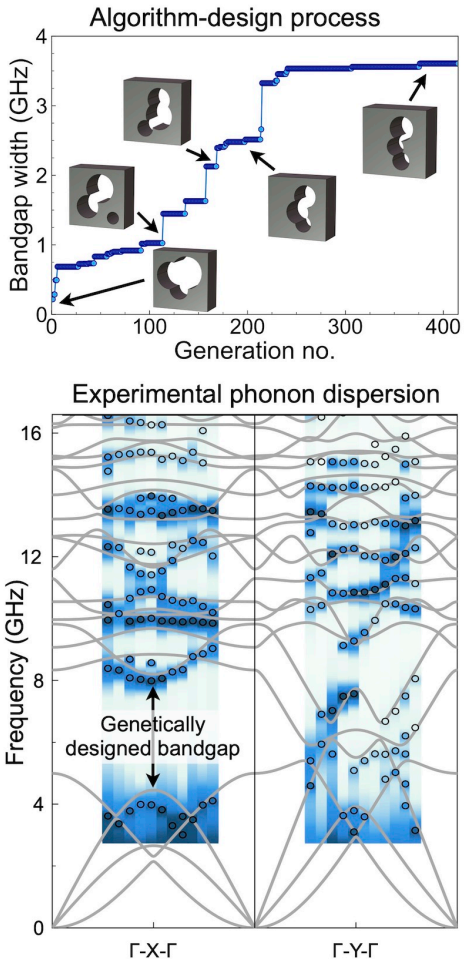

Fig.1 Top: Optimization of the unit cell of the algorithm-designed phononic metasurface. Bottom: Experimental phonon dispersion (color and circles) vs theoretical prediction (solid lines).

The second metasurface is obtained by depositing gold nanopillars on a piezoelectric substrate [4]. The position of the pillars is driven by an algorithm to achieve a hyperuniform distribution, while their shape is defined by a Voronoi tessellation (Fig.2). The interest in hyperuniform structures stems from their unique nature as systems with properties in between ordered and disordered systems, allowing them to combine characteristics of both, such as the presence of bandgaps and resilience to defects.

For both the genetically-designed and the hyperuniform metasurfaces, fabrication constraints are taken into account within the automated design process, allowing us to fabricate the devices by nanoscale cleanroom techniques. Finally, the two structures are characterized using, respectively, Brillouin light scattering spectroscopy and interdigital transducer techniques.

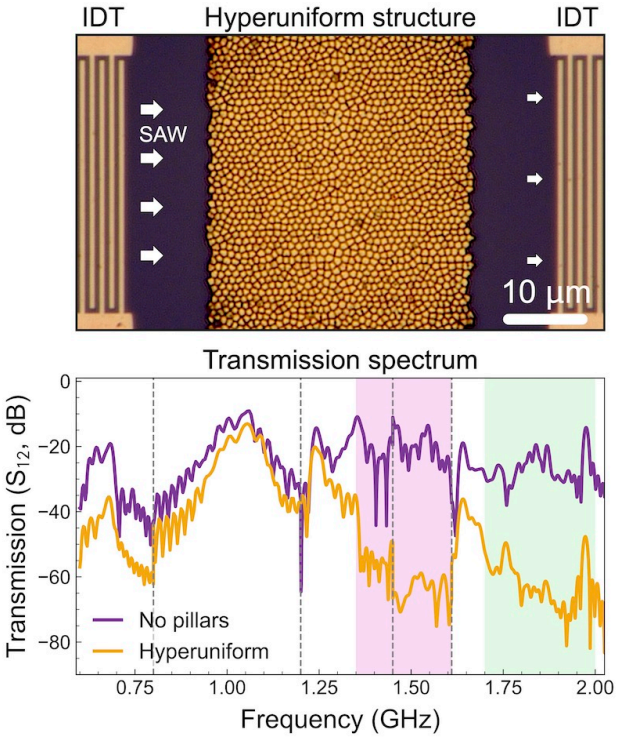

Fig. 2. Top: Hyperuniform metasurface with interdigital transducers (IDTs) on the side for generation/detection of acoustic waves (SAW). Bottom: Experimental acoustic transmission in the presence and absence of the hyperuniformly distributed pillars.

III. Results and Discussion

For the genetically designed phononic metasurface, we measured its phonon dispersion relation and compared it with the prediction obtained from finite-element simulations. The good agreement between experiment and theory confirms the optimized strong anisotropy of the structure, characterized by a large unidirectional bandgap (Fig.1).

For the hyperuniform structure, we observe a broader attenuation of surface acoustic wave transport compared to conventional pillar-based phononic crystals, which typically suppress acoustic waves only within narrow frequency ranges (Fig.2). This behavior is explained by calculating the phononic mode density of states, which shows that the hyperuniform distribution, together with the Voronoi tessellation, broadens the density-of-states peaks and results in broadband acoustic wave attenuation. Finally, we further investigate waveguiding effects for different waveguide shapes by removing pillars from the hyperuniform metasurface. The waveguide structures exhibit high-transmission acoustic modes, demonstrating the effectiveness of hyperuniform devices in supporting acoustic waveguides.

IV. Conclusion

We experimentally realized two examples of phononic metasurfaces for acoustic wave control designed using automated algorithms. The first device is based on genetically designed nanopatterning of a quasi-two-dimensional membrane, while the second relies on hyperuniform nanopillars on a piezoelectric substrate. Both devices exhibit good agreement with the expected phononic properties, showing the effectiveness of the algorithm-based design approach.

***Abstract*—Metallic mechanical nanoresonators' performances are often limited by their strong acoustic damping. Here, we conduct optical pump-probe time-resolved spectroscopy to study the vibrational dynamics of single gold nanodisks supported on different solid substrates. We study the impact of the nanoresonators' morphology, the substrate composition and thickness on these dynamics.**

***Keywords*— Time-resolved spectroscopy, Plasmonic nanoparticles, Vibrations, Quality factor, Finite-element simulations.**

I. Introduction

Mechanical nano-resonators are useful for a variety of applications, including quantum phononics experiments at room temperature or micro-mass sensing [1]. Their performance can be quantified with the fQ product of their oscillation frequencies f and quality factor Q.

Metallic nanoparticles are an interesting system for such applications, thanks to their inherently high oscillation frequencies (in the GHz-THz range). However, it has been observed that they undergo strong acoustic damping, leading to Q factors of the order of a few tens [2]. It is therefore important to better understand and minimize acoustic damping mechanisms in these systems, which are associated with two processes: radiative damping caused by the emission of acoustic waves within the environment, and intrinsic damping, linked to internal phonon attenuation.

In this context, we present an optical investigation of the vibrational dynamics of individual supported gold nanodisks. These experiments were done at the single-particle level using the combination of two single-particle techniques (namely SMS and pump-probe spectroscopy), thus avoiding the spurious statistical effects linked to ensemble measurements.

The nanodisks (NDs) present a simple geometry characterized by two parameters, the diameter D and the thickness h. Our previous work, conducted on a thick sapphire substrate, showed that a significant reduction of radiative damping could be achieved for specific aspect ratios $\eta = \mathrm{D/h}$ of such resonators [2]. This effect is linked to the radiative coupling of two close-frequency acoustic modes, leading to the creation of a Bound State in the Continuum [3]. Here, we propose to extend this study by also exploring the influence of both the substrate composition and thickness on acoustic damping.

II. Methods

The gold NDs were chemically synthesized in a two-step process involving the growth of hexagonal gold plates, later chemically etched, leading to a smooth cylindrical shape. They were later deposited at a low concentration on three distinct substrates: ∼1 mm thick sapphire, ∼1 mm thick silica, and a 40 nm thick silica membrane.

Optical experiments were conducted with a Ti:sapphire pulsed oscillator associated with a frequency-doubling BBO crystal and an Optical Parametric Oscillator, eventually leading to an optical source tunable within a 400-1040 nm range, with an 80 MHz repetition rate and a ∼150 fs pulse duration.

The detection and linear extinction measurement of single NDs was performed using Spatial Modulation Spectroscopy (SMS). This far-field technique is based on a mechanical oscillation of the sample, leading to a temporal modulation of the transmitted beam power when a ND is present in the beam [5]. A displacement amplitude of 300 nm at a 1.5 kHz frequency was used. Light was focused on the sample using a x100 objective microscope, leading to a spot size close to the diffraction limit (about 0.7 times the wavelength). A second-harmonic lock-in detection enables a quantitative measurement of the extinction spectra σ_{ext} as a function of the wavelength (Figure 1a).

For each ND, the extinction spectra exhibit a quasi-Lorentzian Plasmon Surface Resonance, as expected for metal nanoparticles. Since the resonance spectral position and area are strongly linked to the nano-object morphology (D and h), these dimensions could be estimated for each ND by comparing its extinction spectrum with finite-element modeling (FEM) simulations of the ND optical response.

The acoustic dynamics of the NDs were subsequently measured using pump-probe time-resolved spectroscopy. In this technique, the nano-object is illuminated by two light beams separated by a tunable delay t. The first beam (pump-beam) is used to excite the nano-object, with a wavelength set at 410 nm and a fluence of ~ 0.3 J/cm^2. The pump power is modulated through a mechanical chopper at 30 kHz for additional noise reduction.

By measuring the relative transmission $\Delta\frac{\mathrm{T}}{\mathrm{T}}(t)$ of the second

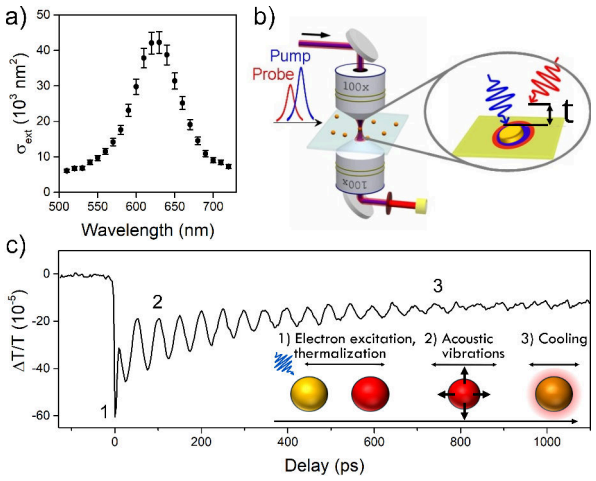

Fig. 1. (a) Linear extinction spectrum of a single gold nanodisk deposited on thick silica. This nano-object exhibits a quasi-Lorentzian plasmonic resonance at a 625 nm central wavelength. beam (probe-beam), the ND transient optical response can eventually be reconstructed, containing the signature of three ultrafast processes (Figure 1b,c): the initial electron heating and thermalization (few ps), the nano-object's acoustic oscillations (few hundreds of ps) and its cooling in the environment (few ns).

The thermal signal was fitted using either one or two decaying exponentials. The acoustic dynamics are then fitted with one damped oscillation:

$$\left(\frac{\Delta T}{T}\right)_{\text{acoustic}}(t) = A \exp\left(\frac{-t}{\tau}\right) \sin\left(\frac{2\pi}{T}t + \phi\right) \qquad (1)$$

where the acoustic mode frequency f and quality factor Q= $\frac{\pi\tau}{T}$ can be extracted. Following this protocol, a systematic study was conducted on all substrates. Experimental frequencies and quality factors were compared with those obtained with acoustic FEM simulations.

III. Results and Discussion

Pump-probe experiments were conducted on over 50 NDs, with diameters ranging from 50 nm to 120 nm, and an average thickness of h = 24 ± 3 nm (as determined through AFM measurements).

A strong dependence of acoustic dynamics on the substrate is observed: NDs of similar aspect ratio show similar oscillation frequencies but markedly different quality factors. For instance, two nanoresonators with $\eta = 3$ on thick sapphire and silica membrane exhibit a quality factor of 19 and 45 respectively (Figure 2). Since intrinsic acoustic damping is expected to be almost independent of the nanodisks' environment, these results confirm that radiative damping plays a crucial role in acoustic mode attenuation.

Both thick sapphire and thick silica samples show a low dependence of the quality factor on η, with an average , Q = 15±3 and Q = 27±3 respectively. However, on silica membrane, a strong η-dependence is observed, with quality factors ranging from 13 (for $\eta = 5.4$) to 51 (for $\eta = 2.2$).

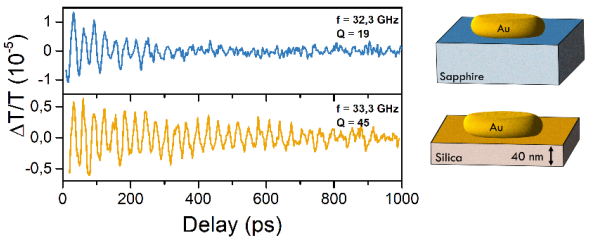

Fig. 2. Acoustic dynamics of two nanodisks with the same aspect ratio ($\eta = 3$).

FEM simulations reveal the existence of two close-frequency acoustic modes within the range experimentally detected. The first mode was the one experimentally detected and shows a relatively low Q modification with η. The second mode (mode 2) consistently presents an important radiative Q-factor exaltation over a broad range of ND aspect ratios, while its excitation amplitude is significantly lower than that of the first mode, thus making its experimental detection challenging. Nevertheless, by increasing the pump-beam fluence, focusing on long-delay dynamics, and increasing the signal averaging, we were able to detect mode 2 on one resonator on the thick sapphire substrate, with an estimated quality factor of 45.

IV. Conclusion

Through this work, we conducted a systematic optical study of both substrate geometry and composition in the design of high-quality factor metallic nanoresonators.

Firstly, we showed that for similar NDs geometries, changing either the substrate composition or thickness has a significant impact on the resonator's quality factor, indicating the dominant role of radiative damping in acoustic dynamics. Moreover, we highlighted the influence of the nanoresonators' aspect ratio on damping processes. In particular, on a silica membrane substrate, the quality factor was improved by more than a factor of 4 for low aspect ratios with respect to higher ones. Finally, we experimentally demonstrated the existence of a second acoustic mode which exhibits lower radiative damping as well as low excitation amplitude.

Optomechanical resonators, where the motion of a solid-state body couples to light trapped in a cavity, form a new class of elementary quantum systems on their own. Operated at the quantum limit, they are pushing our capability to probe forces with higher sensitivity and time resolution. Here we will show how to employ an optomechanical resonator to open a new experimental window in the measurement of a single living cell. Results cover the investigation of cell rheology at high frequencies unexplored so far, as well as the resolution in the membrane region of fluctuating processes at the sub-microsecond scale, two decades faster than allowed by prior techniques.

***Abstract*—We optically probe the vibrations of an ultrasensitive force sensor, a suspended silicon carbide nanowire to map the lateral electrostatic and proximity forces experienced above a metallic nanostructure. We probe and compensate the electrostatic forces at each position above the sample and spatially map the lateral Casimir force field.**

***Keywords*— nanomechanics, electrostatic, force measurements, Casimir forces.**

I. Methods

The lateral vibrations of the SiC nanowire are readout using the reflexion of a laser beam focused on the nanowire vibrating extremity and collected back into a high numerical aperture objective. Exploiting the two quasi-degenerated fundamental mechanical modes of the nanowire, which oscillate along the transverse directions above a sample of interest, the nanowire can be used as a lateral force sensor. As in an atomic force microscope, the force gradients are modifying the eigenmodes properties, causing here both mechanical frequency shifts and rotations of the eigenvectors' orientations, whose measurement allows extracting the four components of the local lateral force field gradients experienced by the nanowire[1], [2]. Furthermore, the static deflexions of the nanowire in the transverse plane are separately recorded to evaluate the static forces produced by the sample.

We developed force and force field gradient sensing protocols of the 2D lateral force fields experienced by the nanowire, featuring a vectorial character with sensitivities in at the $\mathrm{aN}/\sqrt{\mathrm{Hz}}$ level at room temperature (10 $\mathrm{zN}/\sqrt{\mathrm{Hz}}$ at dilution temperatures [3]) operating at a quasi real-time measurement rate (10 Hz), limited by the mechanical coherence time of the nanowire. To do so, we use a reference radiation pressure force produced by a time-modulated pump laser to simultaneously drive both mechanical resonances of the nanowire, and activate two phase lock loops to track the mechanical frequency shifts produced by the force field gradients. By scanning the nanowire above the sample, for different bias voltages, it is possible to map the electrostatic force field and its voltage dependence, which first allow to separate the contribution of the voltage dependent electrostatic fields, and the residual contributions produced by the sample imperfections- electrostatic patches, contaminants- which do not depend on the bias voltages.

By simultaneously modulating the electrostatic potentials applied on the sample, at frequencies close to each mechanical resonance tone, it is possible to also measure the electrostatic force field produced by the sample and compare it to the force field gradients determined independently. This real-time measurement of the electrostatic forces also allows to efficiently determine at each position above the sample, the set of bias voltages that must be applied to compensate the electrostatic force at which the Casimir force field gradients must be measured to operate in the electrostatic vacuum.

The samples are made of a gold layer deposited on top of an insulating SiO_2/Si wafer, and the sub-micron nanostructures are realized with a focused ion beam. Most of the results are obtained on a 400 nm trench drilled in a 150 nm

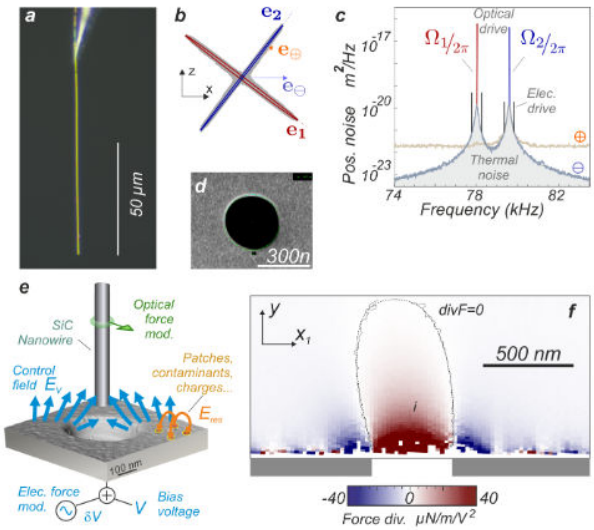

Fig. 1. **a** optical images of a 240 nmn thick nanowire. **b,c** Gray: optically readout thermal noise spectrum of the vibrations of the nanowire extremity, revealing the two transverse mechanical eigenmodes, whose orientations in the transverse horizontal plane can be identified by resonantly driving each eigenmode, here with a radiation pressure force produced by a time-modulated pump laser. Applying a voltage modulation on the sample of interest at frequencies close to the mechanical resonances allow to measure the local electrostatic force experienced by the nanowire. **d** SEM image of a 300 nm hole drilled in a 100 nm gold layer whose AFM image is used to build the image of panel **e**. The local electrostatic field can be controlled and modulated by external gate voltages, aiming at compensating the residual electrostatic fields produced by surface imperfections (patches, contaminants, charges..). Scanning probe image obtained by scanning the nanowire above a hole. The patch structure is visible at low altitude.

thick gold layer, which separates two electrodes which can be independently voltage biased to control the vertical and horizontal components of the electrostatic field above the trench. The measured electrostatic patches are produced by the 50 nm grains of gold. The inhomogeneity of the residual field they produce vanishes with the altitude above the sample and become sufficiently smooth for altitudes above 100 nm to be compensated by the electrodes.

The nanowire force probes are specifically adapted to this experiment. We chose rather large diameters, above 350 nm to enhance the Casimir forces (and adapt the trench diameter accordingly). We artificially enhance their relative mechanical frequency splitting, up to 10 percents, by adding a smaller nanowire at their base, to break their rotational symmetry in the region of large dynamical strain and we orientate the eigenmodes and the trench orientation at 45 degrees of the laser axis. We control the perpendicularity between the nanowire axis and the sample with an approx. 1° precision, which allows to get rid of the vertical forces produced by the sample. Finally, the laser wavelength- and the nanowire diameter- are chosen not to be resonant, to minimize the optical absorption, which can cause unwanted photothermal effects [6].

II. Results and Discussion

The Casimir repulsion of a needle above a hole in vacuum was theoretically predicted in [4] but the faintness of the forces have for the moment precluded from experimental observation. The elongated character of the nanowire deviates from the proposed needle geometry, so that the vertical repulsion does not exist with a nanowire, but the lateral Casimir repulsion persists. Beyond this aspect, our measurement also allows to map the Casimir force field above nanostructures, with sub-micron dimensions and approx. 50 nm lateral resolution. For small nanowire diameters, this measurement method can also be viewed as a mapping of the spatial density of vacuum fluctuations above nanostructures. This dual electrode scheme allows to map and cancel both the horizontal and vertical components of the electrostatic field, and enables the measurement of the lateral Casimir forces which persist at zero field. In a first step, we measured the force and force gradients above the nanostructure, while varying the different bias voltages over a wide range in each position. We extracted the set of bias voltages which allow cancelling the electrostatic force- and thus the electrostatic field components and evaluated the Casimir force divergence in each position. Those measurements allowed a complete analysis of the force and force gradients and provided a good force/divergence comparison and Casimir divergence reconstruction but was time consuming and sensitive to low-frequency drifts in the experiment. Implementing the real-time measurement of the electrostatic forces, based on electrostatic force sidebands, we demonstrated the possibility to use a dual feedback loop on the two bias voltages to cancel the demodulated electrostatic force at each position above the sample. This method provided similar results to the previous method but helped significantly reducing the measurement time and thus the sensitivity to the experimental drifts.

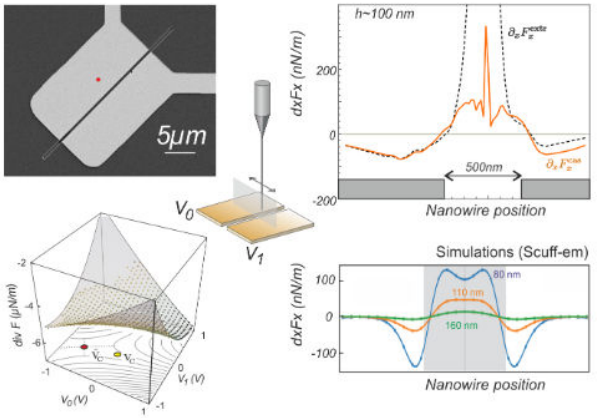

Fig. 2. **a** SEM image of the samples employed for the Casimir measurements: a 400 nm wide trench is drilled in a gold layer, and a separate bias voltage can be applied on each side of the trench. **b** measurement of the force field divergence at a fixed nanowire position above the trench, while varying the two bias voltages. The obtained quadratic form serves to determine the electrostatic force properties, while the simultaneously measured electrostatic force serves to identify which set of bias voltages allow compensating the electrostatic force, revealing the Casimir force field gradient. **c** Reproducing similar measurements at different positions above the trench (see inset) serves to measure the lateral gradients of the lateral Casimir force (orange curve, preliminary measurements), revealing a laterally repulsive character (positive values) above the trench. Those measurement are in agreement with the original prediction [4], and in qualitative agreement with numerical simulations [5] realized on Scuff-em.

Our measurements demonstrate a laterally repulsive structure above the trench, the nanowire being attracted towards the edges of the trench, as expected from the original theoretical predictions [4] and in agreement with our numerical simulations[5] based on the open-source Scuff-em software. The lateral Casimir force field gradients range from a few $\mu\mathrm{N/m}$ at an altitude of approx. 100 nm, and rapidly decay down to the $\mathrm{nN/m}$ at an altitude of approx. 600 nm above the trench, corresponding to nanowire sensitivity limit in those fast measurement protocols, at room temperature. A clear transition from the near-field to the far field regime is observed, when the nanowire altitude is smaller/larger than the trench width (equal to the nanowire diameter). The corresponding lateral Casimir forces are of a few 100 fN at short distances. Our measurement also allow to map the electrostatic force field above the trench, which dominate the force landscape, especially at large distances due to their weaker decrease with the nanowire elevation, and here again our results are found in good agreement with numerical simulations. Furthermore, these measurements provide information about the electrostatic imperfections of the sample, which are valuable when investigating nano-fabrication processes.

III. Conclusion

With the real-time measurement protocols, we measured the Casimir and electrostatic force fields above metallic nanostructures, achieving a good qualitative agreement with numerical

simulations. The prospects of the work aim at exploring Casimir force fields above more complex nanostructures, at different temperatures [3] and opening connections towards cavity nano-optomechanical experiments realized at small photon numbers realized in the group. [7]

***Abstract*—** We measure interaction-induced vibrational modes in nanoparticle assemblies down to 20 nm and show that the Johnson–Kendall–Roberts (JKR) contact-mechanics model breaks down below ∼100 nm, coinciding with emergence of disordered, weakly connected networks and transition to percolation scaling that establishes mechanical connectivity as the governing mechanism in this regime.

***Keywords*—** nanoparticle assemblies, vibrational dynamics, Brillouin spectroscopy, mechanical coupling.

Introduction

Colloidal nanoparticles can self-assemble into ordered or partially ordered structures whose physical properties are tunable through particle size, interparticle interactions, and fabrication conditions. [1, 2] Such assemblies enable a wide range of applications, including plasmonics [3], biosensing platforms [4], and photonic and phononic materials whose functionality is governed by collective mechanical and vibrational responses. [5, 6] A central challenge is to understand how interparticle interactions control the mechanical and vibrational behavior of nanoparticle assemblies.

Brillouin light scattering (BLS) is a non-contact optical technique that probes gigahertz-frequency acoustic excitations and elastic properties in condensed and nanostructured materials.[7, 8] For isolated, homogeneous spherical nanoparticles, the vibrational response measured by BLS is well described by Lamb theory and dominated by intrinsic spheroidal modes. [9, 10, 11, 12] In dense assemblies, mechanical coupling between neighboring particles modifies the single-particle response and gives rise to additional low-frequency spectral features associated with collective motion. [13, 14, 15]

In particular, interparticle contacts lift the degeneracy of the rigid-body translational $f(s,1,1)$ mode, leading to a finite-frequency interaction-induced collective mode [13], as schematically illustrated in (Fig. 1).

Figure 1. Conceptual schematic of the interaction-induced translational $(s,1,1)$ mode. **Top:** Isolated nanoparticles exhibit rigid-body translation. **Bottom:** Interparticle contacts introduce a restoring force, yielding a finite-frequency collective mode. M_{eff} and K_{eff} denote the effective mass and interparticle stiffness.

Such interaction-induced modes have been reported in polymer nanoparticle assemblies [13, 15], as well as in silica [14], semiconductor [16], and metals. [17] For ordered or partially ordered assemblies with well-defined contacts, their frequency scaling has been successfully described using classical contact-mechanics frameworks, most notably the Johnson–Kendall–Roberts (JKR) model, yielding a characteristic size dependence $f \propto d^{-7/6}$. [18, 13] These studies have predominantly focused on assemblies composed of particles larger than approximately 100 nm, where contacts are relatively uniform and structural order is preserved.

As a result, it remains unclear whether contact-mechanics descriptions developed for ordered assemblies remain applicable as particle size decreases, where even minor absolute size variations result in larger relative polydispersity that can hinder long-range ordering and periodicity. In this study, we therefore investigate self-assembled polystyrene nanoparticle assemblies in the sub-100 nm regime, where structural disorder and heterogeneous connectivity are expected.

Methods

Monodisperse polystyrene (PS) nanoparticles (20–200 nm) were used as received. The particles consist of plain polystyrene cores with polydispersity $\leq 2\,\%$, verified by TEM. Films were prepared by drop-casting 10 µL of a 1 wt % suspension onto cleaned glass substrates and drying at room temperature, producing coffee-ring patterns and multilayer assemblies with micrometre-scale thickness, as confirmed by SEM. Brillouin measurements targeted regions of high particle coverage.

Brillouin spectra were acquired using a home-built VIPA-based confocal backscattering spectrometer. A 640 nm continuous-wave diode laser delivered ∼45 mW at the sample and was focused with a 0.80 NA objective, yielding a spot size of ∼1 µm. Backscattered light was collected through the same objective, filtered to suppress elastic scattering, and dispersed by a VIPA etalon with a free spectral range of ∼30 GHz. Spectra were recorded on an sCMOS camera with 1 s exposure time. Brillouin peaks were extracted using Lorentzian fits. The interaction-induced mode was identified by its low-frequency spectral position and separation from intrinsic Lamb modes.

Interaction-induced translational modes were analyzed using two complementary descriptions. For assemblies with homogeneous contacts, nanoparticles were modeled as rigid masses coupled by JKR model springs, predicting the classical scaling $f \propto d^{-7/6}$.

For disordered assemblies, a percolation-based elastic network model was considered, in which rigidity is governed by a fractal load-bearing backbone ($D_f \approx 2.5$) and

effective stiffness scales as $K_{\text{eff}} \propto d^{\alpha}$ ($\alpha \approx 1.7$), leading to:

$$f(d) \propto d^{(\alpha - D_f)/2}. \quad (1)$$

Results and Discussion

Brillouin measurements were performed using the VIPA-spectrometer setup described in the Methods. The central experimental findings are summarized in (Fig. 2), which combines frequency scaling, mechanical schematics, and structural characterization to capture the collective vibrational dynamics of polystyrene nanoparticle assemblies across the investigated size range.

The Brillouin data (Fig. 2b) reveal an interaction-induced translational mode whose frequency decreases monotonically with increasing particle diameter, consistent with previous reports on polymer nanoparticle assemblies.[13, 15] For larger particles, the measured frequencies approach the JKR contact-mechanics scaling $f \propto d^{-7/6}$, as expected for assemblies with homogeneous elastic contacts.[13, 15] For diameters above 100 nm, the mode shifts to lower frequencies, increasing overlap with elastic scattering in the VIPA; tandem Fabry–Perot interferometer was used to resolve the Brillouin peak.

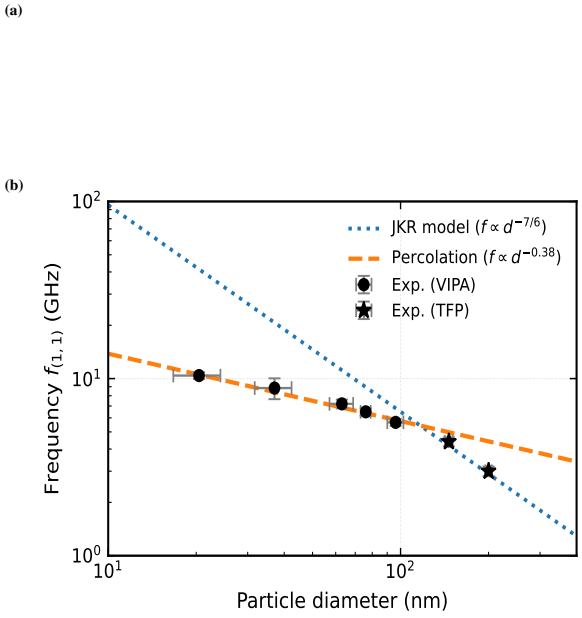

Figure 2 — Crossover from contact-limited to connectivity-limited vibrational mechanics in nanoparticle assemblies. **a** Schematics illustrating connectivity-limited coupling in disordered assemblies (percolation regime) and contact-limited coupling in ordered assemblies described by Johnson–Kendall–Roberts (JKR) mechanics. **b** Log–log scaling of the interaction-induced translational mode $f_{(s,1,1)}$ with particle diameter, showing a shallow percolation-based scaling $f \propto d^{-0.38}$ at small sizes and convergence toward the JKR prediction $f \propto d^{-7/6}$ as assemblies become ordered and fully connected.

At smaller particle sizes, however, the experimental data deviate strongly from JKR predictions and instead follow a much shallower size dependence, $f \propto d^{-0.38}$. This deviation suggests a change in the underlying mechanical coupling as particle size decreases.

Complementary structural characterization provides insight into this crossover. As particle size increases, SEM reveals a progressive evolution in structural organization: assemblies formed from 40 nm particles are strongly disordered, 100 nm particles exhibit mixed or partially ordered domains, and 200 nm particles form extended, close-packed structures with continuous interparticle contacts (Fig. 3). The increasing structural order with particle size is consistent with the assumptions of classical contact mechanics.

In contrast, assemblies composed of 40 nm particles exhibit disordered packing with heterogeneous and incomplete contacts, consistent with previous observations in disordered nanoparticle systems.[14, 13] This structural evolution coincides with the observed crossover in vibrational scaling.

The transition therefore reflects a change in mechanical connectivity. In ordered assemblies, elastic coupling is governed by well-defined particle–particle contacts, yielding contact-limited mechanics described by JKR theory. In disordered assemblies, however, elastic coupling is governed by a weakly connected elastic network rather than pairwise contacts.

Figure 3 — Structural evolution of nanoparticle assemblies with particle size. SEM images of assemblies formed from 40 nm, 100 nm, and 200 nm particles showing the transition from disordered packing to progressively ordered, close-packed structures as particle diameter increases.

As illustrated schematically (Fig. 2a), this connectivity-limited regime is captured by a percolation-based description, in which rigidity emerges from a load-bearing backbone with fractal mass dimension $D_f \simeq 2.5$ and effective stiffness scaling $K_{\text{eff}} \propto d^{\alpha}$ with $\alpha \simeq 1.7$[19, 20], yielding $f(d) \propto d^{(\alpha - D_f)/2} \approx d^{-0.38}$.

Together, (Fig. 2) establishes a clear crossover from contact-limited to connectivity-limited vibrational mechanics as particle size decreases, identifying mechanical connectivity—not contact geometry alone—as the dominant control parameter governing collective vibrational dynamics in nanoparticle assemblies.

Conclusion

This study demonstrates that interaction-induced vibrational modes provide a sensitive probe of mechanical connectivity in nanoparticle assemblies. By combining Brillouin spectroscopy with structural characterization, we access collective dynamics that are invisible at the single-particle level and directly reflect interparticle mechanical coupling. Beyond polystyrene nanoparticles, these results highlight the importance of connectivity-controlled mechanics in disordered nanostructured materials, where classical contact-based descriptions are limited. More broadly, direct access to interaction-driven vibrational modes establishes Brillouin spectroscopy as an effective approach for probing collective mechanical behavior in heterogeneous nanoscale systems.

I. Introduction

Quantum light has recently been shown to be a powerful probe of electronic and vibrational dynamics in condensed phase molecular systems. This sensitivity arises from the unique characteristics of quantum photon states, such as entanglement and squeezing, and from the ability to detect changes in nonclassical photon statistics induced by the material response [1].

Optical microcavities enable strong light–matter interactions that are particularly useful platforms for low-intensity quantum-photon spectroscopies. Such interactions give rise to hybrid light–matter quasiparticles known as polaritons, formed via the coupling between cavity photons and elementary material excitations. Given recent advances in polariton chemistry, quantum-light spectroscopy offers promising opportunities for probing molecular cavity polaritons. At the same time, emerging studies on the unique properties of cavity quantum materials open new perspectives for applying quantum-light techniques as sensitive probes of strongly correlated electronic, vibrational, orbital, and spin degrees of freedom. Advancing the use of quantum-light techniques in this context calls for the development of theoretical frameworks capable of describing the scattering of entangled photon states by cavity polaritons in strongly correlated condensed-matter systems.

In this work [2], we develop a generalized scattering-matrix framework that directly relates input and output biphoton states, while consistently incorporating both coherent and dissipative polariton dynamics. This methodology provides a unified and systematic approach to modeling biphoton scattering in quantum cavity materials and molecular condensed-phase systems.

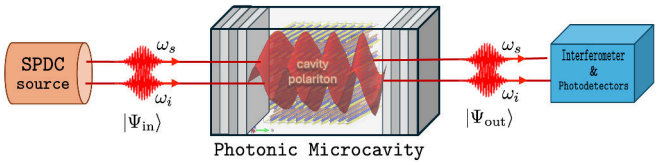

Fig. 1. Schematics of a photonic microcavity containing quantum emitter, e.g., semiconductor nanostructure, where the interaction between a cavity photon mode and nanostructured material excitons forms a hybrid light–matter quasiparticle — the cavity polariton. The polariton steady state can be prepared by applying a weak incoherent pump to the quantum emitters (not shown in the plot), which also results in a steady-state cavity photon population. The polariton state is further probed by scattering an input entangled photon pair, $|\Psi_{\text{in}}\rangle$, generated via spontaneous parametric down-conversion (SPDC), with the output state, $|\Psi_{\text{out}}\rangle$, detected after transmission through the interferometric setup.

II. Methods

As illustrated in Fig. 1, we consider the scattering of a frequency-entangled photon pair by a photonic cavity containing a material system, such e.g., a semiconductor nanostructure. The electronic excitations of the material system are assumed to be in resonance with the confined cavity photon mode, leading to the formation of polaritons. Both the input and output entangled photon pairs can be described as quantum wave packets, $|\Psi_{\text{in/out}}\rangle = \iint d\omega_s d\omega_i \mathcal{F}_{\text{in/out}}(\omega_s,\omega_i)|\omega_s\rangle\omega_i\rangle$, where $|\omega_s\rangle$ and $|\omega_i\rangle$ denote the signal and idler photon states, respectively. All information about signal-idler entanglement is encoded in the two-photon joint spectral amplitude (JSA) $\mathcal{F}_{\text{in/out}}(\omega_s,\omega_i)$, which can be measured experimentally and analyzed by calculating the entanglement entropy [2].

The relation between the input and output JSAs is given by

$$\mathcal{F}_{\text{out}}(\omega_s,\omega_i) = \iint d\omega_s' d\omega_i' \mathcal{S}(\omega_s,\omega_i;\omega_s',\omega_i')\mathcal{F}_{\text{in}}(\omega_s',\omega_i'). \quad (1)$$

where $\mathcal{S}(\omega_s,\omega_i;\omega_s',\omega_i')$ is the polariton scattering matrix that accounts for both single-polariton and correlated bi-polariton structure. Using the Tavis-Cummings model for cavity (bi-)polaritons together with a Feynman diagrammatic expansion shown in Fig. 2, we calculated the scattering matrix amplitudes and analyzed the resulting output JSA.

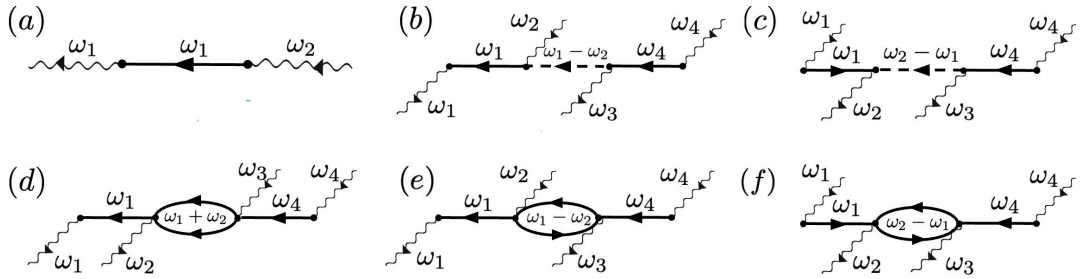

Fig. 2. Feynman diagrams describing (a) single-photon scattering by polariton mode, (b, c) bi-photon scattering involving the steady/ground state polariton propagation. The other diagrams describe the bi-photon scattering events that involve (d) the bipolariton coherence and (e,f) the polariton-polariton excited state coherences and populations. Adopted from Ref. [2].

III. Results and Discussion

Figure 2 shows the output JSA (panel c) obtained from the scattering of the input SPDC JSA (panel b) by the polariton branches indicated by the red dashed line in panel a where strong light-matter coupling occurs. The observed in Fig. 2 d increase in entanglement entropy after scattering is attributed to bi-polariton dynamics, providing their quantitative signatures. Such signatures could be measured experimentally, offering a means to probe correlated bi-polariton fluctuations over the quantum vacuum. Our analysis demonstrated that the entanglement entropy of the outgoing biphoton state arises not only from the interplay between decoherence processes and bipolariton correlations that lead to entropy production, but also depends on the input photon entanglement entropy encoded in the biphoton JSA. This distinction must be taken into account when employing entangled biphoton states to probe bipolariton correlations. Furthermore, isolating these correlations requires subtracting the contribution from coherent biphoton scattering. Since our analytical formulation explicitly separates these terms, the present theory provides a clear prescription for modeling and subsequently removing the coherent component while analyzing experimental data.

IV. Conclusion

In conclusion, we have developed a tractable scattering theory framework for describing the scattering of a biphoton wavepacket through a photonic cavity supporting polariton and bipolariton quasiparticles. The adopted Green function representation provides a versatile approach for modeling quasiparticle dynamics in molecular and semiconductor materials coupled to a cavity mode. Our model calculations based on the TC model revealed that the output JSA is a result of an interplay between polariton and bipolariton Fano-type resonance and the input JSA. Moreover, we identified the limitations imposed by the structure of the input JSA and demonstrated the sensitivity of the technique for probing polaritons supported by a cavity in the vacuum state.

***Abstract*— Van der Waals heterostructures host strongly correlated phases tunable *in situ* via electrostatic gates. Their conductive layers, including the gates themselves, can form plasmonic self-cavities for terahertz light due to finite-size effects. Here we investigate how these effects enable cavity engineering in the ultrastrong coupling regime, with and without light.**

***Keywords*— van der Waals heterostructures, graphene plasmons, cavity engineering, on-chip THz spectroscopy, ultrastrong coupling.**

I. Introduction

Van der Waals heterostructures, formed by stacking two-dimensional crystals, host a wide range of quantum phenomena that can be tuned *in situ* with electrostatic gates. Each 2D material including the gates, which are most commonly made from graphite, can inherently act as plasmonic self-cavities, where finite-size effects confine the light into standing wave patterns of current density. As the plasmonic resonances of typical graphite gates fall in the GHz-THz range that corresponds to the same μeV-meV energy scale as the quantum phenomena they electrostatically control, it is possible that the self-cavity modes of graphite gates could also dynamically shape these emergent quantum phases.

However, probing such cavity-mediated electrodynamics has remained challenging. Device dimensions are deeply sub-wavelength compared to the relevant wavelengths of THz light, limiting the reach of conventional far-field spectroscopy.

II. Methods I

To overcome the size mismatch, we employed on-chip THz spectroscopy to investigate the intrinsic cavity conductivity of gate-tunable graphene heterostructures. As the carrier density is tuned, we observed spectral weight transfer and an avoided crossing between graphene and graphite plasmonic modes (see Fig. 1), demonstrating their ultrastrong coupling [1].

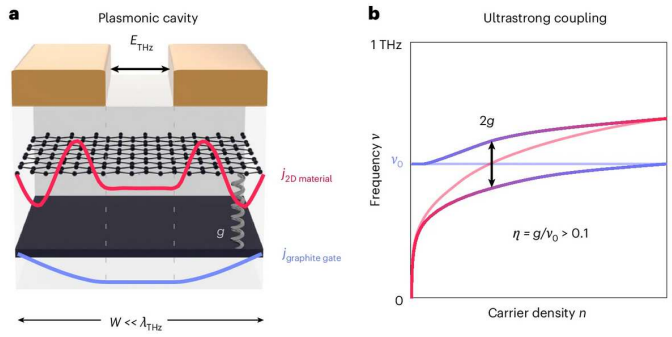

Fig. 1 **a**: Schematic of a subwavelength vdW heterostructure: a 2D material (in this work graphene) and a graphite gate embedded in a micropatterned dielectric created from the metallic transmission line of the on-chip THz spectroscope. Plasmonic self-cavity modes of a 2D material (red) and a graphite gate (blue) can couple. **b**: The 2D material's screened plasmon frequency (light red) is tuned via carrier density into resonance with the graphite mode, ν0 (light blue). The self-cavity modes of the 2D material and the graphite couple of different momenta couple due to resonant enhancement of unscreened currents in the transmission line gap, leading to an avoided crossing with energy splitting 2g. For $\eta = \frac{g}{\nu 0} > 0.1$, the system reaches the ultrastrong coupling regime. Figure adapted from [1] under a CC BY 4.0 license.

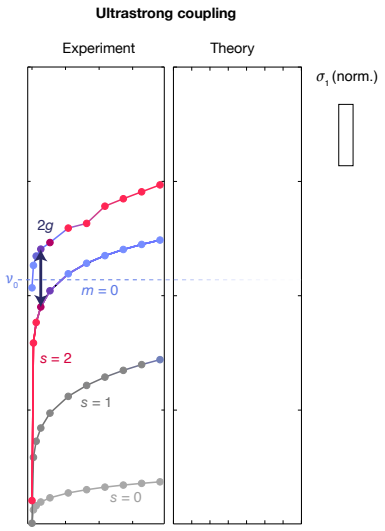

Fig. 2: The frequencies of the screened plasmonic modes in graphene can be tuned with carrier density into resonance with the screened graphite mode, ν0. The resonance condition can be achieved between the s = 2 (magenta) and m = 0 (blue) mode within the explored carrier density range. Both experimental data (left panel) and simulated data from the analytical theory (right panel) reveal that the coupling of graphene and graphite modes of different momenta exceed $\eta > 0.1$, marking the entry to the ultrastrong coupling regime. Figure adapted from [1] under a CC BY 4.0 license.

We developed an analytical theory [2] to capture these effects and provide design principles [3] for engineering cavity responses including guidelines to maximize or minimize the self-cavity coupling strength. Specifically, the coupling strength can be tuned through the geometry of the metallic transmission lines in the on-chip THz spectroscope. Wide transmission lines separated by a narrow nanogap yield negligible self-cavity coupling ($\eta = \frac{g}{\nu 0} \approx 0$), whereas narrow lines with a wide gap can reach the ultrastrong coupling regime, defined by $\eta > 0.1$, where cavity engineering of the thermodynamic ground state is expected to emerge [4].

III. Results and Discussion

Experimental results show:

- Multimodal plasmonic coupling between a graphene layer and its graphite gate across a measurement bandwidth of 0.05 – 1 THz.
- A normalized coupling strength of $\eta = 0.12$, indicating entry into the ultrastrong coupling regime.
- Strong agreement between measured and calculated spectra (see Fig. 2).

Calculations with the developed analytical theory show:

- A tunable self-cavity coupling mechanism governed by the sample and metallic transmission-line geometry, enabling coupling strengths in the range $0 \lesssim \eta \lesssim 0.2$ by design.

IV. Methods II

A remaining key question is whether THz illumination is required to activate these self-cavity effects, or whether vacuum fluctuations themselves can be reshaped by finite-size effects and a deliberately microstructured dielectric environment. Even in the absence of real photons, the electromagnetic vacuum at absolute zero exhibits quantum fluctuations that profoundly influence physical systems, giving rise to phenomena such as spontaneous emission, the Lamb shift [5], and the Casimir force [6]. Engineering these fluctuations through a (self-)cavity therefore offers a compelling route to tailor material properties.

In this context, we have recently demonstrated that a hovering complementary split-ring resonator (CSSR), operating in the absence of external illumination, can strongly influence a high-mobility GaAs heterostructure subjected to a magnetic field at millikelvin temperatures. These experiments revealed a breakdown of the topological protection of edge states in the integer quantum Hall regime [7], an enhancement of the quantum Hall energy gap at several fractional filling factors [8], and the cavity-QED stabilization of thermally disordered quantum Hall stripe phases [9].

Here we now extend this hovering-cavity concept to the much smaller length scales of van der Waals heterostructures to

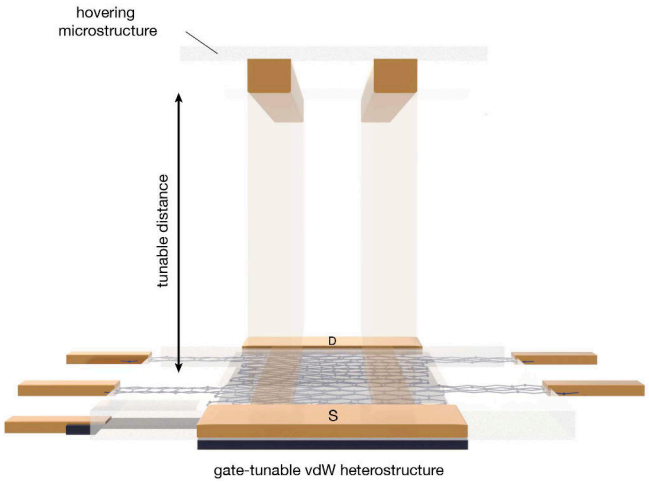

Fig. 3: Schematic of the hovering microstructure platform to explore the impact of the microstructure on the DC transport properties of a gate-tunable vdW heterostructure.

explore whether both intrinsic and externally engineered cavity vacuum fields can reshape the thermodynamic ground states of their emergent phases (see Fig. 3). The resulting platform enables systematic studies of cavity-modified vacuum fluctuations, with *in situ* referencing provided by a movable hovering microstructure architecture. By comparing DC transport measurements taken with the microstructure positioned in close proximity to the sample to those obtained when it is retracted far above it, we can directly determine the influence of the microstructure on the material's properties.

V. Conclusion

We have shown through on-chip THz spectroscopy that cavity engineering in van der Waals heterostructures is not only feasible but can arise intrinsically. Owing to finite-size effects, many of the constituent materials naturally form plasmonic self-cavities, enabling coupling strengths that reach the ultrastrong coupling regime. As experimental evidence for ground-state modification in these systems is scarce, we are now developing a hovering microstructure platform for van der Waals heterostructures that operates in the dark at millikelvin temperatures and strong magnetic fields.

Restoring Bloch's Theorem for Cavity Exciton Polaron-Polaritons

Michael AD Taylor[1,*] and Yu Zhang[1,†]

***Abstract*—We introduce a hybrid photon–exciton–phonon quantum electrodynamics Hamiltonian to restore Bloch's theorem. The interchange of momenta between fermions and bosons breaks crystalline excitons' translational symmetry. Restoring said symmetry, we efficiently compute experimentally accessible observables, enabling investigations that elucidate material properties in strong coupling.**

***Keywords*— quantum electrodynamics, 2D materials, polarons**

In recent years, cavity and polariton physics have advanced dramatically, both experimentally and theoretically. We are now able to reach and probe the strong- and ultrastrong-coupling regimes for a wide variety of materials and cavity structures. Hybrid light-matter states created in these platforms offer powerful tools for engineering electronic structure and elementary excitations, with far-reaching implications for quantum materials, quantum information science, and micro- and optoelectronics. However, as theoretical studies seek to explain increasingly more complicated physical systems, the computational cost grows exponentially, necessitating approximations to make the calculations computationally tractable.

In condensed matter physics, Bloch's theorem drastically simplifies the complexity of calculating periodic systems by allowing each wavevector of the total Hamiltonian to be treated independently. However, this structure can break down upon interactions with other systems such photonic and phononic fields. In minimal-coupling cavity QED the transverse vector potential does not commute with the crystal momentum unless long-wavelength or single-mode approximations are imposed, and Fröhlich-type electron-phonon couplings similarly exchange momentum with the lattice. The resulting light-matter-phonon Hamiltonian is no longer block-diagonal in Bloch momentum, forcing many recent studies to resort to the site-basis under harsh approximations, removing any advantages gained by the periodic symmetry of the fermionic system.

In this work, we restore Bloch's theorem for an exciton model strongly coupled to both photonic and phononic modes, so-called exciton polaron-polaritons. This is done by performing a gauge-like transformation on the total system that changes the momentum frame from the exciton momentum to the polaron-polariton momentum. We demonstrate on a 2D exciton model how to formulate such a Hamiltonian, and demonstrate how the new framework drastically simplifies calculations of experimentally accessible observables like the dielectric function. By treating all degrees of freedom on the same footing while conserving translational symmetry, this theory opens the door to quantitatively accurate and symmetry-efficient simulations of cavity-modified quantum materials. This is particularly timely for Moiré superlattices and other van der Waals heterostructures, whose very large real-space unit cells make existing polaron-polariton simulations that rely on site bases and broken translational symmetry prohibitively costly. The theory presented here, however, does not suffer from the same shortcoming, and can be applied to existing inter-layer exciton models for Moiré superlattice structures, incorporating strong exciton-boson coupling without breaking the translational symmetry.

By taking advantage of the symmetries of the interactions between these degrees of freedom, we can create new quantum number, a so-called polaron-polariton wavevector, which turns our Hamiltonian block-diagonal in wavevector without using the long-wavelength approximation. While we demonstrate the advantages of this for static calculations such as band structures and dielectric functions, this method will drastically improve that computational speed of dynamics simulations, allowing each individual k-point to have its own independent dynamics. We expect this representation has far-reaching implications for strongly coupled fermion-boson systems due to its fundamental nature, opening the door to more investigations that elucidate materials properties in strong coupling with applications in tuning electronic/optical properties, and enhancing coherent transport. These have the potential enable research in very impactful fields like quantum transduction for quantum information science and quantum transport for microelectronics, whose systems can capitalize on this dynamic interplay between photons, phonons, and fermions.

***Abstract*— Perovskite quantum dots (PCDs) have emerged as efficient room-temperature quantum light sources. This invited talk presents recent advances in controlling single- and multiphoton emission using plasmonic metasurfaces, doping, and van der Waals encapsulation, enabling reversible emission switching and enhanced photostability for practical quantum photonic applications.**

***Keywords*— quantum emitters, perovskite quantum dots, metasurfaces, nanophotonics, plasmonics.**

I. Introduction

Room-temperature quantum emitters are key enablers of scalable quantum communication and integrated quantum photonics. PQDs combine high radiative efficiency, short lifetimes, and solution-processable fabrication, making them attractive candidates for practical quantum light sources. However, challenges related to deterministic emission control, environmental stability, and the realization of advanced functionalities - such as tunable photon statistics and on-demand reconfigurability - at the single-emitter level remain.

II. Methods

We address these challenges through photonic and materials engineering. Plasmonic metasurfaces are employed to tailor the local density of optical states and actively control emission dynamics, including reversible switching between single-photon and multiphoton regimes. Complementary strategies such as transition-metal doping and van der Waals encapsulation are used to suppress photodegradation, blinking, and spectral diffusion at ambient conditions.

III. Results and Discussion

Coupling individual PQDs to plasmonic metasurfaces enables strong modification of their radiative properties through Purcell enhancement and tailored local electromagnetic environments. [1] By controllably varying the emitter-metasurface separation, we demonstrate reversible switching of photon statistics from antibunched single-photon emission to multiphoton emission, without altering the chemical composition or structural integrity of the PQDs. This metasurface-mediated control provides an active and noninvasive route to engineer quantum emission dynamics at the level of individual nanoemitters.

To address the intrinsic instability of PQDs under ambient conditions, complementary materials-engineering strategies are employed. Transition-metal (nickel) doping leads to exciton localization and substantially suppressed photodegradation, enabling highly pure and stable single-photon emission with narrow linewidths at room temperature.[2] In parallel, van der Waals encapsulation using hexagonal boron nitride creates an effective diffusion barrier against moisture and oxygen, strongly reducing blinking, spectral diffusion, and photobleaching while preserving the intrinsic emission characteristics.[3]

Together, plasmonic control and materials stabilization form a versatile platform for quantum light engineering. The combination of on-demand control over photon statistics, room-temperature operation, and enhanced environmental robustness establishes PQDs as reconfigurable building blocks for hybrid metasurface-quantum photonic systems.[4]

IV. Conclusion

The presented results demonstrate that PQDs, combined with metasurface and materials engineering, offer a powerful and scalable route toward practical quantum light sources. Active control, room-temperature operation, and enhanced stability position these systems for future integrated quantum photonic technologies.

***Abstract*— This talk introduces novel telecom-wavelength quantum dots, grown by chemical beam epitaxy in indium phosphide. These bright emitters generate photons in both the telecom O- and C-bands and whose transitions approach the transform limit (i.e. are highly coherent). Nanophotonic structures are fabricated about these quantum dots, controlling and enhancing their interaction with photons.**

***Keywords*— quantum nanophotonics, quantum dots, photonic engineering, telecom-wavelength quantum optics.**

I. Telecom-Wavelength Quantum Dots

Telecommunication quantum light sources will be key components of emerging large-scale quantum technologies, and especially of any future quantum network. Such sources must be efficient, providing high quality – and in particular noiseless, photons in the telecom C-band where ultralow loss fibers are available. Here, we introduce a new platform for the generation and control of telecom-wavelength quantum light, based on self-assembled indium arsenide quantum dots (QDs) grown in an indium phosphide matrix. These QDs, grown in an ultrapure environment, are capable of supporting near noiseless light-matter interactions with no enhancement or charge control. We then present an integrated photonic platform based on these quantum dots, discussing how this enables highly directional light-matter interactions needed for scalable and on-demand quantum technologies.

Subradiant entangled states in plasmonics and the quantization of radiative systems

Angela Demetriadou[1,*]

[1]School of Physics and Astronomy, University of Birmingham, Birmingham, B15 2TT, uk
*Corresponding author: a.demetriadou@bham.ac.uk

***Abstract*—Significant advances have been achieved in quantum nanoplasmonics in recent years. We demonstrate that, under appropriate conditions, plasmonic nanocavities can support the formation of subradiant entangled states between quantum emitters. In addition, we introduce an exact and complete second-quantization framework for open photonic systems with intrinsic radiative losses.**

***Keywords*— quantum plasmonics, nanoplasmonics, quantization, subradiant entanglement.**

I. Introduction

Since the demonstration of room-temperature strong coupling in nanoplasmonic systems, the field has progressed rapidly, enabling unprecedented control of light–matter interactions at the nanoscale. These advances have translated into a broad range of successful applications, including plasmon-enhanced photocatalysis and emergent ultrasensitive spectroscopies, alongside experiments achieving detailed control of polariton-exciton interactions in complex nanostructures. Despite this maturity, nanoplasmonic platforms are still widely viewed as incompatible with genuinely quantum operations and functionalities. Strong Ohmic and radiative losses in metallic nanostructures, together with rapid molecular decoherence at room temperature, are commonly believed to fundamentally limit coherence, thereby preventing the generation of entanglement, the preparation of nonclassical quantum states, or the execution of coherent quantum operations with meaningful fidelity.

In this talk, I show that plasmonic losses—traditionally regarded as a fundamental limitation for quantum plasmonics—can instead be exploited to facilitate the formation of persistent sub-radiant entangled states [1]. I will further discuss how the presence of multiple multipolar modes in plasmonic systems impact the formation of such entangled states [2] and how this understanding can be used to design new plasmonic devices that enahnce and stabilize sub-radiant entanglement [3]. Beyond the physical insights, I will introduce a new second quantization scheme for open, non-Hermitian nanophotonic systems [4] that incorporates radiative losses, without relying on an external bath or other phenomenological assumptions. This approach reveals intrisically non-Markovian dynamics in the interaction between open nanophotonic structures and quantum emitters, uncovering memory effects that are often not captured by other descriptions.

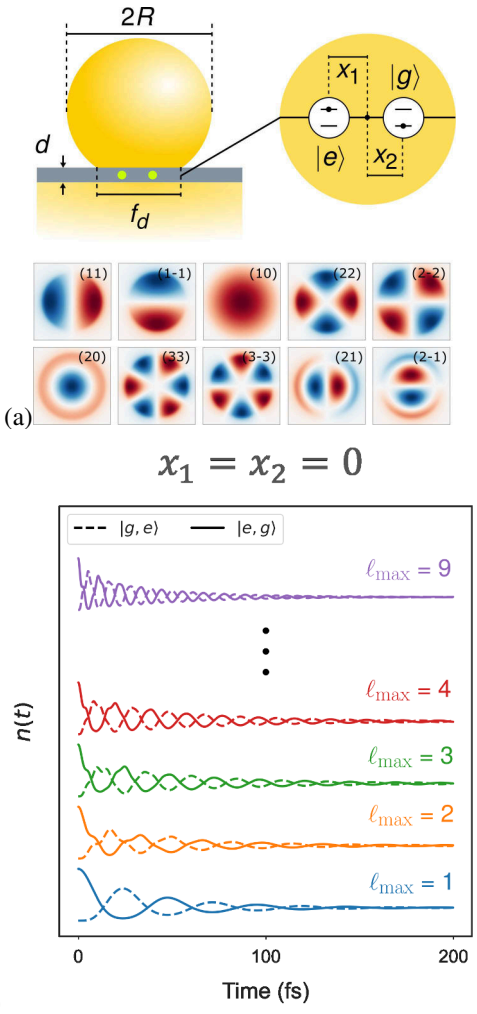

Fig. 1. (a)Nanoparticle on mirror geometry hosting multiple emitters in the gap and supports multiple multipolar modes. (b) The quantum dynamics of the two quantum emitters as they are increasingly coupled to higher-order modes.

II. Results and Discussion

We start with a phenomenological cavity Quantum Electrodynamics description for a system of multiple quantum emitters j in a plasmonic cavity with multiple multipolar

modes ξ (see Figure 1) [1], [2], [3]:

$$\mathcal{H} = \sum_{\xi=1}^{N} \omega_\xi \, a_\xi^\dagger a_\xi + \sum_{j=1}^{M} \frac{\omega_e}{2} \, \sigma_z^j + \\ + \sum_{\xi,j}^{N,M} \left[g_\xi(\mathbf{r}_j) \, a_\xi^\dagger \sigma_j + g_\xi^*(\mathbf{r}_j) \, a_\xi \sigma_j^\dagger \right], \tag{1}$$

where $a_\xi^\dagger$, a_ξ are the creation/annihilation operators of the plasmonic mode ξ with frequency ω_ξ and $\sigma_j^\dagger$, σ_j are the raising and lowering operators of the jth quantum emitter with transition frequency ω_e. The position-dependent coupling strength $g_\xi(\mathbf{r}_j)$ between mode ξ and quantum emitter j at position $\mathbf{r}_j$) is a complex quantity given by $g_\xi(\mathbf{r}_j) = g_\xi e^{i\phi_{\xi j}}$, with g_ξ its magnitude and phase $\phi_{\xi j}$ defined by the phase of the mode [2].

For such multimode systems, the population trapping mechanism is satisfied when a dark state $|\psi_D\rangle = \cos\theta \, |e,g\rangle + e^{i\chi} \sin\theta \, |g,e\rangle$ is decoupled from the cavity, while the corresponding bright state $|\psi_B\rangle = -e^{-i\chi} \sin\theta \, |e,g\rangle + \cos\theta \, |g,e\rangle$ decays rapidly. Here, $\theta \in [-\pi/2, \pi/2]$ and $\chi \in [0, 2\pi]$. So in general, the state $|\psi_D\rangle$ is dark (and therefore persistent) under the conditions $\left(\frac{g_{\xi 1}}{g_{\xi 2}}\right) e^{i(\phi_{\xi 1} - \phi_{\xi 2})} = -e^{i\chi} \tan\theta$, which is valid for any dissipative multimode cavity [3]. For plasmonic nanocavities, this condition is satisfied when the emitters are only coupled to either the even modes (see Figure 1(b)) or only the odd modes of the system, and hence only in these two cases persistent sub-radiant entangled states are formed. When both types of modes are simultaneously coupled to the quantum emitters (even if off detuned from the quantum emitter transition frequency), the sub-radiant entanglement is either rapidly decaying or cannot be formed. Based on these new findings, we design new plasmonic nanocavities that allow us to spatially separate the even and odd modes, and hence allow for the persistent formation of subradiant entangled states.

However, the aforementioned method phenomenologically accounts for radiative losses in the system by coupling the closed system into a reservoir bath, which effectively dissipates the energy in the system. Most methods use similar or equivalent techniques to model the radiative losses. Recently, we developed an exact and complete second quantization scheme for radiative, open and non-Hermitian systems that intrinsically accounts for the radiative losses of the photonic environment [4]. We start by enclosing the photonic system with a putative surface S whose shape matches the geometry of the nanophotonic device on which we apply the boundary condition $(\mathbf{E} \times \mathbf{H}) \cdot d\mathbf{S} = 0$ (Figure 2). This boundary is subsequently taken to infinity, which leads to a continuous set of Helmholtz solutions $\mathbf{u}_\xi(k, \mathbf{r})$. These mode functions are then transformed into a set of discreet set of pseudomodes

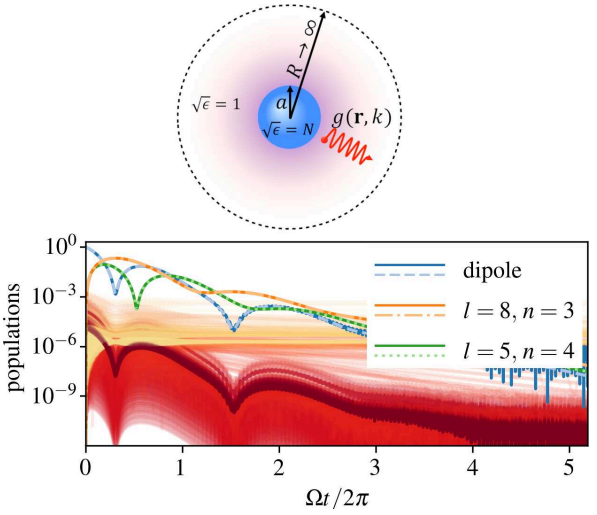

Fig. 2. The pseudomode picture by enclosing a scatterer with a surface, which is then taken to infinity, and the quantum dynamics of a spherical silicon particle coupled to a quantum emitter (dipole).

$\mathbf{v}_\xi(\mathbf{r})$, determined by the transformation [4]:

$$\int_0^\infty k \mathrm{d}k \rho(k) \mathbf{u}_\xi(k, \mathbf{r}) \mathbf{u}_\xi(k, \mathbf{r}') e^{-ick\tau} = \\ = \sum_n z_{\xi n} \mathbf{v}_{\xi n}(\mathbf{r}) \mathbf{v}_{\xi n}(\mathbf{r}') \Theta(\tau - \Delta_t(\mathbf{r}, \mathbf{r}')) \, e^{-icz_{\xi n}\tau}, \tag{2}$$

where $c_0 z_{\xi n}$ are the complex frequencies of the pseudomodes corresponding to the n^{th} resonance of mode ξ, and $\Theta(\tau - \Delta_t(\mathbf{r}, \mathbf{r}'))$ is a Heavyside-step function that physically accounts for the finite time delay for light to propagate from $\mathbf{r}'$ to $\mathbf{r}$. Now the electromagnetic fields can be expressed exactly by a time-dependent superposition of pseudomodes, with the intensity found from the field quadrature acting on $|\psi(t)\rangle$ [4]:

$$\mathbf{E}^+ |\psi(t)\rangle = i \sum_{\xi,n} \sqrt{\frac{\hbar c z_{\xi n}}{2\varepsilon_0 \varepsilon(\mathbf{r})}} \mathbf{v}_{\xi n}(\mathbf{r}) \tilde{b}_{\xi n}(t - \Delta t) \, e^{-icz_{\xi n} t}, \tag{3}$$

where $\tilde{b}_{\xi n}(t - \Delta t)$ is the pseudomode population.

We apply this method for a spherical silicon particle of radius $1\mu m$, and show the quantum dynamics of the system (Figure 2). The quantum emitter is on resonance with the two photonic modes $(8, 3)$ and $(5, 4)$, while all the other detuned modes give rise to many more dynamics of which some demonstrate non-Markovian (memory) effects, often ignored in quantum nanophotonics [4].

III. Conclusion

We have shown that subradiant entangled states can be formed in plasmonic nanocavities, given the right conditions, and introduce a new second quantization scheme that provides an exact and complete description for open, non-Hermitian photonic systems.

Quantum optical metasurfaces for photon pair generation

Igal Brener

Center for Integrated Nanotechnologies, Sandia National Laboratories, USA
ibrener@sandia.gov

***Abstract*—Resonant dielectric metasurfaces with multiple engineered modes, especially high-Q qBICs, enable efficient nonlinear conversion and quantum-light generation without bulk phase matching. They provide control of biphoton polarization, allow two-photon interference between overlapping SPDC channels, and, via symmetry-designed nonlocal quadromer lattices, yield orders-of-magnitude enhancement of four-wave mixing.**

***Keywords*— metasurfaces, SPDC, photon-pairs, quantum, nonlinear optics**

I. Introduction

Resonant dielectric metasurfaces are emerging as a single platform where nonlinear frequency conversion and quantum-light generation can be engineered by design rather than by bulk phase matching. [1] In subwavelength nonlinear media, metasurface resonances effectively define which nonlinear pathways are accessed and how the generated light is structured in spectrum, directionality, and polarization. By incorporating multiple resonances—particularly high-Q quasi-bound states in the continuum (qBICs)—metasurfaces move beyond "field enhancement" toward devices that can shape both classical and quantum states of light.

A key capability enabled by qBIC-based metasurfaces is polarization engineering of spontaneously generated photon pairs. Polarization tomography of nondegenerate SPDC shows that the polarization state of a resonant photon can closely follow the far-field polarization of the driving qBIC mode, making polarization an intrinsic design parameter set by symmetry breaking and the chosen resonances. [2] Furthermore, controlling the Q-factors of the resonances associated with the signal and idler photons can enable separable two-photon polarization states that are attractive for heralded single-photon generation with programmable polarization.

With sufficient efficiency, multichannel SPDC in a single metasurface becomes accessible and allows quantum interference effects to appear directly in the biphoton spectrum. Using a favorable crystal orientation in GaAs to improve overlap with $\chi^{(2)}$ boosts SPDC rates enough that photon pairs generated through a high-Q qBIC channel and a low-Q Mie-like channel can contribute simultaneously over the same spectral region. When a polarization analyzer erases the distinguishability between these two pathways, the biphoton spectrum exhibits a Fano lineshape, providing evidence of biphoton interference. [3]

Further improving parametric processes to include $\chi^{(3)}$ nonlinearities requires a different paradigm for designing multiresonant nonlocal metasurfaces. A symmetry-based rational framework built around "quadromer" lattices (four elements per unit cell) uses double band folding and selection rules to realize several qBIC resonances whose free-space polarizations, Q-factors, mode profiles, and spectral separations can be chosen in a predictable and fabrication-robust way. Applying this design paradigm to $\chi^{(3)}$ processes enabled several-orders-of-magnitude enhancement of four-wave mixing compared to unpatterned films. [4, 5]

Overall, these results point to a coherent route toward compact meta-optics where symmetry, nonlocality, resonance engineering, and material orientation jointly enable efficient nonlinear conversion and programmable quantum-light generation, including controlled interference between resonant channels.

***Abstract*—We use single organic dye molecule at cryogenic temperatures as a readout of the state of a nearby two-level system (TLS). The temperature dependence of the TLS behavior allows us to perform nanoscale thermometry with sub-millikelvin sensitivity. We report on the detection of sub-picowatt heat generation from a single molecule.**

***Keywords*— quantum emitters, dye molecules, single-molecule spectroscopy, nanothermometry.**

Single organic dye molecules at cryogenic temperatures serve as high-quality quantum emitters, demonstrating large light-matter interaction cross-section, negligible dephasing, high photon count, and narrow transition lines[1]. Importantly, their transition frequency and linewidth are sensitive to the properties of the environment such as electric field, strain, and temperatures. This lets them function as an optical interface to the local excitations, an important capability for realizing hybrid quantum systems.

In our work, we use dibenzoterrylene (DBT) dye molecules inside nano-printed anthracene crystals, which has been demonstrated as a versatile platform for quantum optical experiments[2]. We investigate in detail a molecule which is dispersively coupled to a nearby two-level system (TLS). Due to the narrow optical linewidth, different TLS states lead to resolved peaks (see Fig. 1a) in the molecule absorption spectrum, which lets us investigate the TLS dynamics by observing the molecule's spectral jumps. We find that the transition rate between the two TLS states obeys the Arrhenius activation law and is, therefore, extremely sensitive to the local temperature. Thus, combined with the molecular readout, it implements an optically-addressable nanometer-scale cryogenic thermometer with mK-level temperature sensitivity[3].

We first showcase this sensitivity by detecting temperature changes caused by laser-induced heating with a power of about $5\,\mathrm{nW}$ induced about $10\,\mu\mathrm{m}$ away, resulting in a temperature change of $1.5\,\mathrm{mK}$. After that, we use another "heater" molecule at a distance of about $100\,\mathrm{nm}$ as a localized optically-induced point heat source. Surprisingly, despite estimated heating power of about $1\,\mathrm{pW}$, such molecular heater induces a much larger temperature change of about $50\,\mathrm{mK}$ (see Fig. 1b). This is about three orders of magnitude larger than the expectations from the standard Fourier heat transport suggesting $\Delta T \propto 1/r$, which highlights qualitatively different heat behavior at these short length scales and cryogenic temperatures.

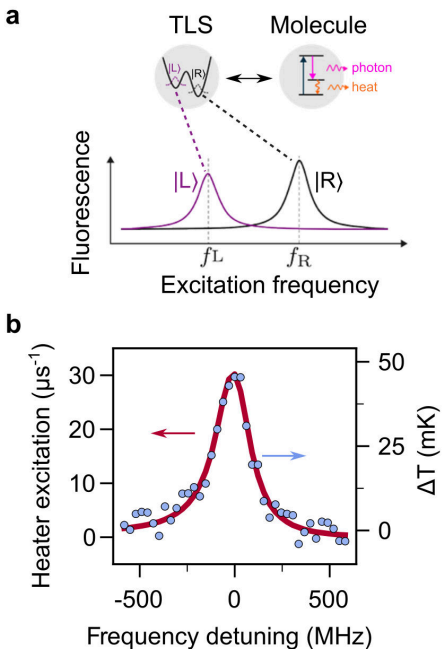

Fig. 1. (a) Illustration of dispersive coupling of a TLS to a single molecular emitter. (b) Excitation rate of a heater molecule (red line, left axis), and the corresponding change in the detected temperature (blue dots, right axis).

Our work demonstrates the utility of dye molecules for detecting and manipulating their environment, serving both as optical interfaces for detection of the nearby TLS state, and as a local optically controlled heat source. In the future, we plan to extend the TLS thermometry approach to different kinds of heaters and environment geometries to explore the intricacies of nanoscale heat transport.

***Abstract*—We show the first demonstration of photon thermalization in a scattering medium interacting with Rhodamine molecules. Scattering and fluorophores' absorption and emission cycles drive dramatic changes of the emission spectrum. A delicate balance between these phenomena leads to an emission spectrum following a Bose-Einstein distribution with a non-vanishing chemical potential.**

***Keywords*— Thermalized radiation, Scattering, Fluorescence, Blackbody**

I. Introduction

A blackbody is a source whose emission depends only on its temperature. The number of emitted photons and their wavelength is described by the Planck's law. In such source, photons exhibit a vanishing chemical potential, meaning that their number is not conserved when the temperature of the blackbody is varied.

It has been shown that a different behaviour can be observed for photons emitted by laser-pumped Rhodamine fluorescent molecules in a cavity [1]. In such a system, multiple absorption-emission cycles generate an equilibrium photon gas characterised by the temperature of the dye solution, and by a chemical potential that depends on the population of the excited and fundamental electronic molecular levels. The chemical potential is therefore controlled by the external pumping, independently of temperature.

Multiple scattering of light in a disordered medium can be used to increase the time that photons spend in the medium. Therefore multiple scattering can replace the role of a cavity in an apparently simple and efficient way and can be used to promote absorption-emission cycles by an ensemble of emitters immersed within the medium. Replacing the cavity by a multiple scattering medium is at the heart of the generation of random laser emission [2].

II. Results and Discussion

In this talk we will show the first demonstration of photon thermalisation in a scattering medium interacting with Rhodamine molecules [3], in a regime which is far from the one of random lasers that require both multiple scattering and large pump power. Studied samples with a fixed density of Rhodamine and increasing densities of scatterers are shown in fig.1. We will show a dramatic change of the Rhodamine emission spectrum driven by both scattering and fluorophores' absorption and emission cycles. Such modification strongly depends on the density of scatterers and fluorophores. A delicate balance between these phenomena leads to photon thermalisation in which the emission spectrum follows a Bose-Einstein distribution with a non-vanishing chemical potential. We demonstrate that the number of emitted photons is driven by the chemical potential, set by the external pumping, and that the spectrum is thermalised at the temperature of the sample.

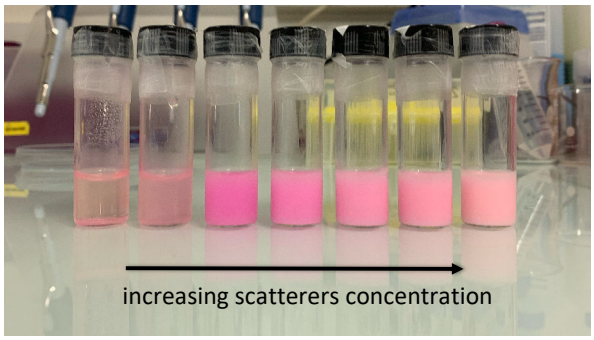

Fig. 1. Samples containing an aqueous solution of Rhodamine and increasing densities of scatterers.

III. Conclusion

We have demonstrated thermalisation of photons in an active scattering random medium. This work opens interesting outlooks for the study of thermalisation and of Bose-Einstein condensation in simple disordered scattering media and its difference from the random laser regime.

Enhanced Plasmon-Emitter Coupling and Emission at the Single-Molecule Level

R. Margoth Córdova-Castro[1,*]

[1]Department of Physics, University of Ottawa, Canada
*Corresponding author: rcordova@uottawa.ca

***Abstract*— We show that using Purcell enhanced emitters coupled to high LDOS metamaterials and detected at the single-molecule level, can serve to translate very minute changes in the electromagnetic environment and in nanopositions impossible to detected, to measurable signals such as bright point sources.**

***Keywords*— bright single-emitter, Purcell factor, dispersive metamaterials, plasmonic, single-molecule super localization microscopy.**

I. Introduction

Controlling emitter-matter interaction beyond the nanoscale resolution and at the single-emitter level is a key challenge for on-chip emerging quantum applications. The rate at which an emitter can convert its excited-state energy into a photon increases as more photonic states are available to radiate into, which is quantified by the local density of states (LDOS) and the Purcell factor. The efficiency with which a single quantum emitter can generate photons in a prescribed optical mode depends on a number of factors: efficiency of excitation (absorption cross-section of the system), the quantum yield of emitted fluorescence and overall collection efficiency.

Coupling single emitters to nanostructures that support very small mode volumes can enhance the interaction. Using the Purcell enhanced emitters can serve to translate very minute changes in environment and nanopositions impossible to detected to measurable signals such as bright point spread functions (PSFs) in an imagine system and the spontaneous emission lifetime via single-photon avalange diodes.
Achieving experimentally systems composed of single quantum emitters coupled to metasurfaces and plasmonic nanoantennas that presents high density of photonic states raises several difficulties, namely: the difficulty of fabricating nanodevices at such small dimensions where high localization and enhancement of electromagnetic fields can be achieved, fabricating the nanomaterial in a controllable and scalable way, coupling the emitters to it (in particular to the regions featuring high LDOS), and observing where these light-matter interactions occur at the nanometer scale. Yet, controlling and measuring these effects at super resolution opens new possibilities for non-invasive quantum nanometrology for sensing small electromagnetic fields and a small density of viruses and viral fragments. In this work, we aim to overcome these challenges by coupling single emitters to a unique plasmonic nanomaterial platform that supports a very rich spectrum of optical modes with extremely high field enhancement and photonic density of states.

II. Methods

We apply super-resolved measurements which unveil unprecedented non-averaged high Purcell factors, giving us access to observe the fine details of quantum light-matter interaction at the nanoscale; simultaneously mapping the position of single emitters and its spontaneous emission decay rate modified by the enhanced density of photonic states in unique engineered material platforms. Far-Field Single-Molecule Super Localization Microscopy (SMLM) allows the detection of single- emitter position and emission rate modification without disrupting the local environment with metallic probes. The single-photon emission lifetime is measured by a single-photon avalanche diode connected to a time correlating single photon counter (TCSPC) with picoseconds resolution and correlated with SMLM to image the Purcell factor enhancement below the diffraction limit. technologies. To compare our measured single-emitter interactions at the nanoscale, we numerically solved Maxwell's equations to analyze the interaction of single electric dipoles with the 3D plasmonic nanorod and hollow nanocone metamaterials, we carried out total and radiated contributions at various positions $\boldsymbol{r}_i$, considering two distinct dipole orientations (in-plane and out-of-plane), across the visible spectrum. To assess the enhanced radiated power, we simulated finite square arrays of increasing size, monitoring the convergence of the results.

III. Results and Discussion

The strong variation of the single emitter properties when coupled to the truncated plasmonic cones placed in a square array with 250nm lattice constant, makes this approach ideal for molecular sensing at the nanoscale resolution, inferring the nano-position and orientation of molecules, or electromagnetic variations inside the 3D nanomaterial.
Hyperbolic nanorod metamaterials represent a cutting-edge approach to manipulating light at the nanoscale, we used plasmonic nanorod metamaterial with 100 nm lattice constant, for spontaneous emission enhancement in the hyperbolic

dispersion region observed significant enhance from nanosecond to picosecond lifetime at the single-molecule level. Both 3D plasmonic metamaterials can be manufactured with centimeter scalable fabrication technique. In addition to their unique anisotropic dispersion, spectral tunability, and fabrication versatility offer promising routes toward scalable quantum photonic devices, ultrasensitive sensors, and light sources with unprecedented efficiency.

Non only for photoactivatable organic single-molecules but for blinking CdS quantum dots and quantum platelets we observe significant improvement of the photophysical properties when coupled to the plasmonic metamaterials in the visible spectra range.
By acceleration of the spontaneous emission process the number of photons per second can significantly increase achieving a bright single photon, yielding quantum light behavior at room temperature. In addition, this makes the single-photon emission rate a precise measure of location, far more accurate than the optical resolution from the same photon. The calculated total decay rate enhancement values vary depending on the emitter position and dipolar moment orientation. For the hollow nanocones the highest values are observed for dipoles placed on the top ring of the truncated cone while for the nanorod metamaterial the coupling effect between nanostructures is more pronounced, showing the highest enhanced emitter-plasmon interaction in the middle of the metamaterial along the rod axis.

IV. Conclusion

We apply super-resolved measurements on coupled plasmon-emitter system with enhanced LDOs, which unveil unprecedented non-averaged high Purcell factors, giving us access to observe the fine details of quantum light-matter interaction at the nanoscale; simultaneously mapping the position of single emitters and its spontaneous emission decay rate modified by the enhanced density of photonic states in unique engineered material platforms. Our findings demonstrate the promise of single-molecule emitters in nanoscale devices to developing quantum nanophononics technologies.

***Abstract* — We analyze the plasmonic properties of highly doped GaN thin films on Si, and show that they exhibit low optical losses and frequencies up to 3 µm. We identify the epsilon-near-zero (ENZ) and near-zero-index (NZI) regions and demonstrate the ENZ character of the polaritonic mode near the plasma frequency.**

***Keywords* — GaN, epsilon-near-zero, near-zero-index, hybrid plasmon-phonon polaritons, thin layers.**

I. Introduction

Epsilon-near-zero (ENZ) materials, defined by $|\mathrm{Re}(\varepsilon)| < 1$, enable the confinement of light within sub-wavelength regions, along with other unique light propagation characteristics. [1,2] To reduce losses in this regime, materials with both near-zero permittivity and $n < 1$ refractive index, known as near-zero-index (NZI) materials, are desired. When both conditions are satisfied, the resulting region is classified as a low-loss ENZ medium combining strong light confinement with reduced optical losses. [2] To achieve this behavior in the mid-IR, heavily doped semiconductors are required, and those compatible with current technologies are most desirable. [3]

Although gallium nitride (GaN) is one of the key semiconductors in industry today, it has not been widely investigated within the plasmonic field or for ENZ-related applications. The present work addresses this gap by providing the first comprehensive study of the plasmonic properties of GaN over Si, including the experimental demonstration of a plasmonic low-loss ENZ mode in the mid-IR. We report highly doped GaN thin films and by analyzing its optical behavior, we establish GaN as a viable low-loss plasmonic ENZ material in the mid-IR.

II. Methods

All the samples employed in this work were grown by molecular beam epitaxy (MBE) on resistive Si (111) substrates. Each sample consists of a highly doped, 100 nm-thick GaN layer deposited on a 100 nm-thick AlN layer, grown on a 2-inch substrate.

Reflectance measurements were carried out in a Fourier Transform Infrared (FTIR) Spectrometer, using p-polarized incident light. Additionally, to match the light in-plane momentum to the polariton momentum and excite the SPPs and SPhPs, the attenuated total reflectance (ATR) technique was used in Otto configuration, using a ZnSe prism with a value of the refractive index of 2.37. The angle of incidence at the prism−air gap interface was controlled from 39° to 59°.

Simulations of the reflectance spectra and the dispersion curves of our structures were made employing the Transfer Matrix Method (TMM), defining the full layer structure of our samples by defining each material by its individual dielectric function and thickness.

Calculations of the band structure and charge distribution were performed using the simulation software *BandEng*. [4]

III. Results and Discussion

Five samples of highly doped GaN thin layers are analyzed in terms of their plasmonic response. **Fig. 1 (a)** shows the measured reflectance spectra of all samples in the region where the minimum corresponding to their plasma frequency is observed in each case. By fitting the measured spectra with the TMM model, we extract the values of plasma frequency (ω_p), which ranges from 2500 cm^{-1} (4 µm) to 3350 cm^{-1} (3 µm), and the optical losses, showing values of 25-30% of the plasma frequency in all cases. The dielectric function of GaN for each sample is then calculated using these extracted parameters, in addition to those related to the phonon resonances of GaN, which are likewise measured and fitted using the TMM model, following the same procedure as for the plasma frequency. **Fig. 1 (b)** shows the case of the most heavily doped sample, showing a zoomed-in version of the spectral region near the plasma frequency, where the ENZ and NZI conditions are satisfied and indicated in dark and light blue bands, respectively. It is important to note that a spectral band exists where these two regimes overlap, resulting in a low-loss ENZ behavior of the material at those frequencies. In the case represented in **Fig. 1 (b)**, the low-loss ENZ regime is found from 2990 to 3540 cm^{-1}.

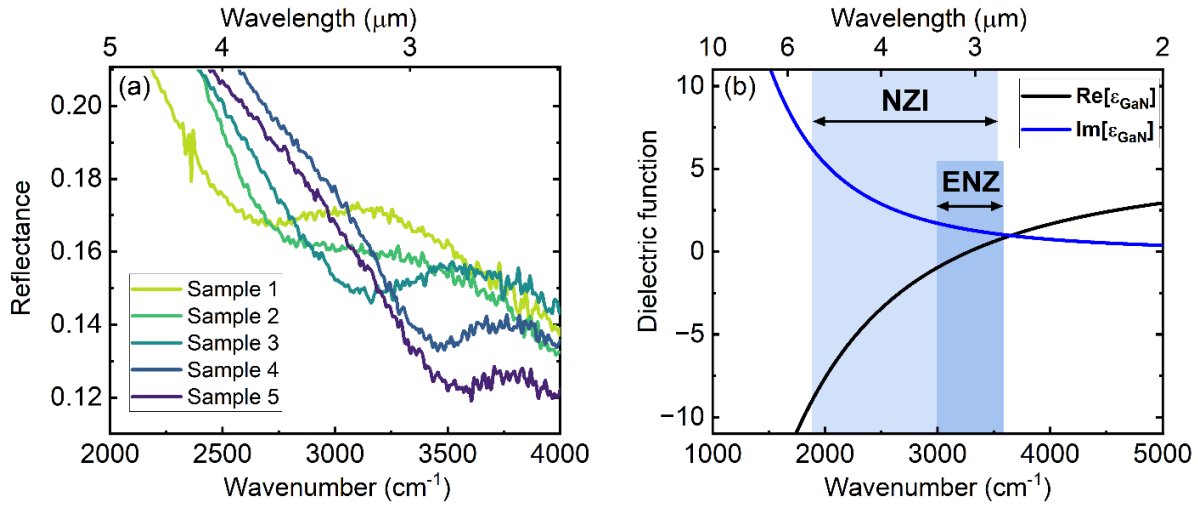

Fig. 1: (a) Reflectance measurements of the series of five samples used in this work, showing the region where the minima corresponding to the plasma frequency are found. (b) Calculated dielectric function of GaN of the most heavily doped sample in the spectral region near the crossover wavelength, including the regions where the material satisfies the ENZ and NZI conditions

Due to the fact that the GaN thin layers in our structures have a thickness of only 100 nm, we anticipate observing a resonance associated with the polaritonic mode near the plasma frequency which is non-dispersive with the incidence angle, a defining feature of ENZ modes in thin films. [2,5] **Fig. 2 (a)** shows the ATR data for the case of the most heavily doped sample. The measurements were made to demonstrate the non-dispersive character of the reflectance minima, which can be deduced from the figure. However, in order to improve visibility, the inset shows the data after a straight baseline has been subtracted, making it evident that the position of the minimum remains pinned when changing the incidence angle. This serves as the experimental demonstration of ENZ nature of the polaritonic mode near the plasma frequency in GaN thin films.

To further validate the ENZ character of the observed non-dispersive mode, we construct the dispersion curves of such sample, shown in **Fig. 2 (b)**. The cone limited by the grey lines represents the measurable range of our experimental ATR setup, and the circular dots are the experimentally resonance frequencies. It can be observed that the high-energy mode is pinned very close to wp, as observed experimentally in **Fig. 2 (a)**, showing a flat dispersion at higher k_x that confirms its ENZ character. On the other hand, the calculation of the dispersion curves allows us to analyze the behavior of all the other polariton modes present in the thin-film structures, at lower frequencies. In particular, it can be observed that the low-energy surface plasmon polariton (SPP) mode couples to the

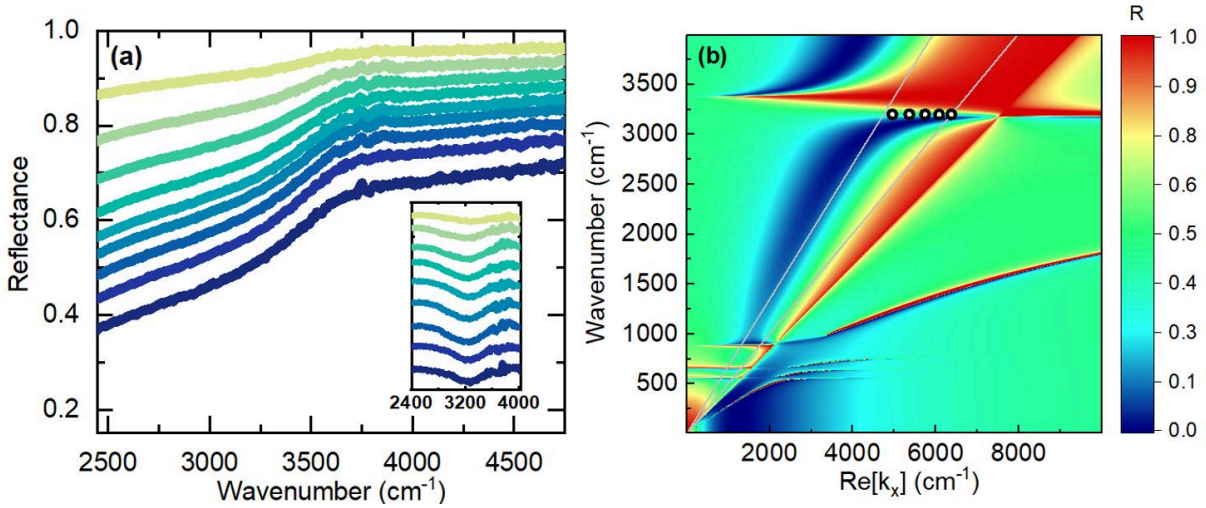

Fig. 2: (a) ATR angle-resolved measurements of the most heavily doped sample. Inset shows the measurements after subtracting a straight baseline, to improve visibility of the minima. multiple surface phonon polariton (SPhP) modes it encounters in its way up in frequency. This coupling indicates the hybrid nature of all surface polariton modes present in the thin film structures.

IV. CONCLUSION

This work provides the first demonstration of a plasmonic ENZ mode in GaN thin films, highlighting GaN as a promising platform for mid-IR ENZ plasmonics and enabling its future integration into infrared photonic technologies.

***Abstract*—Realistic highly symmetric dielectric-metal core-satellite particles are proposed as promising structures to enhance magnetic dipole emission. Magnetic Purcell factors in excess of 200, low losses, robustness to emitter orientation and placement, are all achieved. Quasi-normal modes enhance the optimization, while mode volumes reveal the physics behind the exceptional structure properties.**

***Keywords*— metamaterials, Purcell factor, optics, quasi-normal modes, magnetic emission.**

I. Introduction

Interactions between light and matter are typically dominated by the electric dipole (ED) transitions interaction with the electric field. Nevertheless, the interaction Hamiltonian contains other terms, $H_{int} = -\mathbf{p}\cdot\mathbf{E} - \mathbf{m}\cdot\mathbf{H} - ...$ [1]. In some lanthanide ions, such as Eu^{3+}, which contain a magnetic dipole (MD) transition, ED transitions are parity forbidden. In practice, second order effects, cause the ED transition to become dominant. This motivates the search for other strategies to boost the MD transition over the ED transition. Famously, Purcell showed that the transition rate of an emitter in a cavity can be altered by modifying the photonic density of states in its environment, a phenomenon known as the Purcell effect [2]. Careful resonator design can enhance the MD transition while simultaneously suppressing the ED transition, with a plethora of structures having been proposed to this end [3]. Regardless, challenges still persist, for example, many designs only yield significant enhancements for emitters oriented along a single axis, a factor which is difficult to control experimentally [3]. Plasmonic resonators, are usually associated with large non-radiative losses, while dielectric resonators typically only have large Purcell factors (PF)s for resonators at the micro-scale, with specific emitter locations and orientations, and fabrication remains challenging. More generally, the design of these resonators also remains a challenge due to the large parameter space, which includes the emitters location and orientation, the source wavelength, and any geometrical degrees of freedom for the resonator. We solve both of these problems by designing efficient, isotropic MD emitters with large quantum efficiencies, using existing structures with a known fabrication route. We do so by leveraging a modal design philosophy and exploiting the symmetries of core-satellite nanostructures.

Highly symmetric dielectric-metal core-satellite structures with N satellites (N-pods) have recently emerged as promising candidates for enhancing the magnetic PF. Silica-silver N-pods in particular, are nano-scale structures that have both a large MD moment at optical frequencies and a clear fabrication route for $N \leq 12$ [5], [6]. Modal design is enabled via the use of quasi-normal modes (QNMs) [7], [8], which removes much of the computation expense for the wavelength and emitter locations and orientations while providing significant physical insight into the mechanism of the magnetic PF enhancement. The QNMs are calculated once for a structure, after which nearly any quantity of interest may rapidly be obtained by projecting the QNM fields onto an exciting dipole moment.

We consider these plasmonic N-pods, with Eu^{3+} emitters in the dielectric core, which have a MD transition at 590 nm and an MD transition at 610 nm. We show that for N-pods which can already be fabricated, orientation and location independent magnetic PFs in excess of 40, with magnetic purity and quantum efficiency greater than 90% can be obtained. For an optimized particle, magnetic PFs exceeding 200 can be achieved for a structure smaller than 75 nm in diameter. We further show that structures with tetrahedral symmetry are highly desirable for orientation independence of an emitting magnetic dipole enhanced via the Purcell effect.

II. Theory

QNMs are solutions to the source free Maxwell's equations. The field at the real frequency ω is expanded in the QNM basis as $\mathbf{E}(\omega) = \sum_j \alpha_j(\omega, \widetilde{\omega}_j)\widetilde{\mathbf{E}}_j(\widetilde{\omega}_j)$, where α_j is the excitation coefficient of the j'th QNM $\widetilde{\mathbf{E}}$ with complex frequency $\widetilde{\omega}_j$. The magnetic PF for an emitter at $\mathbf{r}_0$ is,

$$\frac{\gamma_m(\mathbf{r}_0)}{\gamma_{0,m}} = -\frac{2}{\hbar\gamma_{0,m}}\sum_j \Im\left(\alpha_j \mathbf{m}^* \cdot \widetilde{\mathbf{B}}_j(\mathbf{r}_0)\right) \qquad (1)$$

where, $\gamma_{0,m}$ is the MD decay rate of the undressed emitter, γ_m the decay rate of the dressed emitter, $\widetilde{\mathbf{B}}$ the magnetic field of the j'th QNM. The electric PF (γ_p) can be similarly defined in terms of the QNMs [8].

The total decay rate γ_m can be decomposed into its radiative, and non-radiative parts, γ=γ^{rad}+γ^{nrad}, where $\gamma^{nrad} = \int \Im(\varepsilon(\mathbf{r}))|\mathbf{E}(\mathbf{r})|^2 \mathrm{d}^3\mathbf{r}$. The quantum efficiency may then be defined as $QE = \gamma^{rad}/\gamma$, and magnetic branching ratio defined as $\beta_m = \gamma_m/(\gamma_m + \gamma_p)$. We further define the orientation and volume averaged PF as $\bar{\gamma}$, the polydispersity factor ψ and the orientation factor φ, (see Figure 1 (a) for a definition of ψ and φ). This allows the definition of a figure of merit (FOM), which completely encompasses the important optical properties of any resonator.

$$\mathrm{FOM} = \frac{\bar{\gamma}_m}{\varphi}\beta_m QE\frac{\psi}{r_s}, \tag{2}$$

where r_s is the radius of the satellites.

An attractive element of the modal method is the ability to calculate the complex mode volumes $\widetilde{V}_\mathrm{A}$, which can be defined for both electric $A = E$ and magnetic $A = H$ fields. In photonics, the mode volume is loosely analogous with the probability density function in quantum mechanics. For the complex mode volume associated with QNMs, $|\widetilde{V}_A^{-1}|$ indicates the interaction strength, while $\arg(\widetilde{V}_A^{-1})$ is indicates the non-Hermitian character of the mode, and importantly, encompasses the retardation of the radiation back action of a perturber on the mode. The complex modal volume is defined as,

$$\widetilde{V}_\mathrm{A}(\mathbf{r},\mathbf{u}_i) = \frac{\int\left[\widetilde{\mathbf{E}}\cdot\frac{\partial\omega\varepsilon}{\partial\omega}\widetilde{\mathbf{E}} - \widetilde{\mathbf{H}}\cdot\frac{\partial\omega\mu}{\partial\omega}\widetilde{\mathbf{H}}\right]\mathrm{d}^3\mathbf{r}}{2\left[\tilde{\mathbf{A}}(\mathbf{r})\cdot\mathbf{u}_i\right]^2}, \tag{3}$$

where $\mathbf{u}_i$ is the orientation of a smaller perturber, such as a quantum emitter.

We consider N-pods with N between 4 and 30, the placement of the satellites is determined via the solution to the Thompson problem [9], exact solutions exist for $\mathrm{N} = 4, 6, 12$, otherwise we use numerically optimized solutions. Examples for $\mathrm{N} = 7$ and $\mathrm{N} = 12$ are shown in the insets of Figure 1 (a) and (b) respectively. Each of these solutions has an equivalent polyhedron, whose face centers correspond to the locations of the satellites. The symmetries of these equivalent polyhedra are crucial in determining the orientation invariance for an emitter. We initially calculate the magnetic PFs at the MD transition wavelength of $\lambda = 590$ nm for each particle with an emitter at the center of the core and oriented along each axis, for the core radius of $r_c = 42.5$ nm, (which corresponds to the experimental realization of these structures), and vary the satellite radii (r_s). These results, along with the average of the orientations, for $\mathrm{N} = 7$ and $\mathrm{N} = 12$ are shown in Figure 1 (a) and (b) respectively. The importance of the symmetries are immediately made clear, $N = 12$ (along with all Platonic solids) have at least tetrahedral symmetry, while $N = 7$ has dihedral symmetry, the result being that $N = 7$ has a large orientation variance along a single axis, while the $N = 12$ particle is completely invariant to the emitter orientation. We call this variance φ. The maximum mean magnetic PFs for all particles, along with the particles symmetry order are summarized in Figure 1 (c), where φ corresponds to the error bars.

Fig. 1. (a-b) The Magnetic PF calculated at $\lambda = 590$ nm as a function of satellite radius for the $N = 7$ and $N = 12$ structures. The insets show the structures, the red circles denote the orientation averaged PF, while the blue diamonds, black inverted triangles and green triangles show the x, y, and z orientations respectively. The orientation and polydispersity factors, φ and ψ respectively, are shown in (a). (c) The left hand axis and blue circles show the maximum of the mean magnetic PF for each N, the error bars show φ, while the right hand side and red diamonds show the symmetry order of the equivalent polyhedra. (d) The blue dots and left axis show the optimal radius size for $r_c = 42.5$ nm while the right axis and red diamonds shows the normalized polydisersity factor. (e) The left hand side and blue dots show the FOM, the P indicates the structures with platonic equivalent polyhedra, the left side and red inverted triangles, red diamonds, show the magnetic branching ratio and quantum efficiency respectively. (f) Shows Pfs of the fully optimized dodecapod for wavelengths between 300 and 500 nm with $r_c = 24.8$ nm and $r_s = 24.5$ nm, the left axis and solid blue, dashed blue curves show the total and radiated magnetic PF respectively, while the right axis and solid red, dashed red curves show the total and radiated electric PF respectively. (g-j) show the mode volumes of the dominant magnetic mode at the wavelength $\lambda_j = 580+41$ nm for the dodecapod with $r_c = 42.5$ nm and $r_s = 32.5$ nm, (g) shows $|\widetilde{V}_H^{-1}|$, (h) shows $\arg(\widetilde{V}_H^{-1})$, (i) shows $|\widetilde{V}_E^{-1}|$, while (j) shows $\arg(\widetilde{V}_E^{-1})$.

Another experimentally important parameter is the robustness of the optical properties to structural polydispersity, this is characterized by the full width half maximum of the mean PF, and is summarized in Figure 1 (d). It is desirable for ψ to be large and Figure 1 (d) shows a rapid decrease in ψ with increasing N, for example, when $N = 20$ a deviation in r_s of only 1 nm results in a PF decrease of 50%.

Next, we investigate the radiative properties of the optimized particles with $r_c = 42.5$ nm, by calculating γ^{nrad}, β_m, QE and the FOM. These results are summarized in Figure 1 (e), and show that the radiative properties of all particles is exceptional. The branching ratio rapidly asymptotes to above 95% with increasing N, while the QE slowly decreasing to a minimum of $\approx 90\%$ at $N = 30$. The FOM shows very clearly that structures with a platonic equivalent polyhedra are always preferable, and that the dodecapod ($N = 12$), is the most desirable particle. As such we perform a downhill simplex optimization [10] to maximize the cost function $f = \gamma_m^{rad}\beta_m QE$ at the MD transition wavelength of 590 nm, where we vary both r_c and r_s. The structure obtained has remarkable properties, shown in Figure 1 (f), these properties include, a total magnetic PF of nearly 250, a magnetic branching ratio approaching unity and a quantum efficiency of $\approx 72\%$. The QE's associated with the structures here, are surprisingly high for plasmonic based resonators, particularly for structure with the larger core where $QE > 90\%$ for nearly all structures.

To determine the reason for these exceptional properties, we calculate the mode volumes of the dominant magnetic mode. For the optimized dodecapod, the magnetic emission is dominated by a single QNM with the complex wavelength of the mode at $\lambda_j = 582 + 41i$ nm, which is close to the MD emission frequency. The plots of $|\widetilde{V}_A^{-1}|$ and $\arg(\widetilde{V}_A^{-1})$, for $A = E$ and H are shown in Figure 1 for the optimized dodecapod with $r_c = 42.5$ nm. Figure 1 (g) and (h) show a large and spatially uniform interaction strength with a MD in the core of the structure indicated by $|\widetilde{V}_H^{-}1|$, there is also minimal dephasing in the core as $\arg(\widetilde{V}_H^{-1}) \approx 0$. On the other hand, Figure 1 (i) and (j) show a weak interaction with an ED in the core with significant dephasing. Additionally, Figure 1 (i) shows that the electric field is almost entirely confined outside of the metal satellites, which explains the large QE's of the structure.

III. Conclusion

We have explored the use of dielectric-metal core-satellite resonators, which can already be fabricated, as candidates for enhancing MD emissions. An analysis technique, using quasi-normal modes was employed, which enhances the optimization speed while providing significant insight into the physical mechanisms behind the exceptional properties of the structures. The proposed structures have a large magnetic Purcell factor, large quantum efficiencies and branching ratios, and are insensitive to dipole orientation and location. These properties are explained with the aid of symmetries of the structures equivalent polyhedra and the complex mode volumes of the dominant magnetic mode.

***Abstract*— Cd(Zn)O alloys have arguably the best figure of merit for plasmonics in the mid-infrared. However, reports on Cd(Zn)O nanostructures are scarce. This works presents our results on Cd(Zn)O self-assembled nanoparticles and top-down processing of nanostructures with a focus on the near field enhancement.**

***Keywords*— CdO, mid-infrared, self-assembly, dry etching, near-field enhancement, nanoparticles**

I. Introduction

The mid infrared (IR) is a region of the electromagnetic spectrum receiving a great deal of research attention for the development of plasmonic materials and devices. This is in part due to the interest of this region for molecular detection and identification, since many molecules have bonds with vibrational resonances in this, so-called molecular fingerprint region. Thermal imaging and emission, taking advantage of the atmosphere's transparency windows in this region, are also of great interest [1].

Traditionally, the materials of choice for plasmonic structures in the mid-IR have been noble metals, but they suffer from losses that sparked the search for new, better-suited materials. Among these, doped semiconductors and conducting oxides have received a great deal of attention [2]. The latter group include CdO and its related alloys, with arguably the best figures of merit in the mid-IR range due to the large plasma frequency (~4000 cm^{-1}, screened) and low losses (around 15% of the plasma frequency) [3].

Many reports on the plasmonic properties of CdO have been published in the last decade, but mostly focused on thin films; reports on CdO nanostructures have been scarce. Some of these dealt with the synthesis of CdO and related nanoparticles [4], [5], [6]. Our group has also reported self-assembled Cd(Zn)O nanoparticles on GaAs substrates [7], [8]. However, it has not been until very recently that we have reported the first ever top-down approaches for Cd(Zn)O processing by electron beam lithography and dry etching [9].

This work focuses on the results about near-field enhancement by Cd(Zn)O nanostructures from our groups. This will be split in two approaches: self-assembled Cd(Zn)O nanoparticles on GaAs substrates, on the one hand, and nanostructures fabricated on CdO thin films on sapphire substrates, on the other.

II. Methods

The Cd(Zn)O materials presented in this work were deposited by metal-organic chemical vapour deposition (MOCVD) using tertiary butanol, dimethylcadmium, and diethylzinc as O, Cd, and Zn precursors, respectively, with N_2 as the carrier gas. Two different substrates were employed. On the one hand, *r*-plane sapphire, which has a good lattice match with respect to Cd(Zn)O. Thin films (~100 nm thickness) grown on these substrates have shown good crystalline quality and excellent plasmonic properties in the past [10], [11]. Currently, we can fabricate nanostructures on these thin films via electron beam lithography and inductively coupled plasma (ICP) etching. On the other hand, GaAs is employed as a substrate as well. In this case, due to the lattice mismatch between Cd(Zn)O and the substrate, self-assembled Cd(Zn)O nanoparticles (NPs) with very good crystalline quality can be formed [7].

The top down approach to process nanostructures on Cd(Zn)O/*r*-sapphire films consists on standard electron beam lithography with poly(methyl methacrylate) (PMMA) photoresist followed by a novel dry etching protocol we have developed using BCl_3 and Ar in an ICP reactive ion etching chamber [9].

The morphology of the Cd(Zn)O nanostructures is assessed by means of scanning electron microscopy (SEM) and atomic force microscopy (AFM). Fourier transform infrared spectroscopy (FTIR) is used to probe the optical properties of

the structures. COMSOL Multiphysics with the waveoptics module is employed to calculate the electric field distribution around the nanostructures in the near field.

III. Results and Discussion

Figure 1(a) shows a set of representative fabricated CdO stripes on *r*-sapphire. The stripes are 1600 nm wide with a 400 nm gap between them. From Figure (b) it is apparent that the vertical walls of the CdO stripe are actually slanted at an angle of approximately 45º. This is due to the initial shape of the PMMA photoresist [9].

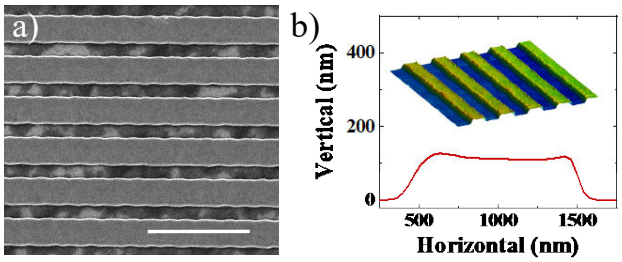

Figure 1. (a) Top-view SEM image of representative CdO stripes on an *r*-plane sapphire substrate. The white scale bar is 5 µm long. (b) AFM profile of a single stripe. The inset shows a 3D AFM reconstruction of a set of stripes.

Figure 2(a) shows the FTIR reflectance of a set of CdO stripes, featuring a reflectance band due to the formation of a localized surface plasmon in the stripes. The figure also includes a calculated reflectance spectrum. The spectra feature several bumps at higher energies than the main peak which calculations show correspond to different modes and field distribution around the edges and corners of the stripes.

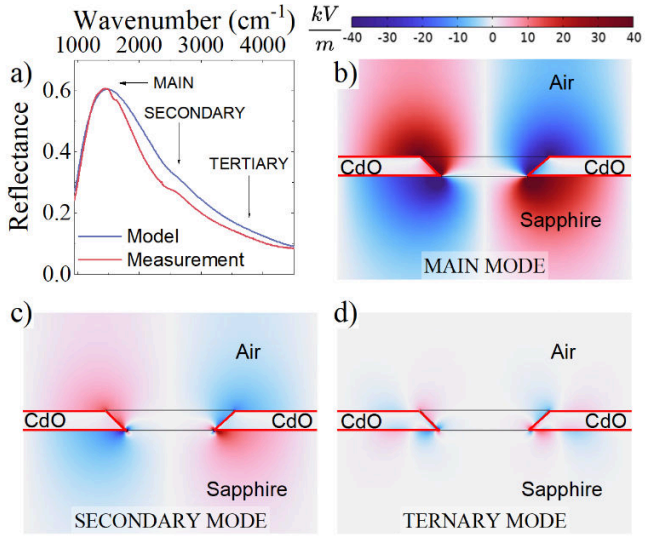

Figure 2. (a) Experimental (red) and calculated (blue) reflectance of a set of CdO stripes. (b) to (d) Calculated electric field around the edges of the stripes at different frequencies in the spectra in (a).

Coupling of these modes to both the phonons of the substrate and also to the resonances of substances deposited on top of the stripes will be discussed. Also, the feasibility of applying this processing protocol to Cd(Zn)O on substrates different from sapphire, such as GaAs and SiC will be discussed.

With regard to the self-assembled Cd(Zn)O NPs, we have produced ensembles of particles with varying radius, which correlates inversely to the surface particle density. It will be shown how the size distribution and surface coverage homogeneity have improved a great deal compared to previous reports from our group (Figure 3(a), compared to references [7], [8]).

Figure 3(b) shows the reflectance spectrum of the NPs. Two modes are apparent, one at lower energy (high reflectance) attributed to electron oscillations along the substrate plane, and another at higher energy (lower reflectance) attributed to electron oscillations perpendicular to the substrate. The low-energy (LE) mode features a large divergence of the electric field at the edges of the hemispherical NPs [7].

It is found from finite element modelling (FEM) that the volume in the substrate in which the electric field is enhanced is much larger for larger nanoparticles (Figure 3(c) and (d)), reaching as deep as 400 nm for NPs of 240 nm radius. This is really attractive from the point of view of e.g. increasing the intersubband absorption by quantum wells located underneath the particles. The implications of this on the performance of quantum well infrared photodetectors (QWIPs) will be discussed and the integration of the NPs on the photodetectors will be shown.

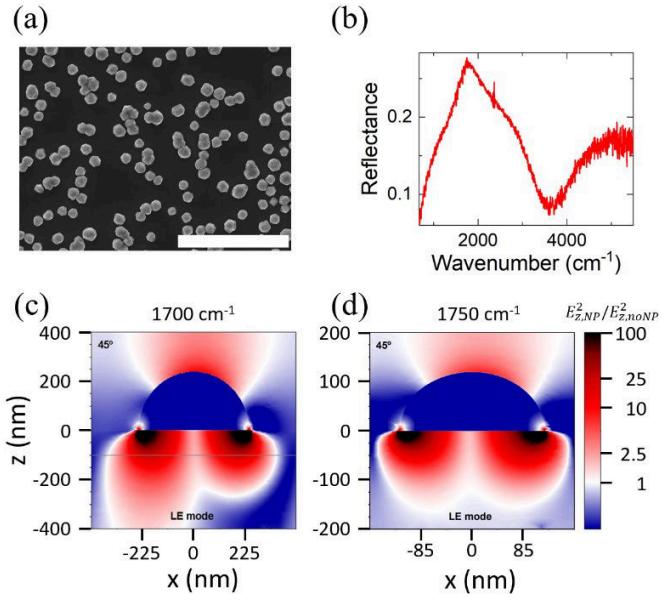

Figure 3. (a) Top view SEM image of a sample with 240 nm-radius NPs. (b) Reflectance spectra of the sample in (a). (c) and (d) Electric field enhancement FEM calculation for a 140 nm-radius NP (c) and for a 240 nm-radius NP (d). Calculations in (c) and (d) are normalized to the case with no NP and performed at the respective low energy-mode frequency. The angle of incidence is 45º. Note the different x and z scale in both cases.

Also, the near-field enhancement atop the NPs is attractive for applications such as surface-enhanced IR absorption (SEIRA). Results in terms of vibrational signal enhancement for several molecular species will be shown as well. Notably, a vibrational signal enhancement from vanillin of around × 4 has been achieved [8].

IV. Conclusion

A novel dry etching protocol to generate nanostructures on Cd(Zn)O thin films grown on *r*-sapphire substrates is presented. Details about the processing and discussion of the field enhancement due to plasmonic (from Cd(Zn)O) and phononic (from the substrate) effects induced by the stripes will be discussed. Currently, this etching protocol is being developed for Cd(Zn)O films grown on other substrates such as GaAs and SiC.

Self-assembled Cd(Zn)O NPs have been demonstrated on GaAs substrates, with two plasmonic modes corresponding mainly to in-plane and out-of-plane electron oscillations. Good control of NP size, with a very good homogeneity of NP size and distribution over the substrate has been achieved. NPs as large as 240 nm in average radius have been deposited, capable of concentrating the electromagnetic field up to 400 nm into the substrate. Applications to SEIRA and QWIP enhancement will be shown.

***Abstract*— Epsilon-near-zero thin films offer unconventional for optics including nonlinear applications. While metal nanostructures can enhance these effects through strong coupling, their fixed permittivity restricts tunability. By replacing metal with a conducting polymer, we can reversibly tune this coupling. Such hybrid system allows for on-demand optical functionalities for reconfigurable nanophotonics.**

***Keywords*— epsilon-near-zero mode, conducting polymers, plasmonic nanoantennas, dynamic coupling, tunable nanophotonics.**

I. Introduction

Materials whose real permittivity approaches zero within a specific wavelength range while maintaining a low imaginary component are known as epsilon near zero (ENZ) media. Thin films of indium tin oxide (ITO) have been employed as a platform for exploring ENZ phenomena that can funnel obliquely incident near-infrared light into highly confined modes and exhibit strong nonlinear optical behavior.[1] Stronger ENZ responses was achieved under normal incidence by integrating metallic nanoantennas on top of the ITO layer.[2] In these hybrid architectures, the localized surface plasmon resonance (LSPR) of the metal antennas couples to the ENZ mode in the ITO. However, this coupling is typically static due to the fixed permittivity of metals. In this work, we demonstrate dynamically tunable coupling to ENZ modes based on conducting polymer nanoantennas.

II. Methods

Finite-difference time-domain method was employed for numerical simulations, using the commercial software Ansys Lumerical. As experiments, we fabricated thin films of poly(3,4 ethylenedioxythiophene) (PEDOT) through vapor phase polymerization of its monomer and employed electron beam lithography to create nanostructures. Sulfuric acid solution and polyethylenimine vapor were used for chemical doping and dedoping of the samples, respectively. For electrical switching, a two-electrode electrochemical setup with ion gel electrolyte was used.

III. Results and Discussion

Conducting polymers offer electrically and chemically tunable permittivity: they act metallic when doped and dielectric when dedoped. [3] This enables adjustable LSPR modes in conducting polymer nanostructures, as demonstrated in our recent studies.[4]–[6] By placing PEDOT nanoantennas on ITO thin film, we realized a hybrid ENZ-plasmonic nanosystem and the results show:

- >90% modulation of the electric field intensity inside the ENZ layer upon doping/dedoping of the nanoantennas (see simulations in Fig. 1a)
- Extinction peak splitting in the spectroscopic measurements, a characteristic of coupling and polariton formation.
- Reversible control of coupling strength applying very low voltages or simple chemical treatments. (see spectra in Fig. 1b)

This work [7] also clarifies the dual role of ITO in many other dynamic conducting polymer nanosystems where ITO thin films are used as electrodes and provides guidelines for electrically switchable plasmonic–ENZ devices.

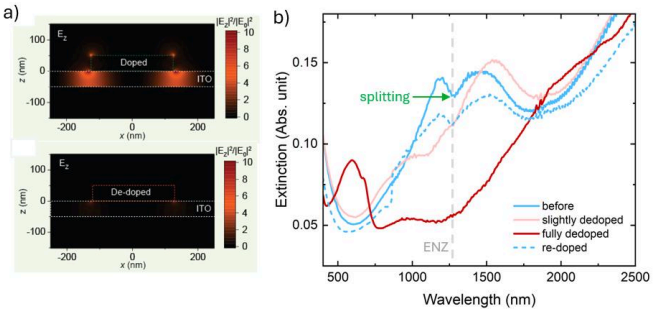

Fig. 1 a) Simulated electric field distribution for doped PEDOT (upper panel) vs de-doped PEDOT (lower panel) antenna on top of ITO thin film. b) Experimental spectra of hybrid ENZ-plasmonic system at varying chemical redox state of PEDOT showing reversible peak-splitting due to coupling.

IV. Conclusion

We demonstrated coupling between the LSPR of conducting polymer nanoantennas and the ENZ mode of an ITO thin film. [7] By leveraging the reversible charge carrier density changes in the polymer through chemical or electrochemical stimuli, the coupling strength was dynamically tuned. Future work can enable local control of the polymer charge density which can further allow spatially programmable ENZ field patterns, offering new capabilities for reconfigurable photonics.

***Abstract*—The ultrafast optical control of microresonators remains underexplored despite many prospective applications in nanophotonics. We demonstrate that ultrafast optical pulses can reversibly modulate whispering-gallery resonances in quantum-dot superparticle microresonators due to combined electronic and thermal effects. The results suggest quantum dot superparticles as metamaterials for photonic switching and optoelectronic nanotechnologies.**

***Keywords*—superparticles, ultrafast, microresonators, quantum dots**

I. Introduction

The self-assembly of nanoscale building blocks such as semiconductor quantum dots (QDs) into ordered superstructures enables the realization of artificial metamaterials with emerging collective properties. Depending on their degree of organization, such assemblies may exhibit phenomena such as exciton delocalization and transport [1], superfluorescence [2], collective plasmonic response [3]. Among the various realizations, superstructures based on fluorescent semiconductor QDs are particularly attractive for photonic and optoelectronic applications. Spherical QD superparticles (SPs) with micrometric dimensions can sustain, so-called, whispering-gallery modes, giving rise to sharp optical resonances that coexist with intense photoluminescence. This combination has recently enabled their use as active microresonators and microlasers [4]. While the steady-state optical properties of these metamaterials have been widely investigated, the ultrafast dynamical response remains far less explored. In particular, the possibility of controlling whispering-gallery mode SP microresonators using ultrashort optical pulses has hardly been addressed, despite representing an appealing route toward all-optical photonic circuits.

Addressing such problems requires experimental techniques capable of simultaneously achieving micrometer-scale spatial resolution and femtosecond temporal resolutions, as required to resolve the fundamental relaxation processes at the nano- and micro-scale. Following our recent work [5], here we report the use of ultrafast optical microscopy to investigate and manipulate the transient optical response of individual SP microresonators under femtosecond excitation. Specifically, we employ ultrafast optical microscopy to probe and manipulate the relaxation dynamics of whispering-gallery-mode microresonators consisting in SPs self-assembled from fluorescent QDs. We show that femtosecond optical excitation can induce reversible modifications of the resonant photonic modes over a wide spectral window, originating from ultrafast variations of the refractive index associated with both electronic excitation and subsequent thermal processes. These findings provide new insight into the picosecond- and femtosecond-scale optical dynamics of active microresonators and suggest potential applications in photonic technologies, including all-optical ultrafast circuitry and optical switching.

II. Methods

We started from CdSe core/CdS shell QDs (10.3 nm size, core diameter 3.5 nm, Figure 1b) to assemble quasi-monodisperse spherical SPs (10.8 μm size) through an approach recently demonstrated by some of the authors [6]. Each SP (Figure 1c), with a clearly defined spherical shape, contains more than 10^8 individual QDs assembled in a regular supercrystalline structure.

As a preliminary study, we investigated the optical properties of SPs individually and at the ensemble level, by steady-state photoluminescence and micro-photoluminescence. Then we carried out micro-pump-probe experiments on individual SPs, in a home-built setup [5] where the spatial resolution is dictated by the probe beam size (2.5 μm) and the temporal resolution is dictated from the pump pulse duration (50 fs). Individual SPs are pumped by light pulses at 400 nm with 50 fs duration, produced by second-harmonic generation of the fundamental beam from an amplified Ti:Sapphire laser, and probed by a

white-light continuum produced by focusing a fraction of the same beam through a water cell. The pump and probe pulses are tightly focused on the sample by a short focal length parabolic mirror, and the transmitted probe is collected by a microscope objective and sent to a spectrometer for analysis.

III. Results and Discussion

Individual SPs assembled from CdSe/CdS QDs exhibit intense photoluminescence accompanied by a distinct comb of narrow spectral features (Figure 1f), confirming their behavior as whispering-gallery mode microresonators. The emission quantum yield exceeds 90% and shows a slight spectral shift relative to that of isolated QDs (compare Figure 1d with Figure 1e and 1f), indicating significant electronic coupling within the assembled structure.

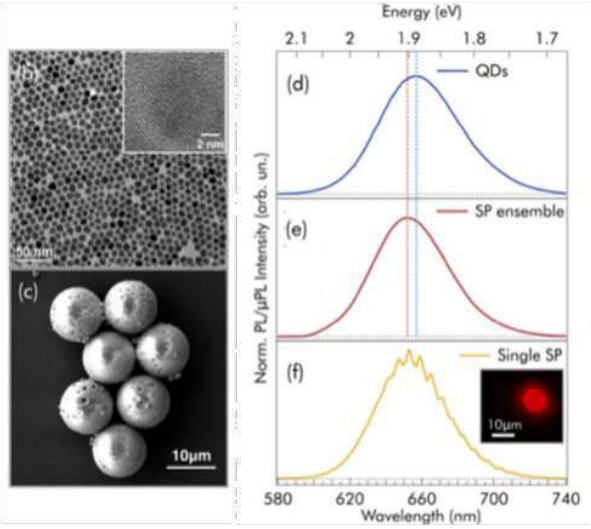

Fig. 1 The self-assembly of nanometrically-sized CdSe/CdS quantum dots (b) leads to the formation of spherical whispering-gallery mode SPs (c). Photoluminescence spectra of quantum dots (d), of SPs at ensemble level (e) and of individual SPs (f). Figure adapted from ref. [5]

A typical result of micro pump-probe measurements on individual SPs is summarized in Figure 2. Ultrafast pump–probe measurements (Figure 2a, 2b) reveal a transient differential absorption signal dominated by a negative contribution associated with so-called state-filling effects [7] in the QDs. While the temporal dynamics of this signal provide information on the electron-electron and electron-phonon relaxation pathways, this will not be discussed here. Superimposed on this broad response, a fine modulation pattern is observed (Figure 2c, 2d), which is the main focus of this work. The modulation pattern can be isolated from the signal envelope by subtracting a smoothed version of the signal (see Figure 2c-2d), yielding the residuals shown in Figure 2e. We attribute these modulations to a photo-induced shift of the whispering-gallery mode structure. In particular, the effect arises from transient changes in the refractive index of the SP following photoexcitation. Small variations in SPs size lead to distinct modulation patterns in different SPs (Figure 2e).

The photo-induced modulation pattern appears as a succession of positive and negative lobes in close succession: because of the differential nature of the transient absorption signal, the negative lobes represent the original spectral positions of microresonator modes, that is, the modes before photo-excitation, while the positive lobes represent the spectral positions of the new modes shifted by photo-excitation. Therefore, from this measurement we infer that photo-excitation induces a transient shift of the mode structure of the SP microresonator. This effect can be used in principle to "switch" the resonance modes of the metamaterial by purely optical means.

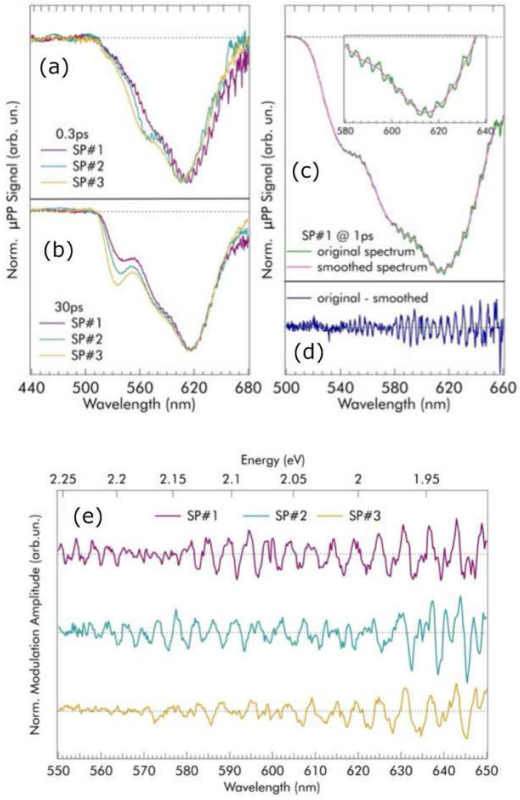

Fig. 2 Differential absorption spectra at two different delays from photoexcitation(a,b), as detected from three different SPs. Isolation of the modulation pattern appearing on top of the broad differential absorption signal (c)(d). Modulation pattern as observed on three different SPs (e). Figure adapted from ref. [5]

Time-resolved analysis of these signals (not shown) shows that the modulation amplitude rises within the pump–probe cross-correlation time, indicating an almost instantaneous electronic contribution. A further increase on the picosecond timescale reflects lattice heating mediated by electron–phonon interactions, followed by a gradual recovery over hundreds of picoseconds as the system returns to equilibrium.

IV. Conclusion

In summary, we showed that femtosecond optical excitation can induce reversible modifications in the modal structure of

whispering-gallery-mode SP microresonators based on fluorescent QDs, through the combined action of electronically- and thermally-driven modifications of the refractive index. Quantum-dot SPs can be seen as a class of metamaterials with considerable potential for photonic applications, including microlasers and micro-scale communication devices. In this context, the ability to reversibly tune their resonator properties using ultrashort light pulses offers new opportunities for all-optical control in advanced quantum-dot-based photonic technologies.

***Abstract*— We present non-Hermitian degeneracies, specifically exceptional points (EPs), in geometry-controlled intersubband polaritonic metasurfaces consisting of two plasmonic resonators strongly coupled to intersubband transitions. By varying the resonator gap, we precisely control the coupling coefficient and demonstrate EP emergence near 9.74 μm through numerical simulations in the mid-infrared regime.**

***Keywords*— Exceptional Points, Non-Hermitian, Metasurfaces**

I. Introduction

Metasurfaces enable precise control over the local phase, amplitude, and polarization of scattered light. Over the past decade, passive flat optical platforms such as metalenses and waveplates have attracted significant attention. In the mid-infrared (MIR) region, polaritonic metasurfaces combining plasmonic ridge resonators with intersubband transitions (ISTs) in multiple quantum wells (MQWs) have demonstrated strong coupling. This strong coupling supports the formation of intersubband polaritonic modes, providing a robust passive platform for polarization control and beam manipulation in the MIR regime.[1]

The non-Hermiticity inherent to metasurfaces originates from their open-system nature, where continuous energy exchange occurs between incident radiation and resonant nanostructures through radiation and dissipative losses. Such non-Hermitian frameworks allow engineered control of coupling strength and loss imbalance, giving rise to unconventional spectral responses and modal behavior beyond conventional Hermitian systems. Exceptional points (EPs) are non-Hermitian degeneracies where eigenvalues and eigenvectors merge, resulting in parity–time symmetry breaking, increased sensitivity, non-orthogonal states, and optical scattering singularities.[2] These unique features have attracted considerable interest across photonics and physics. However, despite extensive studies in other spectral regimes, the realization of exceptional points in the mid-infrared regime has not yet been reported.

In this work, we realize EPs by systematically tuning the coupling coefficient between two plasmonic resonators via precise control of their gap separation. By exploring multiple coupling regimes defined by different gap sizes, we map the parameter space to the condition where the coupling rate balances the loss contrast, leading to eigenmode coalescence at the EP.

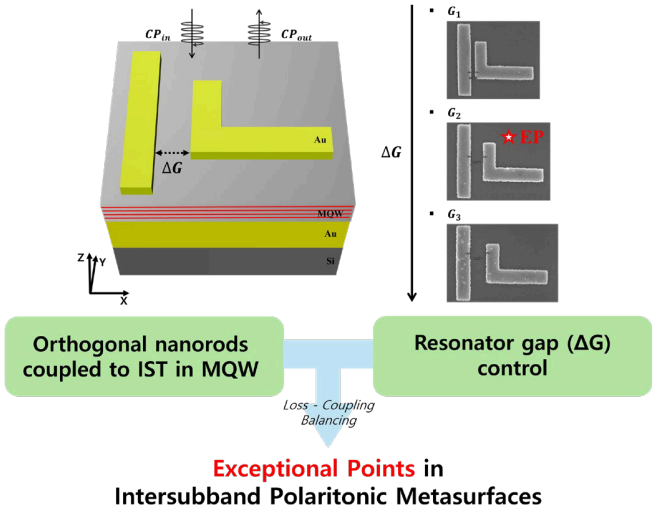

Fig. 1. Concept of the Non-Hermitian Metasurfaces.

II. Device Design

We designed a 300nm-thick MQW layer comprising 16 repetitions of double quantum wells, composed of $In_{0.52}Al_{0.48}As/In_{0.53}Ga_{0.47}As$ heterostructures. The absorption energy of IST between the 1st and 2nd states in the conduction band of the MQW is 122 meV (λ ~ 10.3 μm) at 0 V as shown in Fig. 2(a). Fig. 2(b) displays the unit cell structure, consisting of x- ("L" shape) and y- ("I" shape) polarized plasmonic resonators, supporting two orthogonal modes with different dissipative loss rates. The coupling rate is controlled by the coupling length (ΔG) between the two resonators. As shown in Fig. 2(c)-(d), each resonator can induce plasmonic resonances for x- and y- polarized incident light. These resonances generate enhanced E_z fields inside the MQW layer, which can be strongly coupled to the IST.

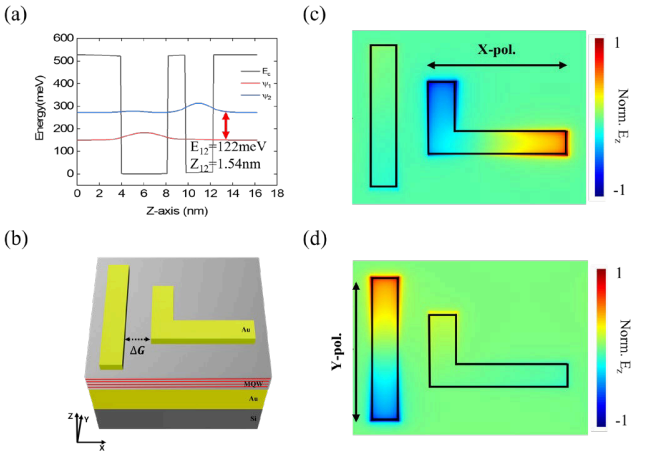

Fig. 2. Design of Non-Hermitian metasurfaces. (a) Conduction band diagram of one period of a MQW at 0 V. The layer sequence (unit: nm) is 4/4.2/1.6/2.5/4 where InGaAs wells are marked in red. (b) Schematic of one unit cell of the metasurface. Top metal(yellow) is gold. (c, d) Top-view cross sections of the normalized E_z field in the MQW layer at $\lambda = 9.74\mu m$ for x- and y-polarized incident light.

III. RESULTS AND DISCUSSION

First, we numerically investigate the evolution of the non-Hermitian eigenvalues and eigenpolarization states by sweeping the ΔG between the two resonators. Fig. 3(a) shows the eigenpolarization states plotted on the Poincaré sphere as the ΔG is swept. As ΔG is gradually tuned, the two eigenpolarization states approach each other and eventually coalesce at a single point, indicating the formation of an EP. Fig. 3(c)-(d) present the simulated eigenvalue magnitude and phase, respectively, mapped as functions of ΔG and wavelength. At ΔG =303 nm and λ =9.74 μm, both the magnitude and phase of the two eigenvalues simultaneously merge, confirming the coalescence of the non-Hermitian eigenmodes at the EP. Fig. 3(b) shows the corresponding eigenpolarization states projected onto the two-dimensional polarization plane. Near the EP, the two states converge to left circular polarization (LCP). As ΔG is further varied beyond this condition, the eigenpolarization states separate again, indicating the transition away from the EP regime.[3]

As discussed in the previous section, the coalescence of eigenpolarization states into the LCP state at the EP prohibits polarization conversion from RCP to LCP. Consequently, the reflection coefficient corresponding to the $R \rightarrow L$ channel approaches zero at the EP condition. Fig. 4(b) presents the circular-basis reflection spectra, where the evolution of the resonances can be observed as the system approaches the EP. By performing a basis transformation from the linear basis to the circular basis, the corresponding circular reflection components are obtained. Notably, the R_{RL} component converges toward zero near the EP, indicating the suppression of cross-circular polarization conversion. To further highlight this effect, Fig. 4 (c) shows the same circular-basis reflection expressed in the dB scale. The contrast between the R_{LR} and R_{RL} channels become significantly enhanced, demonstrating a pronounced circular dichroism with a high extinction ratio. These results confirm that the EP-induced eigenstate coalescence directly leads to unidirectional circular polarization selectivity in the reflected field.

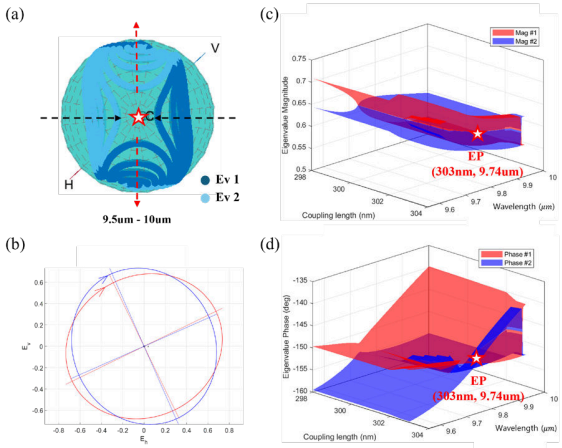

Fig. 3. (a) Poincaré sphere representation of eigenpolarization evolution during a coupling-length sweep, culminating in LCP state coalescence. (b) Near the exceptional point, both eigenpolarization states collapse into a single LCP eigenstate, evidencing polarization-state degeneracy. (c,d) Eigenvalue amplitude and phase dispersions versus coupling length and wavelength, revealing degeneracy and the characteristic branch-point topology of the EP.

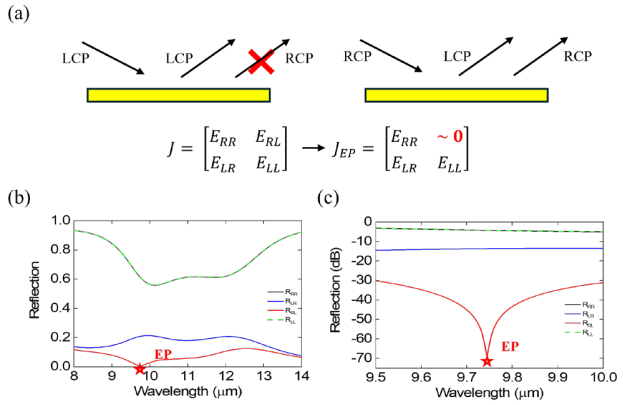

Fig. 4. (a) Chiral degeneracy at the exceptional point, where eigenstate coalescence occurs toward the LCP state. (b,c) Reflection responses in the circular polarization basis near the EP; (b) is shown in linear scale, and (c) is presented in dB scale.

Based on the theoretical predictions presented earlier, we are carrying out fabrication and measurements to experimentally realize the Exceptional Point. Fig. 5(a) shows scanning electron microscope (SEM) images of the fabricated samples with intentionally varied ΔG (or gap). The structures with different gap sizes (e.g., 350 nm, 290 nm, 160 nm, and 80 nm) are well defined, confirming that the geometric parameters were accurately implemented as designed. Using these fabricated samples, we measured the reflection spectra under linearly polarized incidence with an FTIR (Fourier-transform infrared) system, as shown in Fig. (b)–(d). The co-polarized reflection components (R_{xx} and R_{yy}) exhibit resonance features consistent across different gap conditions, while the cross-polarized

component (R_{xy}), shown in Fig. (d), reveals a clear gap-dependent behavior. As the gap decreases, the coupling strength between the two nanorods increases, leading to a significant enhancement of the cross-polarized reflection. This trend confirms that the coupling coefficient can be effectively and systematically controlled through geometric gap variation, providing an experimental pathway toward accessing the Exceptional Point regime.

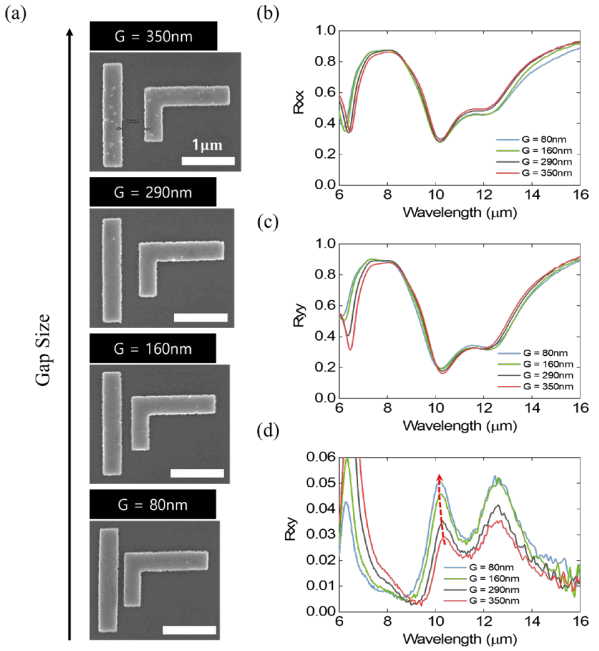

Fig. 5. (a) SEM images of the fabricated metasurfaces with different gap sizes (G = 350 nm, 290 nm, 160 nm, and 80 nm), confirming the controlled geometric variation of the proposed structure. (b–d) Measured reflection spectra under linear polarization basis: (b) $\boldsymbol{R_{xx}}$, (c) $\boldsymbol{R_{yy}}$, and (d) $\boldsymbol{R_{xy}}$. In (d), the cross-polarized reflection increases as the gap decreases, indicating enhanced coupling strength between the two resonators at smaller separations.

IV. Conclusion

In this work, we numerically demonstrated the emergence of an Exceptional Point (EP) by systematically mapping the coupling–loss parameter space and observing the coalescence of both eigenvalues and eigenpolarization states. Based on the fabrication results and measured linear-basis reflection spectra, we experimentally verified that the coupling strength is effectively controlled through geometric gap variation, confirming that the loss–coupling balance required for the realization of the EP can be achieved via coupling engineering.

Having confirmed the controllability of the coupling coefficient toward the EP condition, we are now extending the measurements to the circular polarization basis to directly probe the EP behavior and the associated chiral response.

***Abstract*— Solutions to PDEs in the form of the Helmholtz equation are produced at 193.41 THz by exploiting a network of dielectric waveguides with wave splitters and Bragg gratings. Numerical simulation results will be presented demonstrating the potential for this technique to produce accurate solutions to Dirichlet boundary value problems.**

***Keywords*— Analog computing, PDE solving.**

I. Introduction

Optical analog computing has emerged as an interesting paradigm [1, 2] owing to the advantages of exploiting light as an information carrier [3-7]. Platforms such as plasmonics [8, 9], photonic integrated circuits [4, 10-13] and gratings [11, 14] have proved promising candidates for realizing optical computing. Additionally, the introduction of metamaterials and metasurfaces also has enabled new opportunities in optical analog computing [1, 2, 15], due to the near arbitrary control they enable over propagation in both space and time [16-19]. Various analogue processors have been proposed to solve a range of computing tasks [4, 8, 13, 20-26].

While modern analog computing harnesses light to perform calculations, early examples exploited mechanical [27] and later electrical [28, 29] systems. For instance, analog PDE solutions could be produced by exploiting a grid-like network of electrical lumped elements [28, 29]. Similar approaches have also been applied at higher frequencies. For instance, metatronic circuits embedded in an epsilon-near-zero medium [25] and photonic circuits PICs [4, 13] have been used to produce solutions to the Poisson equation at optical frequencies. It has also been shown how waveguide-based metatronic circuits may be used to produce solutions to the Helmholtz equation at microwave frequencies [26].

In this work, we demonstrate a structure capable of calculating solutions to the Helmholtz equation at optical frequencies ($f = 193.41$ THz). This is done by exploiting a network of dielectric waveguides with wave splitters and Bragg gratings. During the conference, the design process behind the PDE solving network will be presented alongside a full theoretical analysis of the structure. Numerical simulation results will also be presented demonstrating the capabilities of this structure to calculate accurate solutions to Dirichlet boundary value problems.

II. Methods

A schematic representation of the proposed dielectric waveguide-base PDE solving structure is presented in Fig. 1a (right). As can be seen, the network consists of an array of dielectric waveguides, forming a grid, with wave splitters and Bragg gratings. Each wave splitter is constructed from a hollowed dielectric cylinder placed at the crossing point between waveguides [30]. As will be explained in detail during the conference, the geometry of these wave splitters is optimized to ensure that the signals are equally spread throughout the network [31-33], as a requirement of the PDE solving technique [26, 34]. Between each splitter, a Bragg grating is placed. During the conference, a full mathematical study of this structure will be presented, demonstrating how it can emulate the behavior of a quadrilateral finite difference mesh (shown in Fig. 1a, left). When doing so, one should consider the waveguide junctions as analogous to the sampling points of the finite difference mesh, while the Bragg gratings, which control the coupling between splitters, determine the PDE parameters h and k to be solved. Here h is the separation between sampling points in the finite difference analogy and k is the wavenumber of the PDE.

Furthermore, this work exploits a simple waveguide splitting structure which, even after optimization, exhibits non-ideal behavior (scattering losses and non-ideal phase relation). During the conference it will be explained how this non-ideal behavior is considered when producing a mapping between the reflection and transmission coefficient of the Bragg grating and the parameters of the PDE to be solved. In doing so we demonstrate that a wide range of PDE solutions are attainable when exploiting simple non-ideal splitting structures.

III. Results and Discussion

To demonstrate the potential of this PDE solving technique, numerical simulation results of two example solutions are presented in Fig. 1c,d. Here a 5×5 grid is used to solve a Dirichlet boundary value problem in which the boundaries are

all set to $H = 1$. For the 5×5 example, the PDE solution may be extracted from the 9 central junctions (labeled 1-9 in Fig. 1c). Numerical simulation results for the magnetic field sampled at the center of these 9 junctions are presented in Fig. 1d alongside theoretical values corresponding to an ideal PDE solutions. These examples are for networks designed to solve the Dirichlet boundary value problem when $h^2k^2 = 0.05 + 2.54i$ (top panel) and $h^2k^2 = -0.248 - 0.193i$, respectively. As can be seen, the numerical simulation results are in agreement with the theoretical results in both scenarios indicating that the network is indeed producing accurate PDE solutions

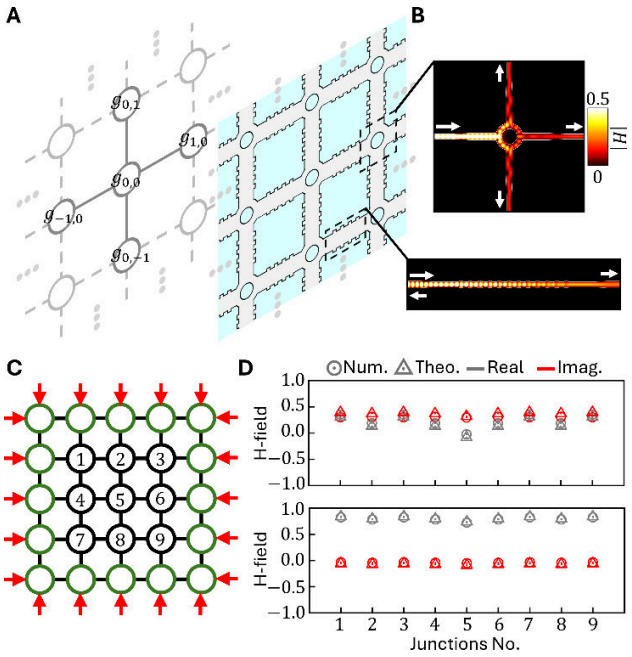

Fig. 1 **a**. Schematic representation of the PDE solving network. **B**. Numerical results of network components: (Top) wave splitter and (bottom) Bragg grating **c**. Schematic representation of a 5×5 network. **d**. Numerical simulation results of the scenario presented in **c** when (top) $h^2k^2 = 0.05 + 2.54i$ and (bottom) $h^2k^2 = -0.248 - 0.193i$, respectively.

IV. Conclusion

A method of producing discretized solutions to PDEs in the form of the Helmholtz wave equation using analog systems at 193.41 THz has been presented. Similar to circuit-based PDE solving techniques, this method exploits a network designed to emulate the performance of a finite difference mesh. During the conference, numerical simulation results will be presented showing networks of various sizes producing accurate solutions to Dirichlet boundary value problems. This demonstrates the potential of this PDE solving approach even when exploiting relatively simple wave splitter designed with non-ideal behavior.

***Abstract*—We investigate the origin of inverse Faraday effect and gyrotropy in epsilon-near-zero films under circularly polarized excitation. We compare four theoretical frameworks: (a) isotropic third-order nonlinearity, (b) Hertel's plasma model with time-averaged charge–velocity interaction, (c) nonlinear free-electron hydrodynamics, and (d) mass-varying Drude theory. Common mechanisms and key differences are discussed.**

***Keywords*— Epsilon-near-zero materials, gyrotropy, inverse Faraday effect, ultrafast photonics, nonlinear optics, plasmonics.**

I. Introduction

Gyrotropic optical effects are typically associated with magnetized or chiral media and manifest as antisymmetric off-diagonal terms in the permittivity tensor. In magneto-optical systems, the constitutive relation is commonly written as

$$\bar{\varepsilon} = \begin{pmatrix} \varepsilon & ig & 0 \\ -ig & \varepsilon & 0 \\ 0 & 0 & \varepsilon \end{pmatrix}, \tag{1}$$

where g is the gyrotropic coefficient responsible for circular birefringence and Faraday rotation. In linear magneto-optics, the gyrotropic coefficient is proportional to the magnetic field applied in the longitudinal direction. In nonlinear optics, for example in a pump-probe setup, the magnetic field may be induced and controlled by an intense pump.

Epsilon-near-zero (ENZ) materials provide an exceptional platform for all-optical symmetry breaking due to their extreme dispersion and field enhancement. Under intense pumping, even small perturbations of the electronic plasma can strongly modify the optical response. In particular, circularly polarized (CP) excitation carries spin angular momentum (SAM), which may be transferred to the electron gas, inducing a quasi-static axial response. This phenomenon can be interpreted in terms of the inverse Faraday effect (IFE), i.e., the conversion of optical SAM into electronic orbital motion and therefore magnetization.

Despite long-standing interest in the IFE [1], [2], [3], the microscopic origin and magnitude of gyrotropy in ENZ plasmonic films, and, more generally, in plasmonic systems, remains debated, especially in ultrafast regimes where time-varying conductivity, effective mass, and carrier density may play a major role. This work compares four theoretical models predicting light-induced gyrotropic responses in ENZ films, highlighting common physical foundations and critical differences.

II. Models and Physical Mechanisms

A. $\chi^{(3)}$ Inverse Faraday Effect

The classical approach to the IFE assumes an isotropic, instantaneous, third-order response and links the light-induced gyrotropy to a cubic nonlinear polarization term. The analogy of IFE to degenerate four-wave mixing has been discussed in [4] and [5]. For a monochromatic pump field $\mathbf{E}$, one obtains an antisymmetric nonlinear polarization contribution proportional to [1], [2], [3]

$$\mathbf{P}_0^{(3)} \propto \chi^{(3)}\, i\,(\mathbf{E}\times\mathbf{E}^*)\times\mathbf{E}. \tag{2}$$

In particular, the vector $i(\mathbf{E}\times\mathbf{E}^*)$ is proportional to the optical spin density and points along the propagation direction for CP pumping, and it may be interpreted as an effective, light-induced magnetization in the longitudinal direction. This model has the great advantage of compactness and applicability to a variety of materials, both opaque and transparent. However, the approach is inherently perturbative and fails to elucidate the physical origin of the nonlinear effects in ENZ structures, where the contribution of free electrons is generally dominant.

B. Hertel's model

Hertel [6] derived an IFE model for conducting plasmas where longitudinal magnetization emerges from charge continuity. A CP pump induces transverse electron velocity oscillations, while the continuity equation enforces a correlated density modulation. Their nonlinear mixing yields a nonzero time-averaged current circulation with a solenoidal component that may be associated with a longitudinal magnetization:

$$\mathbf{M}_0 = i\frac{ne^3}{4m^2\omega^3}\mathbf{E}\times\mathbf{E}^* \tag{3}$$

where m and n are the electron effective mass and density, respecitvely, e the elementary charge, and ω the angular frequency of the pump. This model explicitly ties gyrotropy to plasma dynamics and predicts strong dependence on plasma

frequency ($\varepsilon_0\omega_p^2 = ne^2/m$), and it has been invoked to explain the experimental observation of light-induced magnetism in gold nanoparticles pumped with CP light [7]. The appearance of this magnetization leads to symmetry breaking, i.e., to a pump-controlled gyrotropy mediated by the Lorentz force $\mu_0\sigma\mathbf{E}\times\mathbf{M}_0$. Recently, the linear magneto-optic effect in ENZ films has been investigated in the static configuration in which a magnetic field externally applied in the longitudinal direction induces a gyrotropic effect [8], [9]. The Faraday rotation is significantly enhanced near the ENZ wavelength. Here we will assess the ability of this model to quantitatively predict the amount of light-induced Faraday rotation in ENZ films.

C. Hydrodynamic Nonlinearities

Hydrodynamic approaches provide a more complete classical description of nonlinear electron motion in plasmonic media, incorporating convective, Coulomb, and Lorentz second-order nonlinear contributions, as well as the impact of losses [10], [11]. In such models, the coupled current-density equations generate a DC effective magnetic field arising from quadratic mixing of the pump-induced oscillating velocity (or current):

$$\mathbf{B}_{\text{eff}} \sim \langle \mathbf{v} \times \mathbf{v}^* \rangle \propto i\,(\mathbf{J} \times \mathbf{J}^*)\,. \tag{4}$$

The quasi-static field breaks time-reversal symmetry and modifies the effective permittivity experienced by a probe via magnetic Lorentz force. According to this model, the amount of gyrotropy associated with the IFE effect is mediated by the following effective magnetization:

$$\mathbf{M} = i\frac{|\sigma(\omega)|^2}{2n_0 e\omega}\mathbf{E}\times\mathbf{E}^* \tag{5}$$

in which $\sigma(\omega) = \frac{ne^2}{m(\gamma - i\omega)}$ is the complex conductivity. This represents an extension of the Hertel model to the case of a lossy plasma ($\gamma \neq 0$). The hydrodynamic model also predicts IFE from the orbital angular momentum of light [11], as well as surface nonlinear IFE whose role in light-induced gyrotropic effects has not been yet assessed.

D. Mass-varying Drude model

A further mechanism is associated with ultrafast carrier heating. In ENZ and plasmonic materials, strong pumping generates hot-electrons. The rate of change of the effective mass of these carriers introduces an additional damping term in the hydrodynamic model with anisotropic features. Recently, ultrafast polarization control has been observed in ENZ films [12]. The mass-varying Drude model provides a complete explanation of all the observed anisotropic effects, including the appearance of a handedness-dependent, time-varying gyrotropic conductivity [12]. This model suggests that gyrotropy can arise not only from applied or induced magnetization static fields, but also from pump-induced modulation of transport parameters.lin

III. Results and Discussion

All investigated models share a unifying physical picture: CP pumping produces an axial DC quantity proportional to the optical spin density

$$\mathbf{S} \propto i(\mathbf{E}_p \times \mathbf{E}_p^*), \tag{6}$$

which induces either a quasi-static magnetization $\mathbf{M}_0$, an effective field $\mathbf{B}_{\text{eff}}$, or an antisymmetric correction to the conductivity tensor. In each case, the probe experiences a permittivity tensor producing polarization rotation and circular birefringence.

However, the models differ in predictive scaling laws. The $\chi^{(3)}$ model provides a perturbative Kerr-like dependence but lacks explicit plasma transport physics. Hertel's approach captures charge continuity but predicts polarization rotation angles much smaller than those observed in the experiments. Hydrodynamic models with second-order multipolar nonlinearities incorporate interface effects, making them particularly suitable for nanometric ENZ films, but their bulk contribution is on the same order of the Hertel's model. Hot-electron models, such as the mass-varying Drude model, provide an additional contribution associated with ultrafast modification of the effective mass m and γ. This mechanism can be the most relevant in pump-probe experiments in ENZ films [12], and its contribution becomes increasingly significant for few-cycle and subcycle pulses.

IV. Conclusion

We compared four theoretical models predicting gyrotropic responses in plasmonic and ENZ films driven by circularly polarized pumping: isotropic $\chi^{(3)}$ IFE, Hertel plasma magnetization, nonlinear hydrodynamic models, and hot-electron effective mass anisotropy. All approaches rely on the conversion of optical SAM into electronic angular momentum, generating antisymmetric permittivity terms. Hydrodynamic and plasma-based models appear most consistent with ENZ thin-film physics, especially when interfaces and ultrafast parameter renormalization are significant.

***Abstract*—Carrier Drift Modulation imparts a transient drift momentum to free carriers using few-cycle optical excitation, producing strong anisotropy in nominally isotropic conductors. This ultrafast mechanism enables hyperbolic dispersion and supports time-periodic amplification, offering a practical route to low-loss hyperbolic media in standard semiconductor platforms.**

***Keywords*— hyperbolic media; photonic time crystals.**

I. Introduction

Temporal modulation of optical media has emerged as a powerful tool for reshaping electromagnetic response in ways that static materials cannot achieve [1]. By altering material parameters on timescales comparable to or shorter than the optical period [2], one can access regimes where the usual constraints of causality, dispersion, and spatial symmetry are fundamentally modified [1]. Such temporal control has enabled concepts ranging from time refraction and time reflection to photonic time crystals with engineered Floquet band structures [3], [4], [5].

Despite this promise, most approaches to ultrafast temporal modulation face significant limitations [6]. Mechanisms based on carrier density modulation require high fluence and suffer from slow relaxation. Nonlinear optical methods demand extreme intensities and often introduce unwanted heating. Electro-optic modulation is fundamentally bandwidth-limited. As a result, achieving strong, reversible modulation at optical frequencies has remained a central challenge.

Carrier Drift Modulation (CDM) [7] offers a fundamentally different route. Instead of modifying the number of carriers or their temperature, CDM uses a few-cycle optical pulse to impart a net drift momentum to the electron gas. This directional shift of the carrier distribution is extremely fast – limited only by the duration of the optical pump pulse – and naturally reversible on the carrier relaxation timescale. Because real electronic bands are non-parabolic, the drift modifies the effective mass tensor and produces a transient anisotropy that can be surprisingly large even for a moderate drift.

This anisotropy is strong enough to induce a topological transition to hyperbolic dispersion in an initially isotropic conductor. When the drift is applied periodically, the system becomes a hyperbolic photonic time crystal (HTC), combining the high-wavenumber support of hyperbolic media with the parametric amplification inherent to time-periodic systems. The resulting platform supports tunable dispersion, ultrafast reconfigurability, and intrinsic gain – all using standard semiconductor materials and commercially available ultrafast sources.

II. Carrier Drift Modulation

A sub-cycle pump pulse $E_M(t)$ transfers a net impulse

$$p_0 = e\int_{-\infty}^{\infty} E_M(t)\,dt, \tag{1}$$

shifting the carrier distribution to

$$f_M(\mathbf{p},t) \simeq f_0(\mathbf{p}-\mathbf{p}_0), \tag{2}$$

for $\tau_M \ll t \ll \tau_0$. This shift is conceptually simple but physically profound. The electron gas is then displaced in momentum space. Because the effective mass depends on the magnitude of the momentum, this displacement changes the inertia of the carriers in a direction-dependent manner, producing an anisotropic dielectric response.

For a moderate drift when the transferred impulse is less than the Fermi momentum ($p_0 < p_F$), the non-parabolicity of the band yields

$$\Omega_{\parallel}^2 \simeq 3\frac{\alpha_*\omega_p^2}{m_0}p_0^2, \tag{3}$$

$$\Omega_{\perp}^2 \simeq \frac{\alpha_*\omega_p^2}{m_0}p_0^2, \tag{4}$$

leading to the permittivity tensor

$$\epsilon_{\parallel,\perp} = \epsilon_\infty\left(1-\frac{\omega_p^2-\Omega_{\parallel,\perp}^2}{\omega^2}\right). \tag{5}$$

The resulting anisotropy is not a small perturbation: even a modest drift can shift the plasma frequency in the directions parallel and perpendicular to the free carriers drift, opening the hyperbolic dispersion window for

$$\sqrt{\omega_p^2-\Omega_{\parallel}^2} < \omega < \sqrt{\omega_p^2-\Omega_{\perp}^2}. \tag{6}$$

This transition occurs on a timescale much shorter than τ_0, making it effectively instantaneous from the perspective of the probe field. The medium abruptly switches from isotropic to hyperbolic, enabling ultrafast control of high-wavenumber modes and directional propagation.

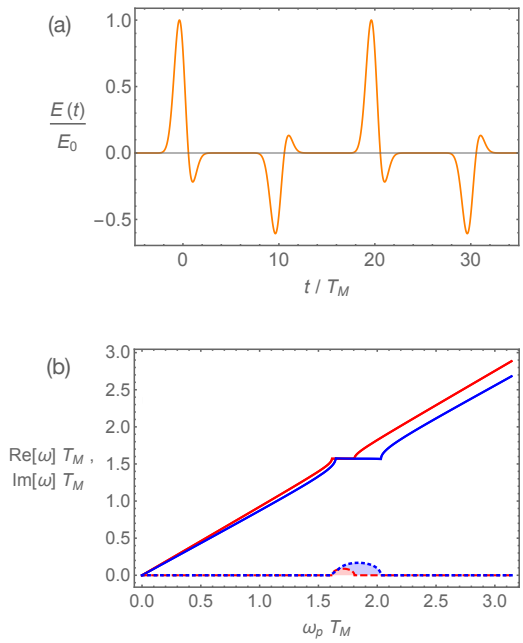

Fig. 1. (a) Modulation pulse sequence and resulting drift-momentum pattern defining the temporal unit cell. (b) Floquet–Bloch quasi-frequency versus the scaled modulation interval $\omega_p T_M$, showing its real and imaginary components for different modulation strengths (red and blue color). Solid and dashed lines represent the real and imaginary parts of the Floquet–Bloch frequency, respectively. Complex quasifrequencies indicate the onset of parametric gain.

III. Hyperbolic Time Crystal

Periodic drift modulation produces a temporal photonic crystal whose Floquet bands depend sensitively on the modulation period. For short periods, the system behaves as a temporal metamaterial with effective parameters given by the time-averaged permittivity. In this regime, the medium behaves like a conventional hyperbolic material, but with tunable anisotropy and ultrafast switching capability.

As the modulation period increases and approaches a significant fraction of the optical cycle, the full Floquet structure becomes important. The system develops bandgaps in the temporal domain, analogous to spatial photonic crystals. However, because the modulation is strong and anisotropic, these bandgaps occur in a regime where the medium is already hyperbolic. This leads to a hyperbolic time crystal, a new class of photonic structure that combines the unbounded-k support of hyperbolic media with the temporal band engineering of time crystals.

Figure 1 illustrates the corresponding modulation protocol in panel (a), and the resulting quasifrequency spectrum (panel (b)) – which highlights the emergence of complex quasifrequencies, marking the transition to an amplifying regime. These features arise directly from the strong, ultrafast anisotropy produced by CDM.

The Floquet dispersion reveals a rich structure, including avoided crossings, band folding, and regions of complex quasifrequency. The latter correspond to parametric amplification, where the modulation pumps energy into the probe field. The interplay between hyperbolic dispersion and temporal periodicity produces a landscape of modes that have no analogue in either static hyperbolic media or conventional time crystals.

IV. Parametric Gain and Loss Compensation

One of the most important consequences of CDM is that the same mechanism that creates hyperbolic dispersion, also provides parametric gain. When the modulation period satisfies a simple resonance condition, the Floquet bands acquire a positive imaginary component. This corresponds to the exponential amplification of the probe field.

In realistic materials such as crystalline semiconductors GaAs or InGaAs, the gain can reach or exceed the intrinsic absorption of the medium. This directly addresses a long-standing challenge in hyperbolic photonics, where substantial intrinsic losses have consistently restricted the performance and applicability of such materials. CDM provides a route to low-loss hyperbolic media, something that has been sought for more than a decade. The ability to compensate losses without introducing external gain media or complex architectures represents a significant step toward practical nanophotonics.

V. Practical Feasibility

A key advantage of CDM is that it requires no exotic materials or extreme fields. The required pump impulses correspond to peak fields on the order of a few hundred kV/cm – well within the capabilities of commercial few-cycle IR sources. The materials themselves are standard: heavily doped semiconductors and transparent conducting oxides, both widely used in photonics and electronics.

The modulation is ultrafast, reversible, and compatible with high-repetition-rate operation. Because the drift momentum decays only on the carrier relaxation timescale, the modulation can be applied at tens of terahertz without requiring continuous high-power pumping. This makes CDM suitable for integration into on-chip photonic platforms, where compactness and compatibility with existing fabrication processes are essential.

VI. Conclusion

Carrier Drift Modulation provides an ultrafast route to inducing hyperbolic dispersion in isotropic conductors. Periodic modulation forms a hyperbolic time crystal with intrinsic parametric gain, enabling low-loss hyperbolic media using standard semiconductor materials and readily available ultrafast sources.

***Abstract*—Wavelength-multiplexed metasurfaces offer a compact platform for multifunctional optical imaging, yet achieving reconfigurable operation with low crosstalk remains challenging. Here, we present a wavelength-driven multifunctional metasurface that enables reconfigurable optical imaging within a single device. The metasurface selectively generates a focused beam at 450 nm for bright-field imaging and a vortex beam at 532 nm for edge-enhanced imaging. Experimental results demonstrate robust, crosstalk-suppressed mode switching across geometric, resolution, and biological samples, validating the proposed approach as a versatile platform for adaptive compact optical systems.**

***Keywords*— Wavelength-multiplexing, reconfigurable imaging, metasurface.**

I. Introduction

Optical imaging provides access to fine spatial and morphological details, underpinning diverse applications from biological observation and machine vision to industrial inspection.[1-3] Comprehensive sample characterization often necessitates multiple imaging modalities. In particular, bright-field imaging captures subwavelength structural details, while edge-enhanced imaging emphasizes object boundaries by filtering high-frequency components. Integrating both functions into a single system remains challenging due to inter-channel crosstalk arising from competing phase and amplitude requirements.[4-7]

Wavelength multiplexing offers a promising route to channel isolation, yet its implementation with conventional refractive optics is hindered by limited design freedom and bulky configurations.[8-9] Optical metasurfaces-ultrathin arrays of subwavelength scatterers-enable precise, wavelength-dependent wavefront control within a compact platform.[10] Although recent metasurface designs have realized single or dual functionalities under fixed illumination, a robust strategy for fully independent, switchable multi-wavelength operation is still needed.

Here, we demonstrate a wavelength-multiplexed metasurface that supports reconfigurable bright-field and edge-enhanced imaging in a single device. Under linearly polarized light, the metasurface generates a focused beam at 450 nm and a vortex beam at 532 nm, corresponding to the two imaging modes. Through complex-transmission-coefficient optimization and superimposed phase engineering, crosstalk is suppressed while maintaining high efficiency. Experimental characterization and imaging of geometric, resolution, and biological samples confirm reliable mode switching and functional versatility, establishing a practical platform for multifunctional compact optical systems.

II. Methods

Our methodology integrates simulation, optimization algorithms, and experimental feedback: Current optical imaging techniques face a trade-off between spatial resolution and edge contrast. Conventional wide-field microscopy is straightforward but diffraction-limited; confocal methods enhance resolution at the cost of complexity; and edge-detection systems typically rely on bulky 4f setups with limited functional versatility. To overcome these limitations, we propose a wavelength-multiplexed metasurface that integrates bright-field and edge-enhanced imaging within a single planar device.

As illustrated in Fig. 1a, the metasurface comprises periodic rectangular TiO_2 nanoposts on a silica substrate (period: 0.35 μm, height: 0.5 μm). A meta-atom library was constructed via FDTD simulations by varying nanopost dimensions, providing full 2π phase coverage with high transmission under both x- and y-polarizations at the two target wavelengths: 450 nm and 532 nm. The design encodes two independent phase profiles: a focusing phase for 450 nm TE polarization (Eq. 1) and a vortex phase carrying topological charge $\ell = 1$ for 532 nm TM polarization (Eq. 2). These profiles are spatially combined into a single metasurface layout through a phase-superposition strategy, enabling dual-wavelength and dual-polarization operation without crosstalk. Figure 1b illustrates the operational principle: under 450 nm x-polarized light, the device focuses the beam for bright-field imaging; under 532 nm y-polarized light, it generates a focused vortex for edge-enhanced imaging. The fabricated metasurface (diameter:

90.3 μm) is shown in the SEM images in Fig. 1c and 1d, confirming uniform nanopost arrangement and geometric variation.

$$\varphi_{TE}(x,y) = \frac{2\pi n}{\lambda_1}\left(f - \sqrt{x^2+y^2+f^2}\right) \quad (1)$$

$$\varphi_{TM}(x,y) = \frac{2\pi n}{\lambda_2}\left(f - \sqrt{x^2+y^2+f^2}\right) + \ell \tan^{-1}\frac{y}{x} \quad (2)$$

where x, y are the in-plane coordinates of the metasurface. The wavelengths λ_1 and λ_2 are 450 nm and 532 nm, serving as the beams for bright-field and edge-enhanced imaging, respectively. The refractive index of air is denoted by n, f represents the focal length, and ℓ symbolizes a topological charge.

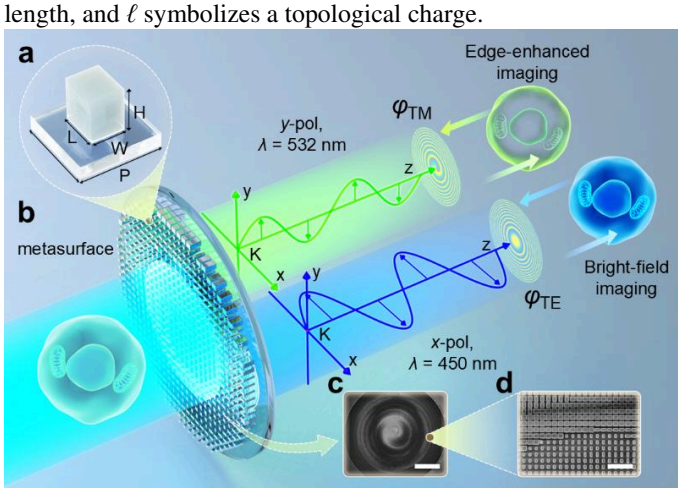

Fig. 1 Unit cell geometry of the proposed metamaterial. Dual-wavelength and dual-polarization metasurface design and characterization. (a) Unit cell consisting of a TiO_2 nanopost on a silica substrate. (b) Operating principle: under 450 nm x-polarized light, the metasurface produces a focused beam for bright-field imaging; under 532 nm y-polarized light, it generates a vortex beam for edge-enhanced imaging. (c) Scanning electron microscopy (SEM) image of the fabricated metasurface (90.3 μm × 90.3 μm; scale bar, 30 μm). (d) Zoomed-in top-view SEM showing rectangular TiO_2 nanoposts with varying aspect ratios (scale bar, 2 μm).

III. Results and Discussion

To assess practical imaging performance, we next evaluated the metasurface on real samples with complex structures. Figure 2a illustrates the experimental setup, which employs linearly polarized illumination for enhanced stability and alignment robustness compared to circular polarization[41]. As schematized in Fig. 2b–c, the metasurface operates as a high-pass spatial filter: it suppresses low-frequency background while selectively enhancing high-frequency edge components in the spatial-frequency domain, thereby achieving optical edge enhancement.

Figure 2d–e presents images of four 3D-printed geometric patterns under 450 nm (bright-field) and 532 nm (edge-enhanced) illumination. In bright-field mode, overall shapes and internal details are clearly resolved. In edge-enhancement mode, boundaries are accentuated with a relief-like appearance, while uniform regions are suppressed—consistent with the high-pass filtering behavior. Intensity profiles across these images (Fig. 2f–g) show distinct peaks at object edges, confirming effective edge extraction.

Further validation was performed using a USAF resolution target (Fig. 3a–b). The 450-nm channel faithfully reproduces fine structural details, whereas the 532-nm channel emphasizes intensity transitions at edges, improving boundary contrast. Quantitative line profiles (Fig. 3c–d) exhibit sharp peaks corresponding precisely to physical edges, confirming background suppression and edge resolution. Consistent performance across different magnifications underscores the reliability of the wavelength-multiplexed design.

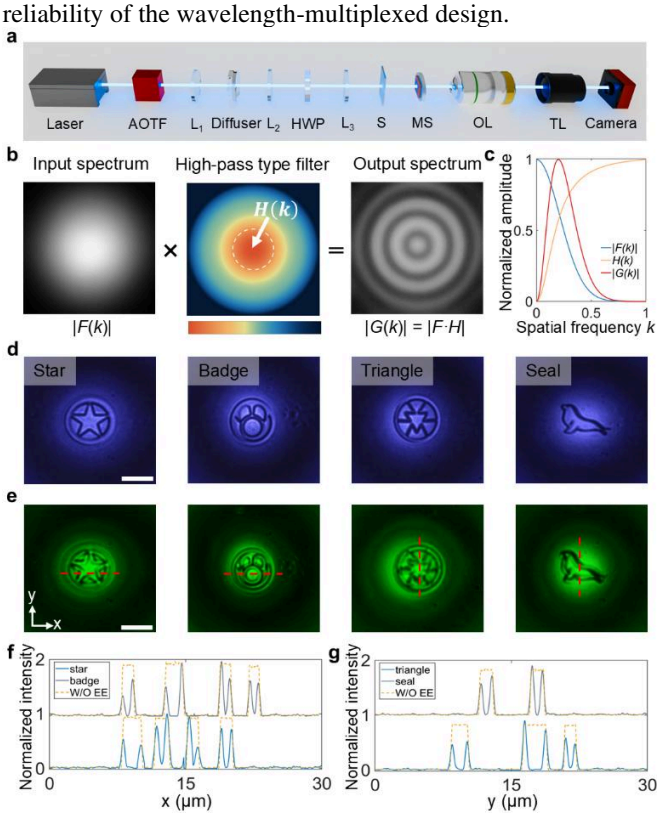

Fig. 2 | Experimental demonstration of dual-wavelength imaging via metasurface beam shaping. (a) Schematic of the optical imaging setup. (b) Conceptual diagram of edge-enhanced imaging: the metasurface acts as a high-pass filter, attenuating low-frequency background and amplifying high-frequency edge components in the spatial-frequency domain. (c) Normalized frequency-response curves illustrating the high-pass filtering mechanism. (d) Bright-field images of 3D-printed test patterns obtained under 450 nm illumination. (e) Corresponding edge-enhanced images of the same patterns under 532 nm illumination. Scale bars: 20 μm. (f, g) Intensity profiles along the dashed lines in (e), showing enhanced edge signals compared to the ideal profiles without edge enhancement (labeled "W/O EE").

The metasurface was further applied to biological imaging using transverse stem cells from a monocot plant. Under 450 nm illumination, bright-field imaging clearly resolved intracellular structures, including the nucleus and cytoplasmic strands (Fig. 3e). In contrast, under 532 nm illumination, the vortex-based edge-enhancement mode suppressed low-frequency background—characteristic of weakly scattering cells—resulting in diminished internal details while emphasizing high-frequency features such as the cell wall (Fig. 3f).

Quantitative spatial-frequency analysis (Fig. 3g) showed that the bright-field channel retained spectral power across a broad frequency range, whereas the edge-enhanced channel exhibited steeper decay at higher spatial frequencies. Edge-gradient statistics (Fig. 3h) further indicated stronger local intensity variations in bright-field images (median gradient ≈ 0.34, P90 ≈ 0.65) compared to edge-enhanced images (median ≈ 0.25, P90 ≈ 0.54), consistent with the preservation of fine intracellular textures in the former.

In multicellular samples, bright-field imaging at the cell-wall plane captured continuous cellular contours and overall tissue organization (Fig. 3i). Edge-enhanced imaging under the same condition accentuated inter-cellular boundaries, improving individual cell delineation (Fig. 3j). When focused on the nucleus plane (Fig. 3k–l), the 532 nm channel revealed subtle intra-nuclear intensity variations, suggesting sub-nuclear heterogeneity that was less apparent in bright-field mode.

These results demonstrate that the metasurface supports reliable switching between two complementary imaging modes within a single device: bright-field imaging for holistic structural morphology and edge-enhanced imaging for boundary-specific contrast enhancement, confirming its versatility across varied imaging scenarios.

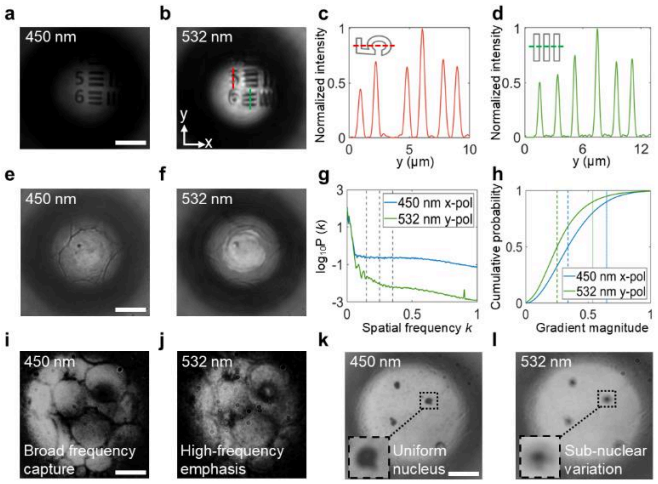

Fig.3 | Experimental imaging performance of the dual-wavelength metasurface. (a, b) USAF resolution target images under 450 nm (bright-field) and 532 nm (edge-enhanced) illumination. (c, d) Intensity profiles along the dashed lines in (b), showing clear edge-enhanced peaks. (e, f) Single-cell images captured at 450 nm and 532 nm, respectively. (g, h) Corresponding log-scale radial power spectra (dashed lines mark spatial frequencies k = 0.15, 0.25, 0.35) and edge-gradient cumulative distribution functions (CDFs). Median and 90th-percentile (P90) gradient levels are indicated. (i–l) Multi-cell images focused on the cell-wall plane (i, j) and the cell-nucleus plane (k, l) under the two wavelengths. Scale bars: 20 μm.

IV. Conclusion

In summary, we have developed a wavelength-multiplexed metasurface that enables independent wavefront control at two visible wavelengths (450 nm and 532 nm), supporting switchable bright-field and edge-enhanced imaging within a single planar device. Using propagation-phase modulation and a complex-transmission-coefficient-based design strategy, the metasurface achieves high-efficiency amplitude and phase control with suppressed inter-channel crosstalk. Operation under linear polarization ensures alignment robustness and system compatibility. Experimental imaging across geometric, resolution, and biological samples confirms reliable mode switching and dual-function performance. This work establishes a practical route toward compact, multifunctional optical systems and paves the way for extending wavelength-multiplexed metasurfaces to broader spectral ranges and more complex imaging modalities.

***Abstract*—We report an experimental observation of a new plasmon mode in the metasurface made up of two-dimensional electron system strips. A collective effect from the superlattice, along with lateral screening between the strips are the key properties of the novel resonance. The developed analytical approach accurately describes the observed behavior.**

***Keywords*— metasurfaces, plasmons, terahertz.**

I. Introduction

Plasma excitations in two-dimensional electron systems (2DES) have been the focus of active research for the past 50 years. The metasurface made up of a grating of 2DES strips shows great potential for terahertz applications. Predictions suggest that such a tunable metasurface could function as an effective THz amplitude and phase modulator, enabling beam steering and wavefront shaping [1]. The tunability of the 2DESs is achieved by changing the electron density or applying an external magnetic field, allowing for continuous tuning of the properties of the plasmonic metasurface.

In the present talk, we report on terahertz spectroscopy experiments on the GaAs membranes with a grating of strips formed lithographically in a high-mobility 2DES. The developed metasurface demonstrates a strong plasmonic response when the incident radiation polarization is perpendicular to the strips.

II. Methods

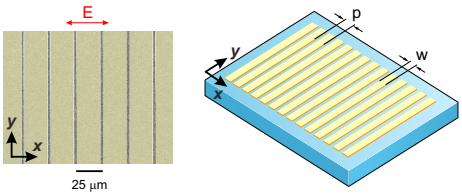

Fig. 1. (Left) E-beam photo of the sample comprising a grating of isolated 2DES strips. The area of the 2DES is highlighted in yellow. Each 2DES strip has a width of $w = 23$ μm, and the period is $p = 25$ μm. (Right) Schematic of the plasmonic metasurface device. The two-dimensional electron system is represented in yellow, while the GaAs substrate is shown in blue.

The samples were made from the industrial GaAs heterostructures with a 20 nm wide quantum well grown at a distance of 210 nm below the crystal surface. The quantum well hosts the 2DES with the density $n_s = 9.3 \times 10^{11}$ cm^{-2} and electron mobility $\mu = 10^5$ cm^2/Vs at $T = 5$ K. The effective mass of electrons is $m^* = 0.071\, m_0$. A grating of 2DES isolated strips (Fig. 1) is lithographically fabricated on the 1×1 cm^2 samples. For eight of them, the metasurface period is fixed $p = 25$ μm and the strip width varies from $w = 13$ μm to 23.7 μm. The phase/intensity of the electromagnetic wave that passed through the sample was investigated using a Mach-Zehnder interferometer. All experiments were conducted at a base sample temperature of 5 K.

III. Results and Discussion

The inset to Fig. 2 shows the transmission spectrum recorded for a metasurface period of $p = 25$ μm and a strip width of $w = 21.5$ μm. A clear plasmon resonance is observed at $f_p = 0.2$ THz, superimposed on the Fabry-Pérot transmission function of the bare dielectric membrane. To eliminate the Fabry-Pérot background and spurious resonances of the quasi-optical path, we divide the transmission at $B = 0$ T by the transmission through the sample at $B = 7$ T. At such a strong magnetic field, the motion of the 2D electrons in the quantum well plane is quenched in cyclotron orbits. As a consequence, the 2DES does not affect the transmittance. The resultant normalized transmission spectra recorded for three samples with different 2DES strip widths $w = 13, 21.5$ and 23.7 μm but fixed metasurface period $p = 25$ μm are shown in Fig. 2. The plasmon resonance moves to a higher frequency as the gap between the strips is increased.

However, the experimentally obtained values of the plasmon frequency differ significantly from those predicted by the standard dispersion equation:

$$\omega_p(q) = \sqrt{\frac{n_s e^2}{2\, m^* \varepsilon_0 \varepsilon_{\text{eff}}} q} \qquad (q \gg \omega/c). \tag{1}$$

Here, q is the wave vector of the plasmon excitation, n_s and m^* are the density and the effective mass of the 2DES electrons, while ε_0 and ε_{eff} denote the vacuum permittivity and the effective permittivity of the surrounding medium. For the 2DES strip with a width of w, the wave vector is typically assumed to be $q \approx 3\pi/4w$ [2].

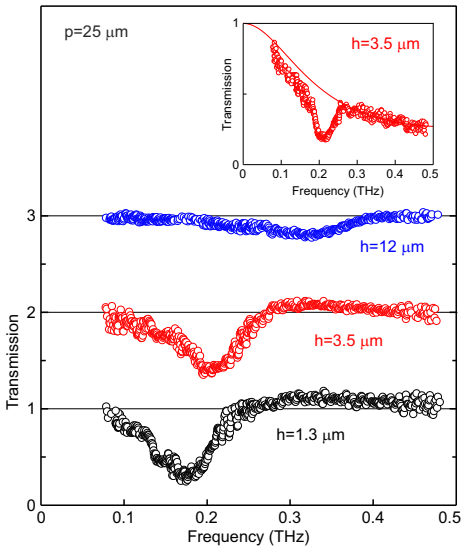

Fig. 2. The normalized transmission spectra of three samples with different strip spacings, specifically $h = 12$, 3.5, and 1.3 μm. All three samples share the same period, $p = 25$ μm. For clarity, the curves have been vertically shifted by 1 unit. The inset shows the transmission spectrum of the $h = 3.5$ μm sample without normalization. The solid red line represents the Fabry-Pérot function for the bare dielectric membrane with no 2DES.

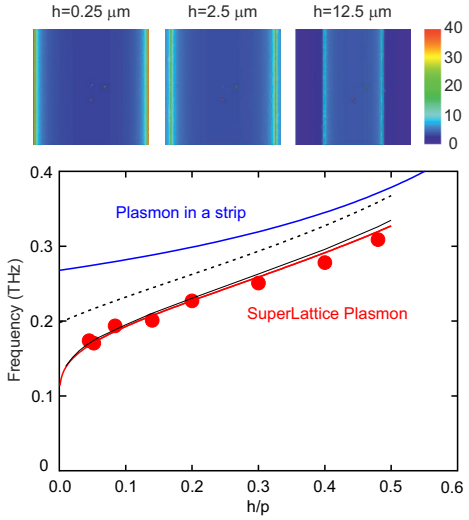

Fig. 3. Dependence of the plasmon frequency on the h/p. The period of the plasmonic metasurface was maintained at a fixed value of $p = 25$ μm. The solid red line represents a theoretical prediction (2), while the blue line presents the standard 2D plasmon frequency (1) in a single strip with wave vector $q = 3\pi/4w$. The solid black line shows the result of simulation in the HFSS 3D high-frequency simulation software. The dotted curve in Fig. 3 depicts the result for the analytical prediction from [2]. Top inset displays the color maps of field-$|E|$ distribution at the plasmon resonance for $h = 0.25$, 2.5, and 12.5 μm ($p = 25$ μm). The 2DES strip is located at the center of each color map.

Indeed, Fig. 3 shows how the plasmon frequency depends on the gap between the 2DES strips $h/p = (p - w)/p$. This dependence was measured across eight samples, all with the same period of $p = 25$ μm. The solid blue line in the Figure represents the theoretical prediction based on equation (1) with $q = 3\pi/4w$. It is clear that there is a significant discrepancy between this theoretical prediction and the experimental results, even with significant spacing between the individual strips. To better understand the situation underway, we have developed a theoretical framework to describe the behavior of the plasmonic metasurface under consideration.

The theoretical analysis follows to that applied in Refs. [3], [4] devoted to the electromagnetic response of plasmonic crystals. Under a number of reasonable assumptions [5] we arrive at the final expression for the frequency of the fundamental superlattice plasmon mode:

$$\omega_{sp} = \sqrt{\frac{n_s e^2}{2\, m^* \varepsilon_0 \varepsilon_{\text{eff}}} \frac{\pi}{p} \frac{1}{\ln\left(\dfrac{p}{2\pi h}\right) + 2}}, \qquad (2)$$

where p is the metasurface period, $h = p - w$ is the gap between the 2DES strips, and $\varepsilon_{\text{eff}} = (1 + \varepsilon_{\text{GaAs}})/2$ is the effective dielectric permittivity. It is the logarithmic factor that represents the mutual capacitance between the strips leading to zero frequency of the superlattice plasmon mode as the gap h closes. There is a remarkable agreement between the analytical formula (2) displayed in Fig. 3 by a solid red curve and the experimental data.

IV. Conclusion

In conclusion, we discovered that a collective effect from the superlattice, combined with lateral screening between the strips, gives rise to the emergence of a new superlattice plasmon mode. This mode arises from the superposition of standing plasma waves across all wave-vectors of the metasurface's reciprocal lattice [5]. We developed an analytical expression for the frequency of the mode, which shows remarkable agreement with experimental results. The distinguishing feature of the novel mode is that its frequency approaches zero as the gap between the strips closes.

***Abstract*—We designed a tunable quasi-BIC metasurface using machine learning. Strong coupling with monolayer WS_2 achieved 29.3 meV Rabi splitting, increased to 35.64 meV *via* a PMMA layer. The PMMA enhanced transmission and the electric field. The PL and Raman intensities increased 5.9-fold and 2.4-fold respectively, confirming metasurface-enhanced light–matter interactions.**

***Keywords*— metasurfaces, strong coupling, WS_2 monolayer, quasi-bound states in the continuum.**

I. Introduction

All-dielectric metasurfaces supported quasi-bound states in the continuum (q-BICs) provide a pathway to develop a new paradigm for trapping and confining resonant optical modes with high quality factors (Q-factors) in q-BIC , as well as broad spectral tunability and strongly enhanced near-fields for boosting both surface-driven and material-intrinsic processes in the field of nanophotonics [1-3]. Q-BIC can be obtained by breaking the in-plane symmetry of the structure, and the ultrahigh Q-factor resonance modes in the q-BIC can be readily tuned by the degree of asymmetry [4, 5]. Herein, slotted disk metasurface designs are used to obtain strong light-matter interaction between the metasurface q-BIC and the excitons in a WS_2 monolayer. To further increase the Rabi splitting energy, a PMMA overlayer was introduced. The PMMA overlayer increases the refractive index around metasuraface, inducing a redshift of the q-BIC resonance and enhancement of the field confinement by reducing top□bottom index asymmetry [6]. It also protects the WS□ monolayer from environmental degradation, ensuring stable optoelectronic properties.

II. Methods

The Si_3N_4 metasurfaces were designed using machine learning algorithms implemented in Python. Full-wave electromagnetic simulations were performed using the finite-difference time-domain method (Lumerical). The structures were modeled with experimentally determined dimensions. The Si_3N_4 metasurfaces were fabricated on fused silica substrates via Helium Ion Lithography (Raith) followed by reactive ion etching (RIE, CHF_3/O_2 plasma). Key parameters are period (P P_x = 400 nm, P_y = 420 nm), disk radius (r = 170 nm), height (h = 120 nm), and slot width (varied from 70 to 90 nm). A PMMA layer (100 nm thick) was spin-coated at 6000 rpm for 60 s and cured at 120°C for 2 min, forming a PMMA/WS_2 stack. Finally, the stack was transferred onto the slotted disk metasurface with alignment under an optical microscope.

III. Results and Discussion

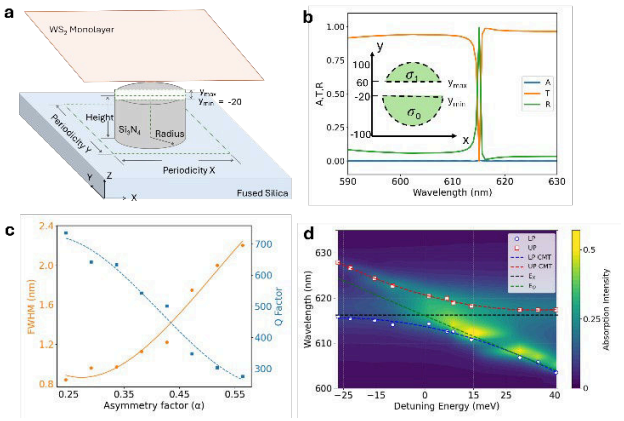

Fig. 1 (a) Three-dimensional schematic of a single period of the hybrid system consisting of monolayer WS_2 and a Si_3N_4 all-dielectric metasurface. (b) Reflection (R), transmittance (T), and absorption (A) spectra of a lossless bare metasurface in air, calculated using the ML-assisted structural design parameters. the dimension parameters are P_x = 400 nm, P_y = 420 nm, y_{min} = −20 nm, y_{max} = 70 nm, r = 170 nm, h = 120 nm. (c) Quality factor Q as a function of the asymmetry parameter (α), showing an inverse square relationship. (d) A color map of the absorptance spectra of the WS_2/Si_3N_4 metasurface/fused

silica hybrid structure as a function of detuning energy of $\Delta = E_Q - E_X$. The black dashed line represents the exciton energy E_X, the dashed green line represents the tuned q-BIC mode resonance E_Q, and the red and blue dashed curves (UP CMT and LP CMT) are the fitted polariton dispersion of the lower polariton (LP) and upper polariton (UP) branches using coupled-mode theory (CMT).

The goal is to realize strong coupling between monolayer WS_2 and a silicon nitride metasurface featuring asymmetric slotted disks that support quasi-bound states in the continuum, as illustrated in Fig 1(a). The q-BIC resonance is tuned by optimizing the unit cell period, disk thickness (H), radius (r), and slot width (G). Initial simulations were performed using Lumerical's Finite-Difference Time-Domain (FDTD) solver. Machine learning (ML) was subsequently employed to accelerate the design process. Artificial Neural Network (ANN) achieves the lowest Mean Squared Error (MSE, 0.0043) compared to Extreme Gradient Boosting (XG Boost) and Support Vector Regression (SVR). Fig 1(b) shows the simulated reflectance, transmittance and absorbance spectra with the q-BIC resonance at 616 nm. The q-BIC mode is confirmed in Fig 1(c). Fig 1(d) shows the simulated absorption spectra as a function of detuning energy with varying the slot width. An anticrossing behavior is clearly visible in the colour map, indicating strong coherent interaction between q-BIC mode and the excitonic mode. where the two peaks correspond to the upper polariton (UP) branch and lower polariton (LP) branch. The Rabi-splitting energy difference between the UP and LP branches at zero detuning is 29.43 meV. The simulated spectra were fitted using coupled-mode theory (CMT) with Eq. (1) [1]

$$E_{\pm} = \hbar\omega_{\pm} = \frac{\hbar}{2}\left[\omega_X + \omega_Q + i\left(\gamma_Q + \gamma_X\right)\right] \pm \frac{\hbar}{2}\sqrt{4\Omega^2 + \left[\left(\omega_X - \omega_Q\right) + i\left(\gamma_X - \gamma_Q\right)\right]^2} \quad (1)$$

The corresponding resonant frequency and damping rate are ω_Q (ω_X) and γ_Q (γ_X), respectively, and they coherently exchange energy with coupling constant, Ω. The vacuum Rabi splitting, defined as the minimum energy spacing between the two branches, is $\hbar\Omega_R = \mathrm{Re}(E_+ - E_-)_{\min}$. When $\omega_X = \omega_Q$ it yields $\hbar\Omega_R = \sqrt{4\Omega^2 - \left(\gamma_Q - \gamma_X\right)^2}$. To observe the characteristic anticrossing of strong coupling, the Rabi splitting must exceed the total dissipation of the hybrid system: $\hbar\Omega_R > \hbar(\gamma_Q + \gamma_X)$. Thne criteria of strong coupling or polaritonic coupling are:

$$\hbar\Omega > \hbar/2\,|\gamma_Q - \gamma_X|, \quad \hbar\Omega = \sqrt{\frac{1}{2\left(\gamma_Q - \gamma_X\right)^2}} \quad (2)$$

The extracted values of $\hbar\Omega_R$ =29.43meV, $\hbar\gamma_Q$ = 31.33meV, and $\hbar\gamma_X$ =27meV clearly meet the criterion in Eq. (2).

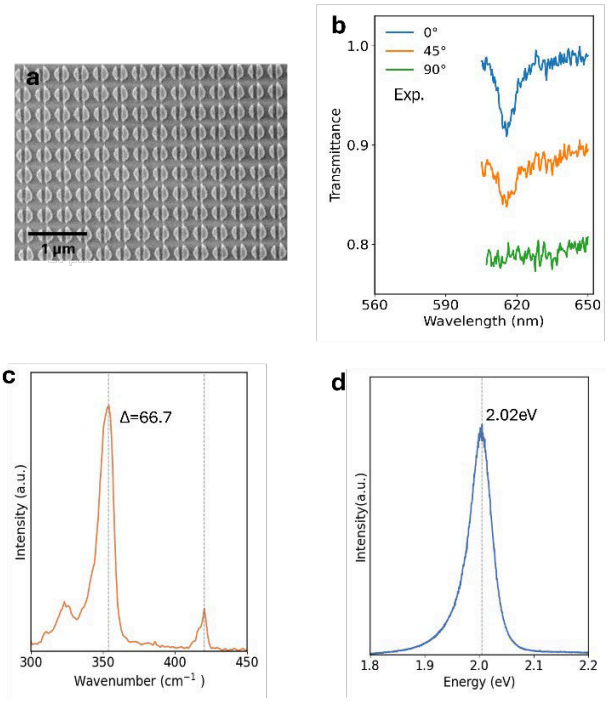

Fig. 2 (a) SEM image of the Si_3N_4 disk array on the fused silica substrate. (b) Polarization dependent transmittance spectra of the experimental Si_3N_4 metasurface. (c,d) Raman and PL characterization of the monolayer WS_2.

The slotted Si_3N_4 disk metasurface was fabricated by helium ion beam lithography followed by reactive ion etching as shown in Fig 2(a). At 0° polarization, a distinct transmittance resonance is observed experimentally, while its amplitude decreases continuously and eventually disappears at 90° as shown in Fig 2(b). A monolayer WS_2 film was transferred onto the metasurface the characteristic $E_{2g}{}^1$and A_{1g} vibrational modes of monolayer WS_2 appear at approximately 352.3 cm^{-1} and 419 cm^{-1}, respectively, yielding a frequency separation Δ≈ 66.7 cm^{-1} (Fig 2(c)) in line with expectations for monolayer WS_2. Room-temperature photoluminescence (PL) measurements reveal strong excitonic emission at 2.02 eV in agreement with values reported for monolayer WS_2.[7, 8] (Fig 2(c)).

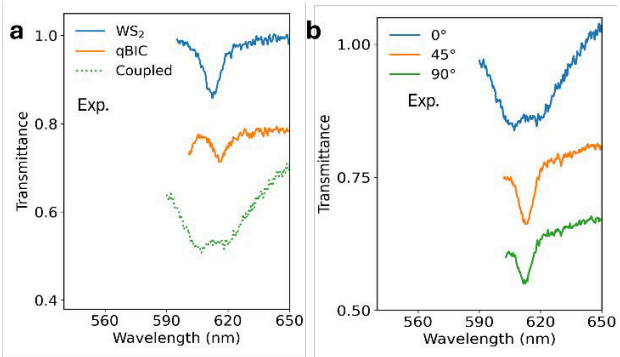

Fig. 3 (a) Transmittance spectra of the bare WS_2, the Si_3N_4 metasurface and the coupled WS_2/Si_3N_4 metasurface under x-polarized illumination (b) Polarization dependent transmittance spectra of the WS_2/Si_3N_4 metasurface coupled system.

For the hybrid WS_2-Si_3N_4 metasurface a clear mode splitting emerges, giving rise to two well-resolved peaks at 617.8 nm and 608.9 nm (Fig 3(a)), corresponding to a Rabi splitting of 29.3 meV. Polarization-dependent transmission measurements were performed on the coupled system in Fig 3(b), As the polarization angle increases from 0° to 90°, the spectral splitting gradually diminishes due to the weakened excitation of the qBIC mode.

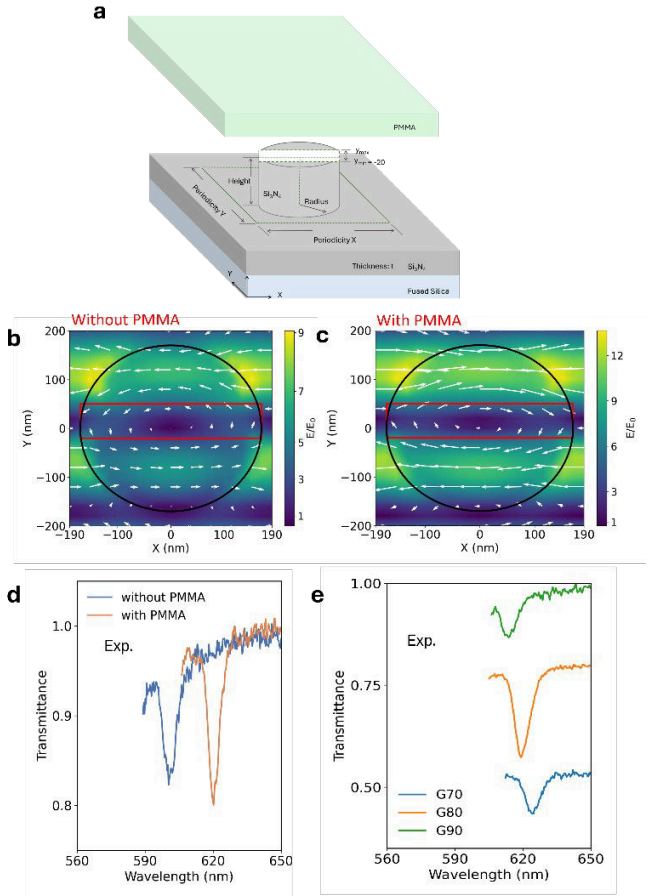

Fig. 4 (a) Schematic of PMMA/Si_3N_4 metasurface hybrid system. (b, c) Electric field distribution maps in the X-Y plane at the top surface of the disk without and with the PMMA layer. (d) Experimental transmittance spectra with and without PMMA. Structural parameters: P_x = 380 nm, P_y = 400 nm, y_{min} = −20 nm, y_{max} = 70 nm, r = 170 nm, h = 90 nm, and bottom- layer thickness t = 30 nm. (e) Experimental transmittance spectra of the Si_3N_4 metasurface with different slot widths (70 nm, 80 nm, and 90 nm).

To further increase the Rabi splitting energy, a PMMA overlayer was introduced onto the Si_3N_4/Fused silica metasurface as the schematic shown in Fig. 4(a). In the first instance the impact of the PMMA layer on the q-BIC resonance is explored. The simulations indicate that the in-plane electric field intensity increases from 9 to 13.7 when a 100 nm-thick PMMA film is added on top of the metasurface (Fig 4(b)). In the experiment, the PMMA-coated metasurface (slot width = 80 nm) exhibits a 12 nm redshift of the q-BIC resonance, accompanied by a noticeable increase in the amplitude q-BIC mode (Fig 4(d)). Fabricated samples with slot widths of 70 nm, 80 nm and 90 nm, each coated with a 100 nm− thick PMMA layer, are shown in Fig 4(e), with the q-BIC mode redshifting from 607 nm to 623 nm with increasing slot width.

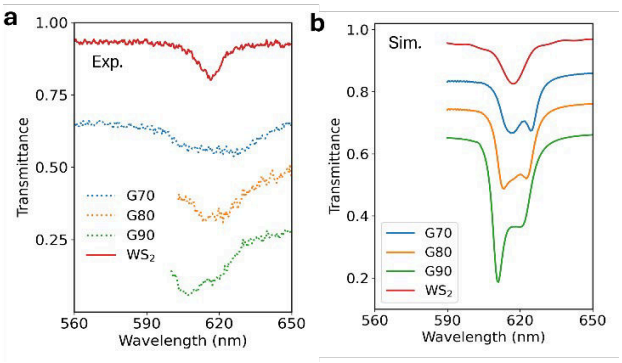

Fig. 5 (a, b) Experimental and simulated transmittance spectra of the PMMA/WS_2/Si_3N_4 metasurface with varying slot width (70 nm, 80 nm and 90 nm).

The transmittance spectra of the PMMA/WS_2/Si_3N_4/fused-silica system exhibit spectral splitting (Fig 5(a)), where the q-BIC resonance splits into upper and lower polariton branches around the excitonic transition. The extracted Rabi splitting energy is 35.64 meV. The experimental results show excellent agreement with the simulated results, which predict a Rabi splitting energy of 36.56 meV (Fig 5(b)).

IV. Conclusion

We have demonstrated a metasurface supporting a quasi-BIC resonance. Utilizing a machine-learning-assisted design the structural parameters for the 590–650 nm range were determined. Experimentally, strong coupling with a WS_2 monolayer yields a Rabi splitting of 29.3 meV, which increases to 35.64 meV after introducing a PMMA layer on the top. The 100 nm PMMA layer increases the transmission peak intensity and enhances the field. Simulations reveal an increase in the in□plane electric field from 9 to 13.7, attributed to suppressed radiation loss in the PMMA− glass symmetric sandwich structure.

***Abstract*—We fabricated 8-inch wafer-scale, quartz-monolithic ultraviolet metalenses operating at 325 nm using ArF photolithography. This platform circumvents the scarcity of high-index dielectrics that are CMOS-compatible and transparent in ultraviolet, while maintaining high optical efficiency. This work presents a cost-effective pathway for scalable manufacturing of highly compact ultraviolet optical systems.**

***Keywords*— wafer-scale, quartz-monolithic, ultraviolet, metalenses, ArF photolithography, CMOS-compatible**

I. Introduction

Ultraviolet (UV) optical components are essential in photolithography and high-resolution spectroscopy, but face significant hurdles in fabrication due to the limited selection of UV-transparent materials and the requirement of stringent fabrication tolerances [1]. While metasurfaces offer a compact alternative, their adoption in the UV regime has been stifled by the non-negligible absorption of high-index materials (e.g., Si, TiO_2, Nb_2O_5, and Ta_2O_5) necessary for sustaining their performance [2]. Even for transparent candidates such as HfO_2, wafer-scale fabrication is hindered by low throughput due to the slow atomic layer deposition (ALD) process. Crucially, regardless of the material choice, heterogeneous integration creates fragile interfaces prone to delamination caused by thermal expansion mismatches.

To address these challenges, we present quartz-monolithic UV metalenses fabricated using ArF photolithography on an 8-inch wafer, eliminating the need for heterogeneous high-index materials and slow electron-beam writing.

II. Methods

We designed a metalens with a diameter of 2 mm and a numerical aperture (NA) of 0.3, corresponding to a focal length of approximately 3.18 mm at an operating wavelength of 325 nm. The unit cells consist of fused quartz cylinders with a height of 1020 nm on a square lattice with a period of 430 nm.

We specifically selected cylindrical geometry to prevent pattern bridging issues during ArF photolithography. Furthermore, the 1020 nm height overcomes the relatively low refractive index of fused quartz. This tall structure provides the required phase modulation without excessively enlarging the cylinder diameters, effectively securing an ample gap between adjacent structures. Although the lattice constant of 430 nm deviates from the strict sub-wavelength regime, we leveraged the property that low-index platforms suppress higher-order Bloch modes, enabling high efficiency even with increased lattice constants [3]. Ultimately, the strategic configuration of high-aspect-ratio cylindrical nanopillars with a widened lattice constant effectively alleviates the stringent resolution requirements of the lithographic process while maintaining robust optical performance.

III. Results and Discussion

To rigorously validate the wafer-scale uniformity and optical performance of the mass-produced metalenses, we characterized 20 metalenses sampled across the fabricated 8-inch wafer at a wavelength of 325 nm (Fig. 1). Quantitative analysis revealed high optical efficiency for the fused quartz UV metalenses. The best-performing metalens achieved a focusing efficiency of 51.92% and a diffraction efficiency of 59.87%, along with a transmittance of 86.72% and a focal length of 3.173 mm. Furthermore, statistical analysis across the 20 metalenses demonstrated manufacturing consistency, yielding an average focusing efficiency of $47.65 \pm 2.47\%$ and a diffraction efficiency of $54.20 \pm 3.20\%$. The measured focal lengths showed precise agreement with the design value, averaging 3.178 ± 0.004 mm, which confirms the high fidelity between the fabricated structures and the original design (Fig. 2).

These results experimentally verify that our monolithic fused quartz platform is highly effective for the UV regime. Moreover, this consistent performance demonstrates the feasibility of uniform wafer-scale manufacturing of metalenses, overcoming the scalability limits of conventional nanofabrication. Ultimately, this work provides a robust and scalable foundation for the mass production of high-performance UV meta-optics.

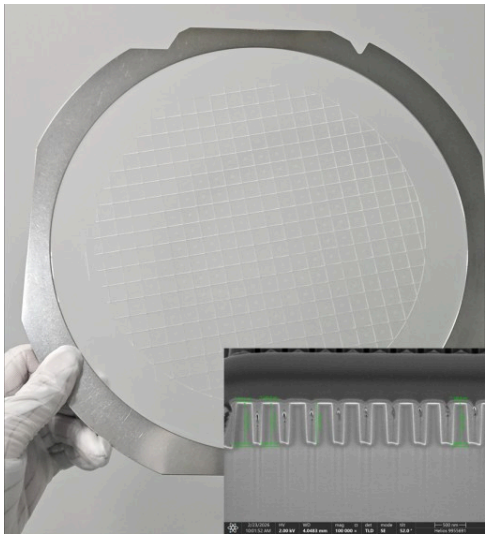

Fig. 1 Fabricated metalenses on an 8-inch fused quartz wafer. Inset: Cross-sectional SEM image of the fabricated metalens.

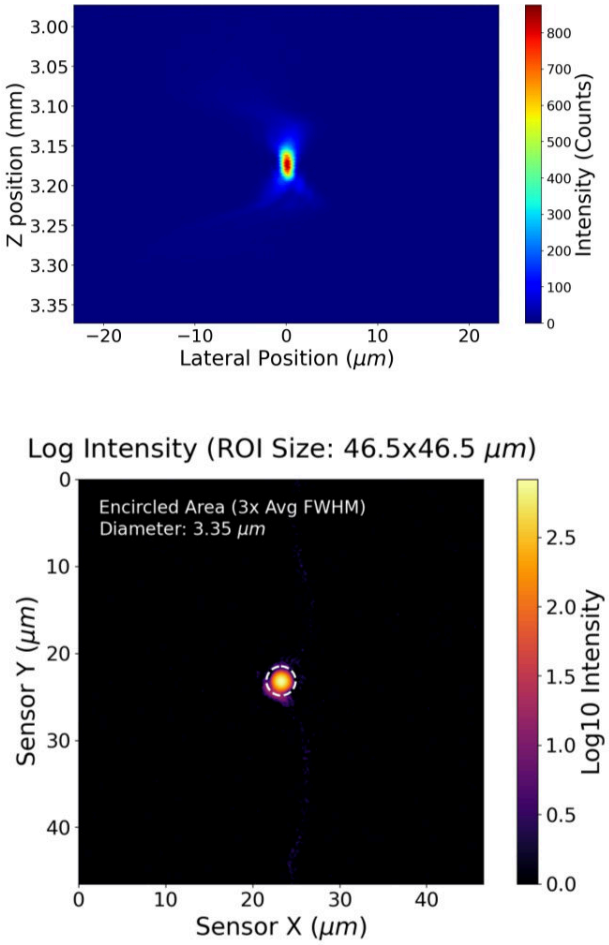

Fig 2. Measured beam profile along the optical axis (Top) and point spread function (PSF) at the focal plane (Bottom).

IV. Conclusion

We have successfully demonstrated the wafer-scale realization of quartz-monolithic metalenses for the UV regime using high-throughput ArF photolithography. By adopting the strategic configuration of high-aspect-ratio cylindrical nanopillars with a relaxed lattice constant, we ensured a sufficient fabrication margin that prevented pattern bridging and enabled the precise transfer of 2 mm diameter metalenses across an 8-inch wafer. Our results confirm that the monolithic, low-index fused quartz platform eliminates the absorption losses and interfacial instabilities associated with traditional heterogeneous high-index UV platforms, while maintaining high optical efficiency.

The experimental validation, showing high fabrication uniformity and optical performance, proves that this approach effectively overcomes the longstanding material and fabrication bottlenecks inherent in conventional UV optics. This work establishes a robust and scalable framework for the mass-production of high-performance UV meta-optics, offering a new pathway for compact UV optical systems in semiconductor manufacturing and high-resolution spectroscopy.

***Abstract*— Colorimetric thermography enables emissivity-independent temperature measurement but requires bulky optics. We present a compact dual-band metalens for LWIR colorimetric thermography at 9.5 and 12.5 μm. It images low-emissivity objects and measures temperature without presetting emissivity, reducing errors by 50.16% (60–180°C), enabling compact multi-target IR systems.**

***Keywords*— Infrared detection; Colorimetric thermography; Emissivity; Dual-band metalens.**

I. Introduction

Infrared (IR) thermography is widely used but its accuracy is compromised by unknown emissivity variations of objects. Colorimetric thermography determines temperature from the ratio of radiances in two spectral bands, theoretically eliminating emissivity effects. However, conventional implementations require bulky filters, spectrometers, or complex sensor structures. Metalenses offer a compact, customizable alternative for spectral manipulation. Here we demonstrate a dual-band metalens that performs IR colorimetric thermography with a simple optical setup, achieving accurate temperature measurement of low-emissivity targets without prior knowledge of emissivity.

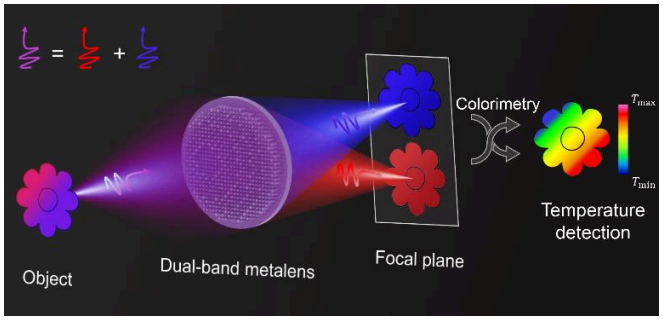

Fig. 1 Schematic of dual-band metalens imaging principle.

II. Methods

Principle. For a gray body with emissivity ε(T), the intensity ratio in two spectral bands is

$$R(T) = \frac{M_1(T)}{M_2(T)} == \frac{\int_{\lambda_{start}}^{\lambda_{end}} M_b(\lambda, T) * F_1(\lambda) d\lambda}{\int_{\lambda_{start}}^{\lambda_{end}} M_b(\lambda, T) * F_2(\lambda) d\lambda} \quad (1)$$

, which is independent of ε(T). The function T = f(R) is obtained by calibration.

Metalens design. The metalens (diameter 2 cm, focal length 1 cm) is designed to focus 9.5 μm and 12.5 μm light at laterally separated spots (offset ±0.5 cm). Phase profiles are

$$\Phi_1(x,y) = -2\pi n(\sqrt{(x+x_0)^2 + y^2 + f^2} - f)/\lambda_1 \quad (2)$$

$$\Phi_2(x,y) = -2\pi n(\sqrt{(x-x_0)^2 + y^2 + f^2} - f)/\lambda_2 \quad (3)$$

The metasurface consists of cylindrical silicon pillars (height 7 μm, radius 0.6–2 μm, period 5 μm) on a silicon substrate, providing full 2π phase coverage and high transmission at both wavelengths. Fabrication used maskless lithography and deep reactive-ion etching.

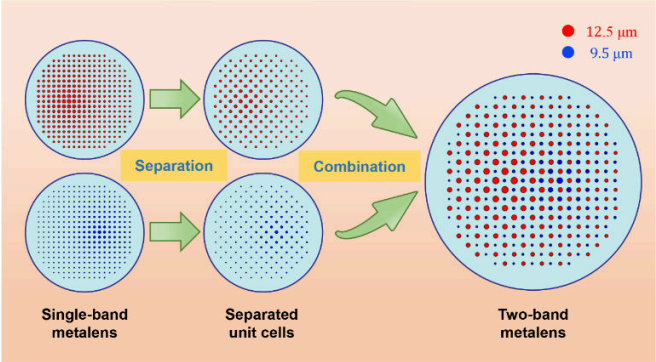

Fig. 2 Schematic of a dual-band metalens constructing process.

III. Results and Discussion

Experimental results show:

Dual-band imaging. The fabricated metalens produces two distinct focal spots separated by 1.03 cm on the sensor plane (Fig. 3a). When illuminated by a broadband IR source, it forms two images corresponding to the two spectral channels. Imaging of test patterns confirms wavelength-selective focusing (Fig. 3b).

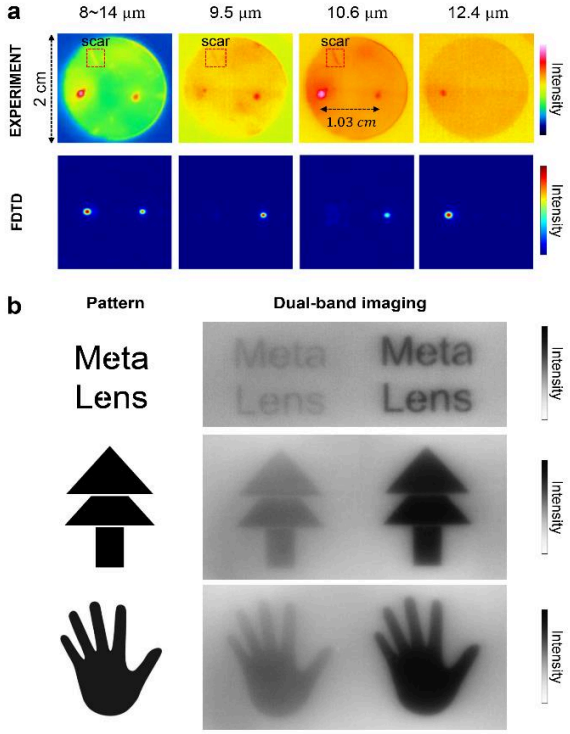

Fig. 3. Bi-focusing and dual-band imaging.

Colorimetric thermography. The ratio–temperature calibration curve was obtained using a glass plate ($\varepsilon \approx 0.9$) heated from 60°C to 180°C, yielding a linear fit $R = -1.7\times10^{-4}T + 1.006\times10^{-4}$ (R^2=0.9992). A CuO plate ($\varepsilon \approx 0.51$) was then measured. Conventional thermography without emissivity input gave errors up to ~50°C, while our colorimetric method reduced the average error by 50.16% (Fig. 2). Temperature maps derived from the two images show excellent agreement with the actual temperature.

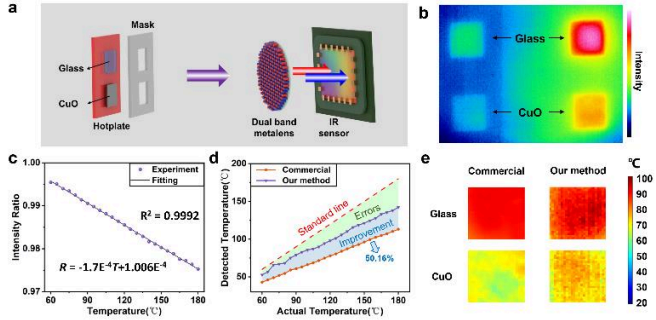

Fig. 4. Experimental setup and results of colorimetric thermography.

These results confirm that the dual-band metalens enables accurate emissivity-free thermography in a compact format.

IV. Conclusion

We have demonstrated a long-infrared dual-band metalens for colorimetric thermography. The approach eliminates the need for bulky optical components and prior emissivity knowledge, reducing measurement errors by half. It opens new possibilities for compact, multi-target IR thermography in dynamic environments.

***Abstract*— We demonstrate a terahertz metasurface platform capable of implementing up to five distinct logic operations within a single passive architecture, representing a record level of multifunctionality. The system enables low-power operation and scalable THz signal processing, advancing the transition from electronic to optical logical decision-making.**

***Keywords*— All-optical Boolean operations, terahertz metasurfaces, photonic computing, polarization-encoding, mechanical reconfigurability.**

I. Introduction

Terahertz (THz) metasurfaces have emerged as promising candidates for ultrafast and compact optical logic platforms due to their subwavelength control of amplitude, phase, and polarization. Most reported THz logic metasurfaces, however, rely on active materials, electrical biasing, or complex multilayer architectures, which increase system complexity and power consumption. Furthermore, many designs are restricted to a single logic function or require structural modification to switch between operations [1,2].

To overcome these limitations, passive metasurface logic platforms that exploit intrinsic electromagnetic responses are highly desirable. In this work, we present two complementary approaches for realizing multifunctional, passive THz logic metasurfaces: (i) a frequency-multiplexed fractal metasurface and (ii) a mechanically reconfigurable L-shaped metasurface. In both platforms, logical inputs are encoded in the polarization state of the incident THz wave, and the logic output is retrieved using fixed transmission-intensity thresholds.

II. Methods

The first platform consists of a fractal H-shaped metasurface designed to support multiple resonant modes across a broad THz spectral range [3]. The fractal geometry introduces self-similar resonant paths, enabling several polarization-dependent resonances at distinct frequencies. Full-wave simulations were performed using frequency-domain solvers, i.e. COMSOL Multiphysics to obtain polarization-resolved transmission spectra (Fig. 2a-b).

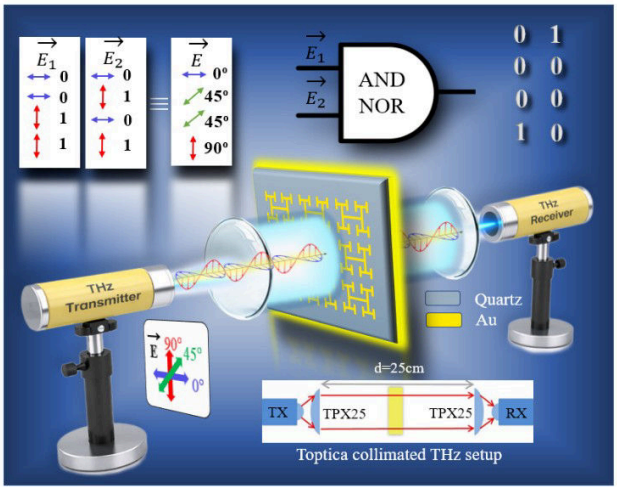

Fig. 1. Frequency-multiplexed logic operation in the fractal H-shaped metasurface, showing logic states realized at multiple resonant frequencies within a single passive structure.

The second platform employs an array of asymmetric L-shaped gold resonators fabricated on a 25 µm polyimide substrate [4]. The unit cell dimensions were chosen to support two electric-dipole-dominated resonances near 0.9 THz and

1.66 THz. The metausrface was designed to be mechanically reconfigurable through in-plane rotation and mirror-flip operations, which effectively reshape its induced polarization response. This further allows flexible control over co- and cross-polarized transmission channels without altering the physical structure, offering a robust way for realizing programmable flat-photonic systems.

In both platforms, logical inputs were encoded using three polarization states: 0°, 45°, and 90°, representing the Boolean combinations (0,0), (0,1)/(1,0), and (1,1), respectively. Output logic states were determined using fixed transmission-intensity thresholds.

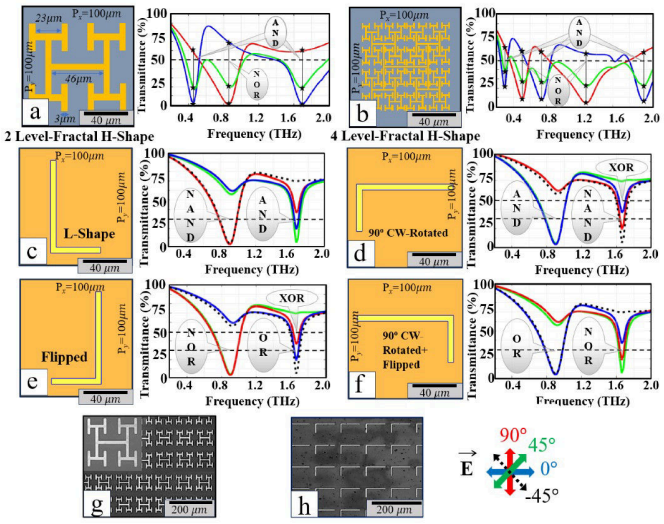

Fig. 2. Polarization-dependent transmittance characteristics of THz metasurfaces with varying geometries and logic functionalities. (a–b) 2-level and 4-level fractal H-shaped metasurfaces with corresponding spectra demonstrating multi-frequency responses. (c–f) L-shaped metasurface and its rotated/flipped variants showing distinct logical behavior under different polarization angles (0°, 45°, 90°, −45°), including AND, OR, NAND, NOR and XOR operations. (g–h) Optical microscopy images of fabricated 2-level fractal H-shaped and L-shaped metasurface arrays.

III. Results and Discussion

The fractal H-shaped metasurface exhibits multiple polarization-dependent resonances across the 0.2–2.0 THz range. At each resonance, different input polarizations produce distinct transmission levels, enabling simultaneous implementation of multiple logic functions at separate frequencies. This frequency-multiplexed behavior allows a single passive structure to perform parallel logic operations without mechanical or electrical tuning (Fig. 1).

The L-shaped metasurface demonstrates a complementary form of reconfigurability. Due to its anisotropic geometry, the structure exhibits a fully populated Jones matrix with unequal diagonal and nonzero off-diagonal terms, enabling strong polarization-dependent coupling. Two dominant resonances are observed at approximately 0.9 THz and 1.66 THz (Fig. 2c-d).

By applying in-plane rotation or mirror-flip transformations, the Jones matrix elements are deterministically redistributed. As a result, the polarization-dependent transmission spectra are reconfigured without changing the physical structure or excitation conditions. Depending on the metasurface orientation and operating frequency, different Boolean logic gates—including AND, OR, NAND, NOR, and XOR—are obtained using fixed intensity thresholds.

Experimental THz time-domain spectroscopy measurements show good agreement with simulations, with consistent resonance positions and logic-state transitions across all configurations. Minor discrepancies are attributed to fabrication tolerances, finite conductivity of gold at THz frequencies, and beam-profile effects.

Together, the two platforms demonstrate two distinct but complementary passive logic mechanisms:

- Frequency multiplexing: multiple logic functions realized simultaneously at different resonant frequencies using a fractal geometry.
- Orientation reconfiguration: dynamic switching between logic gates via simple mechanical transformations of an anisotropic metasurface.

Both approaches eliminate the need for active materials, electrical biasing, or nonlinear effects, significantly reducing system complexity and energy consumption.

IV. Conclusion

We have demonstrated two passive metasurface platforms for multifunctional THz logic operations: a frequency-multiplexed fractal H-shaped metasurface and a mechanically reconfigurable L-shaped metasurface. The first enables parallel logic processing across multiple spectral channels, while the second allows dynamic switching among logic gates through geometric transformations. These complementary strategies provide scalable, energy-efficient solutions for future THz photonic computing and signal-processing systems.

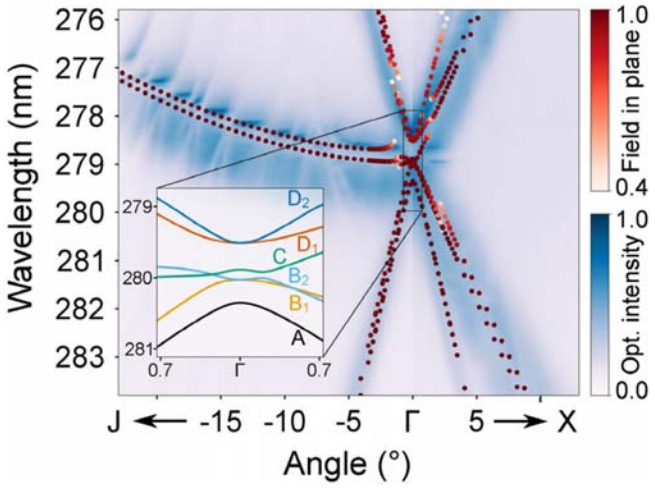
***Abstract*— We demonstrate the first optically pumped deep-ultraviolet photonic-crystal surface-emitting lasers operating below 280 nm. By optimizing the photonic crystal's filling factor, single-mode emission at 279 nm with sub-degree beam divergence is achieved. These results establish PCSELs as a promising platform for high-beam-quality, high-power deep-UV semiconductor lasers.**

***Keywords*— Deep-ultraviolet (UV-C) lasers, Photonic crystal surface-emitting lasers (PCSELs), Photonic band engineering.**

Semiconductor lasers have become the light source of choice for many applications in optical communication, metrology, and spectroscopy, especially in the infrared and visible parts of the electromagnetic spectrum. Ultraviolet-C (UV-C, $\lambda < 280$ nm) semiconductor lasers, on the other hand, remain limited by low efficiency and poor beam quality. While edge-emitting lasers have recently achieved electrically injected deep-UV operation [1], they inherently suffer from multi-mode emission and large divergence. Photonic crystal surface-emitting lasers (PCSELs), first demonstrated in 1999 [2], offer a pathway to simultaneously achieve high output power and excellent beam quality, as shown in infrared devices exceeding 50 W in single-mode operation [3], and recent blue PCSEL advances.



Comparison of experimentally and numerically obtained band structure.

Here, we report the first optically pumped deep-UV PCSELs operating below 280 nm [4]. The devices are based on an AlGaN multiple-quantum-well heterostructure incorporating a hexagonal photonic crystal (period 140 nm) etched into the top AlN cladding. Achieving two-dimensional (2D) optical feedback in AlGaN is challenging due to its low refractive index contrast and enhanced scattering at short wavelengths. By carefully engineering the photonic crystal geometry—particularly the hole filling factor—we are able to engineer the photonic bands and allow for sufficiently large local field enhancement to enable lasing.

Under 266 nm pulsed optical pumping at room temperature, the devices exhibit single-mode lasing at 279 nm with a linewidth of 17 pm (spectrometer-limited) and a clear threshold around 17 MW/cm². Optimized devices show a characteristic doughnut-shaped far-field light distribution with beam divergence below 1°, representing a major improvement over conventional deep-UV edge-emitting lasers

These findings establish PCSELs as a viable architecture for high-beam-quality deep-UV sources and mark an important step toward electrically injected Watt-class UV-C PCSELs.

***Abstract*—We show photoluminescence enhancement up to a factor of 43 with respect to unetched layers in Ge all-dielectric metasurfaces. Our results point to band-to-band recombination as the dominant emission mechanism. Emission peaks correspond to multipole modes of coupled Mie resonators, and are controlled by lateral nanostructuring.**

***Keywords*— all-dielectric metasurface, photoluminescence, RCWA, germanium.**

I. Introduction

For decades, silicon photonics has been the leading platform for integrated optics, primarily geared towards optical data transmission. Recently, the field has diversified considerably, towards applications in optical sensing, quantum technologies, and computing. While coherent sources are essential to optical communications, light-emitting diodes have been proposed for photonic computing[1]. Monolithic integration of the required emissive materials into silicon technologies remains a challenge, due to band structures of silicon and germanium favoring nonradiative transitions. Nanostructuring can be used to engineer radiative lifetimes through the Purcell effect, particularly using all-dielectric metasurfaces[2], [3]. This can boost light emission, potentially up to the point of practical applicability in light emission devices.

Here, we present photoluminescence (PL) results in Ge metasurfaces etched from material grown in an industrial chemical vapour deposition system on 200 mm wafers, with the ultimate goal of process-integrated vertical light emitting diodes. We achieve considerable, structurally tunable PL enhancement even in thin Ge layers.

II. Methods

We grew epitaxial Ge (150 nm) and Si (45 nm) on a silicon-on-insulator (SOI) substrates with a buried oxide thickness of 2 μm and a Si layer of 65 nm using chemical vapour deposition. After photolithography, the stack was down to the SOI substrate, creating periodic arrays of nanopillars with various pitches. As the samples were originally intended for electrical contacting, etch stopped within the SOI Si layer. Finally, the samples were covered in silicon dioxide using plasma-enhanced chemical vapour deposition for passivation. We created six periodic arrays of metasurface nanopillars with diameters of 300 nm pitches increasing from 850 nm to 1200 nm. Schematic layer stacks can be found in figure 1, the fabrication flow has been published in more detail elsewhere[4].

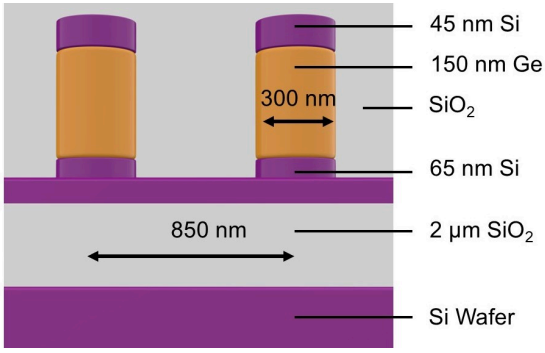

Fig. 1. Schematic layer stack.

We performed micro-photoluminescence spectroscopy measurements at 80 K and room temperature under excitation by an 1064 nm Nd:YAG laser source. The pump power was 34.4 mW, spectra were recorded using HORIBA iHR320 spectrometer and a SYNAPSE/SYMPHONY InGaAs detector. A low-magnification (5X) objective was used, in order to achieve near-vertical incidence at the sample surface.

Optical simulations were carried out using an own implementation[5] of the rigorous coupled-wave analysis (RCWA)[6]. We considered Fourier orders up to $N = 5$ and relied on literature values for the relative permittivity of materials[7], [8], [9].

III. Results and Discussion

We observe distinct PL peaks in the metasurfaces. The signal exceeds that of an unetched reference area with the same layer stack, and a bulk Ge wafer reference. Increased PL, despite smaller material volume, points to a spontaneous emission increase in the resonant metasurface cavity through the Purcell factor[2], as well as enhanced absorption of the 1064 nm pump. We report PL enhancement up to a factor of 43 with respect to unetched material. Based on simulation, pump absorption enhancement is < 3 as the metasurface is not matched to the pump wavelength, so the effect we observe is mostly due to emission enhancement.

With increasing array pitch, resonances and their related emission peaks shift to lower wavelength. Generally, emission

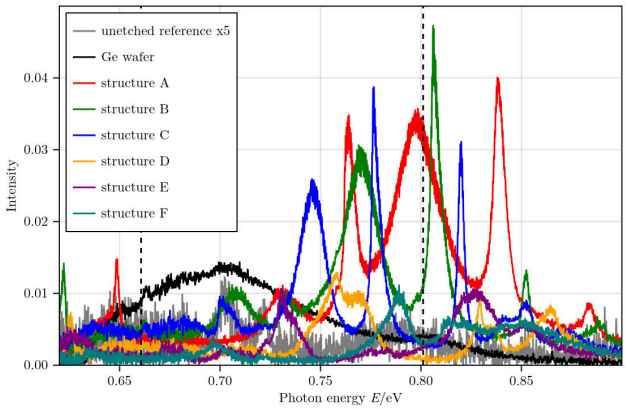

Fig. 2. PL spectra of all-dielectric metasurfaces, compared to an unetched reference area on the same sample (multiplied by 5 for visibility) and a bulk Ge wafer. Dashed black lines indicated the direct and indirect bandgap of Ge at 0.8 and 0.66 eV.

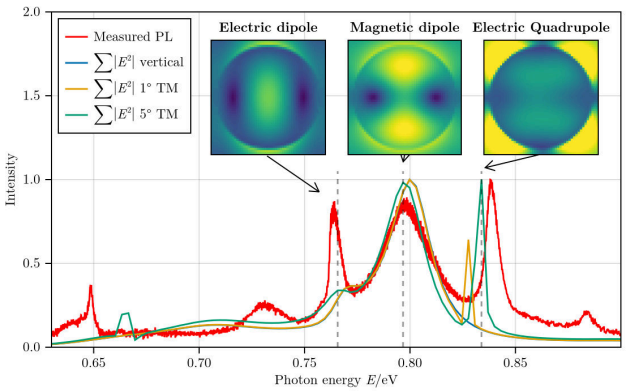

Fig. 3. Measured PL compared to simulated field enhancement under plane-wave excitation for the sample with a pitch of 850 nm. The insets show the absolute electric field along a lateral cross-section through the center of the Ge pillars.

peaks are highest when their geometry-dependent resonances are close to the direct gap. Comparing peak intensities I for different excitation powers P_0 yields a power-law dependence $I \propto P_0^k$, with k between 1.52 and 1.74, this indicates direct band-to-band transitions[10]. This confirms that our metasurfaces boost direct bandgap emission through a reduction in radiative lifetime.

Changing the sample temperature only slightly affects the resonance peaks, as it modifies the refractive index. However, the change in bandgap with temperature modifies the relative amplitudes of the peaks with respect to each other.

We conducted RCWA simulations to understand the resonant modes leading to enhanced emission. While direct simulation of emission is difficult, we rely on reciprocity in Maxwell's equations, as plane waves excited due to local fields are equivalent to local fields excited by plane waves[3]. Notably, we achieve better agreement for simulation with slightly grazing incidence. This is due to the fact that we use a 5X objective for illumination, so the angle of incidence is not strictly vertical, but a distribution. The three primary peaks related to the sample with 850 nm pitch can be related to coupled multipole Mie resonance - an electric dipole, a magnetic dipole and an electric quadrupole within the Ge pillar, respectively (Fig. 3). The peak related to electric quadrupole resonance vanishes under vertical illumination due to symmetry.

IV. Conclusion

We have demonstrated emission enhancement at the direct bandgap in intrinsic germanium up to a factor of 43, due to the use of resonant metasurface cavities. The resonances can be explained with multipole modes in coupled Mie resonators, and tuned based on geometry variation. Further research in cavity optimization and the modification of the process to include electrical contacts will be conducted in order to obtain Ge light emitting diodes in our 200 mm electronic-photonic integrated circuit pilot line.

***Abstract*— Reflective-type color filters based on meta-atoms were monolithically integrated into the OLED pixel structure. The meta-mirror was optically and electrically integrated with the OLED pixel cavity. The OLED pixel pitch was 4.8 μm, corresponding to 5,000 PPI.**

***Keywords*— meta-mirror, OLED, monolithic integration, 5K PPI**

I. Introduction

In XR devices, microdisplays are required to achieve extremely high resolution within a very small area, leading to a growing demand for high-PPI panels. In the case of OLEDoS, products with pixel densities exceeding 4K PPI have already been commercialized [1], and ultimately, pixel densities on the order of 5K PPI are expected to be required [2].

However, implementing color using conventional approaches in such highly integrated OLEDoS panels is technically very challenging. Recently, a method for realizing color filters for 10K-PPI OLEDs using metasurfaces has been proposed [3]. While this approach achieves optical integration with OLED pixels, it lacks electrical integration, which is expected to pose significant challenges for practical panel-level fabrication and operation.

In this presentation, we propose a method for monolithically integrating metasurface-based color filters into the OLED pixel integration structure and present the corresponding experimental results..

II. Methods

Our approach to monolithically integrating metasurface-based color filters into OLED pixels is to utilize a reflective meta-filter as the anode of the OLED, while employing a transparent electrode material that is electrically conductive and optically transparent as the medium forming the metasurface.

Among transparent electrode materials commonly used in display applications, indium tin oxide (ITO) is known to provide the best combination of optical transparency and electrical conductivity. However, due to the relatively high optical refractive index of ITO, the effectiveness of dielectric-based metasurfaces is significantly reduced when ITO is used as the constituent medium.

As illustrated in Fig. 1, by constructing the metasurface using aluminum (Al) as a reflective electrode, it is possible to realize a high-efficiency reflective metasurface suitable for color filtering.

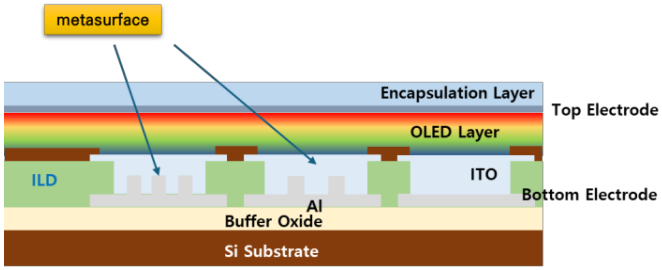

Fig. 1 Schematic of an OLED structure integrated with a meta-mirror–based color filter.

III. Results and Discussion

By tuning the Fabry–Pérot resonance modes through the phase delay introduced by the ITO layer and the phase modulation induced by the meta-mirror on the anode of the OLED device, pixel-level color control can be achieved. Considering the emission characteristics of the white OLED device and the reflectivity of the top metal electrode, the thickness of the ITO layer and the diameter of the meta-atoms were optimized to achieve optimal color gamut performance.

As a result, when the ITO thickness was fixed at 65 nm and the height of the cylindrical Al meta-atoms was fixed at 100 nm, red pixels were realized with a pitch of 351 nm and a diameter of 276 nm, while blue pixels were formed with a pitch of 400 nm and a diameter of 60 nm. For green pixels, replacing the metasurface with an ITO layer enabled a color gamut exceeding 85% of the DCI-P3 standard.

The fabrication process flow of the OLED pixels integrated with the metasurface is as follows. First, an Al layer used for

both the reflective layer and the metasurface was deposited, followed by meta-pattern formation using a nanoimprint lithography (NIL) process and patterning of the Al reflective layer. Next, an insulating layer was deposited, and only the pixel regions were etched to expose the reflective layer and the Al meta-atoms. An ITO layer was then deposited over the entire surface, followed by etching and planarization via chemical mechanical polishing (CMP), leaving ITO only in the pixel regions and electrically isolating adjacent pixels. Subsequently, banks were formed, after which the OLED functional layers and the top electrode were deposited, followed by encapsulation.

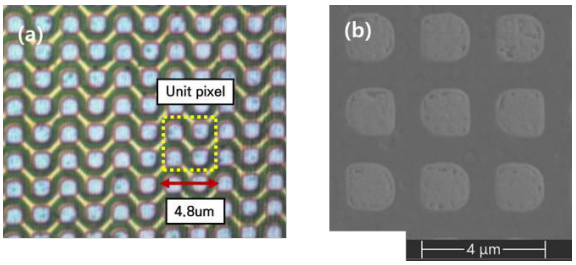

Fig. 2 Top-view images of the fabricated OLED pixel: (a) optical microscope image and (b) SEM image..

As shown in Fig. 2, an image of the pixel array obtained during the fabrication process prior to OLED layer deposition confirms a pixel pitch of 4.8 μm, corresponding to a pixel density of 5K PPI. Figure 3 presents a cross-sectional image of a pixel region, clearly showing the formation of an ITO resonance layer on top of the reflective layer.

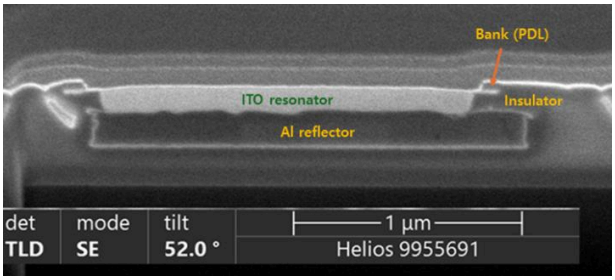

Fig. 3 Cross-sectional SEM image of the fabricated OLED pixel.

The fabricated devices exhibited good electroluminescent characteristics of the OLED, and detailed optical characterization results will be presented.

IV. Conclusion

By forming meta-atoms on the reflective layer of the OLED device and surrounding the meta-atoms with a transparent electrode material, a meta-mirror–based color filter was monolithically integrated into the OLED device. For a pixel structure corresponding to 5K PPI, a calculated color gamut of 85% was achievable. This integration of OLED devices with metasurfaces is expected to significantly contribute to the realization of future ultrahigh-resolution OLED pixel architectures..

***Abstract*—We show that metamaterials made from gold nanoparticles self-assembled in layered aggregates with nanometer-sized gaps, exhibit remarkably high refractive index. When the aggregate is shaped into a disc it forms a resonator that hosts an anapole, which combined with the field enhancement from the nanogaps results in extreme light-matter interactions.**

***Keywords*— metamaterials, plasmonics, anapoles, high-index.**

I. Introduction

Metamaterials have transformed our ability to design devices with new and extreme optical properties, often not found in nature [1]. Frequently, top-down fabrication techniques (e.g. electron beam lithography) are employed to fabricate metamaterials and metasurfaces, since they give great control over the desired meta-atom shape and periodicity. However, with top-down techniques, feature or gap sizes between meta-atoms are limited to ∼5-10nm [2]. On the other hand bottom-up approaches provide an alternative way to fabricate metamaterials. Self-assembly-driven synthesis allows for both precise control of nanoparticle shapes and the sub-nanometer gaps between them by carefully choosing the spacer molecules binding the meta-atoms together [3], [4]. Here we consider metamaterials synthesized with gold nanoparticles, carefully self-assembled into aggregate layers, achieving a high and dispersionless effective refractive index in the mid-IR regime, while maintaining low loss. The high refractive index is tunable with the size of the nano-gaps, which also provide extreme field enhancement within them. By structuring the nanoparticle aggregates into disk shapes, we create resonators that support anapoles that provide an additional boost the field enhancement. This further enhances light-matter interactions, and paves the way towards metamaterial applications in sensing, enhancing non-linear processes, such as frequency conversion or lasing.

II. Methods

The effective parameters for the metamaterial are obtained via a standard retrieval method [5] using frequency domain simulations: a unit cell of an infinite metasurface made of gold spheres is modelled, the complex reflection and transmission coefficients are calculated and inserted into the analytic formulas for homogeneous slab, then inverted to obtain the effective refractive index.

We consider spherical gold nanoparticles of diameter $D = 100$nm arranged in a closed hexagonal packing and embedded in a chemical environment of refractive index $n_s = 1.5$ that enables for their self-assembly to occur, and surrounded by air, as illustrated on Fig.1.a. Current self-assembly methods can ensure extremely small gaps between the spherical nanoparticles, even with size of $g = 1$nm, for which we find the effective refractive index to be $n = 4.2 + 0.10i$ for a single layer aggregate at long wavelength [6], see Fig.1.b. This system has a resonance of the refractive index in the near-IR,

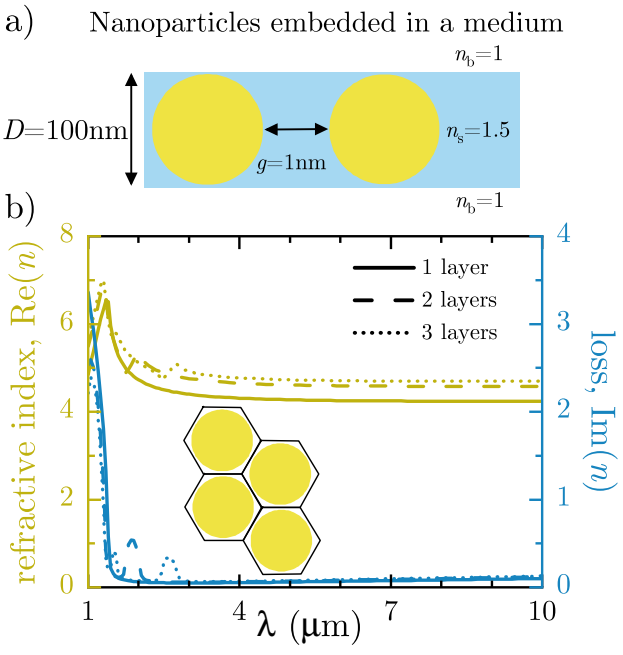

Fig. 1. a) Schematic illustration of the system with spherical nanoparticles of diameter D and gap size g embedded in a host medium with refractive index n_s and surrounded by air $n_b = 1$. b) Effective refractive index and loss of the metamaterial in the mid-IR as the number of tightly stacked layers increases. Inset shows the hexagonal packing of the nanoparticles.

and a nearly dispersion-less effective refractive index for a very broad frequency regime in the mid-IR. Additionally, the effective loss of this metamaterial is very low throughout the mid-IR regime. Therefore, this metamaterial behaves effectively as a low-loss dielectric for an extremely broad mid-IR regime and beyond, in stark contrast to the fact that is primarily made of metal (60% of volume is gold).

The stacking of additional layers of nanoparticles in close packing arrangement, increases slightly the refractive index to $n = 4.7 + 0.13i$ for a multilayer system, due the volume fraction of gold increasing in the unit cell. The gap size between the nanoparticles is controlled by the functionalization molecules that binds the nanoparticle together, with larger nanoparticle gap sizes reducing the field enhancement in the gaps and the effective polarizability of each nanoparticle, leading to a reduction in the effective refractive index [3], [4]. On the other hand, faceted nanoparticles increase the volume fraction of the gold in the unit cell and increase the effective refractive index [6]. For 1nm gaps the infinite metasurface structure provides a field enhancement factor of $EF \approx 90$ in the mid-IR region, and thus capable of enhancing non-linear processes by several orders of magnitudes.

III. Results and Discussion

We now shape the nanoparticle aggregate to form a disk resonator. The infinite metasurface at normal incidence excitation only support Fabry-Pérot resonances, however a disk resonator has a more complex mode spectrum. Such a structure supports anapoles, which are non-radiative states, characterised by a strong field confinement in the center of the resonator, and appear as strong dips in the scattering spectra [7], [8]. On Fig.2.b we show the scattering cross section spectra for a disk made of a single layer of nanoparticle aggregate. The spectrum of the homogenized disk (green line) shows a strong dip at $\lambda = 4\mu$m, and the field at this wavelength shows the typical features of an anapole, see Fig.2.b inset. Comparing this spectrum with the one for an inhomogeneous resonator made of gold spheres (gold line) we see a very good agreement between the two, suggesting the existence of an anapole in the inhomogeneous structure as well at the same frequency. The match in spectral position, but the small mismatch in amplitude suggest that the effective loss κ of the resonator is overestimated at longer wavelengths.

To confirm the existence of the anapole in the inhomogenous structure we plot the field along the radius of the resonator, parallel and perpendicular to the incoming field $\mathbf{E}_0$, see Fig.2.c and Fig.2.d. As the electric field is expelled from the metal, and confined to the gaps, it appears as sharp peaks on the plot. We also plot the field in the homogeneous resonator, which we scale up by a factor of 90, which is the enhancement factor in the infinite metasurface. We can see that the envelope of the peaks of the field in the inhomogeneous structure follows the field of the anapole in the homogeneous structure, confirming that an anapole exist in the inhomogeneous resonator. Importantly, the anapole is emerging across the whole resonator, and not just in a single unit cell as it is designed most often [9], [10], [11]. This means that the field enhancement in the nanogaps is further amplified by the anapole compared to what is found in the infinite metasurface to $EF \approx 300$, providing additional orders of magnitude boost to non-linear processes.

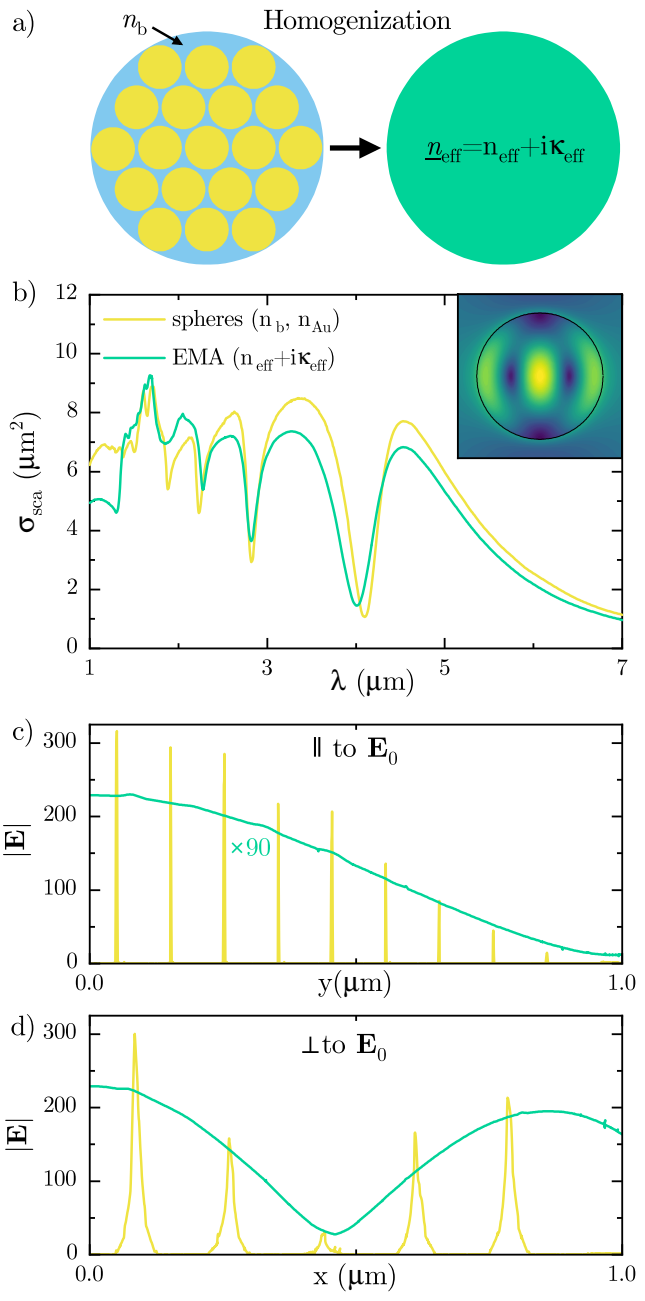

Fig. 2. a) Schematic illustration of the homogenization for the disk shaped resonator. b) Scattering cross section spectra for the homogenized resonator modelled with effective parameters, and the inhomogeneous resonator made of golds spheres. Inset shows the field amplitude inside the homogeneous disk at $\lambda = 4\mu$m. c) field inside the resonator along the radius parallel to the incoming field, which is polarized along the y direction. d) as c) but perpendicular to the incoming field.

IV. Conclusion

We have shown that self-assembled plasmonic nanoparticles behave as effective dielectrics with negligible dispersion or loss in the mid-IR. We have shown that when the aggregates is formed into a disk shape, the effective parameters obtained for an infinite metasurface remain valid despite the structure becoming finite. Importantly, the field enhancement due to the nano-gaps is amplified by the anapole in the disk resonator. The combined extreme field enhancement from this structure opens new pathways to enhance non-linear processes and light-matter interactions in the mid-IR region.

High-Efficiency Off-Grid-Positioned Metasurface Color Router for Sub-Micron CMOS Image Sensors

Po-Han Fu[1,*], Chin-Chuan Hsieh[1]

[1]Visera Technologies, Hsinchu, Taiwan

*Corresponding author: Pohan_Fu@viseratech.com

***Abstract*—We propose off-grid-positioned metasurface replacing traditional microlenses in 540 nm × 540 nm Bayer-pattern CMOS image sensors. By optimizing cylindrical meta-atom diameters and off-grid coordinates, our design efficiently routes visible light to corresponding color filters, mitigating severe diffraction and significantly enhancing overall optical efficiency.**

***Keywords*— CMOS image sensor, light routing, metasurface, off-grid positioning, sub-micron pixel.**

I. Introduction

As the demand for ultra-compact and high-resolution imaging continues to grow, the pixel size of CMOS image sensors (CIS) has aggressively scaled down into the deep sub-micron regime. At dimensions as small as 540 nm × 540 nm, the traditional optical stack encounters fundamental physical limitations. Specifically, conventional microlenses (MLs) suffer from severe diffraction at this scale, failing to focus light efficiently. Consequently, a large portion of the incident light is either scattered or directed into adjacent pixels, where it is subsequently absorbed by the color filter (CF) array. This traditional reliance on dye-based CFs to absorb unwanted spectral bands inherently wastes approximately two-thirds of the incident optical energy.

To overcome the diffraction limits of ML and the absorption losses of CFs, metasurface-based color routers have emerged as a highly promising solution. In this paper, we propose replacing the ML array with off-grid-positioned metasurface layered above the existing CF array. Unlike previous designs that restrict meta-atoms to a rigid periodic grid [1–3], our approach introduces spatial coordinates as continuous variables. This off-grid freedom provides unprecedented control over the phase profile, accurately redirecting specific wavelengths to their designated color filters, thereby minimizing absorption waste and maximizing pixel sensitivity [4].

II. Methods

The proposed metasurface is engineered for a standard 2 × 2 Bayer pattern unit cell, where each of the four sub-pixels occupies a 540 nm × 540 nm area, resulting in a total supercell footprint of 1.08 μm × 1.08 μm. The structure consists of TiO_2 cylindrical meta-atoms arranged on a transparent spacer layer directly above the CF array, as shown in Fig. 1.

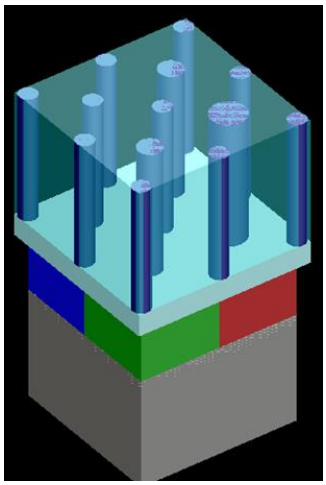

Fig. 1 Unit cell geometry of the proposed structure.

To intelligently exploit the design space, we employ a hybrid spatial arrangement of the meta-atoms across the supercell. Specifically, cylindrical meta-atoms located at the corners of the 540 nm × 540 nm pixel grid are fixed in both spatial coordinates and diameter (120 nm), serving as a structural baseline. Conversely, the meta-atoms positioned near the center of each sub-pixel are granted off-grid freedom; their diameters D_i and continuous spatial coordinates (x_i, y_i) are treated as free optimization variables, as shown in Fig. 2. This selective parameterization strategically balances computational efficiency with a highly non-linear design space. Because this expands the design into a highly non-linear and multi-dimensional parameter space, we utilize global optimization algorithms, (e.g., Genetic Algorithms), seamlessly coupled with rigorous 3D Finite-Difference Time-Domain simulations. The figure of merit is defined to maximize the optical transmission of target wavelengths into their respective CF regions while strictly penalizing inter-pixel crosstalk.

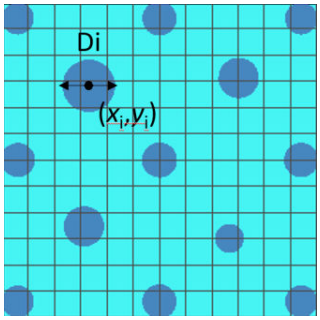

Fig. 2 Arrangement of proposed metasurface, D_i and (x_i, y_i) are treated as free optimization variables, i = 1, 2, 3, 4.

III. Results and Discussion

By simultaneously optimizing the off-grid positions and diameters, the freeform metasurface effectively shapes the incident wavefront to split and concentrate the broadband visible spectrum before it reaches the color filters. Removing the periodic grid restriction suppresses anomalous diffraction orders that typically plague sub-wavelength periodic structures, enabling a smoother and more precise phase gradient.

Numerical analyses demonstrate a dramatic enhancement in optical transmission compared to the traditional ML-CF stack, the transmittance spectra is shown in Fig. 3. Fig. 4 shows the electric field intensity of the monitor in the *xy* plane at wavelengths of 630 nm, 540 nm, and 450 nm, where the monitor is placed at the bottom of CF. Because the metasurface pre-sorts the photons, the incident light on each specific CF is already heavily weighted toward its transmission band. Consequently, the CFs function primarily as spectral purifiers rather than primary color separators, drastically reducing the amount of light they must absorb. This routing mechanism not only overcomes the severe diffraction limits of 540 nm MLs but also significantly boosts the overall quantum efficiency (QE) and reduces inter-pixel crosstalk.

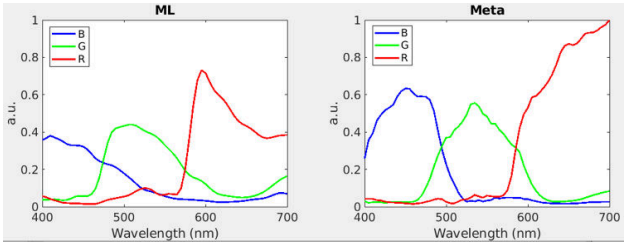

Fig. 3 Transmittance spectra of CIS with ML and proposed metasurface

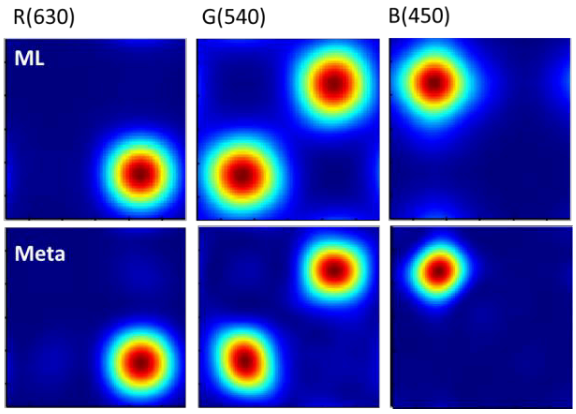

Fig. 4 Electric field intensity of the monitor in the *xy* plane at wavelengths of 630 nm (R), 540 nm (G), and 450 nm (B).

IV. Conclusion

We have demonstrated a high-efficiency metasurface color router tailored for sub-micron (540 nm × 540 nm) Bayer-pattern image sensors. By utilizing cylindrical meta-atoms with continuously optimized diameters and freeform, off-grid positions, the design achieves superior degrees of freedom for phase and dispersion control. Operating in tandem with the existing color filter array, this metasurface successfully replaces the traditional ML, pre-routing light to minimize dye-absorption losses and mitigating severe sub-micron diffraction. This freeform-positioning strategy provides a highly effective pathway for enhancing the sensitivity and color fidelity of next-generation ultra-compact CIS.

***Abstract*—The use of meta-structures in fibre waveguides has allowed for designs that can improve light-matter interaction. In this work we present numerical characterisation of a perovskite ARROW fibre based on a commercially available fused silica template. It is shown to operate close to telecoms wavelengths and support low transmission loss.**

***Keywords*— metamaterials, photonic crystals, fibre optics, telecoms.**

I. Introduction

Photonic crystal fibres (PCFs) are a family of waveguides designed with periodic inclusions arranged transverse to the propagation direction [1]. PCFs have been demonstrated to improve upon some of the challenges faced with step-index fibres, for example the lattice structure can allow for tailored dispersion [2, 3] and they can be combined with exotic materials and shown to support light-matter interactions at low powers and long interaction lengths [4, 5]. An anti-resonant reflection optical waveguide (ARROW) fibre is an example of a PCF where guidance is provided by structures in the cladding that operate in an 'anti-resonant' regime and 'reflect' propagating light back into the core [6]. One fibre design that utilises ARROW guidance is the hollow core fibre, this design guides light in an air core with a very thin periodic silica framework cladding and because of this exhibits low dispersion and can support high power transmission [7]. Another ARROW fibre design employs a solid silica core construction with cladding inclusions of a high refractive index and is more suitable for non-linear applications due to the larger electromagnetic field locality near exotic material inclusions [8].

Perovskites have recently been demonstrated as an exciting material in optics due to their superlative properties. This is encompassed by their large refractive index [9], third order non-linear coefficient [10, 11] and high quantum efficiency [12]. However, one of the challenges with this material is the growth of large continuous single crystals in the confined spaces of small structured devices which may limit its applications in larger metamaterial devices. Typically perovskites are grown from solution in the process of inverse temperature crystallisation [13]. Presently, this process has been demonstrated in the manufacture of fibres with core sizes of hundreds of microns in diameter [14] and in the case of metal free perovskites a fibre core of ≈ 5 µm demonstrating that crystals of perovskite can be grown with large aspect ratios in confined spaces [15].

With this in mind, we propose a design for a $CsPbBr_3$ ARROW fibre that may be exploited for non-linear applications such as all-optical switching and frequency conversion. In this work ARROW guidance of this design is presented and an initial study is shown. From the results an analysis of the transmission loss and characteristic ARROW dispersion is presented. At the conference we will present an in depth study of the proposed silica-perovskite ARROW fibre, including a further study on the shifting of the transmission bands through non-linear processes and potential experimental work.

II. Methods

The wavelength at which to expect transmission bands in ARROW fibres can be approximated by the following equation [8]:

$$\lambda_m \approx \frac{2d\sqrt{(n_{\text{inc}})^2 + (n_{\text{silica}})^2}}{m + \sigma} \tag{1}$$

where n_{inc} is the inclusion index, n_{silica} is the index of silica, d is the inclusion diameter, λ_m is the wavelength of the mth mode and σ configures whether the system is on resonance ($\sigma = 0.5$) or anti-resonance ($\sigma = 0$). From this equation the required inclusion diameter to place an ARROW transmission band at a specific wavelength can be calculated. However, for this initial study the perovskite ARROW fibres were designed based on a commercially available Thorlabs ESM-12B endlessly single mode fibre (ESMF) template. These fibres are constructed out of fused silica with air inclusions placed in a hexagonal lattice. The inclusions make up a larger hexagonal structure around the core consisting of 9 periods wide with a missing inclusion in the centre. The ESMF template is modified where the air inclusions are replaced by $CsPbBr_3$. The lattice parameters of the ESMF template consists of a lattice constant of $a = 8$ µm and inclusion radius of, $r = 1.85$ µm (a schematic of the fibre is included as an insert in Fig. 1b). In the numerical study a dispersive material model for both the fused silica [16] and $CsPbBr_3$ [17] materials was considered. To model the band structure the Mode Analysis solver in COMSOL Multiphysics® was employed with a circular simulation domain with radius of 25 µm and surrounded with a perfectly matched layer (PML) of 10 µm thick. The PML was configured with cylindrical geometry and double symmetry was used so only one quarter of the domain

was simulated. In order to limit spurious modes, the solver was restricted in parameter space to a rectangle defined as $1.39 \leq n_{\text{eff}} \leq 1.52$ and $-1 \times 10^{-3} \leq \kappa_{\text{eff}} \leq 0$ for effective index and extinction coefficient respectively. Additionally, the solutions were filtered based on a mode overlap integral, Ω and compared to a hand selected solution where only solutions with a mode overlap of $\Omega \geq 65\%$ are considered.

III. Results and Discussion

Results of the numerical study are presented in Fig. 1a. Here the effective refractive index is presented in the upper part of the panel and each data point is coloured based on Ω. Additionally, the transmission loss T_{loss}, is displayed in the lower part of the panel. Here two ARROW bands are visible within the spectral window centred at $\lambda_1,\ \lambda_2 \approx 1.45,\ 1.70\ \mu\text{m}$ and with transmission loss of $T_{\text{loss}_1},\ T_{\text{loss}_2} \approx -0.013,\ -0.017\ \text{dB}\,\text{cm}^{-1}$ respectively. It is noted that the transmission loss is likely to be majorly attributed to the waveguide loss as the extinction coefficient for silica and perovskite is low at this wavelength. The transmission bands show good agreement with the analytical model from Eqn. 1 which is shown by vertical dashed lines where red (blue) corresponds to an anti-resonance (resonance) respectively. For each of the two bands the effective refractive index was fitted to a polynomial of order 5 and the results are shown as a red solid line. The polynomial fits were then used to calculate the dispersion coefficient, D, that is presented in Fig. 1b. Here a characteristic feature of ARROW fibres can be observed where for shorter (longer) wavelengths the dispersion tends towards $-\infty$ ($+\infty$) and at the band centre the dispersion is approximately zero.

IV. Conclusion

In this work we have presented the design of an ARROW fibre with $CsPbBr_3$ perovskite filled inclusions. Initial results show transmission bands near telecoms wavelengths, low transmission loss and ARROW fibre like dispersion. This platform may have potential in applications exploiting the highly non-linear nature of the perovskite inclusions and long interaction lengths that fibre optics provide, all while the perovskite remains encapsulated.

***Abstract*—Randomness arising from thermal noise is almost inevitable in self-assembled colloidal crystals and is generally believed to be detrimental to photonic band gaps (PBGs). In this talk, I will present a counterintuitive example in which randomness actually enhances PBGs and discuss its effects on the width of PBGs.**

***Keywords*—photonic crystals, self-assembly, randomness.**

Unlike top-down design, self-assembly, as a bottom-up method, offers advantages such as low cost, low energy consumption, and the ability to produce crystals over large areas. However, randomness arising from thermal noise is almost inevitable in self-assembled colloidal crystals. In this talk, we will present a counterintuitive example where randomness actually benefits photonic band gaps (PBGs) and explore the effects of particle randomness on the width of PBGs. Additionally, we will discuss the realization of chiral photonic crystals using self-assembly approaches.

We report the Rashba spin–orbit coupling in a staggered-gyromagnetic photonic crystal with a modified honeycomb lattice. We confirm the emergence of a Rashba band structure and helical spin textures. Through both simulation and k-p theory. A positive-negative refraction through this structure has also been demonstrated.

***Keywords*— Rashba, spin-orbit couplings (SOC), staggered-gyromagnetic (SG) arrangement, photonic crystals.**

I. Introduction

Among all types of spin-orbit couplings (SOC), Rashba SOC represents a mechanism where inversion symmetry breaking and spin degrees of freedom give rise to spin-split band structures without external magnetic fields. Rashba SOC manifests itself in the splitting of degenerate bands into two branches shifted laterally in momentum space, forming a pair of parabolic dispersions with opposite spin orientations. The corresponding spin texture exhibits a helical pattern in momentum space. This spin-momentum locking results in two concentric iso-energy contours with opposite spin helicities.

In photonics, there has been a growing interest in the optical analogues of the Rashba effect. To date, a direct realization of Rashba-type SOC in photonic crystals, without relying on spatially engineered gauge fields or geometric-phase gradients, has remained elusive. In this article, we demonstrate that Rashba SOC can be realized in photonic crystals with staggered-gyromagnetic (SG) components and modified honeycomb lattice.

Breaking time-reversal-symmetry is essential for photons to realize Rashba (or Dirac cone) like dispersions. To this end, we derive an analytical expression of such system and introduce *k-p* theory to obtain the effective Hamiltonian near G point. The choice of gyromagnetic materials is yttrium iron garnet (YIG), which is an experimentally feasible matter due to its low loss property in microwave frequency range.

II. Methods

Fig. 1a depicts the schematic of the two-dimensional SG photonic crystals with modified honeycomb lattice. The unit cell is extended to a hexagon that contains six cylinders resulting in a four-fold Dirac point at G point because of the band folding of two Dirac degeneracies at K and K' points.

Since the SG arrangement causes the violation of reciprocity but remain the degeneracies, it makes the Dirac degeneracies at K and K' point respond at distinct frequencies. Thus, the band folding near G point facilitates two vertically split conical dispersions. Fig. 1b demonstrates how a four-fold Dirac point evolves. In a regular honeycomb lattice, the SG configuration splits the four-fold Dirac points into a nodal line. Then, the increase of distance of rods from the center of unit cell lifts a complete gap separating two photonic band branches.

The lattice constant of the photonic crystal is a and the radius of cylinders $r = 0.2R$, where R is the distance of each cylinder to the center of unit cell. In a regular honeycomb lattice, R = a/3, whereas R = 0.35a for a modified one. The permittivity of YIG rods $\varepsilon = 15$ and the permeability tensor takes the form

$$\begin{bmatrix} \mu_a & -i\mu_g & 0 \\ i\mu_g & \mu_a & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{1}$$

When a 0.16T uniform magnetic field is applied, the approximate magnitude of $\mu_a = 14$ and $\mu_g = 12.4$ at frequency 4.281 GHz [1], the effect of material dispersion and loss are neglected.

In the presence of magnetic anisotropy, the TE $\left(H_x, H_y, E_z\right)$ polarization gives rise to a 2D master equation where the conventional band theory is applicable. By eliminating the magnetic fields from Maxwell's equations, one obtains

$$\nabla_\perp \cdot \xi(\mathbf{r}) \nabla_\perp E_z + i\left[\nabla_\perp \times \eta(\mathbf{r}) \nabla_\perp E_z\right]_z + \left(\frac{\omega}{c}\right)^2 \varepsilon(\mathbf{r}) E_z = 0, \tag{2}$$

where the elements of inverse permeability tensors $\xi(\mathbf{r}) = \mu_a / \left(\mu_a^2 - \mu_g^2\right)$ and $\eta(\mathbf{r}) = \mu_g / \left(\mu_a^2 - \mu_g^2\right)$.

Fig. 2a-c illustrate the evolution of the TE band diagram for the realistic SG photonic crystals. For a regular honeycomb lattice without SG component, Fig. 2a contains a G-point four-

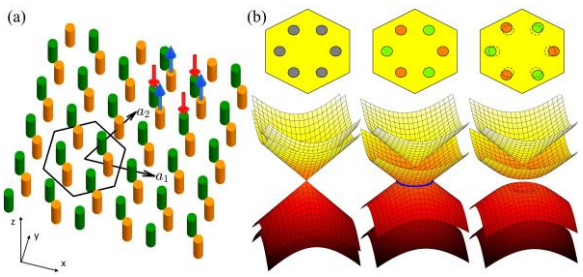

Fig. 1 Structure and band evolutions of a hexagonal photonic crystal composed of two alternating types of cylinders

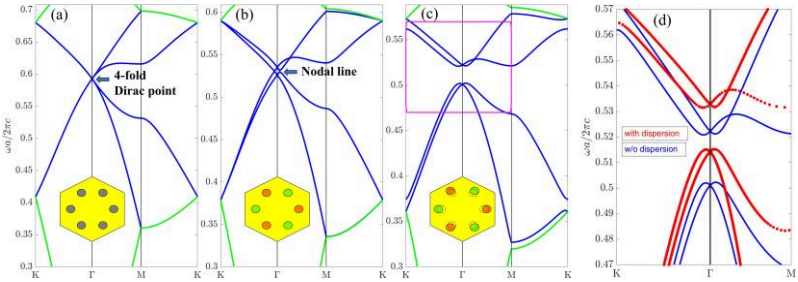

Fig. 2 Evolution of the photonic band structure under different perturbations.

fold Dirac degeneracy between the second and fifth bands at reduced frequency of 0.593. As mentioned previously, this degeneracy converts into a circular nodal line and two two-fold degeneracies when the SG material is employed, as shown in Fig. 2b. The nodal line is then lifted upon introducing a structural perturbation, thereby turning the entire four-band structure into a Rashba band diagram around reduced frequency of 0.52.

In Fig. 2d, it is evident that the influence the material dispersion is insignificant within the desired frequency range. This validates that the Rashba band splitting in Fig. 2d arises from the staggered gyromagnetic ordering (i.e., the specific structural arrangement) rather than from material dispersion, establishing the SG photonic crystal as a platform for realizing Rashba SOC in periodic media.

To construct a four-band reduced Hamiltonian near the Γ point, we use the Bloch wave function at $\mathbf{k}_0$ point as eigenbases. The Bloch state at $\mathbf{k}$ point near $\mathbf{k}_0$ point takes the form [2]-[4]

$$E_{z,n\mathbf{k}}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} u_{n\mathbf{k}}(\mathbf{r}) = \sum_j A_{nj}(\mathbf{k}) \exp\left[i(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}\right] E_{z,j\mathbf{k}_0} . \quad (3)$$

In here, the Bloch state $u_{n\mathbf{k}}(\mathbf{r})$ at $\mathbf{k}$ point has been expanded by the superposition of $u_{j\mathbf{k}_0}(\mathbf{r})$. Plugging (3) into (2) and employing orthonormal property of basis, we obtain the reduced Hamiltonian H_{lj} given by

$$H_{lj} = -(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{p}_{lj} + \left[\mathbf{t}_{lj}\times(\mathbf{k}-\mathbf{k}_0)\right]_z + (\mathbf{k}-\mathbf{k}_0)^2 q_{lj} , \quad (4)$$

where the indices $l, j = 1-4$.

In addition to the p and q coefficients that have been discussed in [3], [4], the t coefficient can be written as

$$\mathbf{t}_{lj} = A_c^{-1} \int_{u.c.} E^*_{z,l\mathbf{k}_0}(\mathbf{r})(\nabla\eta) E_{z,j\mathbf{k}_0}(\mathbf{r}) d^2\mathbf{r} . \quad (5)$$

with A_c denoting the area of the unit cell.

Since the desired bands are significantly separated from others, we only need to consider the two pairs of degeneracies around Γ point to obtain the dispersion relation.

Although the Eq. (4) does not explicitly appear as a direct sum of two conventional Rashba Hamiltonians owing to inter-band coupling among the four bands, it embodies a Rashba effect since the resulting band structure and spin texture are consistent with the nature of Rashba physics. To further validate whether the reduced Hamiltonian reflects underlying physics in our system, we compare the band structures calculated by Eq. (4) with the one calculated by COMSOL.

We then study the spin texture of each band. As stated in [5], the spin degrees of freedom in this six-rod structure are defined as $|\psi_n\rangle = [p_+, p_-, d_+, d_-]$, where $p_\pm = (p_x \pm ip_y)/\sqrt{2}$ and $d_\pm = \left(d_{x^2-y^2} \pm id_{xy}\right)/\sqrt{2}$. On this basis, the spin components can be evaluated through $s_i^{(n)} = \langle\psi_n|\mathbf{1}\otimes\mathbf{s}_i|\psi_n\rangle$, where $\mathbf{s}_i$ consists of three components of Pauli matrices.

III. Results and Discussion

As depicted in Fig. 3b-3d, the spin textures reveal how the pseudo-spin states of light evolve with the momentum of the photons in the SG photonic crystals. These spin textures describe that the photonic spin polarization, analogous to electron spin in the Rashba effect, is coupled to the momentum of the photons.

As k varies within the Brillouin zone, the direction of spin polarization of the photonic modes continuously rotates about the Brillouin center. This rotation of spin polarization is the main feature of Rashba SOC, which is a direct manifestation of the SOC in the system. For different photonic bands near the Γ point, the spin textures are visualized as a vortex-like structure with opposite rotating directions.

Fig. 4 illustrates the phenomenon of double refraction occurring in a SG photonic crystal slab illuminated by an obliquely incident electromagnetic wave at an angle of 20 degrees. The figure clearly demonstrates the splitting of the incident wave upon entry into the photonic crystal, generating two transmitted beams propagating at distinctly different angles.

The directional arrows depicted in the figure explicitly demonstrate the energy flow of the reflected and refracted beams, highlighting the doubly refractive behavior. This double refraction can be expressed by the following mechanism: The upper two branches of the Rashba dispersion can be expressed as $\omega_\pm(k) = Ck^2 \pm \alpha k$ in which C and a denote two constants related to structural geometry and materials. This dispersion yields the group velocities given by $\mathbf{v}_g = (2Ck \pm \alpha)\hat{\mathbf{k}}$.

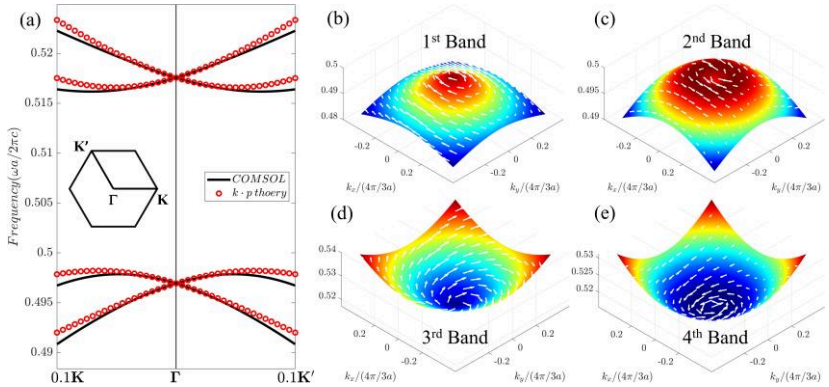

Fig. 3 Validation of the *k-p* band structure and the spin textures of eigenmode near the Dirac point.

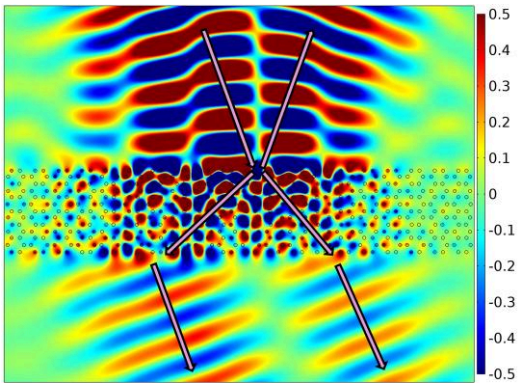

Fig. 4 Double refraction in a SG photonic crystal.

When the operating frequency corresponds to a region where the slopes $(2Ck \pm \alpha)\hat{\mathbf{k}}$ possess opposite signs, the two Rashba branches support energy flow in opposite directions. Consequently, both positive and negative refraction can occur simultaneously under this condition. Additionally, this anomalous double refraction is explained by analogy to the theory of resonant chiral media [6]. Since chiral resonance leads to Rashba-like band structure, the proposed SG structure produces similar conditions for spin states in photonic crystals.

IV. Conclusion

We have demonstrated that Rashba SOC can be effectively realized in SG photonic crystals with a modified honeycomb lattice structure.

By employing YIG rods in a staggered arrangement in a hexagonal lattice, we achieve nontrivial magneto-optical properties which are equivalent to spin-orbit interactions analogous to the electronic Rashba SOC. Using both numerical simulations and analytical *k-p* theory, we achieve photonic band dispersion and validated these findings through excellent agreement with COMSOL simulations.

Our analysis further reveals the formation of unique spin textures associated with each photonic mode near the Γ point. The spin polarization of the photonic modes continuously rotates around the Brillouin zone center, exhibiting a clear spin-dependent characteristic reminiscent of the Rashba effect.

Moreover, the double refraction behavior demonstrates their capability to manipulate electromagnetic wave propagation uniquely, reinforcing their significance for advancing understanding in photonics. Also, a quantitative extraction of the Rashba dispersion parameters based on effective-parameter retrieval is an interesting direction for future work.

Beyond photonics, the mechanism we reveal is universal to wave systems, suggesting a pathway to emulate Rashba-like effects across different branches of physics.

***Abstract*— We propose a novel architecture of waveguide-array optical neural network on the thin-film lithium niobate platform. The superior features of this design enable high-speed, energy-efficient, computationally dense and fabrication-robust performance on optical computation and machine learning inference, aiming at next-generation AI applications.**

***Keywords*— optical neural network, waveguide array, thin-film lithium niobate.**

I. Introduction

Optical neural network has been investigated widely in the recent years, targeting the solution of computational capacity, latency, energy efficiency of the conventional electric chips. Multiple on-chip architectures such as Mach-Zehnder interferometers (MZIs), micro-ring resonators (MRRs) and diffractive optical elements have been proposed, exhibiting the high speed, energy efficient and parallel processing features. However, there is still a challenge to simultaneously achieve all the exceptional performances above with a dense integration. And the tolerance of fabrication errors is also a hinder for optical computing. Herein, we demonstrate a waveguide-array optical neural network (WONN) on the thin-film lithium niobate (TFLN) platform, which enables the compact footprint, high computational density and fabrication robust leveraging the nature of the waveguide array and yields the high speed and energy efficiency by virtue of the characteristics of the TFLN.

II. Methods

The WONN is comprised of a multimode interference (MMI) splitting tree, electro-optic phase shifters, waveguide arrays and coupling gratings. As shown in Fig. 1, the 1550 nm-wavelength light is coupled into the chip and then split by the MMIs. The input features of the tasks are preprocessed and loaded onto the phase of the light. Subsequentially, the modulated light travels through the waveguide array, executing the matrix-vector multiplication, and the outputs of the selected ports give the final inference results. In this process, the waveguide array provides the desired weight matrix which is acquired in the training by adjusting the gap of the waveguides, or the coupling coefficient between the adjacent waveguides. Here, the coupled mode theory and the eigen mode expansion method are used to model the waveguide array and calculate its transmission matrix. By gradient descent optimization, the best arrangement of the waveguides is obtained for the identification tasks.

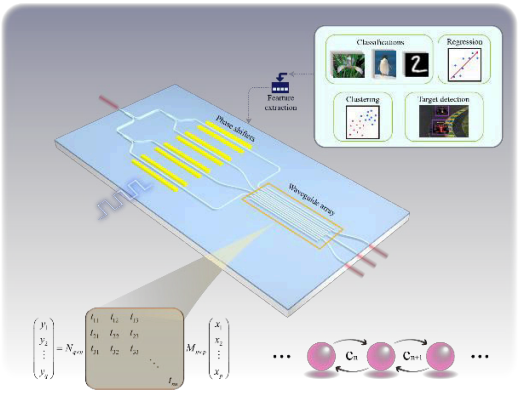

Fig. 1 Schematic diagram of the waveguide array optical neural network.

III. Results and Discussion

In the experiment, the WONN is designed for the iris flower identification task and the handwritten digit classification task, which achieves accuracies of 100% and 89.7% respectively. Moreover, the device maintains over 90% accuracy across a 75nm operating bandwidth in the iris flower identification task, demonstrating the wavelength insensitivity and superior robustness of the waveguide array. The computational metrics are also evaluated and shown a computing speed of 135.6 TOPS, an energy efficiency of 6.28 TOPS/W and a computational density of 9.48×10^4 TOPS/mm^2.

IV. Conclusion

We have demonstrated the matrix-vector multiplication of the waveguide array and constructed optical neural networks on the TFLN platform. The excellent performance of WONN

marks a leading position in the field of on-chip optical neural network and this architecture paves the way for dense, high-speed and energy-efficient optical processors for next-generation AI applications.

***Abstract*— Using spatiotemporal measurements of light propagation in transparent wood composites the main scattering mechanism was identified as refraction on cell wall interface with polymer filler. Based on this insight we show how by controlling the wood-polymer refractive index contrast and lumen shape a truly transparent wood composite can be realized.**

***Keywords*— hierarchical structure, cellulose, composite, light diffusion.**

I. Introduction

Transparent wood (TW) composites combining load-bearing and optical properties were developed a decade ago. Delignified cellulose matrix was impregnated with a refractive index matching polymer for optical transparency. It can host a variety of nanomaterials for advanced optical functions, such as luminescence [1]. However, the main obstacle in large-scale utilization of this novel composite is a high haze. It stems from wood hierarchical structure with pores at micro and nanoscales and multiple interfaces with the filling polymer [2]. In this paper we report on the mechanism of light propagation in such material as revealed by spatiotemporally resolved transmission. Main processes responsible for light scattering were identified and remedies for developing truly transparent wood, as opposite to hazy translucent wood, are outlined.

II. Methods

Using femtosecond laser pulses and a streak camera we detected light transmission through native, delignified and TW with ~ mm spatial and ~ ps temporal resolution for different wood species, cellulose treatment and filler polymers [3,4].

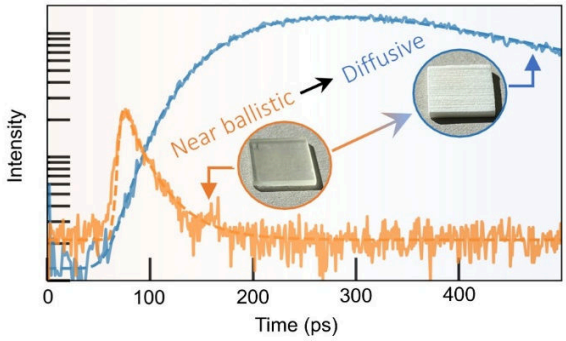

Fig. 1 Typical time-resolved transmission curves for delignified (blue) and transparent (red) wood samples 1 mm thick.

III. Results and Discussion

Time-resolved curves (Fig. 1) reveal that the transmission mechanism changes from diffusive for the native and delignified wood to nearly ballistic for the transparent wood. In addition, the spatial pattern for TW scattering is anisotropic with strong in-plane component. This can be attributed to refraction on the cell wall-polymer interface, as most lumen shapes in the wood are cylindrical [4]. Therefore, the light wavefront experiences high angles at the interfaces. This results in scattering even for a closely matched refractive indices of the wood (~ 1.536) and the polymer (~ 1.5 for PMMA).

To mitigate this unwanted effect both a better controlled refractive index contrast and the shape of the cell wall (lumen) should be considered. We show that some wood species possess more favorable lumen structure for this purpose, namely more rectangular/hexagonal lumens. The refractive index of the filler polymer can be modified by selected additives. Strategies to deal with remaining scattering (Mie or Rayleigh) on nanovoids in the cell wall as well as birefringent effects are discussed.

IV. Conclusion

We show that the high haze (80-90%), typical for translucent wood samples, can be mitigated using insights into the light propagation mechanism obtained from spatiotemporally resolved studies. Developments in this direction towards “wood glass” may offer lower embodied energy alternatives to monolithic glass, which today dominates building envelops.

***Abstract*—Our recently developed multiscale quantum mechanics/classical approach is presented for modeling surface-enhanced (SE) Raman scattering (SERS) spectra of amino acids and nucleobases near plasmonic nanostructures. Atomistic yet classical force fields describe the plasmonic properties of noble-metal nanostructures. SERS results are complemented by SE hyper-Raman spectra, together with experimental data.**

***Keywords*— atomistic modeling, multiscale, SERS, plasmonics, gold and silver nanostructures.**

I. Introduction

Surface-enhanced Raman scattering (SERS) exploits the intense local electromagnetic fields generated by localized surface plasmon resonances in metallic nanostructures, dramatically amplifying Raman signals down to the single-molecule level.[1][2] The optical response of plasmonic nanostructures can be tuned via their shape, size, composition, and surrounding environment, enabling precise control over the spectral features of adsorbed molecules.[3] Complementary techniques to SERS, such as surface-enhanced hyper-Raman scattering (SEHRS) and surface-enhanced infrared absorption (SEIRA), similarly leverage plasmonic field enhancement and are therefore fundamental for probing molecular behavior at nanostructured interfaces.[1]

In this work, we present a fully atomistic multiscale strategy to model the surface-enhanced spectroscopic response of (bio)molecules adsorbed on plasmonic nanostructures. Computed SERS spectra of representative DNA nucleobases and amino acids are compared with experimental data, and SEHRS spectra are calculated to provide complementary information on the bio-nano systems under investigation.

II. Methods

Theoretical modeling plays a crucial role in predicting and interpreting SERS spectra.[4] In recent years, multiscale approaches combining a quantum mechanical (QM) description of the molecule with atomistic, classical, and electromagnetic models of the plasmonic substrates have been proposed.[5]

In our approach, the target (bio)molecule is described at the (time-dependent) density functional theory [(TD)DFT] level, while the plasmonic environment is modeled classically using the atomistic, frequency-dependent Fluctuating Charges (ωFQ) and Fluctuating Dipoles (ωFQFμ) force fields[6][7] (see Fig. 1 for a schematic depiction of the QM/ωFQ(Fμ) model). These classical models capture Drude conduction, quantum tunneling, and interband transitions, providing an accurate yet efficient description of metallic and graphene-based nanostructures under external radiation across diverse sizes, morphologies, and compositions. [8, and references therein]. The QM/ωFQFμ method, initially developed for SERS of molecular subsystems adsorbed on noble-metal nanostructures[6], has also been extended to SEIRA [7] and SEHRS [9], thereby providing a more complete framework for simulating the linear and nonlinear vibrational responses of plasmon–molecule hybrid systems.

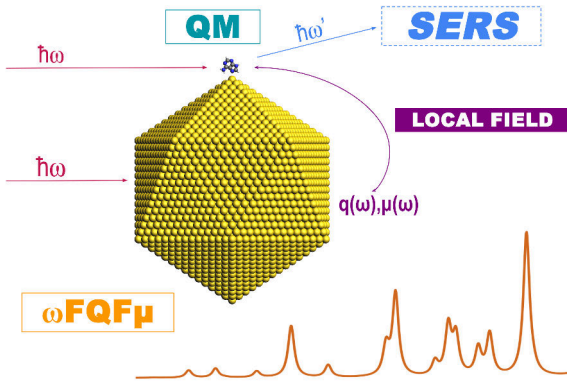

Fig. 1. Graphical representation of the QM/$\omega FQF\mu$ approach for SERS, explicitly including the local field contribution responsible for electromagnetic enhancement.

III. Results and Discussion

We first focus on the calculation of SERS spectra of the adenine nucleobase adsorbed on gold icosahedral nanoparticles, investigating how adsorption sites and molecular orientation influence spectral features and enhancement factors. The computed QM/$\omega FQF\mu$ SERS spectra are benchmarked against experimental data.[7] To identify the most likely adsorption geometries of adenine on gold, Fig. 2 compares the calculated spectra for the three proposed adsorption models (N1/N10, N7/N10, N3/N9) with experimental SERS data. The total averaged calculated spectra ("Calc") reproduce most experimental

features ("Exp"), indicating that N3/N9 and N7/N10 are the most probable adsorption configurations.

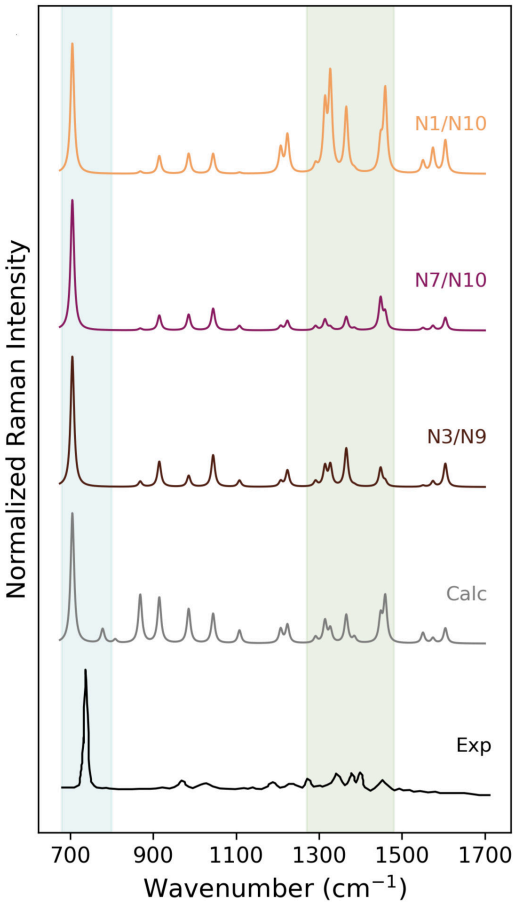

Fig. 2. Normalized QM/$\omega FQF\mu$ SERS spectra, calculated for N3/N9, N7/N10, N1/N10, and all (Calc) adsorption configurations of adenine nucleobase on a gold icosahedral nanoparticle, together with the experimental results (Reproduced from Ref. [10]. Copyright 2009 American Chemical Society.). The characteristic regions of the SERS spectra are highlighted.

SEHRS is a nonlinear technique complementary to SERS that, owing to its stronger electromagnetic field enhancement and distinct selection rules, can provide additional insight into biomolecule–surface interactions.[11] In the present work, computed SERS spectra are used in conjunction with SEHRS and compared with experimental data [12][13] to explore the effects of protonation states and hot-spot enhancement on the aromatic amino acid tryptophan, illustrating the potential of our multiscale simulations to investigate a broader range of biologically relevant molecules.[9]

IV. Conclusion

We have shown that the QM/$\omega FQF\mu$ approach provides an accurate and flexible framework for modeling SERS spectra of small biomolecules on plasmonic nanostructures, capturing the influence of molecular orientation, adsorption sites, substrate morphology, and environmental effects. Complementary SEHRS calculations further support the interpretation of SERS spectra, aiding the understanding of vibrational mode activation and molecule–surface interactions. Applications to representative nucleobases and amino acids demonstrate the predictive power of the method, highlighting its potential to guide the design of plasmonic biosensors and future surface-enhanced spectroscopic studies.

Topological edge-state waveguide fed slot antennas

Shih-Hui Gilbert Chang*

Department of Photonics, National Cheng-Kung University, Tainan, Taiwan
*Corresponding author: gilbert@mail.ncku.edu.tw

***Abstract*— Topological edge states based on the quantum spin Hall effect are implemented in a dual layer PEC structure to form a one-way propagation waveguide. A slot antenna fed by such a topological waveguide exhibits higher order resonant modes and leads to pseudospin flips. The properties of the topological protection, simulated by FDTD, are discussed.**

***Keywords*— photonic topological insultors, finite-difference time-domain method, nanoantennas.**

I. Introduction

Slot antennas used in phase array system are fed by transmission line within a dual-layer PEC structure. The opening of the slot introduces an additional impedance load to the transmission line, drastically altering the phase of the transmission channel. Consequently, designing a phased array with multiple slots requires phase compensators, making the system complex and inefficient. By adopting topological edge states based on quantum spin Hall effect as the transmission waveguide, the system benefits from topological protection. Because this protection is immune to defects such as the slot openings, it should successfully preserve the phase of the transmitted signal for the next slot antenna.

II. Methods

In this work, a dual-layered PEC structure is used to form a TM_0 waveguide, which is sandwiched with dielectric cylinders in a hexagonal lattice. Each unit cell consists of six dielectric cylinders with a fixed radius but varying center-to-center distances to form both trivial and nontrivial photonic topological insulators [1]. By using the order-N method alongside finite-difference time-domain(FDTD) simulations, we calculate the band structure of the trivial and nontrivial topological insulator to verify band inversion in the nontrivial case. A Wilson loop method is employed to calculate the Chern number and verify the system's topological properties. These two topological insulators are stitched together to form a zigzag interface supporting topologically protected edge states. The edge state dispersion is calculated, and its one-way propagation with pseudospin excitation is verified by the FDTD method. Exciting the pseudospin edge state at the interface forms a one-way propagating waveguide mode that is immune to defects and backscattering. Finally, by introducing a hexagonal opening on the upper PEC plane, a slot antenna is formed to extract the waveguide signal into free space. This slot antenna is designed to have a resonant peak at the center of the topological bandgap.

III. Results and Discussion

Analyzing the out-scattering spectrum of the slot antenna reveals two distinct peaks instead of a single broad resonant. An examination of the mode patterns indicates that these two peaks correspond to the m=0 and m=1 modes, respectively. These modes can be viewed as the photonic crystal defect modes introduced by the slot antenna. Underneath the opening of the PEC slot antenna, the periodic structure of the dielectric cylinders provides a stopband for mode confinement. When the pseudospin-up mode is excited as the right-going waveguide mode at the wavelength of the first peak, strong reflection occurs, whereas the second peak exhibits no reflection. Although the slot antenna breaks the Z_2 symmetry which typically leads to a spin flip, the symmetry of the m=1 resonant mode drastically reduced the effect and preserves the edge state mode.

IV. Conclusion

In conclude, by carefully designing the slot antenna and choosing the appropriate symmetry, a topological protected edge state waveguide can radiate an outgoing transmission without a spin flip, thereby maintaining topological protection. This work can provide a novel mechanism for phased array antenna design that avoids complicated phase and interference considerations.

Gradient-Momentum Engineering in Metasurface for Continuous and Asymmetric Beam Steering

Su-Hsiu-Ping[1*], Po-Sheng Huang[1], and Pin Chieh Wu[1]

[1]*Department of Photonics, National Cheng Kung University, Tainan 70101, Taiwan*
* Corresponding author: samwii888@gmail.com

***Abstract*— Advanced optical sensing systems require continuous and high-resolution beam steering over a wide field of illumination (FOI). However, meeting these criteria in a compact transmissive device has yet to be achieved. Here, we develop a transmissive metasurface featuring spatially continuous, independently tunable in-plane momentum gradients, enabling wide FOI coverage of 100° and 70° in the horizontal and vertical directions, respectively. The proposed metasurface attains a theoretical deflection efficiency of 96% and an experimental efficiency of 58%, with a fine angular resolution of ~0.4°. By tuning the gradient momentum distribution, it enables precise control of the angular resolution and FOI along orthogonal axes, making this platform well suited for next-generation applications.**

***Keywords* — Active metasurface, LiDAR, All-dielectric metasurface.**

I. Introduction

With the rapid advancement of optical communications, LiDAR, and AR/VR technologies, there is a growing demand for nanophotonic devices that enable continuous beam steering while remaining highly compatible with existing platforms. Metasurfaces have emerged as a compelling solution due to their ability to manipulate optical properties such as phase, amplitude, and polarization at the subwavelength scale. To date, dynamic beam steering strategies have largely relied on phase-change materials, complicated physic principle, or integration with intricate circuits [1] to modulate the refractive index or the effective geometry of the device. Despite notable progress, these approaches often remain constrained by design complexity and limited operational efficiency.

In this work, we propose a transmissive metasurface that achieves asymmetric, high-efficiency, and continuous beam control with a wide asymmetric FOI at a wavelength of 940 nm [2]. The design principle is to engineer the in-plane momentum through a linear, spatially continuous gradient across the metasurface. Owing to the inherently continuous momentum distribution, the resulting beam steering is smooth and supports fine angular resolution. Furthermore, the momentum gradient can be tuned along selected directions, providing additional degrees of freedom for diverse application schemes. Experimentally, we demonstrate continuous beam deflection with an asymmetric FOI of 100° in the horizontal direction and 70° in the vertical direction, together with high theoretical steering efficiency, indicating strong potential for LiDAR and advanced optical sensing applications.

II. Methods

Continuous, asymmetric, and high-resolution beam steering can be realized using generalized Snell's law, where the spatial distribution of the phase gradient is intrinsically linked to the in-plane optical momentum which determines the direction of light propagation. By exploiting the vector nature of momentum, we design the momentum components independently along the x and y directions, thereby decoupling the deflection behavior along the orthogonal axes. The momentum can also be linearly combined to form a diagonal momentum vector, which enables arbitrary 2D steering trajectories.

Here, we assume linear relationships for the momentum gradients along the x and y directions characterized by distinct slope coefficients, respectively. Specifically, the momentum functions are defined as $k_x = k_0 ax$ and $k_y = k_0 by$ where k_0 is the free space wavevector and a, b denote the slope coefficients. For diagonal paths, the in-plane momentum is given by the vector sum of k_x and k_y. Consequently, the deflection angle can be tuned by shifting the incident beam position relative to the metasurface center, enabling customizable FOI range. Integrating the momentum functions gives the phase profile $\varphi(x, y) = k_0(ax^2 + by^2)$ where the coefficients are determined by the relations $a = \sin(\theta_{\Delta x})/L_x$, and $b = \sin(\theta_{\Delta y})/L_y$, where $\theta_{\Delta x} = \theta_{\Delta x_{max}} = 50°$, $L_x = 2268$ μm, $\theta_{\Delta y} = \theta_{\Delta y_{max}} = 35°$, and $L_y = 1715$ μm (the lateral dimensions L_x and L_y are the half length of the metasurface in x and y axis). Figure 1a and 1b illustrate the design phase distribution and the corresponding in-plane momentum map, respectively. Both exhibit anisotropic behavior, with a larger phase (momentum) variation along the horizontal direction.

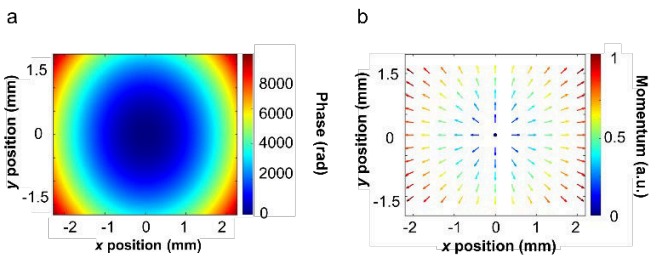

Fig. 1 (a) Design phase distribution which features an elliptical function confirming the asymmetric nature. (b) 2D momentum map for linear momentum design.

III. Results and Discussion

To validate the proposed concept, we performed both numerical simulations and experimental measurements. Figure 2a presents an optical microscope (OM) image together with scanning electron microscopy (SEM) images of the fabricated metasurface, confirming overall structural integrity and uniformity. Figure 2b shows the calculated deflection angles, which form an elliptical angular distribution that reflects the intentionally anisotropic design. The numerical and experimental deflection angles both demonstrate high deflection efficiency and continuous 2D steering, which are in good agreement with theoretical predictions. The discrepancies observed near the corners mainly arise from distortions of the deflected spots at larger steering angles, which hinder complete collection of the optical spot during measurement.

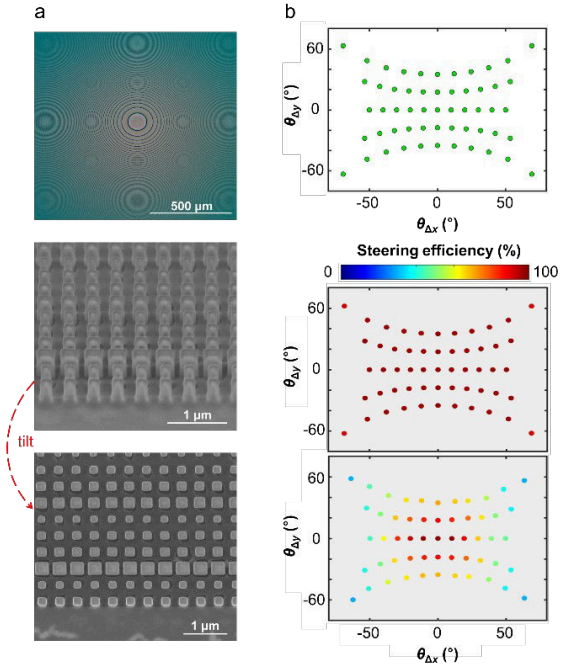

Fig. 2 (a) The OM image (top) and SEM image (center and bottom). (b) 2D map of theoretical deflection angles (top) compares with simulated (center) and experimental (bottom) deflection angles, where color indicates steering efficiency.

Figure 3a shows fine displacement scanning along the x, y, and diagonal directions, where the measured deflection angles follow the theoretical trend with high fidelity. To quantitatively assess the angular precision of the proposed metasurface, we define the angular resolution $\Delta\theta$ as the smallest displacement that yields a resolvable change in steering angle (Fig. 3b). The measured variations remain small and symmetrically distribute about the theoretical prediction line, with average values of 0.401°, 0.387°, and 0.392°, and corresponding standard deviations of 0.143°, 0.190°, and 0.155° for three scan directions. Notably, there is no observable drift or error accumulation across all displacement range. These results confirm that the metasurface maintains consistent beam steering accuracy through the entire scanning range.

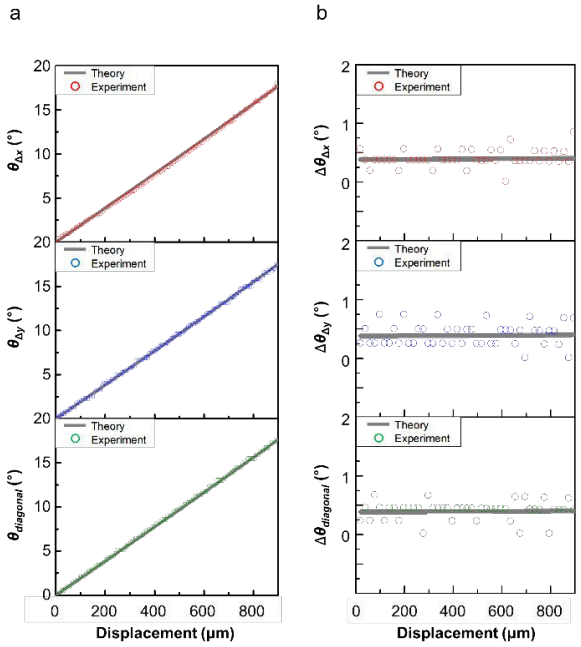

Fig. 3 (a) Beam steering corresponding to 5 μm incremental displacements of the incident beam along three directions. (b) Angular resolution with 20 μm beam displacement interval. Solid lines depict theoretical expectations, and the dots indicate experimental data.

IV. Conclusion

In this work, we develop and experimentally demonstrate a transmissive metasurface capable of continuous and high-resolution 2D beam deflection. By leveraging spatially linear and independently tunable in-plane momentum gradients along orthogonal directions, the proposed design achieves a wide and asymmetric FOI, covering 100° horizontally and 70° vertically, while maintaining high steering efficiency (~96% simulated average). Notably, sub-degree angular precision is obtained for beam steering in all directions, and dense spatial sampling confirms continuous 2D scanning without observable drift. This finding provides a compact, efficient, and versatile beam-steering platform, well suited for next-generation LiDAR, free-space communication and advanced sensing applications.

Multiscale analysis of anisotropic composites

Natalia Rylko

Faculty of Computer Science and Mathematics, Cracow University of Technology, Krakow, Poland

***Abstract*—A new two-dimensional polydisperse model for analyzing two-phase composites is developed. Verification of the model is performed using composite microstructures in which the local inclusion concentration is sufficiently uniform, ensuring that the material does not exhibit a graded structure. The examined microstructure is characterized at the macro-, meso-, and micro-scales through the structural sum e_2, which is equivalent to using the two-point correlation function. An anisotropy distribution $\varkappa(\mathbf{x})$ is then introduced through e_2 for meso-cells centered at position x. This new distribution $\varkappa(\mathbf{x})$ captures and aggregates the geometric features of the considered microstructure.**

***Keywords*— dispersed random composites, polydisperse model, macroscopic property tensor.**

I. Introduction

The classic homogenization theory and its constructive implementations are used to determine the effective constants of deterministic and random composites. Anisotropy is an intrinsic quality of composites arising from geometric structure. The macroscopic anisotropy is expressed by tensors corresponding to various constitutive equations for physical and mechanical fields. For simplicity, we restrict our attention to the two-dimensional conduction mathematically equivalent to the real dielectric permittivity.

II. Anisotropy coefficient

A complex variable for the plane coordinates will be used. Consider a composite with non-overlapping circular inclusions $|z-a_k|<r_k$ $(k=1,2,\dots,N)$ randomly distributed in the periodicity square unit cell and occupied by a material of conductivity σ_1. The conductivity of the host is normalized to $\sigma_0=1$. The truncated form for the normalized effective conductivity tensor for two-phase composites becomes [1]

$$\boldsymbol{\sigma}=(1+2\varrho f)I+\tfrac{2\varrho^2}{\pi}\sum_{k,m=1}^{N}f_kf_m\times \left(\begin{array}{cc}\mathrm{Re}\,E_2(a_m-a_k) & -\mathrm{Im}\,E_2(a_m-a_k)\\ -\mathrm{Im}\,E_2(a_m-a_k) & -\mathrm{Re}\,E_2(a_m-a_k)\end{array}\right)+O(f^{\frac{5}{2}}|\varrho|^3), \tag{1}$$

where I stands for the identity matrix, the contrast parameter $\varrho=\frac{\sigma_1-\sigma_0}{\sigma_1+\sigma_0}$, $E_2(z)$ is the Eisenstein function of second order. Here, $f_k=\pi r_k^2$ and $f=\sum_{k=1}^{N}f_k$ is the total concentration.

We introduce the local polydispercity anisotropy coefficient based on [1]. Let $\mathbf{x}$ be the center of the square cell. This cell will be considered a meso-cell. The local polydispersity anisotropy coefficient is introduced in the considered small square cell

$$\kappa(\mathbf{x})=\frac{1}{\pi}\sum_{k,m}f_m(\mathbf{x})f_k(\mathbf{x})\left[E_2(a_m-a_k)-\pi\right]. \tag{2}$$

The parameters $f_m(\mathbf{x})$ in the right part of (2) are calculated locally in a small cell, hence, depend on $\mathbf{x}$. The geometrical parameters in the brackets are calculated after the normalization to the unit square cell. We will consider the function $\kappa(\mathbf{x})$ from (2) as the global anisotropy value after the appropriate scaling. Thus, the function $\kappa(\mathbf{x})$ is formally defined for a discrete set of $\mathbf{x}$, the centers of meso-cells. It can be considered as a continuous function in $\mathbf{x}$ after a smoothing procedure. Below, we omit the argument $\mathbf{x}$ for shortness.

The macroscopic tensor can be written up to $O(|\varrho f|^3)$ in the form

$$\left(\begin{array}{cc}\sigma_{11} & \sigma_{12}\\ \sigma_{21} & \sigma_{22}\end{array}\right)=(1+2\varrho f)I+2\varrho^2+2\varrho^2f^2\left(\begin{array}{cc}\kappa_1 & -\kappa_2\\ -\kappa_2 & -\kappa_1\end{array}\right), \tag{3}$$

where $\sigma_{11}=1+2\varrho f+2\varrho^2f^2+\kappa_1$, $\sigma_{12}=\sigma_{21}=-\kappa_2$ and $\sigma_{22}=1+2\varrho f+2\varrho^2f^2-\kappa_1$. The principal conductivities are determined by its eigenvalues $1+2\varrho f+2\varrho^2f^2+|\kappa|$ and $1+2\varrho f+2\varrho^2f^2-|\kappa|$. The principal angle θ satisfies the following equation

$$\tan 2\theta=\frac{2\sigma_{12}}{\sigma_{11}-\sigma_{22}}=-\frac{\kappa_2}{\kappa_1}. \tag{4}$$

Two roots θ of equation (4) correspond to the inclinations of the major and minor axes to the original x-axis.

III. Conclusion

The main goal is to derive a formula that determines the anisotropy of phase distribution in composite materials, taking into account both the polydispersity of particle sizes and their location. A prominent application of this new formula is to explore anisotropy across macro-, meso-, and micro- scales following [2]. The obtained results can be extended to the complex-valued permittivity values following [3].

***Abstract*—We utilize chiral materials to unlock Smith-Purcell radiation into modes typically forbidden in two-dimensional achiral structures. Via a Pasteur medium the modes hybridize, allowing excitation by the passing electron's evanescent field. This approach offers a new degree of freedom for wavelength and polarization control.**

***Keywords*— Smith-Purcell radiation, chiral materials, gratings.**

I. Introduction

The interaction between free electrons and periodic photonic structures enables the generation of tunable electromagnetic radiation, known as the Smith-Purcell (SP) effect [1]. This mechanism is fundamental for developing compact and novel light, e.g., in the terahertz and X-ray regimes. While initial designs relied on metallic gratings, recent advancements have shifted towards high-index dielectric structures. These offer lower losses and support resonances with high quality factors, allowing for maximal photon emission and optimized energy loss [2].

Current research focuses on tailoring these resonances to control the emission properties. Recent works have explored anomalous Doppler effects [3] and utilized geometric symmetry breaking, such as glide symmetry in coupled gratings, to direct radiation into specific half-spaces [4]. However, a persistent limitation in conventional two-dimensional (2D) SP devices is the polarization constraint: the electron beam naturally couples to Transverse Magnetic (TM) modes, leaving Transverse Electric (TE) modes largely inaccessible in standard 2D achiral models.

To overcome this limitation, we investigate the introduction of constitutive symmetry breaking via chirality [5]. Magneto-electric coupling in chiral (Pasteur) media is known to mix electric and magnetic dipoles, potentially allowing an electric source to excite TM modes [6].

In this work, we numerically demonstrate a Smith-Purcell source that combines a chiral layer ($n = 1.4$) with a silicon (Si) grating separated from a Si substrate. We show that the optical activity of the medium enables the excitation of a high-Q, TE-polarized resonance confined within the Si teeth, a mode forbidden in achiral counterparts. This approach thus offers a new degree of freedom for wavelength and polarization shaping in free-electron photonics.

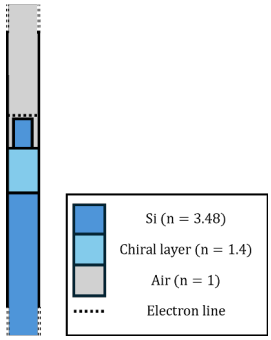

Fig. 1. Schematic of the unit cell geometry. The structure consists of a Si substrate ($n = 3.48$) coated with a chiral layer ($n = 1.4$) and periodic Si grating teeth. The electron beam (dashed line) passes above the grating, exciting Smith-Purcell radiation. In the chiral configuration, the chiral layer possesses a chirality parameter $\kappa = 0.05$.

II. Methods

The SP phenomenon can be efficiently simulated by employing only a single period of the structure. We use the finite-element commercial software COMSOL Multiphysics to solve the electromagnetic wave equation in the frequency domain. The unit cell geometry, see Fig. 1, consists of a Si substrate covered by a continuous chiral material. This chiral layer acts as the active medium ($\kappa = 0.05$), while all other materials remain achiral ($\kappa = 0$). The periodic grating modulation is provided by Si rectangles placed on top of the chiral layer. The upper surrounding background medium is air ($n = 1$).

The computational domain is truncated using Perfectly Matched Layers (PMLs) at the top and bottom boundaries to simulate semi-infinite open regions and suppress non-physical reflections. Floquet periodic boundary conditions are applied along the electron propagation direction (horizontal, x-axis) to mimic the infinite periodic array. The electron beam is modeled as a line current density flowing above the grating with a phase delay determined by the electron velocity, acting as the source term for the simulation [7].

III. Results and Discussion

We first investigate the spectral characteristics of the emitted radiation to assess the impact of chirality. Figure 2 compares the emitted energy density as a function of frequency for an

achiral structure ($\kappa = 0$) and a chiral structure ($\kappa = 0.05$). In the achiral case (Fig. 2a), the spectrum is dominated by a main resonance around 258 THz. As expected for conventional SP radiation arising from a standard grating, this emission is purely TM polarized (solid blue line), with no TE contribution.

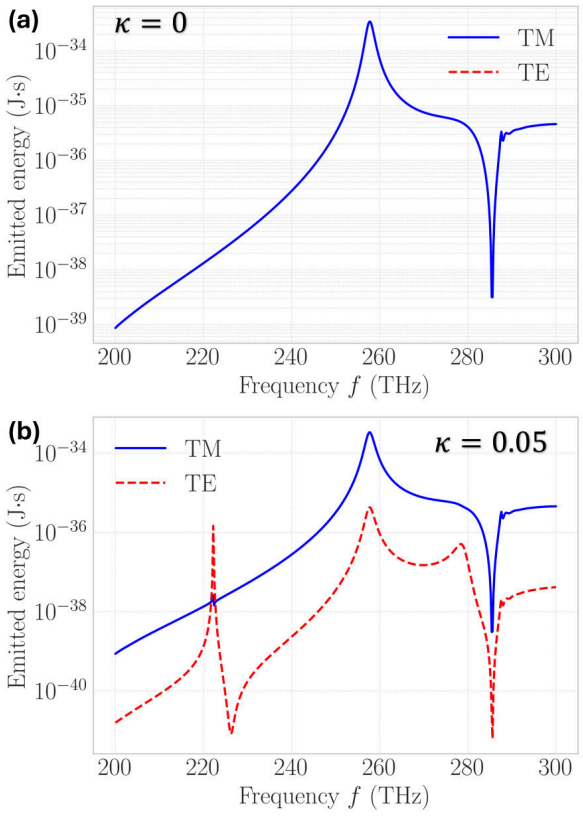

Fig. 2. Spectral density of emitted energy. (a) Achiral case ($\kappa = 0$): The emission is strictly TM-polarized (solid blue line) with a main resonance at 258 THz. (b) Chiral case ($\kappa = 0.05$): A sharp resonance emerges at 222 THz. The polarization decomposition reveals this peak is quasi-TE-polarized (dashed red line), demonstrating the magnetoelectric coupling.

The introduction of chirality in the chiral layer dramatically alters this behavior. As shown in Figure 2b, while the conventional TM peak is preserved, a new, sharp resonance emerges at $f = 222$ THz. Crucially, the polarization decomposition reveals that this chirality-induced peak is mainly TE-polarized (dashed red line). This observation confirms that the optical activity of the chiral medium breaks the symmetry, enabling a coupling to quasi-TE modes that are otherwise forbidden in standard achiral Smith-Purcell geometries. This mechanism offers a direct method to control the polarization and spectrum of the emitted light.

To understand the modes, we analyze the electromagnetic field distribution $|\mathbf{E}|$ at the resonance frequencies. Figure 3 compares the mode profiles for the TM peak and the TE chiral-induced resonance. At 258 THz (Fig. 3a), the TM-field is primarily distributed within the chiral layer and around the Si grating, exhibiting strong scattering and corner effects. In contrast, the chiral-induced TE resonance at 222 THz (Fig. 3b) reveals a field distribution strongly confined inside the Si grating tooth, with a decaying contribution in the chiral layer. This suggests that the chiral material hybridizes the TE mode, providing a channel for the electron beam TM current to couple into.

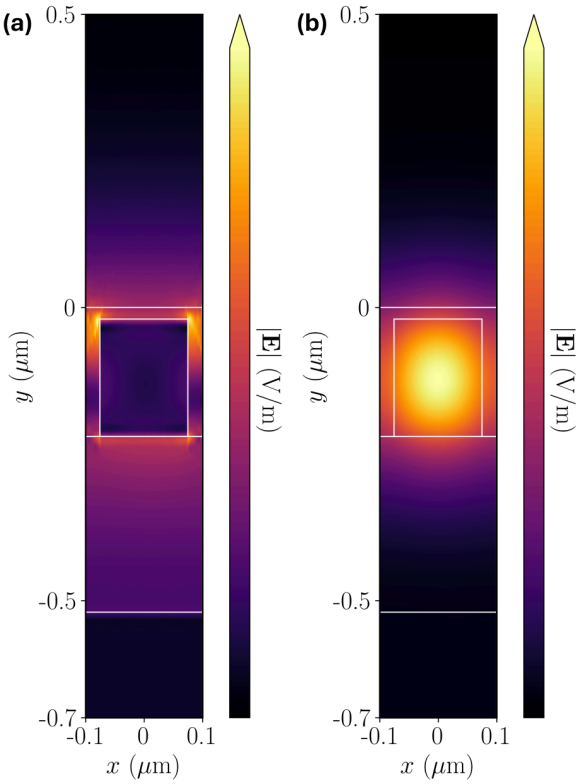

Fig. 3. Electric field norm $|\mathbf{E}|$ distributions (eigenmode analysis). (a) TM mode at 258 THz: The field is concentrated in the chiral layer with corner effects at the Si grating edges. (b) TE mode at 222 THz: The field is strongly confined inside the high-index Si tooth, with an exponential decay into the chiral layer beneath.

IV. Conclusion

We have numerically demonstrated a novel approach to tailor the spectrum and polarization of Smith-Purcell radiation by integrating chiral media into dielectric gratings. Our results show that the magnetoelectric coupling in a chiral layer enables the excitation of a sharp quasi-TE-polarized resonance forbidden in standard achiral geometries. This hybridization mechanism offers a new degree of freedom for free-electron photonics, paving the way for tunable, compact light sources in the terahertz and optical regimes.

***Abstract*—This paper presents an experimental study of graded tensegrity-inspired metamaterials fabricated by additive manufacturing. Compression tests are performed under uniform and concentrated loads on simplex- and expanded octahedron-based lattices to demonstrate the influence of unit cell topology and cell gradation on their mechanical behaviour.**

***Keywords*— tensegrity, cellular metamaterials, additive manufacturing, graded materials.**

I. Introduction

Mechanical metamaterials derive their unusual and highly tunable behaviour from their internal architecture, enabling functionalities that are not attainable in conventional materials. In particular, lattice-based structures allow for the control of stiffness, load-bearing capacity, deformation modes, and the spatial distribution of mechanically stable regions through appropriate design and arrangement of unit cells [1].

Among the various design strategies, tensegrity-inspired lattices provide a compelling framework. Their mechanical response originates from infinitesimal mechanisms stabilised by self-stress states, which enable pronounced nonlinearity and strong sensitivity to geometric modifications [2]. Recent advances in additive manufacturing (AM) have made it possible to fabricate such architectures with rigid joints, while still retaining key features of ideal tensegrity systems [3], [4], [5].

Building on previous experimental and computational studies on two-dimensional (2D) tensegrity-inspired lattices with graded architectures [6], the present work extends these concepts to three-dimensional (3D) systems. The paper focuses on experimental investigation of additively manufactured 3D tensegrity-inspired metamaterials, with emphasis on the influence of gradation on stiffness, load-bearing capacity, and deformation modes. By systematically testing assemblies with varying geometry of unit cells and their arrangement, this study provides experimental information on the mechanical properties of 3D graded tensegrity-inspired metamaterials.

II. Methods

Tensegrity-inspired metamaterials considered in this paper are based on two different unit cells, whose geometry corresponds to that of two basic tensegrity modules: a four-bar simplex and an expanded octahedron. Using these modules, five different configurations of 3D lattices were designed for experimental testing:

- M.sim4.1.uni (Figure 1a) – regular simplex-based lattice,
- M.sim4.1.gra2 (Figure 1b) – graded simplex-based lattice with enhanced cells under concentrated load,
- M.oct1.1.uni (Figure 1c) – regular expanded octahedron-based lattice,
- M.oct1.1.gra1 (Figure 1d) – graded expanded octahedron-based lattice with enhanced lower and upper layers,
- M.oct1.1.gra2 (Figure 1e) – graded expanded octahedron-based lattice with enhanced cells under concentrated load.

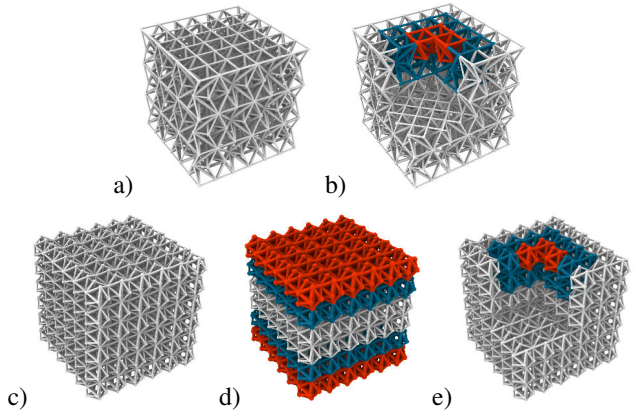

Fig. 1. 3D lattices: a) M.sim4.1.uni; b) M.sim4.1.gra2; c) M.oct1.1.uni; d) M.oct1.1.gra1; e) M.oct1.1.gra2. In b) and e) 1/8 of the model removed to show centric gradation inside the lattice.

All lattices were fabricated by AM using a ProJet® MJP 2500 Plus system (3D Systems). The used MultiJet Printing (MJP) process, which originates from inkjet-based technologies, builds parts by sequentially depositing layers of a UV-curable polymer together with a sacrificial wax support material. This manufacturing route is well suited for tensegrity-like architectures, as the supporting wax can be removed through thermal treatment, enabling effective cleaning of complex and slender structural features without inducing damage.

All specimens were produced using VisiJet® M2R-WT resin. According to the manufacturer's datasheet, the material exhibits a tensile modulus of 2000 MPa, a tensile strength of 39 MPa, and an elongation at break of 20%, determined following the ASTM D638 standard.

Mechanical testing was performed under uniaxial compression using an INSTRON 5567 universal testing machine fitted

with an INSTRON 2525-816 load cell with an accuracy of 0.5 N. The experimental setup is shown in Figure 2. All tests were carried out under displacement-controlled conditions at a constant velocity of 5 mm/min, with the applied force continuously recorded throughout the loading process. Two types of tests were performed: under uniform compression and under concentrated force. The concentrated load was realised using a small cube attached to the loading plate, which allowed the force to be applied to the central nodes of the upper face of the specimen.

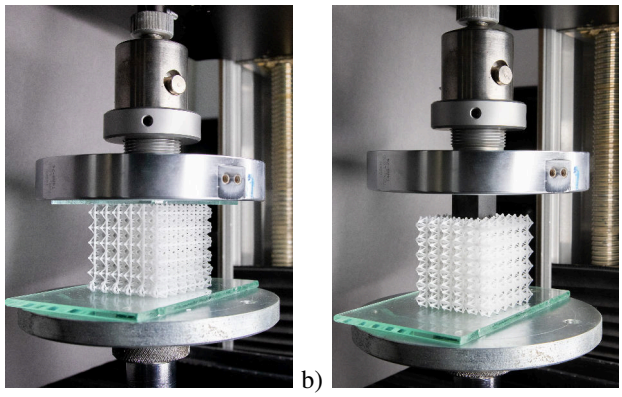

Fig. 2. Experimental setup: a) Expanded octahedron-based lattice under uniform load; b) Expanded octahedron-based lattice under concentrated load.

III. Results and Discussion

The results of the compression tests performed on regular lattices are presented in Figure 3 (each graph represents a mean curve obtained from five specimens), and the deformation of two selected expanded octahedron-based lattices is shown in Figure 4.

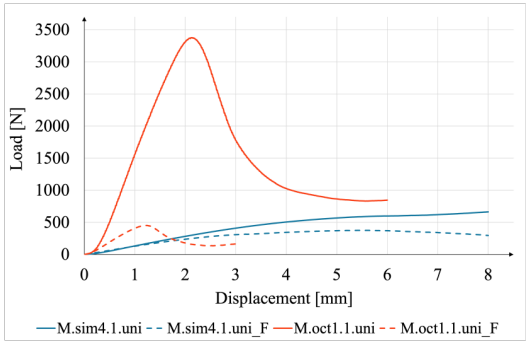

Fig. 3. Force-displacement graphs obtained for regular simplex and expanded octahedron-based lattices under uniform (continuous lines) and concentrated (dashed lines) load.

The expanded octahedron-based lattice exhibits significantly higher initial stiffness and load-bearing capacity under both the uniform and the concentrated load, followed by a sudden drop, which is caused by the loss of stability in two bottom or upper layers (uniform load) or localised damage in the centre of the upper layer (concentrated load). In contrast, the simplex-based lattice shows a more gradual increase in load, reflecting a more distributed deformation process, typical for soft metamaterials.

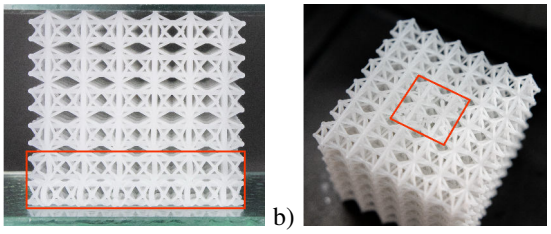

Fig. 4. Deformation of expanded octahedron-based lattices: a) under uniform load; b) under concentrated load. Areas with max. deformation marked in red.

Based on the results of compression tests performed on regular lattices, recommendations for designing graded metamaterials were made: two types of gradations in the expanded octahedron-based lattice and one in the simplex-based one (see Figure 1). The layer gradation in the simplex-based lattice subjected to uniform loading was not considered due to its uniformly distributed deformation – in this case, the gradation would not improve the mechanical behaviour of the structure.

IV. Conclusion

This study focused on the experimental investigation of mechanically graded tensegrity-inspired metamaterials fabricated by AM. Compression tests performed under uniform and concentrated loading conditions demonstrated that the mechanical response of the lattices is strongly governed by the unit cell topology. Expanded octahedron-based lattices exhibited high initial stiffness and load-bearing capacity, while simplex-based lattices showed a more progressive and distributed deformation response. Based on the observed behaviour of the regular lattices, mechanically graded configurations were designed to enhance performance under specific loading scenarios.

***Abstract*—We study dynamical superradiance—the collective oscillation of energy between a cavity mode and emitters—in organic materials by solving the open Holstein-Tavis-Cummings model in the mean-field approximation. We show that superradiance survives for small vibrational coupling, and that for negative cavity detunings, vibrational coupling may even enhance superradiance.**

***Keywords*— vibrational coupling, strong light-matter coupling, cavity quantum electrodynamics, open quantum systems.**

I. Introduction

Superradiance, as first introduced by Dicke in 1954 [1], refers to the collective spontaneous emission of N closely spaced two-level systems in free space. One of the defining features of superradiance is the scaling of the peak emission rate as N^2, compared to N in the case of independent emitters. While in the original superradiance the emitters are in free space and interact with a continuum of electromagnetic modes, related phenomena also exist for emitters inside a cavity. One such phenomenon is termed dynamical superradiance—the subject of this paper—which describes the collective oscillation of energy between N initially excited emitters and the cavity mode. Dynamical superradiance is well understood if the emitters are treated as ideal two-level systems. In that case, the system is well described by the Tavis-Cummings model, and semi-analytical solutions in the large N limit predict that the photon number displays a train of hyperbolic secant pulses [2].

The two-level system approximation, however, does not hold in the case of organic molecules, where electronic degrees of freedom couple to vibrational modes of the molecule. In this work, we study dynamical superradiance in vibrationally dressed molecules using the open Holstein-Tavis-Cummings (HTC) model [3]. In Ref. [4], it was demonstrated that the open HTC model, when starting from a state with some initial coherence (i.e., a superradiant initial state), can be solved using mean-field theory. We show that the cavity detuning has a significant effect on the superradiant dynamics. Namely, for negative detunings, the superradiant photon emission is enhanced by including vibrational coupling, whereas for positive detunings, the photon emission is inhibited.

II. Methods

We consider a collection of N vibrationally dressed two-level systems coupled to a single cavity mode, which can be described with the HTC Hamiltonian ($\hbar = 1$)

$$\hat{H} = \omega_c \hat{a}^\dagger \hat{a} + \sum_{i=1}^{N} \Big[\frac{\omega_0}{2} \hat{\sigma}_i^z + g(\hat{a}\hat{\sigma}_i^+ + \hat{a}^\dagger \hat{\sigma}_i^-) + \omega_\nu \hat{b}_i^\dagger \hat{b}_i + \omega_\nu \sqrt{S}(\hat{b}_i + \hat{b}_i^\dagger)\hat{\sigma}_i^z \Big]. \quad (1)$$

Here, $\hat{a}$ and $\hat{a}^\dagger$ are the bosonic operators of the cavity mode with frequency ω_c, $\hat{\sigma}_i^{\pm,z}$ are the Pauli matrices describing the ith emitter satisfying $[\hat{\sigma}_i^z, \hat{\sigma}_j^\pm] = \pm 2\delta_{ij}\hat{\sigma}_i^\pm$, and $\hat{b}_i$ and $\hat{b}_i^\dagger$ are the bosonic operators for the vibrational mode of the ith emitter with frequency ω_ν. The vibrational coupling is determined by the Huang-Rhys parameter S, and g is the light-matter coupling constant. For $S = 0$, Eq. (1) reduces to the Tavis-Cummings model.

We include dissipation processes via a Gorini-Kossakowski-Sudarshan-Lindblad master equation for the density matrix ρ

$$\partial_t \rho = -\mathrm{i}[\hat{H} + \hat{H}_{\mathrm{LS}}, \rho] + \kappa \mathcal{L}[\hat{a}] + \sum_{i=1}^{N} \big(\gamma \mathcal{L}[\hat{\sigma}_i^-] + \gamma_\uparrow \mathcal{L}[\hat{b}_i^\dagger] + \gamma_\downarrow \mathcal{L}[\hat{b}_i] \big), \quad (2)$$

where $\mathcal{L}[\hat{X}] = \hat{X}\rho\hat{X}^\dagger - \{\hat{X}^\dagger\hat{X}, \rho\}/2$. The rate κ describes the loss of photons from the cavity mode, γ describes the individual loss of molecular excitations, and $\gamma_\uparrow = \gamma_\nu n_B, \gamma_\downarrow = \gamma_\nu(n_B + 1)$ are thermalization rates of the vibrations at a temperature T given by the mean phonon occupation number $n_B = (\mathrm{e}^{\omega_\nu/T} - 1)^{-1}$ (we set $k_B = 1$). The Lamb-shift term $\hat{H}_{\mathrm{LS}} = \mathrm{i}(\gamma_\nu/4)\sum_{i=1}^{N}(\hat{b}_i^\dagger \hat{b}_i^\dagger - \hat{b}_i \hat{b}_i)$ is included to introduce damping through the momentum coordinate [5].

We are interested in the dynamics starting from an initial state

$$\rho(0) = |\psi(\theta)\rangle\langle\psi(\theta)| \bigotimes_{i=1}^{N} \rho_{\mathrm{vib},i}, \quad (3)$$

where $|\psi(\theta)\rangle = |0\rangle \otimes \Big(\bigotimes_{i=1}^{N} \mathrm{e}^{-\mathrm{i}\theta\hat{\sigma}_i^x/2} |\uparrow\rangle_i \Big)$ and $\rho_{\mathrm{vib},i} = (1 - \mathrm{e}^{-\omega_\nu/T})\mathrm{e}^{-\omega_\nu \hat{b}_i^\dagger \hat{b}_i/T}$ ($k_B = 1$). At $t = 0$, there are zero photons

in the cavity mode, and the two-level systems are in an excited state (denoted by $|\uparrow\rangle_i$ for the ith emitter), which is coherently tilted by an angle θ. We term states with $\theta \neq 0$ superradiant initial states due to the initial coherence in the system, whereas states with $\theta = 0$ are termed superfluorescent. In the following, we solve Eqs. (1) and (3) for different values of vibrational coupling S and cavity detuning $\Delta = \omega_c - \omega_0$ using mean-field theory. We stress that we treat the vibrationally dressed emitters as $2N_\nu$-level systems, where N_ν is the number of vibrational levels included in the model; i.e., correlations between the electronic degrees of freedom and the vibrational mode are retained.

III. Results and Discussion

In Fig. 1, we show the numerical results for the average number of photons in the cavity mode obtained from mean-field theory for different values of S. All calculations were performed using the *QuantumCumulants.jl* package [6]. In Fig. 1(a), the cavity detuning is negative, whereas in Fig. 1(b) it is positive. All other parameters are given in the figure caption. The coupling to the vibrations enhances (inhibits) the dynamical superradiance for negative (positive) cavity detuning, which is evident from the fact that the number of photons in Fig. 1(a) increases with increasing S, while in Fig. 1(b) it decreases with increasing S.

To get an idea of the role the vibrations play in the emission process, we calculate the occupation of the νth energy level of the vibrational mode conditioned on the emitter being in the electronic ground state

$$p_\nu^{(g)} = \frac{\langle\downarrow,\nu|\,\rho_m\,|\downarrow,\nu\rangle}{\sum_\nu \langle\downarrow,\nu|\,\rho_m\,|\downarrow,\nu\rangle}, \tag{4}$$

where ρ_m is the reduced density matrix of a single emitter, which includes the electronic and vibrational degrees of freedom. In Fig. 2, we show the occupation for the ground state and the first five excited states of the phonon mode, conditioned on the emitter being in the electronic ground state. For $\Delta = -0.3\,\mathrm{eV}$, the probability of one or more phonons in the electronic ground state is significantly larger compared to $\Delta = 0.3\,\mathrm{eV}$, in which case almost exclusively the ground mode with zero phonons is occupied. This can be explained by the fact that for negative cavity detuning, the cavity frequency $\omega_c = \omega_0 + \Delta$ is smaller than the two-level system energy splitting. It is therefore more favorable for the molecule to undergo a transition from the excited-state manifold with zero phonons to the ground-state manifold with phonons.

IV. Conclusion

We have developed the theory of dynamical superradiance in organic materials, where electronic degrees of freedom couple to vibrational modes of the molecules. To model the many-emitter–cavity system, we have employed the Holstein-Tavis-Cummings Hamiltonian, which includes one vibrational mode per molecule, and added dissipative processes using a Gorini-Kossakowski-Sudarshan-Lindblad master equation. For superradiance initial conditions, mean-field theory is applicable, which allowed us to numerically solve the dynamics for a macroscopic number of molecules. We have shown that dynamical superradiance is possible for small vibrational couplings. If the cavity detuning is negative, vibrational coupling can even enhance the superradiant emission. For positive detunings, the opposite is the case, and superradiance is inhibited. The cavity detuning is an experimentally tunable quantity, which makes our findings experimentally accessible.

***Abstract*— Surface-enhanced Raman spectroscopy (SERS) was applied to investigate sulfur (VI) fluoride exchange reactions at metal–solution interfaces. The study demonstrates that SERS enables monitoring of click reaction, close proximity of metal surface does not significantly change the reaction and elegantly shows that structural changes of adsorbate influence their orientation on metal.**

***Keywords*—surface enhanced Raman spectroscopy, sulfur fluoride exchange, click chemistry, metal interfaces, adsorption geometry.**

I. Introduction

Sulfur fluoride exchange reactions have emerged as a robust and selective click chemistry platform for modular molecular construction in materials science and chemical biology. Their operational simplicity, tolerance to functional groups and predictable reactivity make them attractive for surface functionalization and interfacial chemistry.

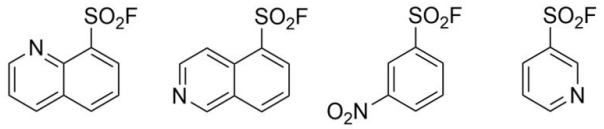

Fig.1 Structers of sulfonyl fluorides investigates in this study (8-quinolinesulfonyl fluoride, 5-isoquinolinesulfonyl fluoride, 3-nitrobenzenesulfonyl fluoride, 3-pyridinesulfonyl fluoride).

At the same time, metal nanostructures and plasmonic substrates provide unique opportunities for real time molecular characterization through surface enhanced Raman spectroscopy (SERS). SERS combines chemical specificity with extreme surface sensitivity and is therefore particularly suited for studying reactions occurring within the first molecular layer at metal solution interfaces.

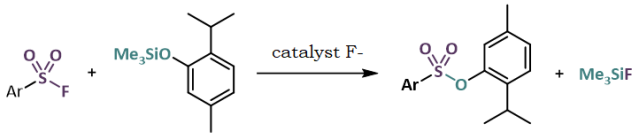

Fig.2 Scheme of the click reaction from this study.

Adsorption on metal surfaces induces specific orientation of reactants. Therefore, an important open question remains whether the close proximity of a plasmonic metal surface perturbs the intrinsic reactivity of sulfur fluoride exchange systems. In this work, we address this issue by systematically investigating sequential adsorption and reaction of sulfonyl fluoride derivatives with silyl protected phenolic substrates on silver electrodes.

II. Methods

Surface enhanced Raman spectra were recorded on electrochemically prepared silver substrates immersed in acetonitrile solutions. A heteroaromatic sulfonyl fluoride served as the electrophilic component (experiments have been performed for: 8-quinolinesulfonyl fluoride, 5-isoquinolinesulfonyl fluoride, 3-nitrobenzenesulfonyl fluoride, 3-pyridinesulfonyl fluoride). The nucleophilic partner was a silyl protected phenolic derivative (thymol trimethylsilyl ether, TMS-thymol). Tetrabutylammonium bifluoride was used as catalyst.

Sequential adsorption experiments were designed to separate adsorption phenomena from chemical transformation. The silver electrode was first exposed to the sulfonyl fluoride, rinsed with solvent and measured. Subsequently, the same surface was immersed either in the phenolic substrate solution or in the substrate solution containing catalyst. For reference, the isolated reaction product was independently synthesized and measured under identical SERS conditions.

To support assignments of Raman bands, density functional theory calculations were performed for the sulfonyl fluoride and reaction products. Geometry optimizations were carried out to determine energetically favorable conformations. Harmonic vibrational frequency calculations were then used to predict Raman active modes and corresponding band positions. Calculated frequencies were scaled and compared with experimental spectra to facilitate reliable assignment of characteristic vibrations, particularly in the fingerprint region and in modes associated with sulfur oxygen stretching and aromatic ring deformations.

III. Results and Discussion

The SERS spectrum of the adsorbed sulfonyl fluoride displayed distinct aromatic ring modes and characteristic vibrations related to the sulfur functional group. After solvent rinsing, these features remained stable, indicating strong adsorption on silver.

Upon exposure to the phenolic substrate, subtle but reproducible changes in selected fingerprint bands were observed (examples of spectral changes observed during the reaction of 5-isoquinolinesulfonyl fluoride and TMS-thymol are shown in Fig.1). Although the dominant sulfonyl fluoride features persisted, relative intensity variations suggested modification of adsorption geometry or local environment due to co adsorption.

Addition of catalyst resulted in the appearance of new spectral contributions that could not be described as a simple superposition of individual component spectra. Comparison with the SERS spectrum of the independently prepared product confirmed the formation of the sulfur fluoride exchange product at or near the metal interface.

The DFT calculated geometries provided insight into conformational preferences of both reactant and product when they do not interact with other molecules. Simulated Raman spectra reproduced the main experimental band positions and enabled assignment of key vibrational modes. In particular, calculated frequency shifts associated with transformation of the sulfonyl fluoride group to the sulfonate product were consistent with experimentally observed changes. This agreement supports the conclusion that the intrinsic reaction pathway is preserved in the vicinity of the metal surface.

At the same time, intensity differences between experimental and calculated spectra indicate that adsorption geometry plays a significant role in SERS enhancement. Structural conversion alters electron distribution and available coordination sites, leading to reorientation of the aromatic framework relative to the silver surface. These orientation effects are directly reflected in the relative enhancement of selected vibrational modes.

Overall, the combined experimental and theoretical approach allows discrimination between mere adsorption, co adsorption and true chemical conversion at the interface.

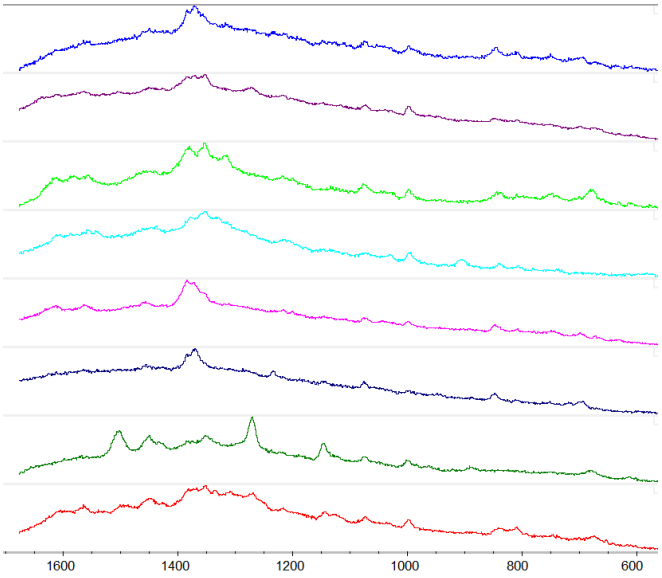

Fig. 3 SERS spectra of (from top to bottom): fluoride, fluoride + catalyst, fluoride + nucleophile, fluoride + catalyst + nucleophile, catalyst, final product, nucleophile, nucleophile + catalyst adsorbed on Ag electrode. As fluoride 5-isoquinolinesulfonyl fluoride was used, as nucleophile TMS-thymol, as catalyst - tetrabutylamonium bifluoride.

IV. Conclusion

Surface enhanced Raman spectroscopy combined with density functional theory provides a robust framework for investigating sulfur fluoride exchange reactions at metal solution interfaces. The results demonstrate that the reaction proceeds without fundamental alteration of its intrinsic pathway in the presence of silver. Structural transformation is accompanied by adsorption induced reorientation, which is reflected in characteristic spectral changes. The study highlights the value of integrating SERS and quantum chemical calculations for mechanistic analysis of interfacial click chemistry.

***Abstract*— Flat band acoustic metamaterials enable interference-driven wave localization. Building on polymer Lieb lattices operating in the ultrasonic regime, a predictive scaling formulation for band tuning has been designed, together with extended Lieb architectures supporting multiple flat bands. Mechanically reconfigurable auxetic–Lieb structures are also demonstrated. These approaches provide scalable and tunable platforms for multi-frequency acoustic localization.**

***Keywords*— metamaterials, Lieb lattices, auxetic materials, phononic crystals.**

I. Introduction

Flat bands in periodic lattices provide a mechanism for wave localization governed by geometry and interference rather than material contrast. They arise from compact localized states (CLSs) [1], as can be seen readily within the tight-binding (TB) framework [2]. For such CLSs, destructive interference between hopping paths confines eigenstates to a small cluster of sites. This interference-driven confinement enables deterministic control of wave transport and spectral response in engineered acoustic metamaterials and phononic crystals [3,4].

In recent work [5] experimentally accessible polymer-based acoustic Lieb lattices operating in the sub-MHz ultrasonic regime were demonstrated, where site-selective vibrational enhancement consistent with flat-band behavior was observed. However, systematic frequency tuning, realization of multiple flat bands within a single structure, and dynamic reconfigurability remain open challenges. In this work, we establish a unified framework that combines predictive geometric scaling, extended Lieb architectures supporting multiple flat bands, and mechanically induced topological transformation through auxetic metamaterials. Together, these developments advance flat-band acoustic systems from static realizations toward scalable and tunable wave-engineering platforms.

II. Methods

A. Predictive Scaling Formulation

In a Cartesian coordinate system with coordinates x^*, y^*, z^* the problem is governed by the time-independent wave equation, known as the Helmholtz equation. The Helmholtz equation is given by[1] [6]:

$$\frac{\partial^2 p^*}{\partial x^{*2}} + \frac{\partial^2 p^*}{\partial y^{*2}} - k^{*2} p = 0 \quad (1)$$

where $p^* = p^*(x^*, y^*, z^*, \lambda^*)$ represents the sound pressure, and k^* is the wave vector defined as $2\pi/\lambda^*$. The wavelength of the mode is λ^*, with an associated frequency f^* in a material that has a speed of sound c^*.

To reveal the geometric scaling behavior of the system, we nondimensionalize the spatial coordinates using a characteristic lattice length L_1^*:

$$x = \frac{x^*}{L_1^*}, y = \frac{y^*}{L_1^*} \text{ and } z = \frac{z^*}{L_1^*} \quad (2)$$

and define the reduced frequency

$$f = \frac{L_1^* f^*}{c^*} \quad (3)$$

The characteristic lengths L_1, L_2,and L_3correspond to the principal geometric features of the unit cell (Fig. 1(a)), namely the resonator diameter, the connecting strut length, and the junction spacing between neighboring sites. These represent the natural geometric scales governing acoustic coupling in the lattice.

With this formulation, the dispersion relation depends only on geometric ratios rather than absolute dimensions. The frequency therefore becomes a function of nondimensional parameters L_i/L_1, allowing the sensitivity of the spectrum to geometric variations to be expressed as:

$$\frac{df}{dL_1} = \frac{\partial f}{\partial L_1} + \frac{1}{L_1}\left(\frac{\partial f}{\partial L_2}\gamma_2 + \cdots \frac{\partial f}{\partial L_n}\gamma_n\right) \quad (4)$$

where $\gamma_i = L_i^*/L_1^*$ denotes the relative scaling factors i.e. the scaling factors for each length scale, in relation to the primary length scale L_1^*.

[1] The asterisk superscript denotes dimensional quantities. The superscript is dropped for the corresponding nondimensionalized quantities

This scaling formulation allows flat-band frequencies to be predicted directly from geometric parameters. As demonstrated in Fig. 1(b), when the frequency axis is expressed in reduced form, the dispersion relations of two different lattice realizations collapse onto a single curve. The two datasets correspond to previously studied structures [5] denoted D4 and D6, which differ in their lattice dimensions but share identical geometric ratios.

The resulting sensitivity relations provide explicit measures of how each geometric parameter influences the dispersion curves and enable inverse design of lattice dimensions for a desired ultrasonic operating frequency.

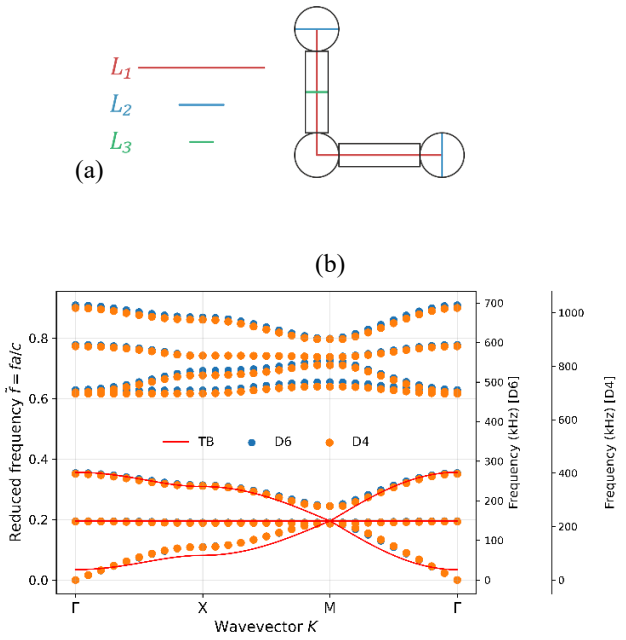

Fig.1 (a) Geometric parameters used in the nondimensional scaling formulation. Three independent characteristic length scales L_1, L_2, and L_3 are defined within the unit-cell geometry. (b) Band structure comparison between the tight-binding (TB) model and finite-element simulations for two lattice designs demonstrating that the dispersion relations of two geometrically scaled structures collapse onto a single reduced-frequency curve.

B. Extended Lieb Architectures

Motivated by this scaling framework, we designed enlarged Lieb unit cells that introduce additional symmetry-equivalent coupling pathways. The corresponding tight-binding description predicts the emergence of additional compact localized states, leading to multiple flat bands in the band structure.

Finite-element simulations were performed to compute the dispersion diagrams. The extended geometries generate several nearly flat bands separated by tunable band gaps. Representative pressure-field distributions for selected modes are shown in Fig. 2(a-b) along with their dispersion diagrams in Fig. 2(c-d), confirming spatial confinement characteristic of CLS behavior.

C. Auxetic–Lieb Transformation

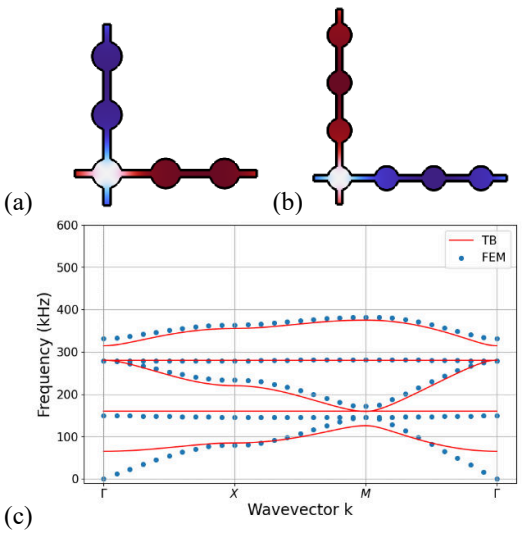
To introduce mechanical reconfigurability, we developed a re-entrant auxetic metamaterial geometry [5] that transforms into a Lieb lattice under uniaxial tensile deformation.

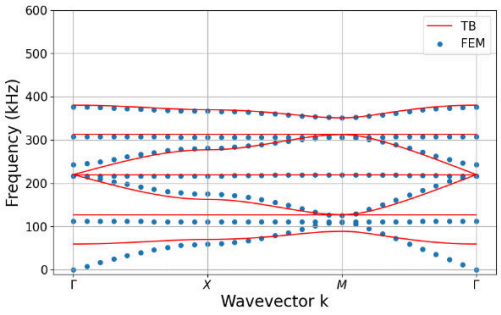
The undeformed configuration, shown in Fig. 3(a), supports conventional dispersive propagation. Upon stretching, the geometry evolves toward Lieb connectivity, as illustrated in Fig. 3(b). Periodic simulations along the deformation direction were used to track the evolution of the band structure.

III. Results and Discussion

The nondimensional scaling formulation demonstrates that flat-band frequencies depend explicitly on geometric ratios, enabling controlled spectral positioning through systematic dimension variation. Numerical evaluation confirms that modest changes in resonator diameter or connection length led to predictable shifts in flat-band frequency without altering the underlying interference mechanism.

Extended Lieb lattices exhibit multiple flat bands within the same structure. The dispersion diagrams in Fig. 2(c–d) show additional flat bands compared to the standard three-site Lieb lattice. In particular, we investigated two extended configurations, denoted Lieb2 and Lieb3, corresponding to unit cells containing five and seven lattice sites, respectively. The tight-binding model predicts that these lattices support multiple compact localized states, leading to the emergence of two flat bands in the Lieb2 lattice and three flat bands in the Lieb3 lattice. For the symmetry-equivalent extended Lieb lattices studied here, the number of flat bands scales with the number of sites in the unit cell. A lattice containing N sites support $N_{FB} = (N-1)/2$ flat bands, corresponding to the number of independent compact localized states formed by destructive interference between the Lieb sublattice sites. The associated pressure distributions in Fig. 2(a-b) reveal distinct compact localized states corresponding to the first flat band of structures Lieb2 and Lieb3 respectively. These results demonstrate that interference-based localization can be engineered simultaneously at multiple frequencies in a single polymer architecture.

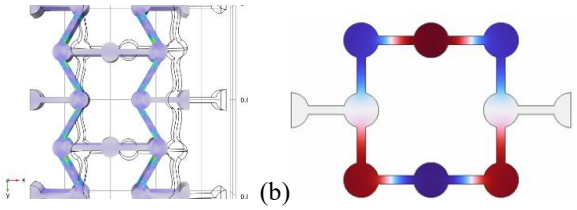




(d)

Fig. 2 (a–b) Unit-cell geometries of the Lieb2 and Lieb3 lattices containing five and seven sites per unit cell, respectively. (c–d) Corresponding dispersion relations obtained from tight-binding (TB) calculations and finite-element method (FEM) simulations.

For the auxetic–Lieb system, simulations reveal a change in the dispersion characteristics of the structure with applied strain. As the lattice is stretched, the negative Poisson-ratio geometry ($\nu \approx -0.5$) causes the internal connections to rotate outward, progressively approaching the orthogonal connectivity characteristic of the Lieb lattice. In our simulations, this configuration emerges at tensile strains of approximately $\varepsilon \approx 0.2$. The pressure fields simultaneously evolve toward compact localized patterns analogous to CLS modes, as shown in Fig. 3(b).



(a) (b)

Fig. 3 Mechanically reconfigurable auxetic–Lieb metamaterial. (a) Re-entrant auxetic lattice undergoing uniaxial tensile deformation. (b) Pressure-field distribution of a representative eigenmode in the deformed configuration, illustrating the emergence of Lieb-like connectivity and compact localized states.

The results establish a coherent strategy for flat-band engineering in acoustic polymer metamaterials. The nondimensional scaling formulation provides predictive frequency control, eliminating trial-and-error geometric tuning. Extended Lieb architecture demonstrates that flat-band localization is not restricted to a single spectral point but can be generalized to multi-band systems through unit-cell enlargement. The integration of auxetic deformation introduces mechanical tunability, enabling strain-controlled activation or modulation of flat-band behavior.

Operating in the sub-MHz ultrasonic regime, these polymer structures remain compatible with standard ultrasonic transducers while offering geometry-driven control of wave localization. The combination of predictive scaling, multi-flat-band realization, and mechanical reconfigurability represents a significant step toward adaptive acoustic devices based purely on structural interference. This unified approach bridges theoretical band engineering and experimentally accessible metamaterial design, opening pathways for tunable energy confinement and frequency-selective wave manipulation.

IV. Conclusion

This work extends polymer acoustic Lieb lattices toward predictive and adaptive flat-band engineering. A nondimensional scaling formulation enables deterministic tuning of flat-band frequencies through geometric parameters. Extended Lieb architectures demonstrate that multiple compact localized states and corresponding flat bands can be realized within a single structure. Furthermore, integrating auxetic geometries introduces mechanical reconfigurability, allowing strain-induced transformation into Lieb-like connectivity and the emergence of flat-band behavior. Together, these results establish a unified framework for geometry-driven acoustic band design, enabling scalable and tunable platforms for multi-frequency localization and adaptive wave control in ultrasonic metamaterials.

Self-configuring linear diffractive optical networks for adaptive imaging through multimode fibres

***Abstract*— When light propagates through complex media, its spatial modes become scrambled, hindering imaging and data transmission. Here we experimentally demonstrate how a linear diffractive optical network can be adaptively trained in-situ to efficiently reverse such scattering across multiple modes simultaneously.**

***Keywords*— diffractive optics, wavefront shaping, complex media, self-configuring**

When light propagates through complex media - such as biological tissue, turbulent air, or multimode optical fibre - the wavefront can be highly distorted, scrambling the spatial information it carries. This scrambling corrupts images and limits data transmission in these environments. Wavefront shaping is a versatile technique capable of reversing such distortions: the wavefront of a single spatial mode of light interacting with the complex medium is reshaped (typically using a spatial light modulator) to turn it back into its original state, thus 'undoing' the medium's effects [1,2]. However, uncorrelated spatial modes require different correction wavefront modulations, which cannot be efficiently multiplexed together onto a single-phase modulating surface. Thus, current wavefront shaping methods are often sequential in nature, dynamically correcting each spatial mode one after the other - and as such are yet to reach the full information capacity of data transmission through complex media.

In order to efficiently unscramble multiple uncorrelated modes at once, a 3D multi-modal beam shaping architecture is required [3,4,5]. In this work we explore how a self-optimising linear diffractive optical network can be used to tackle this problem. Our network consists of a cascade of phase modulating surfaces, each separated by free-space propagation – an optical system known as a multi-plane light converter [6,7,8]. To configure our network, we experimentally demonstrate a new technique we refer to as 'multi-plane wavefront shaping' which jointly optimises the phase profile of all phase planes in the network in-situ, to unscramble multiple different spatial modes simultaneously [4,9].

In our system there are tens of thousands of independently tuneable parameters to configure, so we devise a bespoke algorithm based on the transmission matrix formalism [2], that relies on light solely propagating forward through the device [9]. System convergence is accelerated to a timescale of minutes by constructing the network from a recently developed fast-switching piston-action MEMS phase light modulator operating at kHz rates [10,11] – with scope for substantial reductions in optimization time in the future. Our multi-plane wavefront shaping technique represents a versatile 'model-free' approach to the in-situ training of high-speed free-space linear diffractive optical networks [12], in this case enabling them to begin to adaptively reverse the scattering effects of transmissive complex media they are coupled to.

***Abstract*—We show that small scatterers enable low-energy electrons to excite surface polaritons even when direct coupling is kinematically forbidden. Maximum emission occurs at an optimum scatterer–surface distance, while periodic arrays produce directional polaritonic Smith–Purcell emission. Hexagonal boron nitride disks provide a practical route to spectrally selective excitation of graphene plasmons.**

***Keywords*— surface polaritons, free electrons, graphene plasmons, hexagonal boron nitride, dipolar scatterers, Smith–Purcell emission.**

I. Introduction

Surface polaritons (SPs) enable deep-subwavelength confinement and large near-field enhancement, making them attractive for nanoscale photonics, spectroscopy, and strong light–matter interactions [1]. However, their large in-plane momenta prevent direct far-field excitation. Free electrons offer a natural alternative because they generate broadband evanescent fields with nanometer localization. Still, direct electron–polariton coupling is subject to kinematic constraints: modes above the electron line in momentum–frequency space cannot be excited directly by a passing electron [4]. Here, we show that small nearby scatterers bridge this mismatch by converting the broadband electron field into a localized dipolar response containing the momentum components needed to launch SPs. We further show that periodic arrays of scatterers lead to directional in-plane Smith–Purcell emission of polaritons without patterning the polaritonic surface itself [3], [4].

II. Methods

We consider an electron moving parallel to a planar polariton-supporting surface at velocity $\mathbf{v} = v\hat{\mathbf{x}}$, in the presence of either a single small scatterer or a linear periodic array of scatterers. The surface is described through Fresnel reflection coefficients, while the particle is modeled by a frequency-dependent polarizability tensor. Starting from the frequency-resolved electron field near the interface, we calculate the self-consistent dipole induced on the scatterer, including the field reflected back by the surface. In the regime of strongly confined modes, the problem is treated in the electrostatic limit, which yields the SP emission probability from the imaginary part of the surface Green tensor weighted by the induced dipole amplitude [4].

For an ideal resonant particle, this formulation reveals the role of radiation damping and surface-mediated self-interaction in determining the effective polarizability and the emission maximum. For a realistic implementation, we consider graphene plasmons assisted by a thin hBN nanodisk deposited on a dielectric coating layer above graphene. The layered structure is incorporated through a modified reflection coefficient, while the disk is described by an effective in-plane polarizability obtained from an electrostatic modal expansion.

For periodic arrays with periodicity a, we consider the electron passing parallel to the dipole lattice with velocity $\mathbf{v} = v\hat{\mathbf{x}}$. We include dipole–dipole lattice interactions and determine the allowed n-th diffraction orders from the phase-matching condition $k_{nx} = \omega/v + 2\pi n/a$, which determines the emission direction of each polaritonic Smith–Purcell channel [4].

III. Results and Discussion

For a single scatterer, SP emission becomes possible even in spectral regions where direct electron excitation is forbidden. The emission probability is maximized at a finite scatterer–surface distance because reducing the separation strengthens the near-field coupling to the surface, but also enhances the self-interaction that suppresses the effective particle response. In the semi-analytical treatment of lossless resonant particles, this optimum distance follows the SP wavelength and yields a clean polaritonic signal under conditions where the bare electron does not excite the mode. These results are shown in Fig. 1 of Ref. [4].

A realistic realization is provided by hBN nanodisks coupled to graphene. The geometry under consideration is illustrated in Fig. 1(a), in which the electron passes above a small hBN disk of diameter D placed on top of a graphene layer coated by a dielectric of thickness z_0. The SP emission probability is calculated in Fig. 1(b) as a function of disk–2D-layer spacer z_0 and frequency. The optimum coating thickness z_0 is plotted on top as a yellow curve. The disk resonance near the upper Reststrahlen band filters the broadband electron spectrum and produces narrow-band plasmon generation around selected mid-infrared energies, shown as a dark blue spot in Fig. 1(b). Figure 1(c) also shows the emission rate

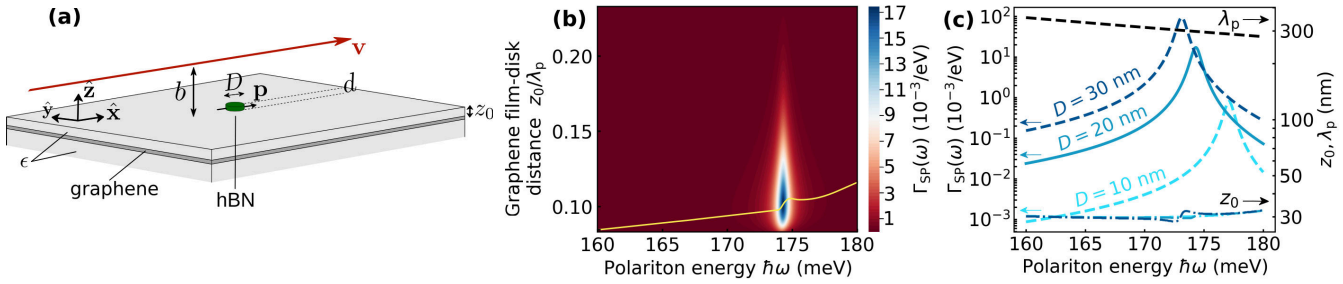

Fig. 1. **Free-electron excitation of graphene plasmons mediated by a hBN disk scatterer**. **(a)** Geometry under consideration, comprising a graphene film and an hBN disk of diameter D and thickness d. The disk is directly deposited on the top dielectric layer of thickness z_0. The electron passes at a distance b above the disk. The dielectric substrate and coating layer have a permittivity ϵ. **(b)** Spectrally resolved probability of graphene-plasmon emission $\Gamma_{SP}(\omega)$ under the conditions of (a) as a function of plasmon energy $\hbar\omega$ and coating-layer thickness z_0 for $D = 20$ nm, $d = 1$ nm, $\epsilon = 2$, $b = 10$ nm, and $v = 0.04\,c$. We set the graphene Fermi energy to $E_F = 1$ eV. **(c)** Maximum $\Gamma_{SP}(\omega)$ (left vertical scale, solid curve) and optimum coating thickness z_0 along with the SP wavelength λ_p (right scale) as a function of emission frequency under the conditions of (b). In (c), we also show results for the maximum $\Gamma_{SP}(\omega)$ with $D = 10$ nm and 30 nm (see labels).

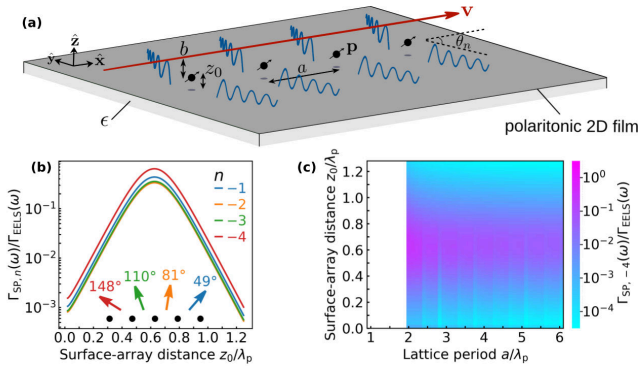

Fig. 2. **Polaritonic Smith–Purcell effect**. **(a)** Scheme with the geometry under consideration. A linear array of particles spaced by a period a along the direction of electron motion. The electron passes at a distance b above the array and induces a dipole moment $\mathbf{p}$ in each scatterer. The array is placed at a distance z_0 from a polaritonic 2D film. The in-plane emission angle θ_n is illustrated. **(b)** Probability of SPP emission $\Gamma_{SP,n}(\omega)$ for different orders n normalized per particle and divided by the self-standing-particle EELS probability $\Gamma_{EELS}(\omega)$ as a function of scaled array–surface distance z_0/λ_p for fixed frequency $\omega = 0.4\,\omega_D$. We assume perfect scatterers, a Drude film, and parameters $a/\lambda_p = 2$, $v = 2.2\,v_0 \approx 0.2\,c/(\epsilon+1)$, and $k_D b = 0.1$. The corresponding emission angles θ_n are indicated in the inset (top-view scheme). **(c)** Ratio $\Gamma_{SP,n=-4}(\omega)/\Gamma_{EELS}(\omega)$ as a function of a/λ_p and z_0/λ_p for $v/v_0 = 2.2$, with all other parameters the same as in (b). The white region corresponds to the condition that the $n = -4$ Smith–Purcell emission is kinematically forbidden. Figure adapted from Ref. [4].

spectra but for different values of the disk parameter D. There is a strong dependence on disk diameter, which tunes the spectral position and magnitude of the maximum. This behavior demonstrates that the scatterer not only enables otherwise forbidden coupling, but also introduces spectral selectivity to the launched graphene plasmons [2], [4].

When the individual scatterer is replaced by a periodic array aligned with the electron trajectory, as schematized in Fig. 2(a), the induced dipoles emit coherently into discrete in-plane diffraction orders n. The resulting polaritonic Smith–Purcell emission is highly directional and again displays an optimum array–surface distance. In Fig. 2(b), we calculate the normalized emission rate for different diffraction orders n as a function of the normalized surface-array distance z_0. As the figure shows, the different orders peak at similar normalized separations but radiate along distinct in-plane angles, indicated by colour-code arrows in the inset. The strongest emission occurs for the order whose propagation direction is closest to anti-parallel to the dipole array, provided it is not kinematically forbidden; in the present case, this corresponds to $n = -4$. Figure 2(c) shows the normalized emission for $n = -4$ as a function of z_0 and the lattice period a. The emission can be tuned through the lattice period, providing extra control over the directionality and efficiency of the launched SPs through the electron velocity and array spacing, while keeping the supporting surface translationally invariant [4].

IV. Conclusion

In summary, small scatterers provide an efficient interface between free electrons and highly confined SPs. They enable low-energy electrons to excite modes inaccessible by direct coupling, while resonant particles add spectral selectivity and periodic arrays provide directional control through polaritonic Smith–Purcell emission. hBN nanodisks illustrate the practical potential of this approach for launching graphene plasmons in realistic layered platforms [4].

***Abstract*—We demonstrate the evanescent and resonant excitation of high transversal modes on long photonic molecules. By inserting the molecule as a link we observe long-range coupling of very distant waveguides. We use this on a one-dimensional lattice and demonstrate the emergence of a topological phase originated by third-order nearest-neighbour coupling.**

***Keywords*— evanescent coupling, transversal modes, femtosecond laser writing, photonic lattices.**

I. Introduction

A one-dimensional (1D) paraxial wave equation is, excepting constants, completely equivalent to a Schrödinger equation; therefore, we can directly interpret a photonic waveguide as an atom and a composed structure as a photonic molecule [1]. The larger structure allows higher-order states [2], depending on the excitation wavelength and propagation distance. Inter-orbital coupling among individual waveguides, which support a fundamental S and a first excited P state, was recently demonstrated in photonics in coupler configurations [3] fabricated using the femtosecond (fs) laser writing technique [4]. In that specific case, a fine-tuning protocol of the propagation constants was mandatory to achieve a resonant coupling among, otherwise, orthogonal states.

On the other hand, the hopping in solid-state-like (tight-binding) systems or the evanescent coupling in photonics is based on localized and exponentially decaying wavefunctions at specific sites. This naturally sets a cutoff for long-range interactions which decay exponentially with the distance [4]. Therefore, artificial lattices utilizing an evanescent coupling suffer from these limitations, leaving multiple interesting topological and transport phenomena out of reach.

II. Methods

We fabricate different photonic structures by means of the fs laser writing technique, as it is sketched in Fig.1(a). We tightly focus a pulse of $\sim$ 200 fs, with a wavelength of 1030 nm, inside a borosilicate glass wafer. The laser induces a weak modification of the refractive index contrast, estimated as $\Delta n \sim 10^{-3}$ over $n_0 = 1.48$ (wafer). A full waveguide is fabricated after translating the glass along its length (coordinate z), at a given writing velocity and power.

III. Results and Discussion

Photonic molecules are obtained by fabricating a sequence of closely spaced waveguides, with distances around 4 μm [see example in Fig.1(a)-inset]. A waveguide (atom) is inserted beside the molecule, at a distance larger than 15 μm to allow a standard evanescent coupling interaction [3]. Fig.1(b) shows different examples for short and long 1D molecules, with clear excitation of the 3rd, the 5th, the 6th, the 7th, the 9th and the 11th orbital molecular states. Fig.1(c) presents the extracted data for a molecule of width of $\sim$ 120 μm (formed by 31 waveguides), showing an almost perfect mode excitation at around specific optimal wavelengths. This data describes quite clearly a resonant-like picture, with very well-defined peaks around specific wavelengths and for different higher-order states. Therefore, the method shows an excellent and simple way of exciting higher-order states, for example as a way of spatial and wavelength multiplexing of optical information [5].

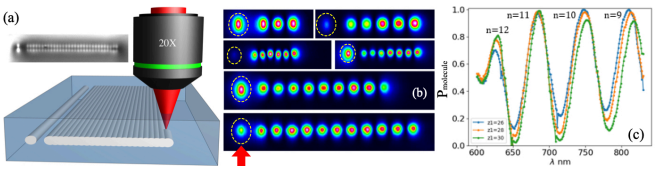

Fig. 1. (a) Illustration of the fs laser writing technique. Inset shows a microscope image of a fabricated 1D molecule composed of 31 single waveguides. (b) Output intensity profiles of different higher-order states excited at different photonic molecules and for different excitation wavelengths, after the excitation of the waveguide located beside each molecule (see red arrow and yellow circles). (c) Extracted data of the power at the 1D molecule versus the excitation wavelength, for three different propagation lengths z1 of the molecule.

Then, we explore two different applications using the resonant excitation of specific modes at the photonic molecule. A standard distance for fan-in and fan-out fiber optics operations inside a photonic chip is 127 μm. This distance allows to couple classical or quantum light coming from a given source using fibers, and then to fan-in to implement a given operation and fan-out to extract the result [6]. However, the curvature of waveguides introduces losses and, therefore, new solutions are always necessary. We specifically explore this idea using a photonic molecular link to connect waveguides which otherwise simply do not interact. Fig.2(a1) shows the sketch and Fig.2(a2) the result for a large wavelength to assure a large coupling. However, at this separation distance, the coupling is simply zero in practice for a 30 mm long glass. We introduce a long photonic molecule in between these two waveguides, as it is sketched in Fig.2(b1), and characterize its performance by a supercontinuum laser source. Fig.2(b2) shows the compiled results for the measured power at the opposite (right) waveguide (red curve) and the power at the molecule (black curve), for an excitation of the left

waveguide. We observe that the performance strongly depends on wavelength, with two optimal regions at around 685 and 770 nm [see Fig.2(b3)], and a $\sim 50/50$ beam splitter at 735 nm.

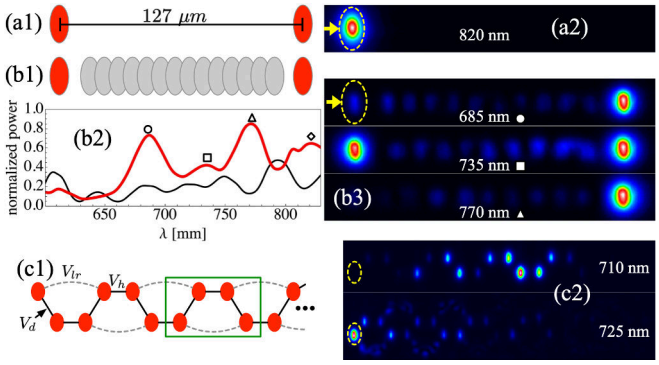

Fig. 2. (a) Sketch of two waveguides separated a distance $d = 127$ μm and (a2) output image at $\lambda = 820$ nm. (b1) Sketch of a coupler including a photonic molecule as a link. (b2) Extracted normalized power vs λ at the non-excited right waveguide (red) and the molecule (black). (b3) Output images at the indicated wavelengths. (c1) A 1D lattice with horizontal Vh, diagonal Vd, and long-range Vlr coupling constants. (c2) Output images, at the indicated wavelengths, after exciting the left edge site (yellow ellipses) of a trivial (top) and a non-trivial (bottom) lattice

Finally, we perform a second fundamental application on a lattice. An homogeneous one-dimensional lattice is trivial in any sense as it only contains a single dispersive band. This means that by exciting any site through the system, only dispersion will be observed as all the excited eigenmodes are spatially delocalized. The sketch in Fig.2(c1) shows a zig-zag-like configuration, and the lattice is completely trivial for $V_d = V_h$ and $V_{lr} = 0$. Fig.2(c2)-top shows the output dispersive profile obtained after the excitation of the left edge (yellow ellipse) with a propagation of 50 mm. We introduce long-range coupling V_{lr} by inserting photonic molecules as indicated with dashed lines in Fig.2(c1). These photonic link allows us to selectively couple specific lattice sites, in this case to the third nearest neighbour. This inclusion allows us to transform a trivial lattice into a topological one, which presents two topological transitions depending on the coupling ratio $V_{lr}/V_{d,h}$ [7]. In our experiments [2], we were able to obtain a ratio ~ 0.5, which allowed us to observe a first topological transition. This experimentally manifests on light localization at the edge, as it is clearly observed in Fig.2(c2)-bottom, with almost no light present at the photonic links.

IV. Conclusion

We have demonstrated the possibility of very long-distance coupling by means of femtosecond laser writing photonic links. This coupling is selectively determined by the excitation wavelength and propagation distance, and it has a resonant-like dependence which depends on the fabrication parameters. Therefore, a specific wavelength can be selectively tuned. This resonant evanescent interaction allowed us to effectively couple very distant waveguides, which otherwise will never interact (for waveguide distances larger than 50 μm, the coupling can be assumed as zero in practice). Our extracted data shows an excellent coupling of $\sim$ 85 % at $\lambda = 770$ nm. Finally, the use of long-range and selective coupling among specific sites allows us to increase the possibilities of lattice research in photonics. As new phenomena could emerge from this extra degree of freedom, new physics is now at hand to be explored. For example, we directly demonstrated a topological transformation of a standard trivial 1D lattice into a topologically non-trivial one by selectively inserting coupling links at third-nearest neighbours. The observation of edge localization at the topological phase constitutes an experimental proof of this transition.

Hyperbolic Super-Resonance and Long-Range Quantum Entanglement

Evgenii E. Narimanov[1] and Eugene A. Demler[2]

***Abstract*—Hyperbolic materials support extreme momentum electromagnetic modes that enable deeply subwavelength field confinement and reshape light–matter interaction. We report the discovery of hyperbolic super-resonance, arising from clustered high-wavenumber modes in finite hyperbolic structures, which enables strong and even ultrastrong light–matter coupling and mediates strong long-range interaction between quantum emitters.**

I. Introduction

Hyperbolic materials provide an optical environment in which electromagnetic waves can access momenta exceeding those available in conventional dielectric media by several orders of magnitude.[1] Their anisotropic permittivity tensor, with opposite signs along orthogonal axes, produces open hyperbolic iso-frequency surfaces that support a continuum of high-wavenumber propagating modes. These waves enable deeply subwavelength field confinement, directional energy flow, and a divergent photonic density of states.[2] As a result, hyperbolic media have emerged as a powerful platform for controlling light–matter interaction at the nanoscale.

In a finite hyperbolic structure, the high-wavenumber modes of the hyperbolic medium form dense clusters of nearly degenerate states. In the effective-medium limit, these clusters collapse into distinct, sharply defined resonances – the phenomenon we refer to as the hyperbolic super-resonance.[3] The resulting field enhancement enables strong and even ultra-strong light–matter coupling for a single quantum emitter placed near the structure. Furthermore, these super-resonant modes also mediate strong long-range interaction between two distant quantum emitters.

II. Hyperbolic Super-Resonance

The physical origin of the hyperbolic super-resonance can be uncovered using a simple example: a long hyperbolic resonator with rectangular cross-section and a high-conductivity metal coating on its surface. The boundary conditions quantize the in-plane and out-of-plane wavevector components according to

$$k_x a_x = \pi n_x, \qquad k_z a_z = \pi n_z, \tag{1}$$

where n_x and n_z are integers. For a deeply subwavelength resonator ($a_x, a_z \ll \lambda_0$), the hyperbolic dispersion relation implies

$$k_x = \sqrt{-\frac{\epsilon_\parallel(\omega)}{\epsilon_\perp(\omega)}}\, k_z. \tag{2}$$

Combining these expressions yields the resonance condition

$$\sqrt{-\frac{\epsilon_\perp(\omega_r)}{\epsilon_\parallel(\omega_r)}} = \frac{a_x}{a_z}\,\frac{n_x}{n_z}. \tag{3}$$

Note that this condition is satisfied not only by a single pair (n_x, n_z), but by the entire integer ladder

$$(n_x, n_z) = (mn_1,\, mn_2), \qquad m = 1, 2, 3, \ldots, \tag{4}$$

all collapsing onto the same frequency; see Fig. 1. This resonance-frequency degeneracy, asymptotically exact in the quasistatic limit $a \ll \lambda_0$, is the *Hyperbolic Super-Resonance* (HSR) – the finite-size counterpart of the broadband hyperbolic super-singularity of infinite hyperbolic media.[2]

While this degeneracy formally extends over infinitely many integer multiples, material absorption suppresses the highest-order members of the ladder. Because the attenuation coefficient grows with the magnitude of the wavevector, higher-order super-resonances experience disproportionately stronger damping. As a result, the most robust and experimentally relevant HSRs arise from the lowest-order integer families.

This mechanism is not restricted to rectangular geometries. Infinite mode degeneracies appear in any hyperbolic resonator whose ray-optical dynamics is integrable – a condition that can be demonstrated by transforming the electromagnetic trajectories to action-angle variables, as in the Einstein-Brillouin-Kramers semiclassical quantization procedure.[4] For example, in a metal-clad cylindrical hyperbolic resonator (Fig. 1(a)), the resonance condition reduces to

$$\sqrt{-\frac{\epsilon_\perp(\omega_r)}{\epsilon_\parallel(\omega_r)}} = \frac{4R}{d}\, m, \tag{5}$$

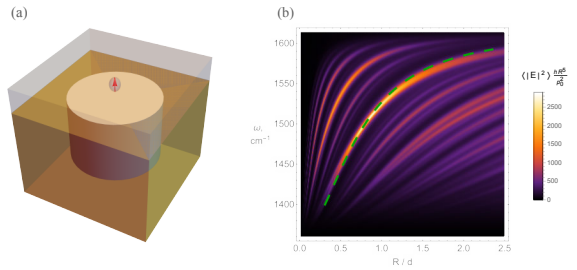

Fig. 1. **Average intensity of light emitted by a point dipole and trapped inside a hyperbolic resonator. (a)** Schematic of the system: a point dipole emitter positioned above a cylindrical hyperbolic resonator. Light-orange indicates the hyperbolic material, gold the metal cladding, and gray the supporting substrate. In a practical realization, the hyperbolic medium is hexagonal Boron Nitride (hBN), the cladding is gold, and the emitter is a donor impurity in silicon. **(b)** False-color plot of the average trapped intensity as a function of the resonator aspect ratio and emission frequency. The dielectric permittivity corresponds to hBN. The dashed green line marks the principal super-resonance defined by Eqn. (5). Note the negligible trapped intensity outside the hBN hyperbolic frequency band [5], [6] $1380\ \mathrm{cm}^{-1} < \omega < 1620\ \mathrm{cm}^{-1}$, and its dramatic enhancement at the super-resonance.

again yielding an asymptotically exact degeneracy over the integer ladder $m = 1, 2, 3, \ldots$

This mechanism concentrates electromagnetic energy into highly localized regions of the resonator, producing field enhancements far exceeding those achievable in dielectric or plasmonic structures of comparable size.

III. Light–Matter Interaction

The extreme mode degeneracy associated with the hyperbolic super-resonance has profound consequences for light–matter interaction. At the super-resonance, a point-like quantum emitter placed in the near field of a hyperbolic resonator couples simultaneously to an entire ladder of high-wavenumber electromagnetic modes whose frequencies collapse onto the same value. Their collective contribution produces an exceptionally large light-matter coupling strength.

A convenient quantitative measure of this interaction is the coupling coefficient g of the Jaynes-Cummings model.[7] For integrable hyperbolic geometries, the same semiclassical quantization that produces the super-resonance also yields a closed-form expression for g; for example, for the cylindrical resonator of Fig. 1,

$$\hbar g = \frac{1 - \cos\left(\frac{\pi m}{2}\right)}{2} \sqrt{\frac{p^2 \hbar \omega}{3 d\, h^2}}, \tag{6}$$

where the integer m is the order of the super-resonance (see Eq. (5)), h is the distance between the dipole and the resonator, and p is the characteristic dipole moment of the quantum emitter.

For a quantum emitter based on deep donor impurities in silicon, with $p \sim e \times 1\,\mathrm{nm}$, the dipole-resonator spacing $h \simeq 3\,\mathrm{nm}$ and cylinder length $d \sim 50\,\mathrm{nm}$, Eq. (6) yields $\hbar g \simeq 0.15\,\hbar\omega$ for the lower-frequency and $\hbar g \simeq 0.1\,\hbar\omega$ for the higher-frequency hyperbolic bands in hexagonal boron nitride.[5], [6] Thus, at the hyperbolic super-resonance, a single quantum emitter placed near a hyperbolic optical resonator naturally operates in the strong-coupling regime.

IV. Material Considerations

Hexagonal boron nitride (hBN) provides a natural platform for realizing hyperbolic super-resonance due to its strong phonon-polariton response and well-established fabrication pathways. The availability of isotopically purified hBN significantly reduces phonon scattering, enabling low-loss operation and enhancing the quality factor of the super-resonant mode.

Other hyperbolic materials – including semiconducting CrSBr [8] and metallic molybdenum oxychloride ($MoOCl_2$) [9], [10] – operate in the technologically important near-infrared range used in communications and information processing. These systems offer additional opportunities for realizing hyperbolic super-resonances and extend the accessible spectral range for the effect.

V. Conclusion

We have uncovered the hyperbolic super-resonance, a phenomenon arising from the clustering of high-wavenumber modes in finite hyperbolic structures. This effect produces strong – and even ultrastrong – light–matter coupling and mediates long-range interaction between quantum emitters, offering new opportunities for quantum nanophotonics and nonlinear optics.

***Abstract*—We investigate topological singularities in scattering matrices of photonic structures in the visible spectrum. Using frequency and momentum as parameter space, we observe features consistent with exceptional lines through Mueller matrix spectroscopy. This approach enables investigation of non-Hermitian topology without complex structural requirements.**

***Keywords*— Exceptional lines, Non-Hermitian photonics, Scattering matrix, Mueller matrix spectroscopy.**

I. Introduction

Topological singularities in wave systems have attracted significant attention for their potential in photonic control and sensing applications. While isolated exceptional points have been demonstrated in various platforms ranging from microcavities to photonic crystals, extending these to higher dimensions remains challenging, particularly in the visible regime where material constraints and fabrication limitations become more pronounced. Exceptional lines, as one-dimensional extensions requiring three-dimensional parameter spaces, have been largely confined to microwave frequencies where complex structures can be more readily implemented through established fabrication techniques. The exploration of these topological features at optical frequencies has remained an outstanding challenge in the field of topological photonics. We present an approach that exploits scattering matrices of photonic structures, which naturally provide the required parameter space through frequency and momentum degrees of freedom, circumventing the need for elaborate structural engineering that would otherwise be necessary for three-dimensional architectures.

II. Theoretical Framework and Methods

We consider systems where the scattering matrix $S(\omega, \mathbf{k}_{\parallel})$ describes the optical response as a function of frequency and in-plane wavevector, providing a complete characterization of the system's reflective properties. For periodic structures with appropriate symmetries, this three-dimensional space can support singularities with non-trivial topology that manifest as characteristic features in the eigenvalue and eigenvector structure.

In systems with material absorption, which is inevitable in realistic photonic structures operating at visible frequencies, the interplay between resonant modes and symmetry breaking can lead to non-Hermitian degeneracies with unique properties. These degeneracies may exhibit characteristic features including distinctive eigenvalue structure with square-root dependencies and polarization properties that differ fundamentally from their Hermitian counterparts. The scattering matrix formalism provides a natural framework for describing these open systems, where energy exchange with the environment plays a crucial role in determining the system's optical response.

Our experimental platform combines Fourier-space optics with polarization-resolved spectroscopy to enable comprehensive characterization across the parameter space. A nanophotonic structure is characterized in the visible range using synchronized polarization control elements that generate multiple measurement configurations, providing complete information about the polarization-dependent scattering behavior. Spectroscopic imaging enables simultaneous access to both frequency and momentum dimensions, allowing efficient mapping of the three-dimensional parameter space without requiring mechanical scanning in multiple directions. Mueller matrix measurements across the parameter space are systematically performed and converted to scattering matrices in appropriate bases, enabling characterization throughout ω-$\mathbf{k}_{\parallel}$ space with high precision and resolution. This experimental methodology represents a significant advancement in the ability to probe topological features in optical systems, providing access to previously inaccessible information about the complete scattering behavior.

III. Results and Discussion

Experimental measurements reveal features in the scattering matrix eigenvalue structure that are consistent with theoretical predictions for topological singularities in non-Hermitian systems. Phase analysis of the scattering matrix elements shows vortex-like structures at certain locations in parameter space, providing direct evidence of the singular nature of these points. Different measurement configurations reveal complementary patterns in the phase and amplitude distributions, indicating polarization-dependent responses that are characteristic of chiral exceptional points with distinct handedness. The spatial distribution of these features suggests extended structures rather than isolated points, consistent with the expected one-dimensional nature of exceptional lines in three-dimensional parameter space.

Systematic scanning along different directions in momentum space traces trajectories that appear to form connected

curves in the three-dimensional parameter space, demonstrating the continuous nature of these topological features. Multiple regions in the frequency-momentum space exhibit similar characteristic signatures in both eigenvalue and eigenvector distributions, suggesting distinct classes of singularities with different physical origins related to the underlying resonance mechanisms. The observed eigenvalue behavior shows certain parameter dependencies near singular points that are consistent with theoretical predictions for exceptional points, including characteristic square-root scaling behavior. Eigenvector distributions exhibit variations consistent with theoretical predictions for such systems, showing evolution from linear to circular polarization states as one approaches the singular points. These features extend across spectral ranges spanning tens of terahertz, indicating inherent robustness in the parameter space and suggesting potential for broadband applications in photonic devices.

IV. Conclusion

This work demonstrates an approach for investigating topological features in optical scattering matrices using relatively simple and scalable photonic structures. By exploiting the natural parameter space available through frequency and momentum, we access phenomena typically requiring more complex implementations involving three-dimensional architectures or active tuning mechanisms. The observed signatures are consistent with higher-dimensional singularities in non-Hermitian systems, providing experimental evidence for these theoretical concepts in the visible regime. The experimental methodology based on Mueller matrix spectroscopy provides comprehensive characterization capabilities for such systems, enabling detailed investigation of both amplitude and phase properties across the full parameter space. The results suggest potential applications in areas where sensitivity to parameter variations or polarization-selective responses are desirable, including enhanced sensing schemes and chiral light-matter interactions. This framework may facilitate exploration of non-Hermitian topological physics at optical frequencies, contributing to both fundamental understanding of wave phenomena and practical photonic applications in communications and quantum technologies. The demonstration establishes a robust and accessible platform that bridges theoretical concepts with experimental accessibility in the visible spectrum, opening new possibilities for investigating complex topological phenomena in photonic systems.

***Abstract*— Surface enhanced Raman spectroscopy is investigated as a tool for probing intracellular pH and local chemical microenvironment using gold nanopopcorn nanostructures functionalized with pH sensitive Raman reporters. The work combines nanoparticle synthesis reporter comparison and cellular studies to evaluate how nanoscale architecture and biological environment determine intracellular SERS response.**

***Keywords*— surface enhanced Raman spectroscopy, intracellular pH, nanopopcorn, Raman reporters, cellular microenvironment.**

I. Introduction

Intracellular pH is a fundamental parameter regulating enzyme activity, metabolism, membrane trafficking, autophagy, and cell fate decisions. Although average cytosolic pH values are relatively well characterized, growing evidence indicates pronounced spatial and temporal pH heterogeneity at the subcellular level. Local pH gradients accompany endocytic maturation, lysosomal acidification, metabolic reprogramming, and stress adaptation. These processes occur on submicrometer length scales and evolve dynamically, making their quantitative characterization experimentally demanding.

Monitoring such local variations requires probes capable of operating within crowded and chemically complex intracellular environments. Fluorescence-based pH sensors are widely used but often suffer from photobleaching, spectral overlap, limited multiplexing capability, and sensitivity to probe concentration. In addition, fluorescence intensity-based measurements may be affected by local optical artifacts and intracellular scattering.

Surface enhanced Raman spectroscopy (SERS) offers an alternative approach providing molecularly specific vibrational information with high photostability and strong spatial confinement of the signal near plasmonic nanostructures. The spectral fingerprint character of Raman scattering allows direct discrimination between protonated and deprotonated forms of reporter molecules. In this work, we systematically evaluate nanopopcorn-type gold nanostructures together with different thiolated Raman reporters in order to develop a reliable and stable platform for intracellular pH measurements..

II. Methods

Gold nanopopcorn nanoparticles were synthesized using a seeded growth approach involving small gold seeds and controlled reduction of metal precursors. For comparison, conventional spherical gold nanoparticles of similar core diameter were prepared or obtained and subjected to identical functionalization and measurement protocols. The resulting anisotropic structures exhibit multiple protrusions and nanogaps that generate intense electromagnetic hot spots. Reaction parameters such as precursor concentration, reducing agent amount, and growth time were optimized to ensure reproducible morphology and colloidal stability.

Nanoparticles were functionalized with thiolated pH-sensitive Raman reporters including mercaptobenzoic acid isomers, mercaptopyridine, and aminothiophenol derivatives. Surface modification was performed under controlled conditions to ensure stable chemisorption via gold–sulfur bonds while minimizing aggregation. After functionalization, particles were purified and transferred into aqueous media compatible with cell culture experiments.

SERS calibration measurements were performed in buffer solutions covering physiologically relevant pH ranges, as well as in cell culture media to evaluate environmental effects. Raman spectra were collected using a confocal Raman microscope with visible or near-infrared excitation. Intensity ratios of selected vibrational bands corresponding to protonation-sensitive modes were used to construct calibration curves.

Cellular uptake, localization, and biocompatibility were assessed using transmission electron microscopy, confocal microscopy, and metabolic viability assays. Intracellular SERS spectra were collected from living cells incubated with functionalized nanoparticles at defined time points to probe pH-dependent spectral changes within endocytic compartments..

III. Results and Discussion

Nanopopcorn nanostructures exhibit substantially enhanced

SERS signals compared to conventional spherical gold nanoparticles of comparable size owing to their complex morphology and high density of electromagnetic hot spots. Direct comparison under identical experimental conditions demonstrates improved signal intensity, higher signal to noise ratio, and more robust intracellular detectability for the nanopopcorn architecture. The presence of sharp protrusions and nanoscale interstitial gaps increases electromagnetic field confinement, which translates into stronger enhancement of reporter vibrational modes.

When evaluated in buffer systems, both spherical and nanopopcorn nanoparticles show pH dependent spectral changes characteristic of the attached reporters. However, the dynamic range and apparent sensitivity are consistently higher for the nanopopcorn structures. In particular, intensity ratios of protonation sensitive bands display improved contrast across the physiological pH window. This difference becomes even more pronounced under biologically relevant conditions.

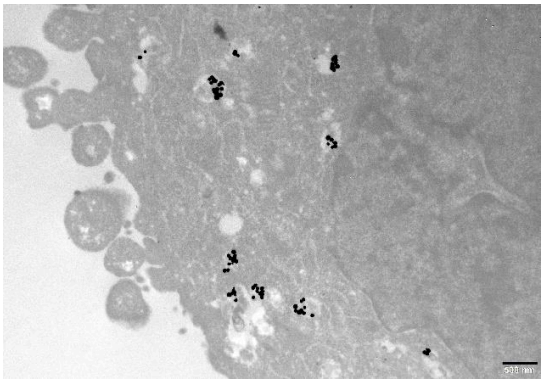

Fig.1 Transmission electron microscopy photography of HeLa cell with internalized gold nanoparticles.

In cell culture media and in living cells, spherical nanoparticles frequently produce weaker and less reproducible intracellular spectra, likely due to lower enhancement efficiency and partial signal masking by background contributions. In contrast, nanopopcorn based nanosensors maintain detectable reporter signatures inside endocytic compartments. The enhanced performance facilitates more reliable extraction of pH dependent band ratios from intracellular spectra.

Comparison of different Raman reporters further reveals that calibration behavior depends strongly on chemical structure. Carboxyl containing reporters show gradual intensity changes associated with acid base equilibria, whereas nitrogen containing heterocycles exhibit distinct band shifts and relative intensity redistribution. Importantly, calibration curves obtained in buffer solutions differ from those measured in cell culture media and inside cells. These shifts indicate that intracellular SERS response is influenced by protein corona formation, ionic strength, confinement effects, and reporter orientation on the nanoparticle surface. Consequently, the measured signal reflects an effective local microenvironment rather than bulk pH alone.

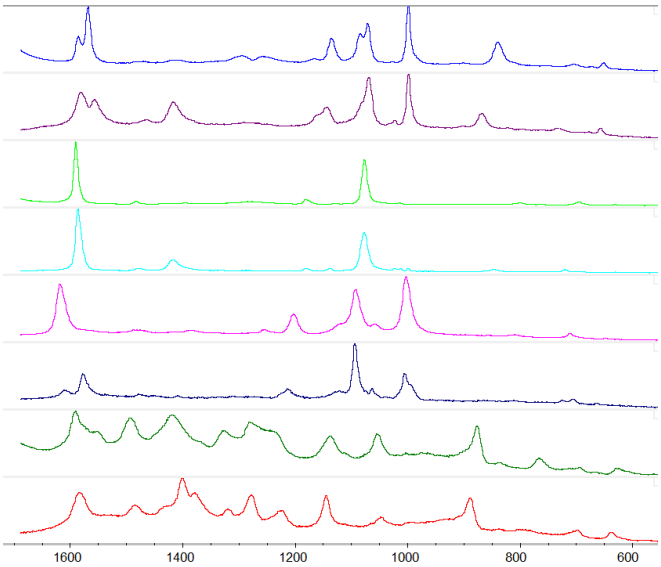

Fig.2 SERS spectra of 1,3 mercaptobenzoic acid (pH 1 and 12), 1,4-mercaptobenzoic acid (pH=1 and 12), 4-mercaptopyridine (pH=1 and 12) and 4-amine-3-mercaptobenzoic acid 9pH=1 and 12).

IV. Conclusion

This study demonstrates that nanopopcorn-based SERS nanosensors provide a versatile platform for probing intracellular pH and chemical microenvironment. Enhanced electromagnetic hot spots combined with carefully selected Raman reporters enable sensitive detection of protonation-dependent spectral changes in living cells.

Reliable interpretation of intracellular SERS measurements requires careful consideration of nanoparticle architecture, reporter chemistry, and biological context. The presented approach establishes a foundation for future development of quantitative SERS-based probes for studying dynamic cellular processes such as endocytic maturation, metabolic adaptation, and stress responses.

***Abstract*—The impact of post-processing on soft magnetic properties and the giant magnetoimpedance (GMI) effect of Fe- and Co-based glass-coated microwires is evaluated. A remarkable improvement of magnetic softness and GMI effect is observed in Fe-rich glass-coated microwires subjected to stress annealing. Frequency dependence of GMI ratio of stress-annealed Fe-rich microwires has been discussed considering frequency dependence of the skin penetration depth, δ, as well as magnetic anisotropy distribution within the metallic nucleus. Annealed and stress-annealed Co-rich microwires present rectangular hysteresis loop and single and fast domain wall propagation. However, Co-based stress-annealed microwires present high magnetoimpedance ratio. Observed stress-induced anisotropy and related changes of magnetic properties are discussed considering internal stresses relaxation and "back-stresses"**

***Keywords*— metamaterials, terahertz, machine learning, photonic crystals.**

I. Introduction

Development of magnetic sensors is focused on the miniaturization of their size, improvement of their features and on finding of new materials. Among new magnetic materials a family of thin wire with reduced dimensions recently gained considerable attention [1]. Glass-coated magnetic microwires prepared using the Taylor-Ulitovsky technique with thin metallic nucleus (typically with diameters 0.5 to 50 μm) covered by flexible, insulating and biocompatible glass are therefore quite interesting for sensor applications [1]. This technique allows preparation of the thinnest rapidly quenched wires with amorphous or crystalline structure of metallic nucleus. Good magnetic properties can be observed either in crystalline or in amorphous magnetic wires, but amorphous magnetic wires present several advantages, such as superior mechanical properties, the absence of the microstructure defects (grain boundaries, crystalline texture, dislocations, point defects,…) [2] and hence precise post-processing is not required. Particularly, amorphous microwires can present giant magneto-impedance (GMI) or magnetic bistability. In the case of glass-coated microwires the magnetoelastic anisotropy contribution becomes relevant since the preparation process involves not only the rapid quenching itself, but also simultaneous solidification of the metallic nucleus surrounded by non-magnetic glass-coating with rather different thermal expansion coefficients [1].

The purpose of this paper is present last results on tailoring of soft magnetic properties and GMI effect in glass-coated microwires paying special attention to achievement of high GMI effect and on optimization of domain wall dynamics.

II. Methods

We studied glass-coated Fe and Co-rich ferromagnetic microwires with metallic nucleus diameter, d, between 10 μm, total diameter, D=22.2 μm, ρ =d/D= 0.88 produced by Taylor-Ulitovsky method described elsewhere [1,3].

Hysteresis loops of studied microwires have been measured using fluxmetric method previously described in details elsewhere [1]. We represent the hysteresis loops as the dependence of normalized magnetization, M/M_0 (where M is the magnetic moment at given magnetic field and M_0 is the magnetic moment of the sample at the maximum magnetic field amplitude) versus magnetic field, H.

The sample impedance, Z, in extended frequency range has been evaluated using the micro-strip sample holder from the reflection coefficient, S_{11}, obtained using Vector Network Analyzer (VNA), as previously described [3]. Such micro-strip holder with sample has been placed inside a long solenoid

producing homogeneous magnetic field, H. The GMI ratio, $\Delta Z/Z$, is obtained from $Z(H)$ dependence as:

$$\Delta Z/Z = [Z(H) - Z(H_{max})]/Z(H_{max}), \quad (1)$$

where H and H_{max} are given and maximum applied fields respectively.

III. Results and Discussion

Studied Co-rich and Fe-rich as-prepared microwires present rather different magnetic properties and hence GMI effect: $Fe_{75}B_9Si_{12}C_4$ microwires present perfectly rectangular hysteresis loops typical for Fe-rich microwires with high and positive magnetostriction coefficient, λ_s, ($\lambda_s \approx 35x10^{-6}$) exhibiting magnetic bistability. In contrast $Co_{69.2}Fe_{4.1}B_{11.8}Si_{13.8}C_{1.1}$ microwires present linear hysteresis loops previously reported for Co-based glass-coated microwires with low and negative λ_s ($\lambda s \approx -10^{-7}$) [3,4] (see Fig. 1a and Fig. 1b). Coercivity, H_c, of $Fe_{75}B_9Si_{12}C_4$ microwires (about 55 A/m) is about an order of magnitude higher that of $Co_{69.2}Fe_{4.1}B_{11.8}Si_{13.8}C_{1.1}$ microwires.

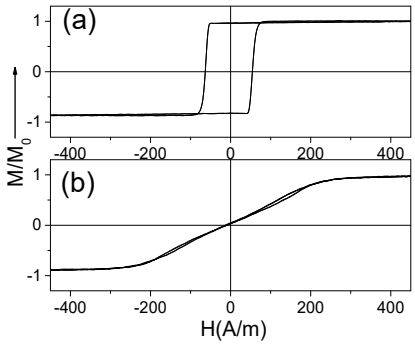

Fig 1. Hysteresis loops of as-prepared $Fe_{75}B_9Si_{12}C_4$ (a) and $Co_{69.2}Fe_{4.1}B_{11.8}Si_{13.8}C_{1.1}$ (b) microwires.

Accordingly, magnetically softer $Co_{69.2}Fe_{4.1}B_{11.8}Si_{13.8}C_{1.1}$ microwires exhibit an order of magnitude higher GMI ratio than $Fe_{75}B_9Si_{12}C_4$ microwires (see Fig. 2).

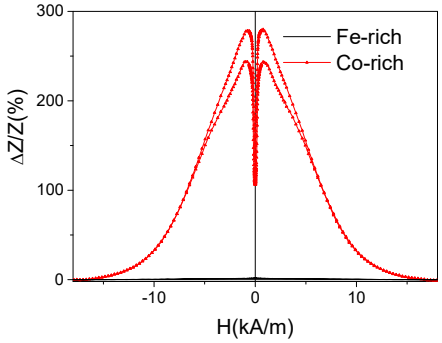

Fig. 2. $\Delta Z/Z(H)$ dependences of as-prepared $Co_{69.2}Fe_{4.1}B_{11.8}Si_{13.8}C_{1.1}$ and $Fe_{75}B_9Si_{12}C_4$ measured at 100 MHz.

Stress annealing of Fe based microwires allows considerable H_c decrease and inducing of transverse magnetic anisotropy, as can be observed from hysteresis loops measured in stress-annealed $Fe_{75}B_9Si_{12}C_4$ microwires (Fig. 3a).

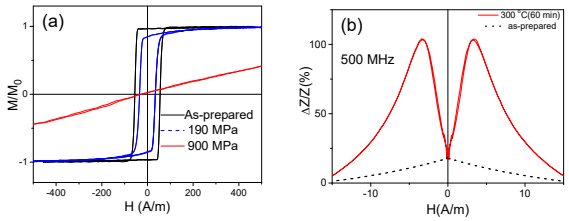

Fig. 3. Hysteresis loops (a) of as-prepared and stress-annealed at T_{ann}=300º C (upon σ =190 and 900 MPa) and $\Delta Z/Z(H)$ dependencies (b) of as-prepared and stress-annealed at T_{ann}=300º C (upon σ = 900 MPa) $Fe_{75}B_9Si_{12}C_4$ microwires.

Magnetic properties are considerably affected by the stress, σ, applied during the stress annealing: induced transverse magnetic anisotropy becomes more noticeable with increasing of σ -values. Accordingly, remarkable improvement of GMI ratio is observed in stress-annealed Fe–rich ($Fe_{75}B_9Si_{12}C_4$) microwires: improvement of $\Delta Z/Z$ –values by an order of magnitude is achieved.

Consequently, appropriate annealing of ferromagnetic microwires allows achievement of interesting combination of magnetic properties. In the Fe-rich microwires stress-annealing allows remarkable improvement of magnetic softness and GMI effect. On the other hand, a substantial GMI effect of Co-rich microwires can be also achieved. Thus, recently we reported $\Delta Z/Z$ –values up to 900% in annealed Co-rich microwires [4]

IV. Conclusion

We provide comparative studies of magnetic properties and GMI effect in Fe and Co-based microwires. Stress annealing allows remarkable improvement of magnetic softness and GMI effect in Fe-based microwires.

Beyond optical chirality density: tensor descriptors of electromagnetic chirality

Ilia Smagin[1], Nikolay Gippius[1], Sergey Dyakov[1]

[1]Department of Physics, Skolkovo Institute of Science and Technology, Moscow, Russia

***Abstract*—Optical chirality density is commonly used to characterize chiral electromagnetic fields, but it is insufficient in anisotropic or structured media. We introduce tensorial descriptors of electromagnetic chirality based on the Lipkin formalism, clarify the physical meaning of their components, and demonstrate how multiple complementary measures of chirality naturally emerge in anisotropic consideration.**

***Keywords*— nanophotonics, optical chirality density, Lipkin tensor.**

I. Introduction

Optical chirality density is widely used as a scalar measure of the chiral properties of electromagnetic fields and their interaction with matter. However, in anisotropic and structured media, a single scalar quantity is generally insufficient to capture the full complexity of chiral field–matter coupling. In this work, we go beyond the conventional optical chirality density and introduce a set of tensor descriptors of electromagnetic chirality based on the Lipkin formalism [1]. These tensor quantities provide a richer and more physically transparent description of chiral electromagnetic fields, particularly in anisotropic environments. The physical meaning of individual tensor components is discussed, and their role in characterizing different aspects of electromagnetic chirality is clarified. In particular, we show that these tensor components naturally emerge when analyzing chiral light–matter interaction beyond isotropic approximations and can be directly linked to observable physical quantities.

II. Methods

To establish a direct link between electromagnetic chirality and observable physical quantities, we analyze molecular emission processes in chiral electromagnetic fields. Our approach builds upon the work of Tang and Cohen [2] and F. Fedorov formalism [3]. Specifically, we consider the period-averaged molecular emission rate in a monochromatic field:

$$A^{\pm} = \langle \mathbf{E}\cdot\dot{\mathbf{p}} + \mathbf{H}\cdot\dot{\mathbf{m}}\rangle = \frac{\omega}{2} Im(\mathbf{E}^*\cdot\mathbf{p} + \mathbf{H}^*\cdot\mathbf{m}) \qquad (1)$$

and use the expressions for dipole and magnetic moments in the anisotropic case [3], [5]:

$$p_\mu = \alpha_{\mu\nu}E_\nu - iG_{\mu\nu}H_\nu, \quad m_\mu = \chi_{\mu\nu}H_\nu + iG_{\mu\nu}E_\nu \qquad (2)$$

where $\alpha_{\mu\nu}$ is electric polarizability, $\chi_{\mu\nu}$ is magnetic susceptibility, and $G_{\mu\nu}$ is mixed electric-magnetic dipole polarizability or so-called optical activity tensor. Substituting (2) into (1) yields a generalized expression for the molecular emission velocity.

For modeling the interaction of chiral light with chiral matter we follow approaches [3], [4] that are expressed by the following material equations

$$\begin{aligned} D_\mu &= \varepsilon_{\mu\nu}E^\nu + \chi_{\mu\nu}H^\nu, \\ B_\mu &= \xi_{\mu\nu}E^\nu + \mu_{\mu\nu}H^\nu. \end{aligned} \qquad (3)$$

and use the Fourier modal method [6].

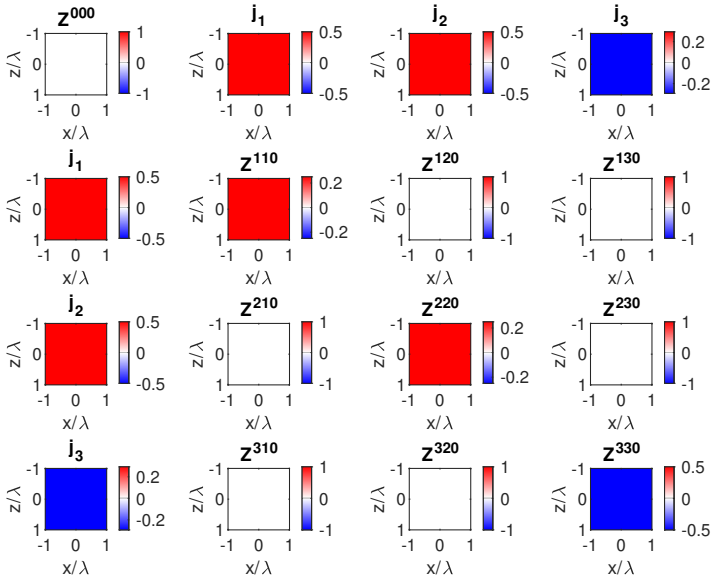

Fig. 1. The average Lipkin tensor components $Z^{\mu\nu 0}$. The optical chirality density $\rho_\chi = Z^{000}$ is equal to zero but diagonal density components and corresponding flux components are not.

III. Results and Discussion

Using the formalism described above, we derive an explicit expression linking molecular emission velocity to the components of the Lipkin density tensor. It appears that the emission velocity of a molecule in the monochromatic case can be represented in the form:

$$A^{\pm}_{ani} = \textit{nonchiral terms} \mp \sum_{m=1}^{6} w_m \overline{Z^{(m)}} \qquad (4)$$

Here $\overline{Z^{(m)}} = \mathcal{G}_{ab}^{(m)} Im(E_a^* H_b - H_a^* E_b) = \overline{Z^{ij0}}$ are one of the six realizations of the zilch tensor density components, $m = 1, ..., 6$ and the coefficients w_m quantify the weight of each chiral channel. Since the coefficients w_m are determined solely by molecular geometry, this expression generalizes the Tang–Cohen result: the chiral asymmetry in the excitation rate of a small molecule in an arbitrary anisotropic environment is proportional to the product of the molecular chirality and the corresponding component of the electromagnetic chirality encoded in the Lipkin tensor. We show that expression (4) in the isotropic case will match the Tang-Cohen result [2] with optical chiral density $\rho_\chi = \overline{Z^{000}}$

$$A_{iso}^{\pm} = \frac{\omega}{2}\left(\alpha''|\boldsymbol{E}|^2 + \chi''|\boldsymbol{H}|^2\right) \pm G''\omega Im(\boldsymbol{E}^* \cdot \boldsymbol{H}) \quad (5)$$

Moreover, the diagonal components of the Lipkin tensor admit a natural interpretation in terms of eigenfields of the chiral interaction operator, providing a basis-independent description of independent chiral channels. This provides a direct link between the Lipkin density tensor components and the molecular emission velocity, clarifying their physical meaning.

To illustrate the practical implications of this tensorial description, we consider a simple yet illustrative example of two plane monochromatic waves in a vacuum with different signs of circular polarization and spreading at different angles to the coordinate axes. The angles are chosen in such a way that the optical chiral density ρ_χ is equal to zero for the total field (see Fig. 1) but the diagonal density components and corresponding flux components are not. This demonstrates that the optical chiral density alone does not provide a complete characterization of electromagnetic chirality.

IV. Conclusion

In this work, we have demonstrated that optical chirality density, while useful, represents only a single component of a more general tensorial description of electromagnetic chirality. Using the Lipkin formalism, we introduced tensor descriptors that naturally arise in anisotropic and structured media and clarified their physical meaning through their connection to molecular emission processes.

We have shown that in anisotropic field configurations, the scalar optical chirality may vanish, even though other components of the Lipkin tensor remain finite and physically relevant. This shows that scalar measures alone can fail to capture essential aspects of chiral electromagnetic fields. In contrast, the tensorial approach provides a more complete and coordinate-resolved description of chirality, revealing contributions that are otherwise hidden.

***Abstract*— More recently, photonic synthetic dimension has become an emerging paradigm. Specifically, the synthetic frequency dimension offers unique advantages due to flexibly reconfigurable gauge potential and long-range couplings. Here, we present the realization of programmable chiral edge states of the Hall ladder in synthetic frequency dimension.**

***Keywords*— synthetic dimension, Thin-film lithium niobate, topological photonics, photonic crystals.**

I. Introduction

Understanding chiral edge states is essential for probing spin-orbit coupling in topological systems, which play a prominent role in topological insulators, valleytronics, and topological photonics [1]. Experiments show that modulating these states via external fields leads to remarkable phenomena such as topological phase transitions, non-Abelian Aharonov-Bohm effects, and chiral Landau levels [2]. Although platforms like photonic crystals and metamaterials have enabled such studies through artificial gauge fields, their inflexibility and fabrication complexity limit the development of fully reconfigurable systems for controlling chiral edge states. The concept of photonic synthetic dimensions has emerged as a powerful strategy, using internal photon degrees of freedom—such as frequency [3], time [4], and orbital angular momentum—to create extra dimensions. Synthetic frequency dimensions have enabled chiral edge modes and spin-momentum locking through tailored gauge potentials. However, a fully reconfigurable and integrated photonic platform remains lacking, hindering further exploration and control of chiral edge states in synthetic dimensions.

II. Methods

In this work, we demonstrate a microring resonator supporting resonant frequency modes in both clockwise (CW) and counterclockwise (CCW) directions on an integrated thin-film lithium niobate (TFLN) photonic platform (Fig. 2). Through traveling-wave electro-optic modulation applied with phase control, we synthetically engineer frequency lattices for each pseudo-spin. The system is described by a tight-binding model:

$$H=-\sum_{m,s}\left[\omega_m a_{m,s}^{\dagger}a_{m,s}+\sum_{l=1}^{\infty}(J_s(t)a_{m,s}^{\dagger}a_{m-l,s}+H.c.)\right]-K\sum_{m}(a_{m,\uparrow}^{\dagger}a_{m,\downarrow}+H.c.),$$

where $a_{m,s}$ and $a_{m,s}^{\dagger}$ are the annihilation and production operators for the m-order frequency mode with pseudo-spin $s\in\{\uparrow(\mathrm{CW}),\downarrow(\mathrm{CCW})\}$. $J_s(t)$ and K represents coupling strength. We first construct a synthetic Hall ladder by applying phase-offset modulations, introducing an artificial magnetic flux. Band structure measurements reveal clear spin-momentum locking. Experimental spectra and current profiles align closely with theory. Furthermore, by applying asymmetric modulation signals, we create a misaligned interface that breaks symmetry between pseudo-spins, resulting in imbalanced chiral edge states. Next, we construct a coupled Hall ladder system supporting versatile chiral phases through next-nearest-neighbor coupling. By programming the phase parameters, we demonstrate several distinct regimes: chirality, single-pseudospin enhancement (SPE) and complete suppression. In conclusion, we have realized a programmable integrated photonic platform for synthesizing and controlling chiral edge states, paving the way for high-dimensional and reconfigurable topological photonic systems.

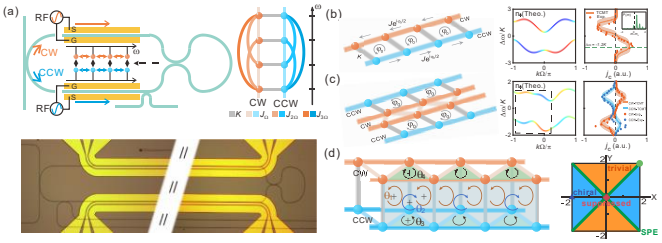

Fig. 1 Reconfigurable chiral edge states via synthetic dimensions in an integrated photonic platform.

III. Results and Discussion

Experimental results show:

- On-chip synthesis dimension platform
- Observation of band and chiral currents (Fig. 1)
- Programmatic Control of Chiral States

IV. Conclusion

We constructed an on-chip synthesis platform and synthesized Hall ladders, enabling observation and programmable modulation of chiral edges. This work establishes a programmable integrated photonic system for emulating and controlling chiral edge states in synthetic space.

***Abstract*—We experimentally demonstrate angle-tunable double-resonant second-harmonic generation in a dielectric metasurface supporting quasi-guided modes. By adjusting the incident angle source, simultaneous resonances at both the fundamental and second-harmonic wavelengths are achieved, resulting in a 27-fold enhancement of the SHG signal.**

***Keywords*— Second-harmonic generation, guided mode, nonlocal.**

I. Introduction

All-dielectric metasurfaces have emerged as an effective platform for enhancing nonlinear light–matter interactions at the nanoscale. However, the relatively weak nonlinear response of dielectric materials often limits the efficiency of processes such as second-harmonic generation (SHG), motivating the development of resonant strategies capable of providing substantial field enhancement. One promising approach relies on high-Q resonances originating from leaky modes, such as quasi-bound states in the continuum (quasi-BICs) and quasi-guided modes (QGMs), where controlled structural perturbations introduce finite radiative coupling while preserving exceptionally large quality factors. QGMs engineered through modulation of grating width and periodicity have been reported to sustain high-Q resonances together with dispersive characteristics in momentum space [1]. The momentum-dependent characteristic of QGMs provides an additional degree of freedom for modal engineering. Exploiting this property, we design a dielectric grating metasurface supporting QGMs near the fundamental wavelength (800 nm) and its second harmonic (400 nm). By tuning the incident angle, corresponding to variation of the in-plane wavevector k_y, we identify a condition satisfying $k_{\mathrm{SH}} = 2k_{\mathrm{FF}}$, where the two QGMs become degenerate. Under this angle-selective degeneracy, simultaneous resonances at the fundamental and second-harmonic frequencies are achieved, resulting in a 27-fold enhancement of SHG efficiency.

II. Methods

The second-harmonic(SH) emission efficiency can be described by the modal overlap factor [2], which is expressed as

$$\beta = \frac{\int d\boldsymbol{r}\, \epsilon E_2^* E_1^2}{(\int d\boldsymbol{r} \epsilon_1 |E_1|^2)(\sqrt{\int d\boldsymbol{r} \epsilon_2 |E_2|^2})} \sqrt{\lambda_1^3}, \quad (1)$$

where E^{ω} and $E^{2\omega}$ denote the electric-field distributions at the fundamental and second-harmonic frequencies inside the structure, respectively. ε is the spatial permittivity distribution ε_{ω} and $\varepsilon_{2\omega}$ represent the permittivities. The SH intensity follows

$$I_{SH} \propto \left|\mathrm{X}_{(2)}\right|^2 |\beta|^2 \quad (2)$$

Indicating that the SHG efficiency increases as the modal overlap between the fundamental field distribution and the second-harmonic mode becomes stronger. Under double-resonant conditions, resonant enhancement at both frequencies increases E_{ω} and $E_{2\omega}$ simultaneously. When the degeneracy condition is satisfied, the modal overlap between the nonlinear source E_{ω}^2 and the second-harmonic mode is maximized, leading to stronger nonlinear coupling.

The dielectric grating metasurface was designed to support QGMs at both frequencies (fundamental and second-harmonic). The geometric parameters were optimized using finite-difference time-domain (FDTD) simulations. The final design consisted of TiO_2 grating with a width of 110 nm and a perturbation parameter $\alpha = 30$nm, arranged with a period of $2P = 390$nm.

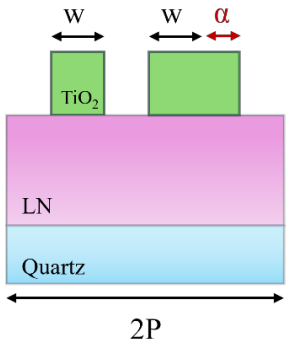

Fig. 1. Unit-cell geometry of the metasurface

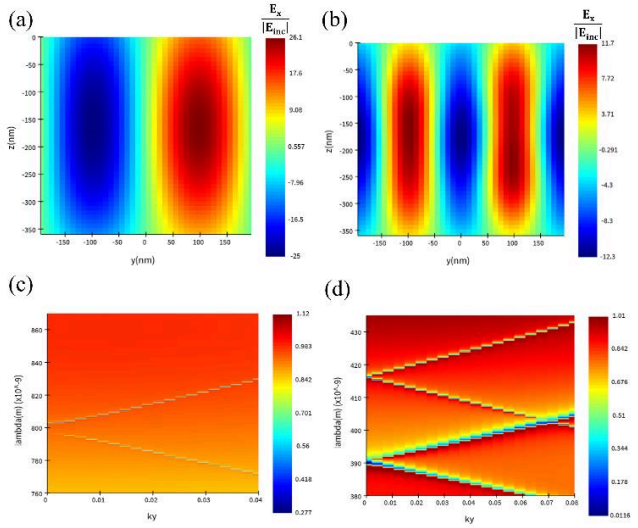

Fig. 2. Simulated QGMs at the fundamental (800 nm) and second-harmonic (416 nm) wavelengths. (a) and (b) Electric-field profiles in LN layer at 800 nm and 416 nm, respectively. (c) and (d) Corresponding dispersion relations

Angle-resolved linear spectrum was measured using a Fourier-plane filtering configuration to confirm the formation of the QGM. The transmitted beam was projected onto the Fourier plane, where each spatial position corresponds to a specific in-plane momentum k_y.

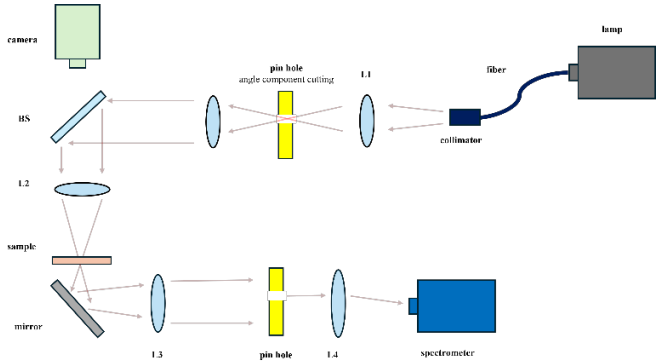

Fig. 3. Experimental setup for momentum-resolved linear spectroscopy. A pinhole placed at the Fourier plane selectively filters a specific in-plane momentum component.

And SHG measurements were performed using a pulsed excitation source and rotation stage.

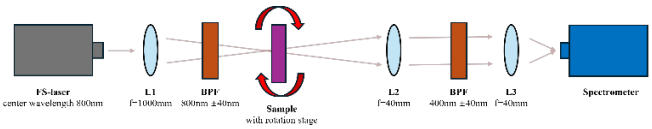

Fig. 4. Experimental setup for SHG measurements. The generated SH signal is spectrally filtered and collected for detection.

III. Results and Discussion

The measured linear transmission map reveals a clear dispersive resonance branch near 800 nm, exhibiting the same dispersion trend predicted by Fig. 2-(c).

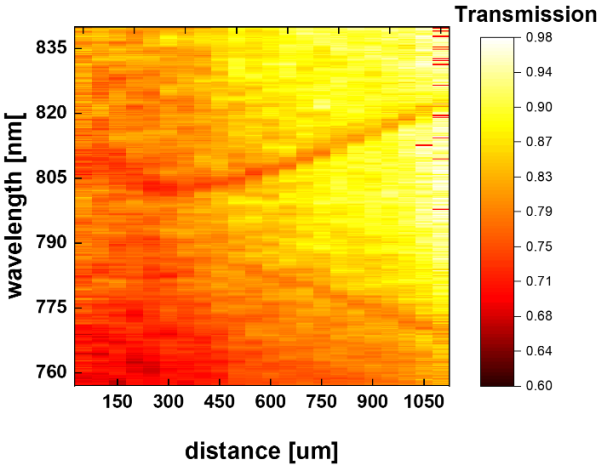

Fig. 5. Measured transmission spectrum. The transmission map is plotted as a function of wavelength and spatial position of pinhole in the Fourier plane (see Fig. 3).

The SH signal was experimentally measured for both an unpatterned reference and the patterned metasurface. This pronounced increase in SHG confirms that the patterned metasurface supports the designed resonant mode, leading to strong nonlinear enhancement.

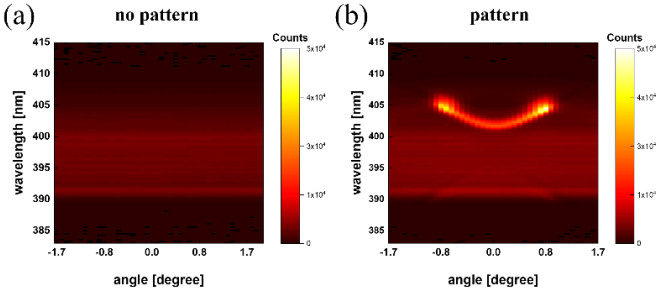

Fig. 6. Measured SHG result for (a) an unpatterned reference sample and (b) the TiO_2 grating patterned metasurface. A pronounced SHG enhancement is observed in the patterned.

In Fig. 7, The SHG enhancement factor was calculated by normalizing the measured SHG intensity of the patterned metasurface to that of the unpatterned reference. A pronounced peak is observed near angles of ± 0.83 degree where the enhancement factor reaches approximately 27.

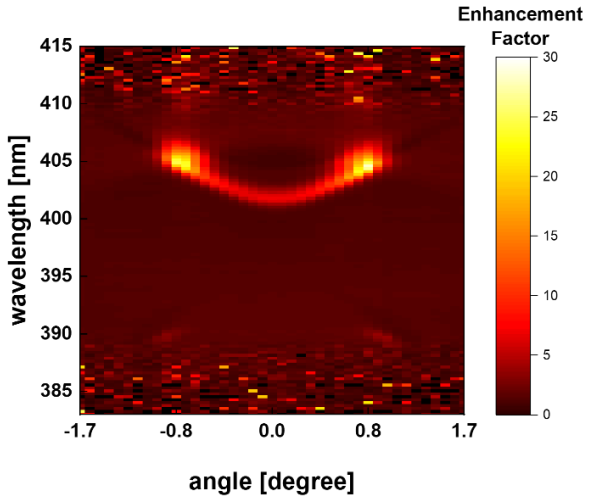

Fig. 7. Measured SHG enhancement factor of the patterned metasurface, defined as the ratio between the SHG intensity of the patterned structure and that of the unpatterned reference. A maximum enhancement factor of approximately 27 is observed near angles of ±0.83 degree

IV. Conclusion

We experimentally confirmed that a pronounced SHG peak is formed at the angle-induced double-resonant condition of the metasurface. By tuning the rotation angle, the dispersive QGMs at the fundamental and second-harmonic frequencies become simultaneously resonant, leading to a strong nonlinear enhancement with a maximum enhancement factor of 27. This result demonstrates that momentum-space engineering provides an effective route to access double-resonant operation without modifying the structural geometry.

3D Stokes Polarimetry of Dipolar Near-Fields

Guillermo Serrera[1,*], Yael Gutiérrez[1], José J. Gil[2], Fernando Moreno[1]

[1]Applied Physics Department, University of Cantabria, Spain
[2]Independent researcher, 29620 Casares Costa, Spain

***Abstract*—Dipolar emitters constitute fundamental building blocks in nanophotonics, yet their polarization behavior outside the far-field approximation remains insufficiently characterized. In this work, we introduce the three-dimensional Stokes formalism as a unified framework to describe the complete polarimetric landscape of dipolar radiation across the near-, intermediate-, and far-field regimes.**

***Keywords*— Stokes, polarimetry, dipolar fields.**

I. Introduction

Dipolar emitters play a central role in nanoscale light–matter interactions, yet their polarization properties remain insufficiently characterized outside the far-field approximation. Conventional 2D Stokes analysis assumes purely transverse fields and therefore cannot capture the intrinsically three-dimensional, vectorial nature of dipolar radiation in the near- and intermediate-field regimes. Recent experimental advances have further underscored this limitation by demonstrating the measurement of full 3D polarization and optical spin in evanescent and near-field environments.[1] A rigorous description of these regimes is therefore essential for nanophotonic applications, where strongly inhomogeneous electromagnetic fields are ubiquitous.

In this work, we apply the 3D Stokes formalism to analyze the emission of a range of dipolar sources, including electric, magnetic, spinning, and chiral dipoles. We show how this formalism effectively describes all polarization phenomenology in real-space, in contrast with approaches based on the Angular Spectrum Representation.[2] Furthermore, we show how, for deterministic fields, the 3D Stokes formalism allows simplification to 2D representations, accomodating the interpretation of complex polarization landscapes to conventional polarimetric techniques.

II. Methods

Our analysis is based on the 3D polarization matrix constructed from the full vectorial electric field of dipolar emitters. The matrix is expanded using the Gell–Mann basis, yielding nine real-valued 3D Stokes parameters.[3] These parameters encode total intensity, linear and circular polarization content, and the relative weight of radial versus transverse field components.

III. Results and Discussion

For linear electric dipoles, the 3D Stokes formalism reveals a fully linear polarization in the near field, dominated by longitudinal components. In the intermediate field, non-zero circular Stokes parameters emerge despite uniform intensity, evidencing transverse optical spin in real space.[2] In the far field, the field becomes purely transverse and is well described by conventional 2D Stokes parameters.

Spinning electric dipoles exhibit uniform azimuthal symmetry and strong circular polarization signatures, with the formalism clearly capturing helicity inversion and the evolution of spin components across regimes.[4]

For chiral dipoles, the near field closely resembles that of an electric dipole, while magnetic contributions become significant in the intermediate regime. The 3D Stokes parameters distinguish chiral circular polarization from electric-dipole–induced polarization artifacts, highlighting potential pitfalls in chiral sensing.

Finally, we show how a reduction of 3D-to-2D polarization states can be achieved by finding an intrinsic system for each point in space. This allows to express the polarization state in terms of the usual 2D formalism, revealing the fundamental nature of evanescent linear and circular polarization components with respect to the energy flow.

IV. Conclusion

We have demonstrated that the 3D Stokes formalism provides a compact, intuitive, and fully analytical framework for characterizing the polarization structure of dipolar emission across near-, intermediate-, and far-field regimes. By explicitly accounting for longitudinal and transverse field components, the formalism captures polarization effects that are inaccessible to conventional 2D Stokes analysis. This approach offers a powerful and accessible alternative to angular-spectrum-based methods and is well suited for the analysis of nanoscale light–matter interactions involving inhomogeneous fields.

Flexible and Programmable Semiconductor Plasmonic Platforms for Near-Infrared Meta-Optics

Debmalya Mukhopadhyay[1] and Bivas Saha[1,2]

[1]Chemistry and Physics of Materials Unit and International Centre for Materials Science, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore 560064, India
[2]School of Advanced Materials (SAMat), Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore 560064, India

Corresponding author: bsaha@jncasr.ac.in

Abstract: Semiconducting plasmonic platforms based on doped ScN and CdO thin films are demonstrated for near-infrared meta-optics. Flexible van der Waals heteroepitaxy enabled ScN exhibits tunable ENZ response, while Sc-doped CdO enables wide spectral programmability via carrier engineering. Attenuated total reflection reveals SPP modes, establishing complementary, low-loss, programmable plasmonic materials.

Keywords: Plasmonics, Dielectric permittivity, van der Waals heteroepitaxy, Surface plasmon polariton

Introduction: Plasmonic materials play a central role in meta-photonics by enabling subwavelength light confinement, enhanced light–matter interaction, and compact photonic integration. However, noble metals like gold and silver suffer from high optical losses, limited tunability, and poor compatibility with flexible or semiconductor platforms, restricting their use in the near-infrared (NIR) regime. These limitations have driven interest in alternative semiconducting plasmonic materials.

Degenerately doped semiconductors provide a powerful route to programmable plasmonics, where plasma frequency and optical response can be engineered via carrier concentration. Transition metal nitrides and transparent conducting oxides represent two complementary classes of low-loss semiconductor plasmonic materials. Scandium nitride (ScN), a refractory rocksalt semiconductor, exhibits epsilon-near-zero behaviour and mechanical robustness, while cadmium oxide (CdO) offers high carrier mobility and wide spectral tunability.

In this work, we present a unified semiconductor plasmonic platform combining flexible ScN and tunable CdO thin films. By controlling dopant incorporation and growth conditions, we demonstrate ENZ response and surface plasmon polariton excitation across a broad infrared range, highlighting their potential for near-infrared meta-optics.

Experimental methods: Flexible ScN thin films were grown on fluorophlogopite mica substrates using van der Waals heteroepitaxy in molecular beam epitaxy system (MBE), while epitaxial CdO films were deposited on MgO (001) substrates using DC magnetron sputtering system. Oxygen incorporation in ScN and Sc doping in CdO were employed to systematically tune carrier concentration.

Optical constants were extracted using variable-angle spectroscopic ellipsometry modelled with Drude and extended Drude approaches. Infrared reflectivity measurements were performed to identify ENZ wavelengths. Surface plasmon polaritons were excited using attenuated total reflection (ATR) in the Otto configuration with TM-polarized light.

Results and discussion: The plasmonic response is governed by the complex dielectric permittivity $\varepsilon(\lambda)=\varepsilon_1(\lambda)+i\varepsilon_2(\lambda)$. Near the plasma frequency, ε_1 crosses zero, yielding the ENZ condition, while negative ε_1 at longer wavelengths enables plasmonic behaviour.

Pristine ScN exhibits a carrier concentration of 3.4×10^{20} cm^{-3}, corresponding to an ENZ wavelength near 2.24 µm. Intentional oxygen doping increases the carrier concentration to 2.4×10^{21} cm^{-3}, shifting the ENZ to 1.14 µm within the NIR window (Figure 1a). Reflectivity minima observed near ENZ confirm plasmonic absorption arising from impedance matching (Figure 1b).

Similarly, pristine CdO shows an ENZ wavelength at ~6.63 µm due to a carrier concentration of 2.8×10^{19} cm^{-3}. Sc doping increases carrier density to 2.3×10^{20} cm^{-3}, shifting ENZ to 2.63 µm (Figure 1d, e). Both materials exhibit low optical loss near ENZ, favourable for meta-optical applications.

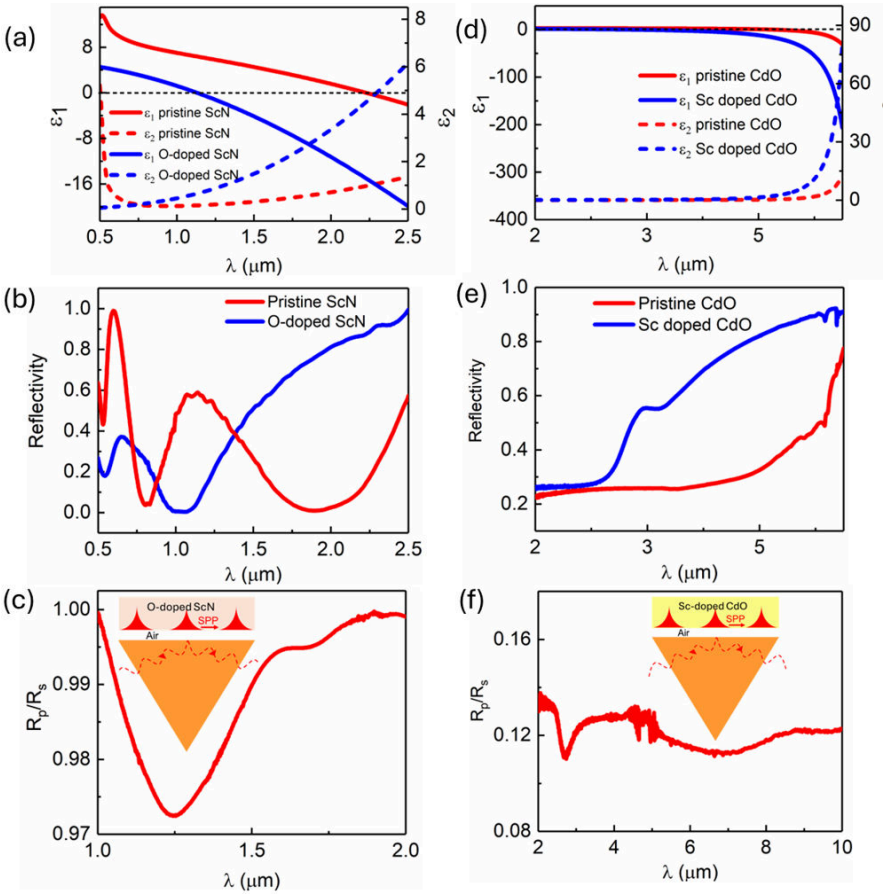

Figure 1. (a) Real (ε_1) and imaginary (ε_2) parts of the dielectric permittivity of pristine and O-doped ScN, showing doping-induced tuning of the ENZ wavelength in the NIR region. (b) Corresponding reflectivity spectra highlighting the ENZ-related reflectance minimum. (c) ATR reflectivity (R_p/R_s) of O-doped ScN in the Otto configuration, confirming SPP excitation at the ScN–air interface. (d) Dielectric permittivity of pristine and Sc-doped CdO illustrating carrier-dependent ENZ tunability in the mid-infrared regime. (e) Reflectivity spectra of CdO films showing doping-induced spectral shifts. (f) ATR spectra of Sc-doped CdO revealing propagating and hybridized SPP modes at the semiconductor–air interface.

Coupling of TM-polarized light with free electrons at a plasmonic material–dielectric interface gives rise to propagating surface electromagnetic waves known as surface plasmon polaritons (SPP). SPPs were excited using ATR in the Otto geometry (Inset of Figure 1c and

1f). For the ScN/air interface, a pronounced reflectivity dip at ~1.24 μm indicates SPP excitation (Figure 1c). CdO heterostructures exhibit two resonance minima at ~2.7 μm and ~7.0 μm, corresponding to hybridized symmetric and antisymmetric plasmonic modes arising from the air/CdO/MgO interfaces (Figure 1f).

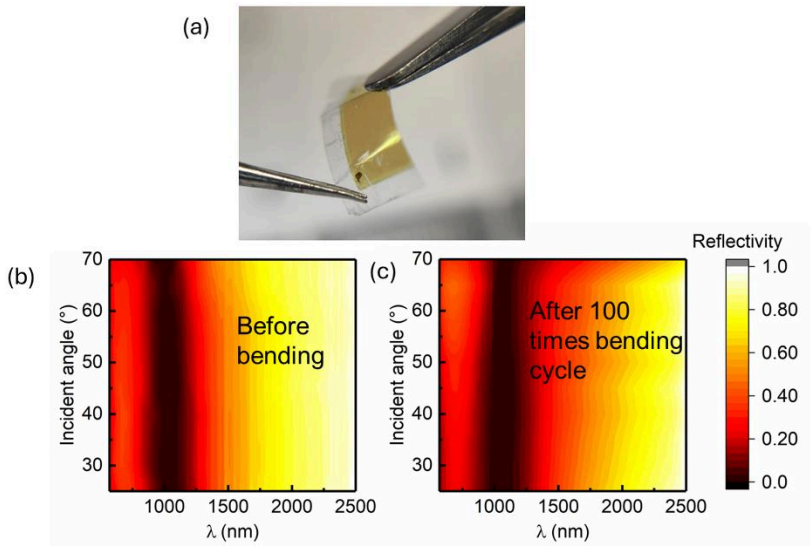

Figure 2. (a) Optical image of the exfoliated O-doped ScN/F-mica film demonstrating mechanical flexibility under bending. (b) Angle-dependent reflectivity map of the O- doped ScN/F-mica film. (c) Angle-dependent reflectivity map after 100 times bending cycle. The unchanged plasmonic response confirms the robustness of the ENZ resonance and surface plasmon behaviour under mechanical deformation.

After establishing the NIR plasmonic response of epitaxial O- doped ScN on F-mica, the mechanical flexibility of the film was examined by mechanically exfoliating the ScN layer with an approximately 5 μm mica support and bending it using tweezers (Figure 2a). Angle-resolved reflectivity maps measured before and after 100 times bending cycle show no noticeable variation in the plasmonic response, confirming the mechanical robustness and stability of the ENZ behaviour in the flexible ScN film (Figure 2b, c).

Conclusion: We demonstrate flexible and programmable semiconductor plasmonic platforms based on doped ScN and CdO thin films, supporting low-loss ENZ behaviour and surface plasmon polaritons across the near- and mid-infrared regimes. The combination of mechanical flexibility, carrier-controlled spectral tunability, and well-defined SPP modes establishes these materials as promising candidates for next-generation metasurfaces and near-infrared meta-optical devices.

***Abstract*— A dynamically beam-steerable metasurface antenna based on a substrate integrated waveguide is presented. Metasurface elements are loaded with PIN diodes to dynamically control the beam steering toward different directions. A modified sidelobe suppression method is also incorporated alongside beam steering and evaluated using analytical array factor calculations and full-wave simulations in ANSYS HFSS. The proposed antenna achieves up to 6 dB sidelobe reduction with minimal main-beam degradation while steering the beam from −25° to +30° in the Ku-band using only 24 elements.**

***Keywords*— metasurfaces, antennas, sidelobe suppression**

I. Introduction

Future wireless technologies are in search of cost-effective and dynamically adaptable beam angle control methods. Traditional phased array architectures are often accompanied by considerable system complexity as they often need highly sophisticated phase-shifting and feeding networks. On the other hand, emerging concepts such as dynamically reconfigurable metasurfaces represent two dimensional artificial electromagnetic (EM) structures engineered to manipulate and control EM wave propagation [1]-[3]. Enabling them to function as antenna radiators allows for the development of cost-effective new techniques for beamforming and beam shaping without additional design complexity [4-5]. When configured as an array of metasurface elements, the required phase shifts for beam steering are inherently derived from a propagating reference wave that travels across the metasurface aperture and a progressive phase to each metasurface element is then provided. By integrating a PIN diode into each metasurface element, the coupling behavior of each can be independently switched. Radiative metasurface antennas based on substrate integrated waveguide (SIW) employ subwavelength polarizable dipole-type metamaterial elements capable of dynamic radiation pattern reconfiguration. In [6], the authors achieved a dynamically reconfigurable metasurface antenna operating at 12 GHz with a gain of 8.35 dBi by employing PIN diodes. In [7], the authors introduced a two-dimensional metasurface antenna operating in the X-band, which achieves beam steering capability by utilizing varactor diodes for electronic tuning with a gain of 10 dBi.

In this work, a one-dimensional metasurface array based on a new metasurface geometry is proposed. Unlike most previous studies, sidelobe-level optimization is incorporated alongside beam steering, and the antenna performance is evaluated using a compact array with a small number of elements through analytical and full-wave analyses in ANSYS HFSS.

II. Substrate Integrated Waveguide Based Single Metasurface Antenna Design

The design methodology begins with the design of a low-loss SIW reference waveguide supporting the dominant TE_{10} mode, which serves as the excitation medium for the metasurface elements, which are complementary electric-LC (CELC) in this work. Subsequently, a single metasurface unit cell is designed and characterized to achieve ON–OFF radiation states using PIN diodes. The SIW can be regarded as a planar equivalent of a dielectric-filled rectangular waveguide, supporting the same dominant TE_{10} mode with an equivalent cut-off frequency [8], which can be calculated as shown in Eq. 1. Here, f_c denotes the cut-off frequency, ε_r is relative permittivity and A_r represents the SIW-width.

$$f_c = \frac{c}{2\sqrt{\varepsilon_r}} - \left(A_r - \frac{D^2}{0.95P}\right)^{-1} \quad (1)$$

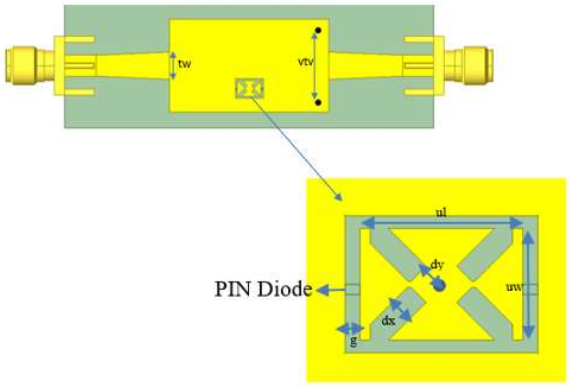

Fig 1. Proposed SIW-Based Metasurface Antenna Element

TABLE I. DIMENSIONS OF THE PROPOSED METASURFACE (IN MM)

uw	ul	dx	dy	g	tw	vtv
2.6	3.8	0.55	1.55	0.35	4.4	11.4

The continuous metallic sidewalls are replaced by two rows of metallized vias with diameter D, and an inter-via spacing P. A Rogers 4003 substrate (1.524 mm thick) is used with the via diameter and inter-via spacing are 0.8 mm and 1.1 mm, respectively. Those were chosen according to the proportional criteria derived in [9] to suppress electromagnetic leakage between adjacent vias. The metasurface dimensions were initially set to $\lambda/10$. A cutoff frequency was defined to cover the center operating frequency of 12.6 GHz, and the SIW width was chosen accordingly. After parameter optimizations, the values in Table 1 were selected as the final design parameters. As an example, Fig. 2 (a) illustrates how variations in the d_y spacing affect the transmission and reflection characteristics, and tune the resonance frequency, when the antenna element is in the open state (i.e., the PIN diode is off). This distance can be interpreted as the separation between the bias via—connected to the DC bias line and located near the center of the metasurface—and the rectangular slot etched on the surface. Variations in this distance directly affect the resonance frequency at which the metasurface unit cell couples to the reference wave. Fig. 2 (b) illustrates the variation in the reflection and transmission coefficients when the metasurface unit cell is offset from the center of the SIW. It can be observed that, as the metasurface offset increases, the return loss improves while the coupling to the reference wave decreases. Fig. 2 (c) demonstrates that the proposed metasurface exhibits a negative refractive index over the frequency range of 12.1–13.2 GHz and a negative group delay at 12.6 GHz when the element is nearly at center. As shown in Fig. 2 (d), the angular difference in the normalized gain of the metasurface element in its active and inactive states is analyzed in its principal plane, when the structure is assumed to be in one-dimensional array. It can be inferred that, within the angular range of −25° to +25°, the gain difference exceeds 8 dB, reaching a maximum value of 13 dB in this range.

III. META-ARRAY ANTENNA DESIGN AND ANALYSES

To enhance radiation control and aperture efficiency, the metasurface is extended into an array configuration, enabling collective element behavior and improved overall antenna performance. Considering the array of 24-element metasurfaces, the inter-element spacing is regarded as a critical parameter, since excessive mutual coupling between adjacent elements is an undesirable effect that can degrade the overall radiation performance. With an inter-element spacing of $\lambda_o/4$, *d*, the array layer exhibits dimensions of 190 mm × 20 mm as shown in Fig. 3

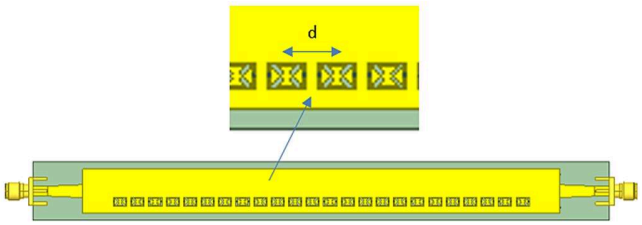

Fig. 3. Meta-array layer consists of 24 elements

As mentioned above, PIN diodes are employed to switch the metasurface elements between on and off states. The waveguide-fed metasurface elements radiate by coupling to the reference wave depending on their switching state. PIN diodes in the proposed design are MADP 000907-14020P by MACOM. It's modelled with a resistor of typically 5.2 Ω in the forward bias, and a capacitor of 0.025 pF in the reverse bias condition in HFSS. When determining the beam direction of the array structure, beam coding is formulated by associating the ON–OFF states of the metasurface elements with a binary coding scheme, where each element is assigned a binary amplitude coefficient (1 or 0) via PIN-diode control. These binary coefficients are then directly used as the amplitude weights in the 1-D array factor (AF) expression in broadside as follows [10]:

$$AF = \sum_{i=1}^{N} a_{m,i}(\omega)\, e^{-jx_i(\beta + k \sin \emptyset)} \qquad (2)$$

Where k is the wavenumber, β is the propagation constant, $a_{m,i}$ is the weighting coefficient of the i-th element, $\emptyset$ denotes the propagation angle normal to the surface of the antenna and x_i is the location of each element. The array factor is inherently dependent on the spatial configuration of the array elements and the phase excitation distribution across them as well as metasurfaces' polarizabilities, or weights. Accordingly, this binary weighting is incorporated into the array factor formulation by means of a unit step function as follows:

$$a_{m,i}(\omega) = \begin{cases} 0, & \text{if } \cos\left(x_i(\beta + k \sin \emptyset_0)\right) < 0 \\ 1, & \text{if } \cos\left(x_i(\beta + k \sin \emptyset_0)\right) > 0 \end{cases} \qquad (3)$$

The amplitude coefficients corresponding to the desired steering angle are calculated using this formulation through mathematical and scientific programming tools, and in this work, the beam codes are obtained using MATLAB. Based on these beam codes, a sidelobe suppression algorithm (SSA) is also applied similar to [11] with some modifications. At each iteration, a cancellation wave with amplitude and phase selected via nested for-loops is applied, and the array factor is recalculated with automatic sidelobe evaluation instead of pre-selection. Moreover, the modified algorithm monitors main-beam degradation during sidelobe suppression, and the optimal array factor is selected accordingly.

Increasing the number of elements introduces more and narrower sidelobes as shown in Fig. 4. However, these additional sidelobes generally exhibit lower amplitudes than those observed in arrays with fewer elements. Therefore, arrays with a higher number of elements may require relatively less sidelobe suppression effort compared to arrays with a smaller number of elements. From the sidelobe suppression perspective, the canceling wave is synthesized at the sidelobe angles of interest and superimposed with sufficient amplitude to suppress the targeted sidelobe and with a phase intentionally adjusted to be out of phase with it.

Fig. 5. Meta-array antenna performance: (a) Theoretical comparison before and after SSA at 12.5 GHz; (b) S-parameters; (c) Simulated radiation pattern at 12.5 GHz; (d) Simulated radiation pattern at 12.95 GHz; (e) Beam steering performance at 12.5 GHz. Each beam represents a separate simulation and beam code.

In Fig. 5 (a), after obtaining the above-mentioned binary amplitude coefficients for beam steering toward -25°, the corresponding theoretical array factor is presented. In the initial case, the SSA is not applied. Subsequently, the binary amplitude coefficients are processed using the SSA, and the resulting calculated array factor is plotted with the applied beam code given in Table II. It is observed that sidelobe reduction is achieved theoretically, particularly effective for the first sidelobes. To investigate the impact of SSA on the antenna return loss, the reflection and transmission coefficient

TABLE II. APPLIED BEAM CODES AND CORRESPONDING ANGLES

Beam To	Applied Beam Codes at 12.5 GHz
-25°	10001010101010101010110
0°	10010100101001011010 1101
+30°	11011001100100110010 0110

responses before and after SSA are presented in Fig. 5 (b). Since the applied beam code is modified by SSA, variations in these characteristics are expected. The extent of this variation is directly related to the degree of deviation from the initial beam code. Although the return loss slightly degrades after the application of SSA, it remains below −10 dB, indicating acceptable performance. Figure 5 (c) presents the normalized radiation pattern at 12.5 GHz. In the initial pattern, a sidelobe asymmetry is observed, with the sidelobe at −10° reaching a level close to 11 dB. After applying SSA, this sidelobe is suppressed by approximately 4 dB, reducing its level to around 15 dB. One noticeable effect after SSA is the emergence of a sidelobe at −50°, which is attributed to the algorithm; however, its level remains below 15 dB. Additionally, a slight reduction is observed in the main lobe at 0°. In contrast, the sidelobe at +10° increases in the SSA-applied case compared to the initial pattern. It should be noted that the increase in the sidelobe at +10° is consistent with the theoretical expectation presented in Fig. 5 (a). As a separate observation, the beamwidth is seen to broaden after the application of SSA, which is also consistent with theoretical expectations. Fig. 5 (d) presents the analysis of the same beam-code-based design at 12.95 GHz. At this frequency, a reduction of approximately 6 dB is achieved in the first sidelobes. The single-frequency beam steering performance of the antenna is analyzed in Fig. 5(e). Each beam is obtained from a separate simulation; therefore, the beam codes listed in Table II are individually applied for each steering angle. SSA is not applied for the 30° case, while the beams steered to −25° and 0° are SSA-optimized. As observed, without SSA, the sidelobe level remains slightly below 10 dB at best. From the analysis of these three beams, it can be concluded that for each steering angle, the sidelobes in the off–main-lobe region of approximately ±45° are maintained below 10 dB.

TABLE III. COMPARISONS WITH SOME OTHER WORKS

ID	Comparison Criteria				
	# of Elements	*Beam Steering with*	*Unit cell size*	*Freq. (GHz)*	*Sidelobe Suppression*
This work	24	PIN Diode	0.1λ x 0.15λ	12.5-13	6 dB
[4]	16	Water	0.15λ x 0.15λ	2.6	N/A
[5]	25	PIN Diode	0.12λ x 0.2λ	1.05	N/A
[6]	16	PIN Diode	0.12λ x 0.2λ	12	N/A
[7]	96	Var. Diode	0.12λ x 0.12λ	10	N/A

IV. Conclusion

A newly introduced metasurface element is designed and analyzed in a one-dimensional linear array with a limited number of elements, where a sidelobe suppression algorithm evaluated at multiple frequencies achieves about 6 dB first sidelobe reduction. Although a slight main-beam broadening is observed as an inherent trade-off of sidelobe suppression, the modified algorithm effectively monitors and minimizes main beam degradation, preserving beam integrity.

As summarized in Table III, unlike most previous works, which primarily focus on beam steering or reconfigurability without addressing sidelobe levels, this work demonstrates that meaningful sidelobe reduction can be realized concurrently with beam steering using binary-controlled metasurface elements. The beam steering to −25°, 0°, and +30° is successfully demonstrated using three distinct beam codes, confirming the robustness of the binary coding scheme and the effectiveness of the metasurface-based radiation control.

Although sidelobe suppression is achieved, slight discrepancies in sidelobe amplitudes and main beam pointing between the theoretically calculated array factor and the simulated radiation pattern are observed. These differences are mainly attributed to inter-element mutual coupling.

The results highlight that meaningful sidelobe suppression can be achieved even with a limited number of elements, which is particularly important for compact metasurface antenna implementations. The antenna can be extended to larger apertures or two-dimensional configurations in future work to further enhance radiation performance and beamforming flexibility.

***Abstract*—We describe a new way of quantising electromagnetic fields in the presence of dispersive, lossless resonators, based on normal mode expansion of the fields. This method is a generalisation of an existing approach, developed for non-dispersive media.**

***Keywords*— plasmonics, quantum optics, quantisation, polaritons.**

I. Introduction

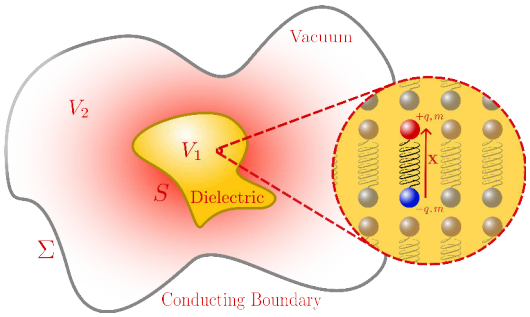

Fig. 1. Diagram of the system under study. An arbitrarily shaped piece of dielectric is surrounded by vacuum and enclosed by a perfectly conducting boundary. The dielectric material is described by the Hopfield model, as a continuous medium, with harmonic oscillator attached at every point.

Much of modern optical sciences focuses on investigating ways to control light and looking at their potential applications, in fields ranging from imaging to telecommunications. In particular, light is a very useful tool for interrogating and manipulating atoms, molecules, and nanostructures (collectively referred to as quantum emitters), due to the overlap between the energy scales of the processes occurring within these systems, and the energies of photons in the infrared to ultraviolet range. Spectroscopy is an obvious example of such a tool, being commonly employed, in its many varieties, to investigate chemical composition.

Coupling of light to individual quantum emitters is limited by the scale mismatch between light wavelengths and molecular dimensions. Plasmonics provides a way of bridging this gap, by coupling light to collective oscillations of conduction electrons in metallic nanostructures. Resulting hybrid modes, known as surface plasmon polaritons, are associated with strong, localised, electromagnetic near fields, bringing light down to the nanoscale, well below the diffraction limit. It has been demonstrated experimentally, that this approach can

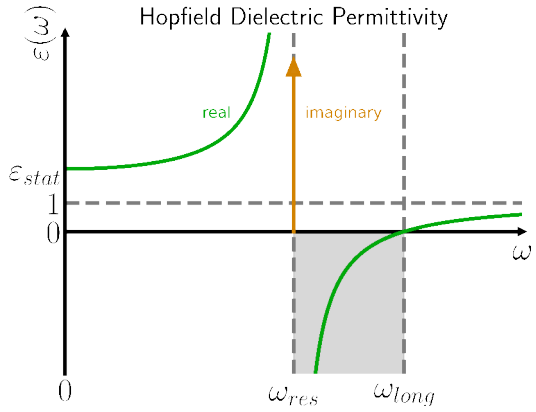

Fig. 2. Dispersion relation for a Hopfield dielectric. The real part of the permittivity varies rapidly near the resonance frequency of the medium oscillators, and becomes negative in a finite interval above it. The imaginary part of the permittivity is non-zero only at the resonance frequency.

give rise to strong coupling between light and individual dye molecules, resulting in mixed light-matter states[1].

Bringing light down to the nanoscale offers a possibility of investigating and exploiting quantum optical phenomena involving single quantum emitters. On the weakly coupled end of the scale, presence of a resonator can change the rate of spontaneous emission by influencing the vacuum field fluctuations in the vicinity of the emitter (Purcell effect). Going beyond spontaneous emission, if the interaction strength is sufficiently large, coupling to radiation can alter the nature of molecular eigenstates [2], shifting their energies (Lamb shift). Dynamically, this manifests itself through vacuum Rabi oscillations, where photons are emitted and reabsorbed by the molecule. The field of polaritonic chemistry is devoted to looking at how such coupling can be used to control chemical reactions[3].

In order to fully understand and exploit any of these phenomena, a rigorous understanding of the quantum behaviour of polaritons and their interaction with quantum emitters is necessary. For it to be complete, such understanding must include the effects of material dispersion and losses, which are of particular importance for metallic systems. Much work has been already devoted to this problem. The case of non-dispersive resonators has been comprehensively treated using normal modes expansion[4]. For uniform media, nor-

mal wave expansion provides a useful tool for quantising dispersive[5][6] and dispersive, lossy media[7]. For the non-uniform case an approach based on Green's functions has been developed[8][9][10]. Here, we describe a new way of quantising electromagnetic fields in the presence of dispersive, lossless dielectric resonators, based on the normal mode expansion.

II. Model

We consider an arbitrarily shaped, uniform, dielectric resonator surrounded by vacuum. Since it is convenient to work with a closed system, we introduce a perfectly conducting boundary around the resonator, not touching it at any point, whose size is eventually taken to be infinite. The dielectric material is described by the Hopfield model[5][6], as a continuous medium, with a single, isotropic, harmonic oscillator residing at each point. The oscillators are coupled to the electromagnetic fields through dipole moments proportional to their displacements. The resulting medium is linear, isotropic, dispersive and lossless. Its dispersion relation is shown on 2. The Lagrangian is a sum of three parts, describing the inside of the dielectric, the surrounding region of vacuum, and the interface between the two. It is given by:

$$\begin{aligned} L = \int_{\mathcal{V}_1} d^3\mathbf{r} \Bigg(\underbrace{\frac{\varepsilon_0}{2}\mathbf{E}^{(1)^2} - \frac{1}{2\mu_0}\mathbf{B}^{(1)^2}}_{\text{EM field}} + \underbrace{\frac{\rho}{2}\left(\partial_t \mathbf{X}\right)^2 - \frac{\rho\omega_{\text{res}}^2}{2}\mathbf{X}^2}_{\text{dielectric}} - \underbrace{\alpha\left(\mathbf{A}^{(1)}\cdot\partial_t\mathbf{X} + U^{(1)}\nabla\cdot\mathbf{X}\right)}_{\text{dielectric–EM coupling}} \Bigg) + \\ + \underbrace{\int_{\mathcal{V}_2} d^3\mathbf{r}\left(\frac{\varepsilon_0}{2}\mathbf{E}^{(2)^2} - \frac{1}{2\mu_0}\mathbf{B}^{(2)^2}\right)}_{\text{EM field}} + \underbrace{\oint_{\mathcal{S}} d^2S\,\alpha U^{(1)}\mathbf{n}\cdot\mathbf{X}}_{\text{dielectric–EM coupling}}, \end{aligned} \tag{1}$$

where $\mathbf{X}$ is a field describing the displacements of the medium oscillators, ρ is their mass density and α is a coupling constant. Through a suitable choice of gauge, the system can be separated into two decoupled parts, one interacting with the vector potential, and the other with the scalar potential.

III. Quantisation

The first step of the quantisation procedure is finding the normal modes of the system. These polariton modes comprise both an electromagnetic and material component. They are described either in terms of the electric field and the matter displacement field, as solutions to the following eigenvalue problem:

$$\begin{cases} \left(\frac{\mu_0\alpha^2}{\rho} + \nabla\times\nabla\times\right)\tilde{\mathbf{E}}^{(1)} + \mu_0\alpha\omega_X^2\tilde{\mathbf{X}} = k^2\tilde{\mathbf{E}}^{(1)} \\ \frac{\alpha}{c^2\rho}\tilde{\mathbf{E}}^{(1)} + \frac{\omega_X^2}{c^2}\tilde{\mathbf{X}} = k^2\tilde{\mathbf{X}} \end{cases} \\ \nabla\times\nabla\times\tilde{\mathbf{E}}^{(2)} = k^2\tilde{\mathbf{E}}^{(2)}, \tag{2}$$

or, alternatively, in terms of vector potential and matter momentum density field, with the eigenvalue problem taking the form:

$$\begin{cases} \left(\frac{\mu_0\alpha^2}{\rho} + \nabla\times\nabla\times\right)\tilde{\mathbf{A}}^{(1)} + \frac{\mu_0\alpha}{\rho}\tilde{\mathbf{P}} = k^2\tilde{\mathbf{A}}^{(1)} \\ \frac{\alpha\omega_X^2}{c^2}\tilde{\mathbf{A}}^{(1)} + \frac{\omega_X^2}{c^2}\tilde{\mathbf{P}} = k^2\tilde{\mathbf{P}} \end{cases} \\ \nabla\times\nabla\times\tilde{\mathbf{A}}^{(2)} = k^2\tilde{\mathbf{A}}^{(2)}. \tag{3}$$

The solutions, corresponding to different frequencies (eigenvalues), are orthogonal in the following sense:

$$\int_{V_1} d^3\mathbf{r}\left(\tilde{\mathbf{E}}_1^{(1)^*}\cdot\tilde{\mathbf{E}}_2^{(1)} + \frac{\rho\omega_X^2}{\varepsilon_0}\tilde{\mathbf{X}}_1{}^*\cdot\tilde{\mathbf{X}}_2\right) + \\ + \int_{V_2} d^3\mathbf{r}\,\tilde{\mathbf{E}}_1^{(2)^*}\cdot\tilde{\mathbf{E}}_2^{(2)} = 0, \tag{4}$$

$$\int_{V_1} d^3\mathbf{r}\left(\tilde{\mathbf{A}}_1^{(1)^*}\cdot\tilde{\mathbf{A}}_2^{(1)} + \frac{1}{\varepsilon_0\rho\omega_X^2}\tilde{\mathbf{P}}_1{}^*\cdot\tilde{\mathbf{P}}_2\right) + \\ + \int_{V_2} d^3\mathbf{r}\,\tilde{\mathbf{A}}_1^{(2)^*}\cdot\tilde{\mathbf{A}}_2^{(2)} = 0. \tag{5}$$

We can expand the fields in terms of both sets of modes. By substituting those expansions into the Hamiltonian and using the orthogonality relations, we can express the Hamiltonian, as that of a collection of uncoupled harmonic oscillators:

$$\hat{H} = \sum_{k\xi}\hbar ck\left(\hat{a}_{k\xi}^\dagger\hat{a}_{k\xi} + \frac{1}{2}\right). \tag{6}$$

Imposing the usual commutation relations on the creation and annihilation operators for these oscillators concludes the quantisation procedure.

IV. Conclusion

We have developed a new approach to quantising polaritons for lossless, dispersive resonators, based on the normal mode expansion of the fields. This method is akin to that already established for the non-dispersive case. It provides a new perspective on macroscopic electrodynamics, distinct to that offered by the Green's function method.

***Abstract*— The sensitive detection of chiral molecules is essential in biochemistry. We present a framework for understanding both optical rotation and circular dichroism in dielectric waveguides coated with chiral molecules. Our approach incorporates the Pasteur parameter into a mode solver to predict an effective index splitting explained by mode coupling theory.**

***Keywords*— circular dichroism, optical rotation, integrated photonics, waveguides.**

I. Introduction

Chiral light–matter interactions play a central role in optical spectroscopy and sensing, as many biomolecules and chemical compounds exhibit handedness-dependent responses. Enhancing the interaction between guided electromagnetic modes and chiral materials is therefore of considerable interest for integrated photonic sensing platforms. Dielectric waveguides provide a controlled environment in which light can interact with nanoscale analytes over extended propagation distances, offering a promising route toward compact and sensitive chiral detection [1-2].

Here, we provide a theoretical framework for predicting both optical rotation and circular dichroism induced by a chiral analyte, incorporated either as a coating or within the core of a cylindrical dielectric waveguide, for sensing applications.

II. Results and Discussion

We employ finite-element simulations to analyze core–shell waveguides with varying diameters and refractive indices. By adding the Pasteur (or chirality) parameter [3-4] to a mode solver, we compute the resulting splitting in the complex effective index of the fundamental guided modes for different Pasteur parameters for both circular polarizations. This effective index splitting directly quantifies the induced optical rotation and circular dichroism, thereby linking the modal

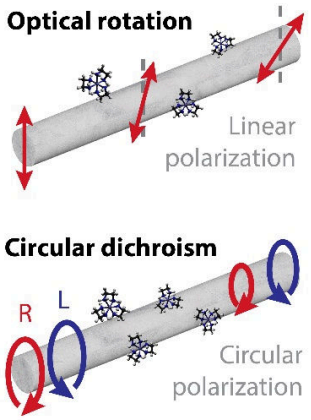

Fig. 1 Chiral sensing modalities for dielectric cylindrical waveguides covered by chiral molecules.

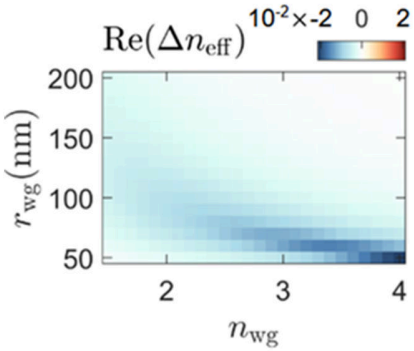

Fig. 2 Optical rotation along dielectric waveguides of different radius and refractive index shown as a difference in effective index for both circular polarizations.

properties to experimentally accessible quantities.

The goal is to determine the waveguide configuration most strongly influenced by material chirality. In our analysis, we identify clear trends in waveguide radius and refractive index contrast, and relate them to the underlying chiral coupling coefficients and chirality-induced mode interactions. In particular, high-index, small-radius waveguides exhibit enhanced sensitivity to nanoscale chiral inclusions. Both configurations—analyte confined to the core and analyte forming a surrounding shell—are examined and compared.

To validate the two-dimensional mode-solver model and account for finite propagation effects, we additionally perform full three-dimensional simulations. By calculating the associated optical rotation and circular dichroism, we can directly compare these results with the effective index splitting predictions of the two-dimensional model.

III. Conclusion

Our combined analysis clarifies the role of material chirality in mode dispersion and coupling, and provides design guidelines for dielectric waveguides optimized for integrated chiral sensing applications.

***Abstract*— Multilayer metamaterial, consisting of periodic Babinet-complementary miniarray patterns in convex-concave-convex layers, was subject of parametric studies, by varying the configuration and topological parameters to achieve better Faraday-isolator properties. Wavelength dependent azimuthal orientation uncovers trade-off between nonreciprocal rotation and asymmetric transmission. Appropriate combination of crucial topological properties results in improvement.**

***Keywords*— metamaterials, topology, isolator, Faraday-rotation**

I. Introduction

Crescent-shaped metal nanostructures can support plasmonic resonances, with high localized fields around the sharp tips [1]. Designing periodic patterns of these nanostructures capable of resulting in metamaterials, with unique optical response. Bianisotropic nonreciprocal metamaterials enable to achieve unidirectional propagation, which is a result of magnetoelectric coupling [2]. Using ferromagnetic materials, the strength of the magnetoelectric coupling, as well as the asymmetric transmission can be significantly increased [3]. Modifying the topological properties of periodic patterns opens novel avenues in light-matter interaction, e.g. photonic topological insulators can be created [4]. Our previous studies on multilayers of convex and concave Babinet complementary patterns proved that negative index of refraction, asymmetric transmission and nonreciprocal rotation can be also achieved [5, 6].

II. Methods

Illuminating the tri-layer with linearly polarized light in plane of azimuthal orientation (γ=90°-α, measured from y-axis) in forward propagation direction, the orientation (β) and ellipticity (τ) of polarization ellipses were determined at the transmission side. In backward propagation direction, wavelength dependent azimuthal orientation was used, meeting the condition $\alpha_{backward}(\lambda) := \beta_{forward}(\lambda)$. The sum of forward and backward polarization rotations was determined for each inspected wavelength, which is the so called cumulative rotation (∑), along with the difference of forward incoming and backward outgoing orientations.

Our goal was for the cumulative rotation to be as close to 90° as possible, to fulfill conditions of a Generalized Faraday Rotator (GFR). In both propagation directions, orthogonal (co- & cross-polarized) transmission components were determined in bases corresponding to the incoming azimuthal orientations. Furthermore, the backward transmission components were also calculated in the corresponding forward coordinate-system. Different kind of asymmetrical transmissions were defined: $AT_{co}^{balanced}$ in order to map the transmission contrast of the structures in mixed bases, and $AT_{co}^{differential}$ to describe a Generalized Faraday Isolator (GFI) capability in the forward bases. Moreover, two figures of merits, GFR-FOM & GFI-FOM, were constructed as indicators of a GFR and GFI capabilities, incorporating $AT_{co}^{balanced}$ & $AT_{co}^{differential}$, respectively.

III. Results and Discussion

γ(λ) configurations

We examined the previously optimized tri-layer constructed with periodic patterns of Babinet complementary miniarrays for different incoming azimuthal orientations in [92°, 96°] interval, around the γ_{GFR} = 95.23°. In backward propagation direction, the azimuthal orientation of incoming linearly polarized light is strongly wavelength dependent in a narrow band, which is inherited from the polarization of beam outgoing in forward propagation direction.

As can be seen in the graphs for the entire inspected spectrum [600 nm, 800 nm], a cumulative rotation of around 90° is achievable only in a small spectral range. In the corresponding wavelength range a noticeable $AT_{co}^{balanced}$ peak is observable. Therefore, more detailed studies were performed with a wavelength step of 0.1 nm in this range [636 nm, 639 nm].

From these high resolution studies, it can be concluded that the optimal wavelengths of asymmetrical transmissions (both $AT_{co}^{balanced}$ and $AT_{co}^{differential}$) and ∑ are nearly identical, as both AT spectra reach their maximal value at 637.8 nm, while the ∑ approaches the 90° asymptote at 637.7 nm. Therefore, a well-defined peak is observable in GFR-FOM and GFI-FOM at this wavelength.

Considering these optimal wavelengths, increasing the azimuthal orientation from 92° to 93°, both AT maxima gradually decrease, while the ∑ better approximates 90°, though the forward ellipticity increases towards 45°. Between 93.5° and 94.5°, AT and forward ellipticity values are significantly smaller, while ∑ deviates more pronouncedly from 90°. Increasing the azimuthal orientation further from 95° to 96°, AT maxima begin increasing again, while the forward ellipticity decreases from 45°, however the ∑ moves away from 90°.

The symmetry with respect to the 94° azimuthal orientation is clearly visible in asymmetrical transmission as well as in forward rotation, forward and backward ellipticity and relative orientation spectra. For 0°≤x≤2° interval around this turning azimuthal orientation, both AT curves corresponding to 94°-x and 94°+x azimuthal orientations are mostly overlapping, while the corresponding forward rotation, forward and backward ellipticity curves are axial reflections of each other for the 0° line as axis of symmetry, as well as the relative orientation for the 90° value.

Although the aforementioned pairs of azimuthal orientations exhibit very similar $AT_{co}^{differential}$ maxima, considering cumulative rotations corresponding to azimuthal orientations in [95°, 96°] are slightly closer to 90° than for azimuthal orientations in [92°, 93°], the former are the optimal azimuthal orientations for achieving Generalized Faraday Isolation around 637.8 nm. However, as has been already established, forward ellipticity is large in this case, indicating a compromised performance. If we consider GFI-FOM, which also includes ellipticity, γ=96° azimuthal orientation seems to be even better at 638.9 nm, where both the forward and backward ellipticity are smaller than 2°, although $AT_{co}^{differential}$ is one-third of the maximum value, and ∑ is 5° away from 90°.

Combination of crucial topological properties

Based on the conclusions of parametric γ(λ) configuration studies on (i) a previously optimized tri-layer, the azimuthal orientation of 95.23° was selected for inspecting the impact of topological changes on the optical responses. Introducing certain novel DOFs, such as (ii) horizontal hexagonal nanocrescent-array orientation, were found favorable in AT and Σ, as well as GFR-FOM and GFI-FOM, therefore it was inherited in all inspected multilayers. Some DOFs have shown potential to construct a metamaterial outperforming the original structure in various measures. However, none was suitable for optimizing all measures simultaneously. Among the inspected multilayers (iii) tri-layer is that best meets the GFR criterion and results in the largest GFR-FOM and GFI-FOM, in which all nanocrescents were at an equal distance of 94.5 nm from the central nanoring.

Another topological property of the hexagonal miniarray, which was found to be the most promising in AT improvement at the expense of smaller Σ is a (iv) specific nanocrescent orientation of 65°, corresponding to **E**-field oscillation along the tips. Two tri-layers were created by introducing dimerization on triangular sub-lattices, (v) nanocrescent orientation of 65° without air, and (vi) with air filling in the holes of the concave layer.

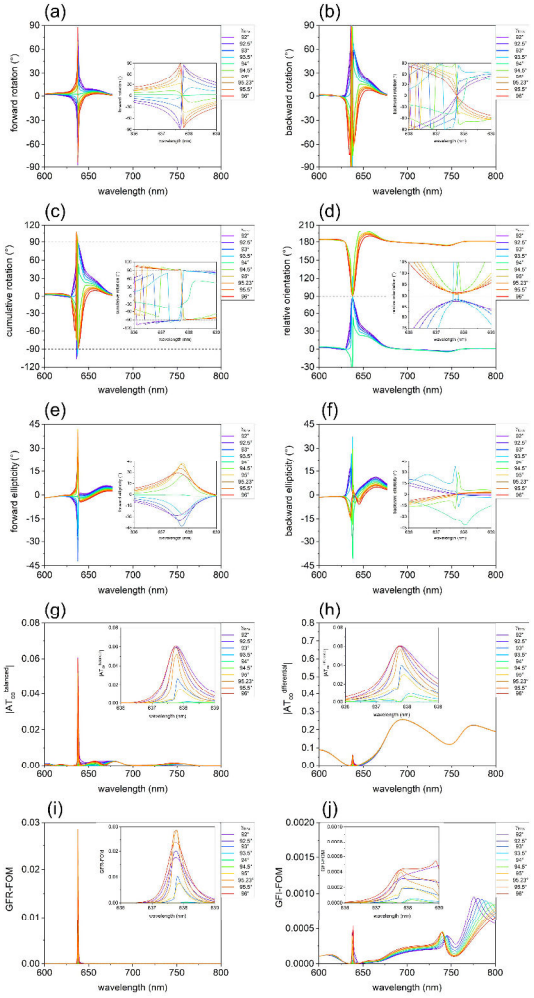

Fig. 1. Original structure. Polarization rotation for (a) forward and (b) backward propagation direction, (c) cumulative rotation (Σ), (d) difference of forward incoming and backward outgoing orientations, ellipticity in (e) forward and (f) backward propagation direction, (g) $AT_{co}^{balanced}$, (h) $AT_{co}^{differential}$, (i) GFR-FOM, (j) GFI-FOM.

However, these TRI-dimers were also compromised both in AT and Σ, though the ellipticity was small in forward /backward direction in (vi)/(v). Therefore, (vii) the elliptical deformation of the nanoring was realized, while keeping its circumference unchanged; which was combined with TRI-dimerization and air filling of the holes of the concave layer. The tri-layer (iv) and (vii) increased $AT_{co}^{balanced}$ and $AT_{co}^{differential}$ significantly, the latter (vii) served as the base of further studies due to its exceptional $AT_{co}^{differential}$ value.

In the following iterations, the advantageous topological properties of previously studied tri-layers were synthesized, namely the quadrumer was horizontal with a radius of 94.5 nm, while the nanoring was elliptical and the nanocrescent's orientation was always at 65°.

Iteration (1) created with elliptical nanoring deformation proved to be promising, despite the simple composition. In iteration (2) the parameters of the elliptical deformation of the nanoring were changed, while in iteration (3) TRI dimerization was introduced as well.

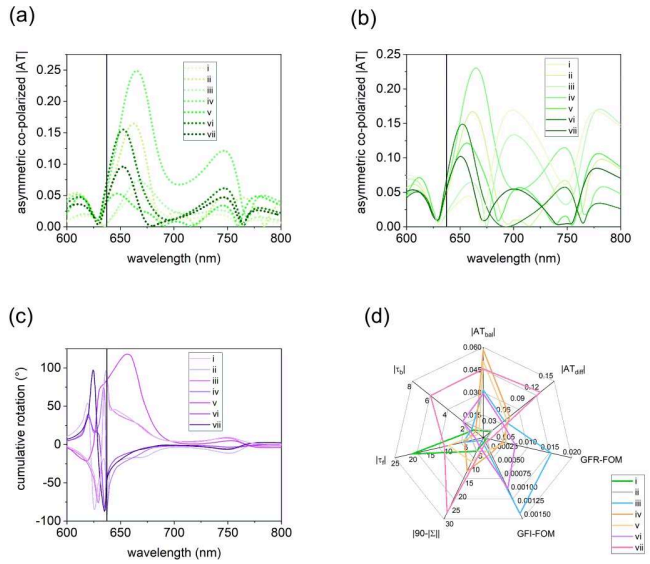

Fig. 2. Systems with parametric changes of topology compared to the originally optimized structure. (a) $AT_{co}^{balanced}$, (b) $AT_{co}^{differential}$, (c) cumulative rotation (Σ), (d) radar graph including $AT_{co}^{balanced}$, $AT_{co}^{differential}$, GFR-FOM, GFI-FOM, |90-|Σ|| and ellipticity in forward- and backward propagation direction.

Based on observations – to be elaborated on below – iteration (4-6) inherited the elliptical nanoring from iteration (1); in addition, in iteration (4) TRI dimerization was likewise for iteration (3); in iteration (5 and 6) air filling in the holes of the concave layer was realized; moreover in iteration (6) TRI dimerization was also inherited from iteration (3 and 4).

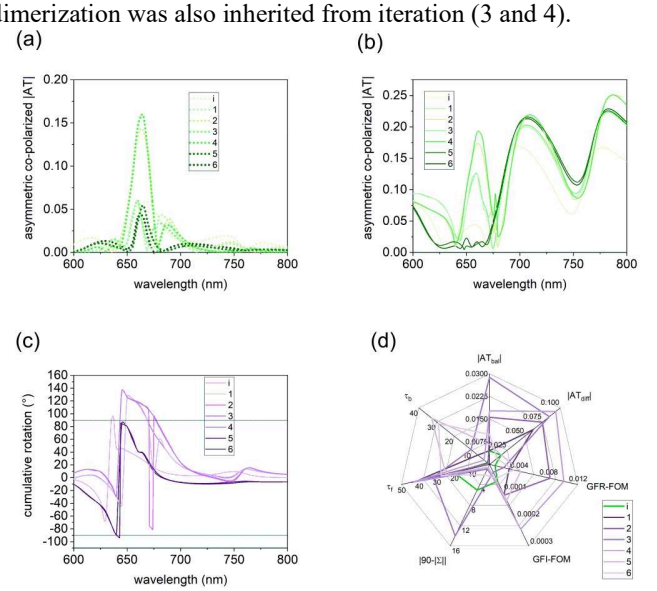

Fig. 3. Combined iterations. (a) $AT_{co}^{balanced}$, (b) $AT_{co}^{differential}$, (c) cumulative rotation (Σ), (d) radar graph including $AT_{co}^{balanced}$, $AT_{co}^{differential}$, GFR-FOM, GFI-FOM, |90-|Σ|| and ellipticity in forward- and backward propagation direction.

At 677 nm iteration (1) can produce the largest $AT_{co}^{differential}$, while having the 3rd best Σ value as well as the best GFR-FOM and GFI-FOM values. This confirms that (1) is the optimal system in all measures considered among the synthesized systems.

The wavelength corresponding to a cumulative rotation of 90° overlaps with an $AT_{co}^{differential}$ peak in this synthesized system, indicating that with topology variation it is possible to approximate 90° with good AT. Using specific elliptic deformation of the nanoring in iterations of (2/3) was particularly /reasonably efficient for achieving Σ~90°, although resulted in significantly larger τ_b values, than other compositions. Iteration (4) is only favorable concerning τ_b, the Σ in iteration (4) takes on the 90° value at a local maximum of $AT_{co}^{differential}$, similar to (1). Despite possessing the largest $AT_{co}^{balanced}$ value, iteration (5) rotates far beyond the desired Σ range, making it less favorable. After comparing the results of iterations (4 - to 5 and 6), air filling in the holes of the concave layer was considered to be disadvantageous based on FOMs. Considering (3 and 6) iterations are not the best in any quantity, conducting further research on these systems is not proposed.

IV. Conclusion

From the γ(λ) dependent studies, one can conclude that with a small change in the azimuthal orientation and wavelength, namely selecting 96° and 637.8 nm – instead of those from previous GFR optimization, – the cumulative rotation better approximates 90°, while the asymmetrical transmissions can further increase. Therefore, GFR and GFI-FOM values improve, despite the larger forward ellipticity. The main advantage of iterations (1&4) compared to the originally optimized structure is that their cumulative rotations not only approximate, but take on the 90° value in monotonously varying cumulative rotation inside a band, where larger $AT_{co}^{differential}$ values can be reached. However, the iterations exhibit larger ellipticity at their respective optimal wavelengths.

***Abstract*— We realized a 1D coupled nanolaser chain enabling topologically protected bright zero modes. Our design exploits coupling sign inversion through photonic crystal barrier engineering. We present the design parameters, numerical simulation results, and preliminary experimental results from the first fabricated structures.**

***Keywords*— topological photonics; nanolasers; photonic crystals.**

I. Introduction

Topological photonics is a rapidly expanding field of research [1]. By combining light states within materials (bulk) and at interfaces (boundaries), it aims to create photonic modes that become robust against fabrication imperfections and mitigate the intrinsic limitations of classical systems. In particular, active systems based on coupled micro- or nanolasers can produce robust laser states, which falls within the research domain of topological lasers [2-3] (Fig. 1a-b).

However, these systems face several challenges that make their practical use difficult. Notably, the so-called zero modes protected by symmetry or by the topology of the lattice, are located at the center of photonic bandgaps and feature out-of-phase oscillation (dark modes) [4]. Consequently, their free-space radiation efficiency is very low and they are typically confined at boundaries (edge-states, Fig. 1d).

In this work we develop a new type of topological laser based on a 1D chain of coupled nanolasers in a photonic crystal (PhC), offering solutions to these issues. Specifically, in this work we have realized a Su-Schrieffer-Heeger (SSH) chain [5] based on a PhC geometry (Fig. 1c). Although similar PhC realizations have already been reported [6], our strategy relies on a unique property of our platform: the sign inversion of evanescent coupling between two adjacent coupled nanolasers [7] (see yellow regions in Fig. 1c). In addition, spatial distributions of gain produced by spatial light modulators (SLMs) enable localized sublattice pumping, and therefore selective lasing zero mode excitation [8-9]. Furthermore, the interplay between localized pumping and engineered coupling might enable bulk zero modes in future realizations [10].

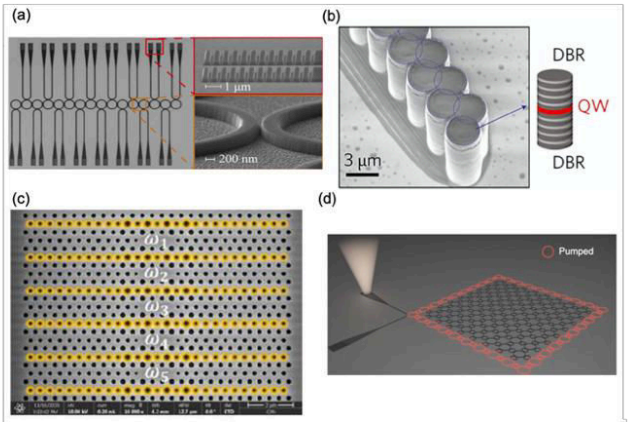

Fig 1: Topological laser arrays. a) Coupled microrings; b) coupled micropillars; c) coupled photonic crystal nanlasers, where regions in yellow highlight the photonic barriers (this work); d) topological edge mode.

II. Nanophotonic design and numerical simulations

We performed numerical simulations to design coupled nanolaser arrays in III-V semiconductor photonic crystals, specifically InP slabs with embedded InGaAsP quantum wells. Our model system is a SSH chain with N=9–10 coupled cavities, exploiting the coupling sign-inversion technique enabled by our photonic crystal platform [7]. This approach allows us to engineer in-phase topological zero modes that become bright, in contrast to conventional out-of-phase edge-localized modes.

Our simulations included: i) Electromagnetic modeling of the photonic crystal cavities to optimize resonance frequencies, mode overlap, and coupling strengths, by means of the Guided Mode Expansion (GME) method; ii) Coupled-cavity Maxwell-Bloch equations, as a nonlinear model for coupled lasers to predict mode dynamics, including gain saturation, and refractive index nonlinearities. We observe lasing zero modes

take a form of localized modes inside the band gaps of the 1D cavity chain, and are protected by either chiral symmetry in the case of N=9 cavities, or by topology in the case of N=10 cavity chains.

Preliminary simulation results confirm that topological lasing zero modes can be robustly excited utilizing localized pumping in one of the sublattices (Fig. 2a-c). Furthermore, by reverting the coupling sign every two sites, the zero modes become bright, in the sense that nanocavity field emission in one sublattice becomes phase locked (Fig. 1c).

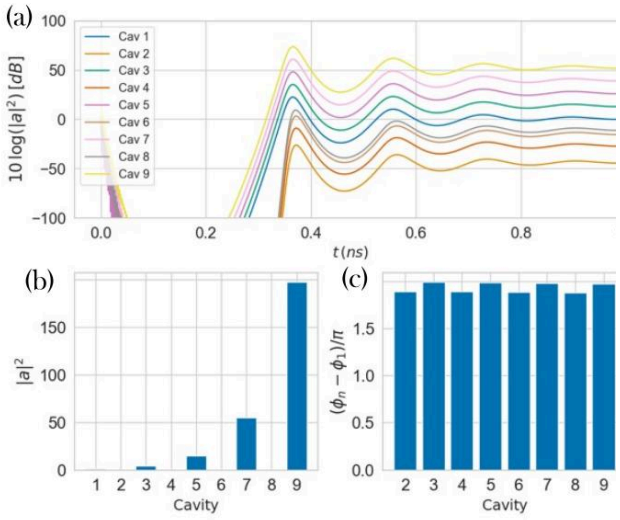

Fig 2: a) time trace of a numerical simulation of coupled Maxwell-Bloch equations under adiabatic elimination of the polarization (class-B lasers), and sublattice pumping in odd cavities ($|a|^2$ is photon number). Parameters are: gain linewidth Γ =1 THz, bare cavity linewidth Γ_{cav} =140.4 GHz, detuning between electronic band-gap and optical resonance δ =3 THz, light-matter coupling parameter g=13.6 GHz, cavity coupling parameters $\kappa_{odd\text{-}even}$= -28 Γ_{cav} and $\kappa_{even\text{-}odd}$ =15 Γ_{cav}, population inversion at lasing threshold ΔN_{th} = 7532, odd-cavity sublattice pumping ΔN_0 = 0.2 ΔN_{th}; b) cavity intensities at steady state, showing that the lasing mode is an edge mode; c) phase difference at steady state, showing that cavity fields in the pumped sublattice are phase locked.

III. Nanofabrication

We have fabricated photonic crystal nanolaser chains with inverted couplings on a suspended InP membrane containing quantum wells, with N=9 and N=10 coupled PhC L3 cavities. The fabrication process includes bonding the active layers onto Si substrates via BCB, electron-beam lithography, ICP etching, and ALD encapsulation. Structural quality and coupling fidelity were confirmed via scanning electron microscopy (SEM).

IV. Conclusion

We have designed and fabricated 1D PhC coupled nanolaser arrays featuring SSH geometry, containing 9 and 10 coupled nanocavities. The originality of our approach is the coupling sign inversion, that enables bright zero modes, which mitigates a serious drawback of standard zero modes: the out-of-phase oscillation becomes in-phase oscillation in our system. We have observed such lasing bright zero modes in numerical simulations, and the first fabricated samples have been obtained and characterized.

I. Introduction

Quasi-bound states in the continuum (qBICs) have attracted considerable attention for a wide range of applications owing to their high quality (Q) factors and strong electric field enhancement. The resulting enhancement of light–matter interactions has become among the key subjects of interest and stimulated particular interest in sensing applications in aqueous environment. Thus far, numerous label-free sensor geometries based on qBICs have been investigated, exploiting resonance wavelength shifts induced by changes in the refractive index of the surrounding medium. In particular, symmetry breaking of symmetry-protected BICs emerging at the Γ point of the Brillouin zone offers a significant advantage for sensing, as sharp resonances can be accessed under normal-incidence excitation from free space. Conventional design strategies for such sensors aim to simultaneously achieve a high Q factor and large refractometric sensitivity [1], capturing *global* refractive index variations in the environment. However, sensors capable of detecting *local* refractive index perturbations, such as the binding of a single nanometer-sized molecule [2], remain elusive and have not yet been demonstrated in BIC metasurfaces. This is because the Q factors of qBICs are highly susceptible to fabrication imperfections, and scattering losses caused by surface roughness restrict the potential for achieving ultrahigh Q factors. To overcome this challenge, we have recently demonstrated a BIC metasurface with Q factors exceeding 100,000 using a low-contrast geometry [3]. The ultrahigh Q factors originate from the inherently high radiative Q factors of a higher-order qBIC combined with reduced scattering losses enabled by shallow-etched designs. These features suggest that low-contrast BIC metasurfaces can simultaneously provide ultrahigh Q factors and small mode volumes, making them highly sensitive to *local* refractive index perturbations.

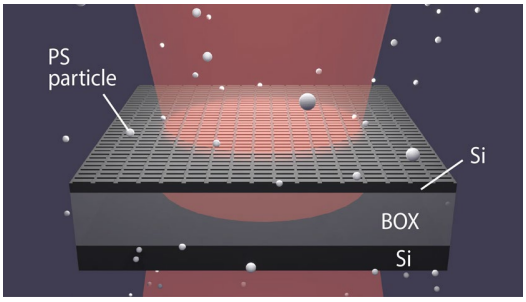

Fig. 1 Schematic illustration of single PS nanoparticle detection using a low-contrast BIC metasurface fabricated on a SOI wafer.

In this study, we demonstrate low-contrast BIC metasurfaces with the sensing resolution down to single nanoparticles. We show that the localized electric fields confined within the shallow-etched structures strongly interact with the virus-sized polystyrene (PS) particles (Fig. 1), manifesting as discrete wavelength steps.

II. Results and Discussion

The low-contrast metasurfaces were fabricated on a silicon-on-insulator (SOI) wafer with a 400-nm-thick top silicon layer. Only approximately 52 nm of the top silicon was dry-etched to form shallow pair-rod nanostructure arrays with a period P of 760 nm, as shown in Fig. 2a. Each unit cell consists of a pair of rods with lengths $L + 2\Delta L$ and $L - 2\Delta L$. The designed rod length L and the width are 640 nm and $L - P/2 = 260$ nm, respectively. By introducing this length asymmetry, the symmetry-protected BIC transforms into a qBIC with an asymmetry parameter $\alpha = 2\Delta L/L$, enabling the experimental observation of sharp qBIC resonances under normal-incidence excitation. Recently, we

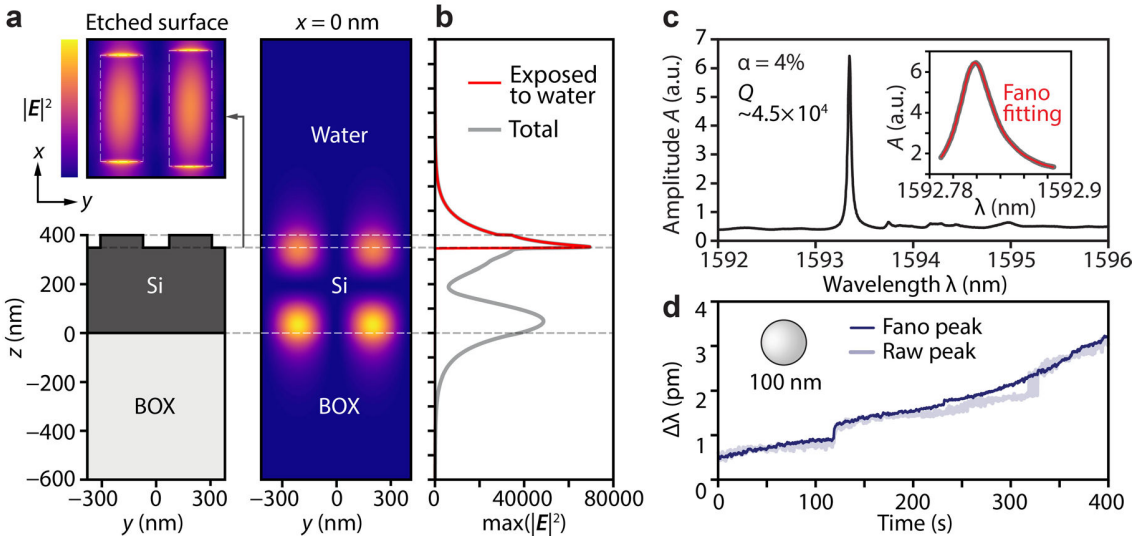

Fig. 2 (a) Cross-sectional schematic in the *yz*-plane (lower left) and simulated electric field intensity enhancement $|\boldsymbol{E}^2|$ at x = 0 nm (right), together with the field distribution in the *xy*-plane at the shallow-etched surface (upper left). (b) Maximum field intensity along the *z*-direction. (c) Representative transmittance spectrum measured in D_2O for the fabricated BIC metasurface with asymmetry parameter α = 4%. The inset shows the spectrum and its Fano fitting obtained under fine wavelength tuning using a piezo-controlled tunable laser. (d) Real-time resonance peak wavelength shift measured in a dispersion of unfunctionalized virus-sized PS particles (d = 100 nm), showing discrete wavelength steps corresponding to single nanoparticle binding events.

demonstrated that an optimal balance between a high Q factor and large resonance amplitude is achieved under the critical coupling condition, where the radiative and nonradiative Q factors are equal, thereby minimizing the impact of wavelength fluctuations [4]. In the present study, the critical coupling condition was experimentally determined to be α = 4%. Therefore, we only focus on this condition in the following discussion. As shown in the electric field distribution in the *yz*-plane (Fig. 2a), two antinodes exist along the *z*-direction, corresponding to a higher-order mode (TE_{122}) that is strongly confined within the top silicon layer and exhibits a large radiative Q factor. In the *xy*-plane at the shallow-etched surface, the electric fields are localized at the edges of both rods, which are exposed to the external medium (heavy water D_2O in our case) rather than to silicon (Fig. 2b). This field localization while keeping the Q factor is a key feature for sensing applications targeting molecular binding events. Fig. 2c shows the transmittance spectrum of the metasurface with α = 4%, measured in D_2O. The experimental Q factor was evaluated to be approximately 4.5×10^4 when a 10 Hz triangular wave piezo voltage was applied to the tunable laser (TSL210V, santec). Next, we injected unfunctionalized, virus-sized PS particles (d = 100 nm) diluted in D_2O containing 100 mM NaCl into a PDMS microfluidic channel and monitored the resonance peak wavelength shift in real-time. As shown in Fig. 2d, we observed discrete wavelength steps, as signatures of single particle binding events. This result can be attributed to the strong interaction between the localized electric field enhancement of the qBIC mode and nanoparticles occurring near the shallow-etched surface.

III. Conclusion

We have demonstrated, for the first time in BIC nanostructures, the detection of virus-sized single PS particles with a diameter of 100 nm in water using the ultrahigh-Q nature of a low-contrast geometry. This sensing capability arises from the strong interaction between the confined electric fields and nanoparticles located within the shallow-etched structures. Owing to the collective resonant behavior of relatively large-area periodic arrays, BIC metasurfaces are inherently position-insensitive and do not require precise alignment of the device. Moreover, normal-incidence excitation from free space provides direct access to sharp qBIC resonances. These advantages offer promising opportunities for simple, cost-effective, and highly sensitive detection of virions and other pathogenic nanoparticles with single nanoparticle resolution.

***Abstract*—Plasmonic nanocavities strongly couple to quantum emitters, but controlling this excitation with external illumination can be challenging. We propose a system of two couple nanocavities each hosting a single quantum emitter, to control the quantum dynamics of the system. This paves the way towards engineering quantum states in plasmonic systems.**

***Keywords*—nanoplasmonics, quantum dynamics, pulsed excitation.**

I. Introduction

Plasmonic nanocavities facilitate strong light-matter interactions due to their ability to extremely confine electromagnetic fields into subwavelength volumes. The field confinement arises from the excitation of plasmons formed by driving the free electrons of the surface of a metal with external electromagnetic fields . This phenomenon has led to several advances in spectroscopy, non-linear optics and sensing. In particular, the nanoparticle-on-mirror (NPoM) configuration formed by placing a nanoparticle above a metallic film, and separated by a dielectric spacer of just a few nanometers, has demonstrated strong coupling with a single molecule even at room temperatures [1]-[2]. It was recently shown that such nanocavities hosting multiple QEs are promising candidates to generate subradiant entangled states at ambient conditions, and the high radiative and Ohmic plasmonic losses in these systems enable the generation of the entangled states [3]-[4]. However, the system needs to be suitably prepared for the entangled states to emerge, which is experimentally difficult when two or more QEs reside in the same plasmonic nanocavity due to the very close proximity of the QEs of just a few nanometers [5]. Additionally, such systems need to be externally excited to prepare them for generating subradiant states which is not understood very well.

In this work, we first study the dynamics of a QE embedded in a nanoplasmonic system, where the cavity interacts with single frequency as well as broadband pulses of various durations, strengths and temporal shapes. Ohmic and radiative losses of the plasmonic system are taken into account with the Lindblad master equation (in the Markov approximation). After identifying the conditions for ambient excitation of the QE, we design a nanoplasmonic system composed of two coupled NPoM cavities, each hosting a single QE. The two nanocavities can be separated by several μm, and coupled with each other via propagating surface plasmon polaritons (SPPs) supported on the flat metallic surface. Since the nanocavity separation is at the micrometer scale, each nanocavity can be selectively excited, therefore initializing only one QE at an excited state as desired.

II. Methods

We start with a single mode plasmonic nanocavity hosting a quantum emitter in its nanogap. A schematic of the system is shown in Fig.1(a) which consists of a spherical gold nanoparticle with radii $R = 40$ nm and facet width $f_d = 16.6$ nm assembled on a gold mirror. The nanoparticle and the mirror are separated by a dielectric spacer of refractive index $n = 2.5$ and thickness $t = 1$ nm. The resonances of this plasmonic system are described by complex frequencies found using QNMEig method with COMSOL Multiphysics. $\tilde{\omega_\xi} = \omega_\xi - i\Gamma_\xi$. When the nanocavity is illuminated with an external pulse, the Hamiltonian of the system in a frame co-rotating with the pulse frequency ω_p is given by

$$\mathcal{H}_S = \Delta_c a^\dagger a + \frac{\Delta_d}{2}\sigma_z + g_\xi(r)(a\sigma_+ + a^\dagger\sigma_-) + \alpha(t)(a^\dagger + a) \quad (1)$$

$a(a^\dagger)$ is the annihilation (creation) operator for the plasmonic nanocavity. The QE is treated as a two-level system with resonant frequency ω_d obeying $[\sigma_-, \sigma_+] = 1$. $\Delta_c = \omega_\xi - \omega_p$ and $\Delta_d = \omega_d - \omega_p$ are the detunings of the nanocavity and the QE from the center frequency of the pulse. The coupling strength of the QE to mode ξ is given by: $g_\xi(r) = \sqrt{\omega_\xi/2\epsilon_0\epsilon V}\boldsymbol{\mu}.\mathbf{E}_\xi(r)$ and depends on the dipole moment of the QE: $\boldsymbol{\mu}$, the electric field eigenvector of the cavity mode at the location of the QE: $\mathbf{E}(r)$ and the mode volume of the cavity: V.

The pulse amplitude $\alpha(t) = \alpha_0 f(t)$, where α_0 is the maximum strength of the pulse and $f(t)$ is proportional to the pulse envelope. We use an open quantum system formalism to account accurately for the Ohmic and radiative loss channels present in the plasmonic system. Here, the density matrix ρ is described by a Lindblad master equation:

$$\frac{d\rho(t)}{dt} = -i[\mathcal{H}_S, \rho] + \sum_\xi \frac{\Gamma_\xi}{2}(2a_\xi\rho a_\xi^\dagger - a_\xi^\dagger a_\xi\rho - \rho a_\xi^\dagger a_\xi)$$

Fig.1(d) shows the time evolution of the QE population as the central pulse frequency ω_p is varied, which shows two peaks at $\omega_p = \omega_c \pm g_\xi$ corresponding to the vacuum Rabi splitting for the upper and lower polariton states $0, \pm$. The vacuum Rabi splitting also shows up as a mode hybridisation in the system's spectral response.

The populations of these states are explicitly plotted in Fig.1(c) for the cases when the pump is resonant with the upper and lower polaritons, respectively. To further populate the polariton states, we have to keep the pulse frequency resonant with either of them and increase the pump strength. The pulse amplitude α_0 and envelope $f(t)$ can be engineered to determine the final state of the system. When the drive is sufficiently weak and resonant with either polariton, the dynamics is restricted to a single excitation subspace given by $\{n,+,n,-,g,0\}$. The transition between the the upper polariton and the ground state of the system is described by the matrix element $\langle 0,+|\alpha(t)(\hat{a}^\dagger+\hat{a})|0,g\rangle = \langle 0,-|\alpha(t)(\hat{a}^\dagger+\hat{a})|0,g\rangle = \frac{\alpha(t)}{\sqrt{2}}$. Therefore, for a rectangular pulse as shown in Fig.1(e), when $\sqrt{2}\alpha_0 \int_0^T f(t)dt = (2n+1)\pi$ the conditions for a π pulse is fulfilled. As the pump strength is increased, higher photon transitions become more probable and the system can no longer be limited to the one excitation basis states. Fig.1(e) and (f) show the population dynamics with the plasmonic losses included.

The new plasmonic system is shown in Fig.2(a) and consists of two spherical gold nanoparticles assembled on a gold mirror. The nanoparticles and the mirror are separated by a dielectric spacer of refractive index $n = 2.5$ and thickness $t =$ 1 nm. The modes follow spherical harmonics nomenclature wherein each mode is labeled with (l, m) where $l = 0, 1, 2, 3...$ is the number of nodes and antinodes along the radial direction and $m = (-l, l)$ is the number of nodal lines intersecting at the poles [6][]. We also find that the propagating SPPs launched by each nanocavity interfere with each other either constructively or destructively, depending on the separation between the two nanocavities, leading to a "bonding mode" (denoted by +), and an "anti-bonding" mode, (denoted by -) for each (l, m) mode as shown in Fig.2(a). These bonding and anti-bonding modes emerge due to the coupling between the two nanocavities that leads to hybridized states. Fig.2(c) shows that the frequency splitting between the bonding and anti-bonding modes depends on the separation distance between the nanocavities and is also proportional to the propagating SPP field overlap from each nanocavity, demonstrating the destructive and constructive interferences.

We then obtain the quantum dynamics of this plasmonic system, where each nanocavity hosts one QE.

$$\begin{aligned}\mathcal{H}_S^{(2)} &= \sum_\xi \omega_\xi a_\xi^\dagger a_\xi + \sum_i \frac{1}{2}\omega_d^{(i)}\sigma_z^{(i)} \\ &\quad + \sum_{\xi,i} g_\xi(r^{(i)})\left(a_\xi^\dagger \sigma_-^{(i)} + a_\xi \sigma_+^{(i)}\right) \qquad (2)\end{aligned}$$

III. Results and Discussion

We have investigated the driven quantum dynamics of a quantum emitter strongly coupled to a plasmonic nanocavity, with particular emphasis on how tailored pulses can be used to control polaritonic states in the presence of plasmonic losses. Using a Jaynes–Cummings description combined with a Lindblad master equation, we analyzed the population dynamics under various pulse shapes accounting for both coherent light–matter coupling and dissipative processes intrinsic to plasmonic systems.

Fig. 1. (a) Schematic of the plasmonic system with external illumination having temporal profile $\alpha(t)$ (b)Population of QE in nanogap as a function of pulse detuning and time for a square pulse of duration 0.52 ps. (c) Quantum dynamics of the system when pump is resonant with the upper and lower polaritons.Population evolution of QE when nanocavity is illuminated with a square pulse of duration for varying pump strengths

Fig. 2. (a) Schematic of the system: excitation of SPP waves on a gold film by two gold nanoparticles, each hosting a QE. (b) Magnitude of electric field $\mathbf{E}_z(x, y, z = 0)$ in the x-y plane of the nanogap for d = 120 nm. (c) Frequency splitting between the bonding and anti-bonding modes is proportional to the overlap integral of the $\mathbf{E}_z$ component of the electric fields. (d) Population of QE_2 as a function of time and d.

The quantum dynamics of the coupled system show damped oscillations in the populations of the plasmonic modes and the QEs due to the presence of losses in the system with rates Γ_ξ and Γ_{vib} as shown in Fig.2(d). The oscillatory behavior in the time domain indicates that our plasmonic-QE system is well into the strong-coupling regime. We then excite the

first nanocavity with a Gauss-6 laser pulse and show the population of QE_2 as a function of time and separation between the nanocavities (Fig.2(d)). The population closely follows the variation seen in the different SPP interaction regimes, implying that the system dynamics is dependent on whether the second nanocavity is positioned at a maxima or minima of the electric field overlap. We further report on how one can customize the external pulsed excitation of the two nanocavities to engineer long-lived entangled states.

IV. Conclusion

We show that the two plasmonic nanocavities are coupled to each other even if they are separated by several μm from each other, due to the long range of propagating SPPs. We show that the interaction between the two nanocavities leads to "bonding" and "anti-bonding" modes that emerge from constructive and destructive interaction between the two nanocavities. This coupling between the two nanocavities directly impacts the quantum dynamics of the system, while the configuration of the system allows us to separately excite each NPoM nanocavity, paving the way for the generation of subradiant entanglement and the engineering of quantum states with nanoplasmonics at room temperature.

***Abstract*— Time variation is a powerful degree of freedom that enables encoding, separation, and recognition of signals beyond what static scatterers can provide. A practical route to time-varying scattering is rotation. Rotating objects play a central role in radar signal analysis because rotor blades generate the micro-Doppler effect, which is widely used for target classification and is especially relevant for monitoring small drones. Here, we introduce a new approach in which rotor blades are tagged with engineered metamaterial scatterers that exhibit a strongly angle-dependent radar cross section. When driven in rotation, these resonant tags produce a large, deliberately shaped micro-Doppler signature, thereby increasing drone visibility and detectability to an interrogating radar. Beyond this immediate application, the same platform serves as a testbed for challenging classical scattering bounds through inverse design. We use multi-objective optimization and meta-learning strategies that operate under experimental constraints and jointly optimize the scattering cross-section, bandwidth, and operational angles, despite the inherent trade-offs among these parameters. We experimentally demonstrate advanced scattering performance in the laboratory and validate it in outdoor drone experiments.**

***Keywords*— Metamaterials, Time-varying metamaterials, Superscatterers, Radars, Wireless Communications.**

I. Introduction

The presentation is based on our recent work [1-8] and on a large set of unpublished data (several manuscripts under review). Furthermore, we will present a range of experimental findings obtained using outdoor radar. These experiments involve detecting airborne targets (small drones) equipped with our superscattering devices, which significantly enhance their visibility, making them highly detectable and thus facilitating surveillance and monitoring tasks.

Electromagnetic scattering on subwavelength structures has long been a subject of extensive investigation owing to both fundamental challenges and practical rewards associated with its maximization or suppression. Interaction with compact structures is well approximated by a multipole series, with lower orders typically sufficient for convergence. The maximal possible scattering into a single multipole is called a channel limit. In a vast majority of cases, a dipolar single channel limit (the maximal scattering cross-section, which a small resonant lossless dipole can approach) is considered. In this case, $3\lambda^2/(2\pi)$, where λ is a free space wavelength, is the value, versus which all the assessments will be made hereafter. Compact subwavelength structures that bypass the single-channel limit are called super-scatterers. While there is no fundamental upper bound on a scattering cross section, several theoretical limits, including the Cho-Harrington limit, which is the most used, have been proposed to account for practical considerations. Bypassing those limits requires accommodating several resonant multipoles that constructively interfere at nearly the same frequency. In this case, a significant near-field accumulation in the vicinity of lossy materials, accompanied by an extremely low fabrication tolerance, is the main known factor limiting the practical demonstration of super-scatterers. Nevertheless, several promising designs have been demonstrated over the last few years and will be reviewed hereinafter. Regardless of their particular realization, they all share the same design principles. The first one is the choice of a material platform. Since high near-field accumulation necessarily implies having high Ohmic losses, constitutive components should be carefully chosen. The second criterion is the capability to perform extensive electromagnetic optimization. In compact structures, internal resonances tend to repel one another, opening frequency gaps. To bypass those design challenges, optimization efforts are needed.

II. SUPERSCATTERING FOR TAGGING

We will present several conceptually distinct strategies for designing and experimentally demonstrating superscattering. Novel and conceptually different architectures will also be demonstrated at the conference. As a practical application, the emerging challenge of air traffic control is addressed. The rapid growth in drone air traffic calls for enhanced radar surveillance systems to ensure reliable detection in challenging conditions. Increasing the scattering cross-section, essential for radar visibility, can greatly improve detection reliability in civilian applications. Here, we introduce the concept of genetically designed metamaterials, specifically engineered to enhance scattering for end-fire incidence. Multi-layer stacks of arrays, encompassing strongly coupled electric and magnetic resonators, demonstrate broadband scattering exceeding 1 m^2 at 10 GHz, despite having an end-fire physical cross-section smaller than one squared wavelength. Despite its compact footprint, the structure achieves over 10% fractional bandwidth, meeting radar requirements where high-range resolution is essential. While the scattering cross-section and bandwidth are typically contradictory in resonant structures, this contradiction is circumvented by applying the resonance cascading principle, in which a series of closely spaced, spectrally aligned resonant multipoles creates a coherent response. The resonance

cascading is engineered using multi-objective optimization, implemented on top of a genetic algorithm operating in a large search space encompassing more than 100 independent variables. The experimentally realized parameters of the compact structure align with the typical scattering cross-sections observed in large airborne targets. Consequently, these performance characteristics enable the exploration of highly scattering structures as identifiers for small airborne targets, supporting effective radar-based air traffic monitoring in civilian applications. We demonstrate the worthiness of this objective through a series of outdoor experiments using the DJI Mini 2 drone. Lightweight, conformal add-ons with substantially high scattering cross-sections can serve as auxiliary tools to enhance passive monitoring systems, adding an additional layer of security in urban airspace.

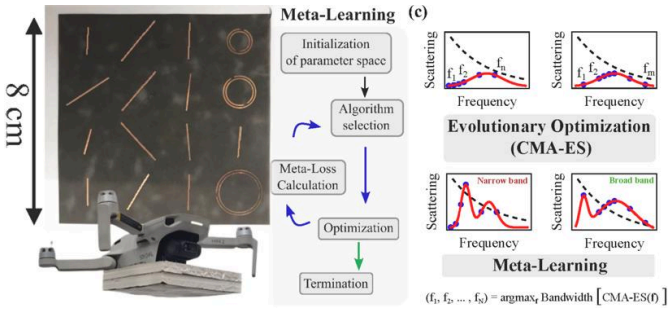

Fig. 1. Superscatterer: our state-of-the-art realization, an ML-based optimization algorithm to break through the Cho-Harrington limit, and the practical realization of a drone tagged with a superscatterer.

III. MICRO-DOPPLER TAGGING

We further extend the ideas of superscattering to rotor blade tagging toward micro-Doppler coding, where the blade rotation serves as a built-in time-varying encoder, and the metamaterial tag becomes an information-bearing scatterer. In this scheme, each blade is assigned a fixed index, and the presence or absence of a resonant sticker on that blade defines a binary state, so a multiblade platform naturally maps onto an 8-bit code word, for example, 11001010, with each bit set by whether the corresponding blade carries a tag. The coded signature arises from the strong angular dependence of the tag response and the time-dependent polarization mismatch between the resonant dipole axis and the incident field, which modulates the scattered signal during rotation and produces a structured micro-Doppler pattern that is much more pronounced than the native return from polymer blades. In practice, not every nominal code is uniquely observable because the radar typically lacks sufficient resolution to separate individual rotors in range and angular bins, and additional redundancies arise from platform symmetries and from different operational behavior of forward and rear blades, so the usable code space must be filtered by identifiability under realistic measurement constraints. To ensure robust decoding under noise and flight variability, the coded spectrograms are treated as inputs to a learning pipeline that includes convolutional neural network classification together with post-processing that quantifies code reliability as a function of signal-to-noise ratio, and dimensionality reduction tools such as PCA and UMAP that visualize code clustering and separation, guiding the selection of codes for outdoor validation. Overall, the approach converts small drones from weak, ambiguous micro-Doppler targets into strongly scattering, uniquely labeled objects, supporting stand-off detection and identification at kilometer-scale ranges, and providing a practical pathway to deployable, low-cost blade retrofits compatible with rapid transfer to industrial radar monitoring systems.

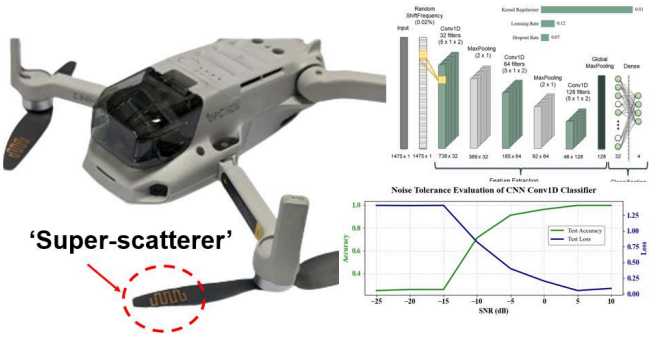

Fig. 2. Photograph of a tagged drone alongside a CNN-based radar processing layout and its performance, demonstrating reliable long-range detection below the noise level and exceeding conventional limits in radar monitoring.

IV. CONCLUSION

Beyond drone monitoring applications, the rotor blade platform provides a fundamental platform for studying rotating metamaterials as mechanically time-varying scatterers. Rotation converts a subwavelength resonator into a periodic spatiotemporal boundary condition, enabling controlled frequency mixing and engineered micro-Doppler spectra without active electronics, bias networks, or high-speed modulators. This framework connects classical micro-Doppler physics with modern metasurface and superscattering design, offering an experimentally accessible setting to explore how angular dispersion, modal interference, and optimization-driven geometry tailoring shape time domain scattering signatures. As a result, rotating metamaterials emerge as a general concept for low complexity spatiotemporal modulation, with applications spanning cooperative radar tags, reconfigurable beacons, and new measurement protocols for probing scattering bounds in dynamic electromagnetic systems.

Metallic Nanohelices as Chiral Metasurfaces & Applications in Chiral Sensing

Thu Hac Huong Le
National Institute of Advanced Industrial Science and Technology (AIST), Japan
*Corresponding author: thu.le@aist.go.jp

***Abstract*— This study presents a wafer-scale self-assembly approach for the fabrication of metallic helices by engineering the residual stresses and gradient strains in thin films, which induce spontaneous folding and twisting. The resulting nanohelices, with submicrometer radii, exhibit pronounced chiroptical responses in the infrared regime, enabling practical applications in chiroptical spectroscopies.**

***Keywords*— nanohelices, chiral metasurfaces, chiral sensing, vibrational circular dichroism.**

I. Introduction

Chiral metasurfaces have emerged as promising platforms for enhancing chiroptical activity in spectroscopic and chiral chemistry applications. Recent theoretical and experimental studies have demonstrated that the chiroptical signals of chiral molecules can be significantly amplified through coupling with chiral metastructures. Among the various chiral architectures reported to date, helical structures are particularly attractive owing to their intrinsic optical chirality arising from their geometrical configuration.[1, 2] Their chirality enables strong light–matter interactions, making them especially suitable for applications such as chiral sensing and stereochemical reactions. However, despite their considerable potential, the fabrication and optical characterization of metallic helices remain relatively underexplored, primarily due to substantial technical challenges, including the tradeoff between precise structural control and scalable, efficient processing.

In this study, we present a self-assembly fabrication technique for nanohelices that offers precise feature control, wafer-scale production capability, and broad material compatibility. Our method involves the single-step transformation of metallic strips composed of multilayered thin films into helical geometries once released from the substrate. This transformation is driven by the nanoscale control of the residual stresses and gradient strains within the thin films, which spontaneously generate the necessary forces for folding and twisting. This technique facilitates the efficient fabrication of centimeter-scale samples, allowing for chiroptical characterization using standard commercial spectrometers. Experimental measurements and numerical simulations confirm strong chiroptical responses in the infrared (IR) region for helices with radii on the order of hundreds of nanometers.

II. Methods

The fabrication process begins with the preparation of micrometer-scale strips of multilayered metallic thin films on a Si substrate, using ultraviolet (UV) lithography, electron-beam evaporation, and lift-off techniques. The substrate is then coated with the electron-beam lithography (EBL) resist, and uniform nanoscale line-and-space patterns are written at a specific angle θ relative to the strip's axis. After development, selective wet etching is performed to partially remove the top metal layer. Upon removal of the EBL resist, microstrips with nanogroove patterns are formed. The substrate then undergoes isotropic reactive ion etching to eliminate the underlying silicon. As the Si beneath the strips is fully removed, the strips detach from the substrate. Residual stresses in the nanogrooves create a periodic strain gradient, causing the strips to fold and twist spontaneously into nanohelices.

III. Results and Discussion

Figure 1(a-b) shows the scanning electron microscope (SEM) images of nanohelices aligned in parallel to the Si substrate, fabricated from aluminum (Al)/titanium (Ti)/aluminum (Al) and gold (Au)/nickel (Ni)/aluminum (Al) trilayer films, respectively. The fabricated helices exhibit diameters ranging from approximately 800 nm to several micrometers, demonstrating the tunability of the structural dimensions achieved by this approach.

Based on the helical geometry, the pitch P between adjacent rings is related to radius R of helix by

$$P = \frac{2\pi R}{\tan\theta} \quad (1) \text{ and}$$

$$R \approx \frac{l}{|\alpha|} \quad (2);$$

where l is the periodicity of the nanogroove patterns and α is the folding angle induced at each nanogroove. These relationships indicate that structural parameters such as R and P can be precisely tuned by adjusting the nanogroove periodicity l, the folding angle α, and the alignment angle θ of the groove patterns. A key advancement of this technique is its ability to achieve wafer-scale fabrication within a relatively

short processing time. The realization of cm^2-sized samples has enabled the characterization of the chiroptical properties of metallic helices using standard spectrometers, eliminating the need for previously required microscope-based setups.

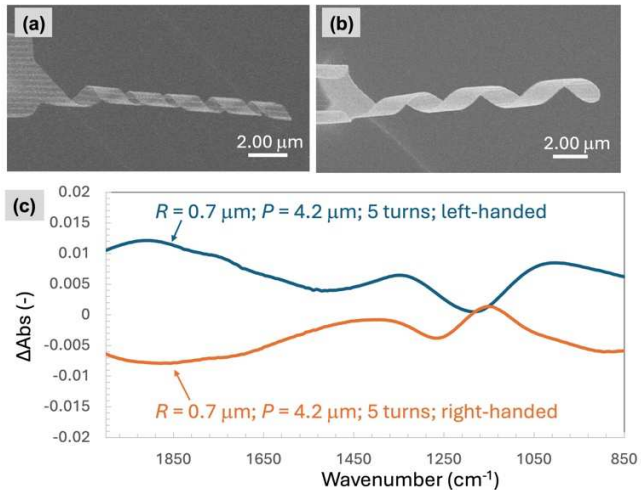

Fig. 1. SEM images of helices fabricated from (a) Al/Ti/Al and (b) Ni/Au/Al thin films, (c) IR-CD spectra of pairs of helices

To verify the chiral responses of the fabricated helices, we measured the extinction spectrum differences for incident circularly polarized light of opposite handedness in the IR range of 850 – 2000 cm^{-1}, using a standard Fourier transform-based IR circular dichroism (IR-CD) spectrometer. The resulting IR-CD spectra, shown in Fig. 1(c) for two Al helices with opposite handedness, reveal distinct circular dichroism (CD) peaks and dips at identical frequencies. The right- and left-handed structures exhibit opposite signs with nearly equal amplitudes, demonstrating the mirror-symmetric behavior characteristic of chiral systems. This can be attributed to the chiral eigenmodes arising from their intrinsic geometry.

The fabricated metallic nanohelices exhibit strong chiroptical responses in the infrared (IR) spectral range of 850–2000 cm^{-1}, which overlaps with the vibrational bands of many molecular functional groups. This spectral overlap makes the nanohelices particularly suitable for applications in chiroptical spectroscopy and chiral molecular sensing. Numerical simulations indicate the formation of a strongly enhanced chiral near field accumulated within the core of the helices, resulting in a high optical chirality density. This chiral near field gives rise to enantioselective interactions with nearby chiral molecules. To experimentally verify this effect, two samples consisting of geometrically identical nanohelices with opposite handedness (left- and right-handed) were uniformly coated with a thin layer of *L*-alanine molecules via thermal evaporation. Infrared transmission spectra were subsequently measured for both samples. The differential transmission spectrum between the left- and right-handed samples, shown in Fig. 2, exhibits a pronounced transmittance difference, including distinct peaks corresponding to the vibrational functional groups of alanine, despite identical molecular coverage on both samples. These observations confirm that chiral molecules interact differently with nanohelices of opposite handedness. Moreover, the results indicate that the nanohelices enable the simultaneous detection of molecular vibrational fingerprints and molecular chirality, providing information analogous to that obtained from vibrational circular dichroism (VCD) spectroscopy. Notably, this approach offer the VCD measurement through a single transmission measurement with enhanced sensitivity, in contrast to conventional techniques, which require complex experimental configurations and typically suffer from limited sensitivity and signal-to-noise ratios.

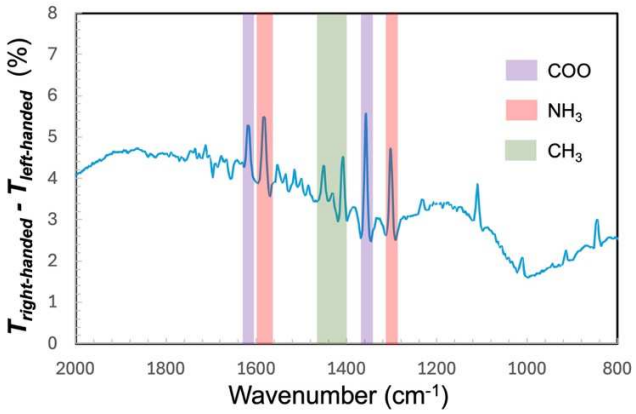

Fig. 2. Differential IR transmittance spectrum of *L*-alanine films covered on left- and right-handed helices revealing the VCD signals

IV. Conclusion

In summary, we have developed a robust and scalable approach for fabricating submicrometer metallic helices by engineering the stress and strain in metallic thin films. The wafer-scale realization of helical structures, together with tunable geometrical parameters and controllable optical responses, establishes this platform as a versatile and transformative chiral metasurface. Furthermore, we experimentally demonstrate the capability of these helices to perform the measurements of vibrational circular dichroism of chiral molecules. The developed metallic nanohelices therefore hold significant promise for practical applications in photonics, chiroptical spectroscopy, and stereochemistry, including chiral sensing, infrared inspection, stereochemical characterization, and enantioselective chemical reactions.

***Abstract*—We numerically and experimentally study a photonic multilayer with SSH geometry supporting localized edge states. Comparison between two structures with identical periodicity but different topological phases show edge states only in the nontrivial phase. An absorber layer confirms the mode is confined to the surface rather than the bulk.**

***Keywords*—surface states, light localization, 1D photonic crystals, topological photonics, SSH, electric field enhancement**

I. INTRODUCTION

Surface states in periodic structures are of great interest in physics and photonics due to their ability to confine light at interfaces, enabling applications in sensing, lasing, and photonic devices. In recent decades, topological photonics has emerged as a promising field to achieve strong edge states that are robust against defects and disorder [1,2].

For one-dimensional (1D) topological systems, the most representative model is the Su-Schrieffer-Heeger (SSH) model [3]. It describes a periodic 1D chain with alternating weak and strong couplings between neighboring atoms. Depending on how the edge of a semi-infinite structure is truncated, two phases arise: topologically trivial and non-trivial. At the interface between different topological phases, a robust edge state is generated [1]. This model has been applied to photonic structures such as waveguides [4,5], ring resonators and nanoantenna arrays [6,7]. While numerical demonstrations exist for multilayer 1D photonic crystals [8], very few experimental demonstrations have been done so far.

In this work, we numerically and experimentally implement the SSH model in a 1D photonic crystal by fabricating two structures with identical periodicity but different edge truncations: structure A with a non-trivial phase, and structure B with a trivial phase.

II. DESIGN

The proposed structures consist of alternating layers of SiO_2 and Ta_2O_5, as schematically shown in Figure 1. The SSH geometry is introduced by alternating thin and thick SiO_2 layers, corresponding to strong and weak bonds (t and t'), respectively. Structure A has four periods and ends on a weak bond (t'), while Structure B includes two extra layers, ending on a strong bond (t). As air has a trivial phase, we expect only Structure A to support a topological edge mode at the surface.

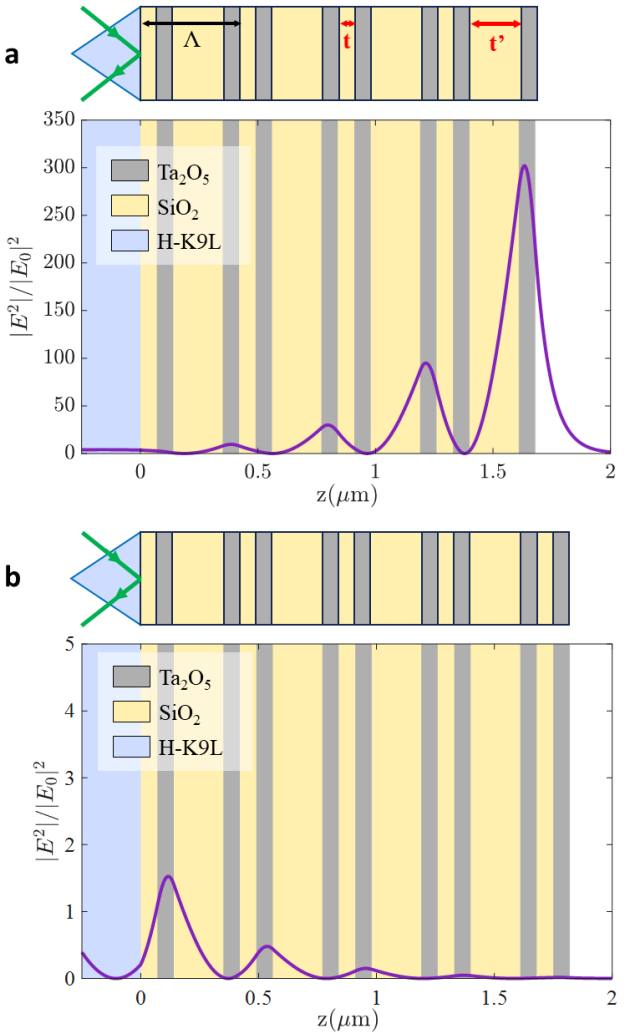

Fig. 2 **(a)** Type A and **(b)** Type B structures. **(Top of subfigures)** Simplified structure scheme (not real scale) of the structures with period Λ, surface termination bond is located at the right end. t corresponds to strong bond, t' to weak bond. **(Bottom of subfigures)** Simulations of the TE electric field intensity distribution normalized to the amplitude of the incident wave at 800nm for Type A structure and Type B structure at angle 68º.

In order to excite and detect the surface modes the multilayers were built on a prism, as seen in the schematics in fig. 1, with the experimental Kretschmann configuration, most known for detection of surface plasmon waves in metals but also used for Bloch surface waves detection in multilayers [9]. Light incident on the prism undergoes total internal reflection, generating an evanescent field that penetrates the multilayer. When angle and wavelength match the surface mode condition, energy couples into the mode. The coupling will lead to a decrease (dip) in the reflected intensity, facilitating the detection of the mode.

Transfer Matrix Method has been used to numerically calculate the electric field intensity distribution on the structures. Simulations in Fig. 1 show that at 800 nm and TE polarization, Structure A exhibits a highly localized surface state with a 300-fold field enhancement, while Structure B does not.

III. Results and Discussion

We measure the reflection spectra of both structures and we find that Structure A shows a resonance in reflection near 800 nm (precisely, at 798 nm) when the surface mode couples, while Structure B exhibits total reflection. To confirm the resonance originates from the surface rather than guided modes inside the multilayer, we coat the surface of the samples with a very narrow layer of absorbing dye. The absorption within the dye enhances the resonance without altering the mode, proving its surface nature. Figure 2 summarizes our experimental results: for the same angle of incidence, structure A without the absorber layer (blue plot) and with the absorber (yellow plot) present a resonance at the same wavelength, but we can clearly see that the presence of the absorber improves the resonance depth. For Structure B (orange plot), even with the absorber, no resonance appears, confirming that truncation determines the presence of the edge state.

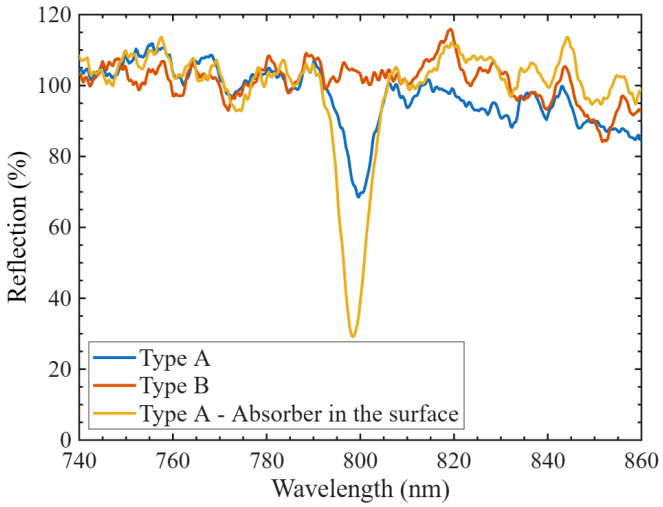

Fig. 2 Experimentally measured reflection spectrum of structure A for angle of incidence 67.9° without (blue line) and with (yellow line) the absorber layer on top and of structure B (orange line).

IV. Conclusion

In conclusion, we have constructed two multilayer structures following the SSH geometry and demonstrated, numerically and experimentally, that the choice of the end truncation at the edge of the structure defines whether a topological surface state emerges. Using the Kretschmann configuration and absorber coating, we verified that the detected mode is indeed a surface state, not an internal guided mode. This work provides an experimental pathway for implementing topological photonic concepts in 1D photonic crystals. Furthermore, the topological surface state exhibits large field enhancement at the interface, which in turn strengthens light–matter interactions in its vicinity. Such enhanced field localization makes these structures promising platforms for sensing technologies, where strong surface fields can boost sensitivity to refractive-index changes or molecular absorption.

***Abstract*— Amorphous Rh–Se mesoporous nanospheres synthesized via micellar self-assembly enable semiconducting SERS substrates with tunable composition, curvature, and amorphization, achieving sensitive detection of hexachlorobenzene and Teflon microplastics through electronic modulation, challenging high-surface-area paradigms and guiding design of advanced metal–selenium sensing materials for catalysis and electronics applications beyond conventional semiconductors worldwide.**

***Keywords*— Mesoporous metals; Amorphous alloys; Surface-enhanced Raman scattering; Chemical enhancement mechanism; Persistent organic pollutants**

I. Introduction

Amorphous materials provide unique advantages for catalysis and sensing because of their isotropic structure, high density of defect sites, and tunable electronic properties. However, producing amorphous nanostructures based on noble metals remains challenging due to their tendency to crystallize. Metal–selenium alloys provide a promising route to stabilize amorphous phases while introducing semiconducting behavior.

Surface-enhanced Raman spectroscopy (SERS) traditionally relies on plasmonic metals where electromagnetic enhancement dominates. Semiconductor SERS, in contrast, depends mainly on chemical enhancement via charge transfer between substrate and analyte. Despite progress, semiconductor substrates struggle to detect non-absorbing and weakly polarizable molecules because of limited adsorption and inefficient electronic coupling.

Here we demonstrate that combining amorphization with nanoscale curvature engineering in mesoporous Rh–Se nanospheres allows efficient detection of persistent pollutants such as hexachlorobenzene (HCB) and polytetrafluoroethylene (PTFE) microplastics. The results challenge the prevailing assumption that high surface area is the dominant factor in SERS performance and instead reveal electronic structure control as the key parameter.

II. Methods

Amorphous Rh–Se mesoporous nanospheres were synthesized using a one-step micellar self-assembly reduction approach. Diblock copolymers served as dynamic templates, enabling control over pore size and curvature. By varying polymer molecular weight, three curvature regimes were obtained corresponding to small, medium, and large pores.

Compositional control was achieved by tuning Rh/Se precursor ratios. Post-synthesis annealing under inert atmosphere allowed systematic control of crystallinity.

Structural characterization was conducted using SEM, TEM, XRD, XPS, BET surface analysis, and X-ray absorption spectroscopy. Surface electronic properties including work function and valence-band features were measured using Kelvin probe force microscopy and XPS.

SERS measurements were performed with 532 nm excitation after premixing substrates with analytes. Detection limits and enhancement factors were determined through calibration measurements. Adsorption and charge-transfer mechanisms were further examined using molecular dynamics and density functional theory simulation.

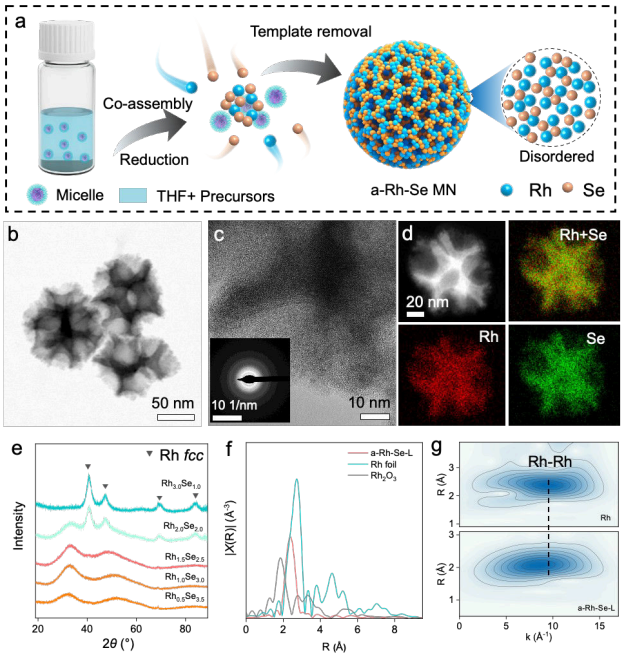

Figure 1. Schematic of material synthesis and characterization of a-Rh–Se-L MNs.

III. Results and Discussion

Curvature Engineering and Electronic Effects

Although higher curvature structures exhibit larger surface area, SERS experiments revealed that low-curvature mesostructures produce significantly stronger Raman enhancement. Surprisingly, the substrate with the lowest surface area delivered the highest enhancement factor.

Electronic measurements revealed that decreasing curvature shifts the d-band center closer to the Fermi level while reducing the work function. These changes promote efficient electron injection and improve orbital alignment between substrate and analyte, thereby enhancing chemical SERS mechanisms.

Thus, electronic structure modulation dominates over surface-area effects in determining SERS activity.

Role of Amorphization

Thermal annealing progressively transformed amorphous Rh –Se into crystalline phases. Increasing crystallinity caused strong reduction of SERS performance, confirming that amorphous disorder is critical for charge transfer.

Simulations showed that highly disordered structures provide stronger adsorption pockets and enhanced charge transfer to adsorbed molecules. Disorder-induced states facilitate carrier excitation and enable efficient photoinduced charge transfer under laser excitation.

Detection of Persistent Pollutants

The optimized amorphous low-curvature Rh–Se substrates enabled detection of HCB down to nanomolar concentrations with stable response across complex wastewater matrices. Signal reproducibility remained high over months of storage.

The platform also enabled quantitative detection of PTFE microplastics, which typically cannot be measured by conventional SERS due to low polarizability and poor adsorption. Compared to Au nanoparticles, Rh–Se substrates produced stronger and more uniform signals, indicating superior particle–substrate affinity.

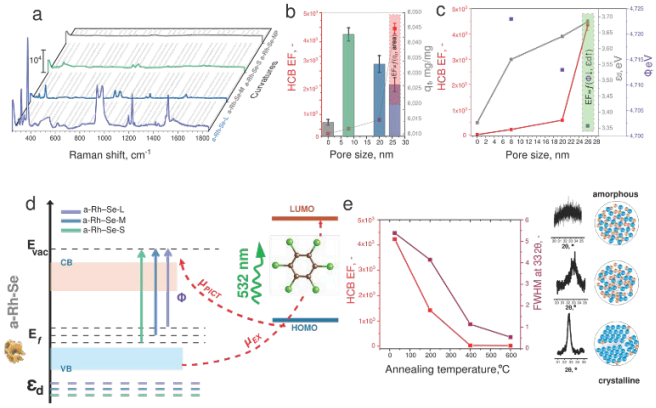

Figure 2. Probing SERS sensing of HCB on a-Rh-Se-S/M/L with different curvature degree.

D. Mechanistic Implications

Charge transfer processes contributing to enhancement include ground-state orbital hybridization, photoinduced electron transfer, and intramolecular excitation of adsorbed molecules. Amorphization and curvature jointly tune work function and electronic density of states, enabling resonant charge mobility and strong chemical enhancement.

Overall, the results overturn conventional SERS design strategies centered on maximizing surface area or electromagnetic hotspots.

IV. Conclusion

We developed amorphous mesoporous Rh–Se semiconductors with tunable curvature and crystallinity enabling efficient SERS detection of chemically resistant pollutants. Reduced curvature and enhanced amorphization modulate electronic descriptors, promoting charge transfer and chemical enhancement.

This strategy extends semiconductor SERS toward practical environmental sensing applications and provides design guidelines for future semiconductor-based SERS materials

High-performance Wide-angle Metalens for Optical Receiver

Wei-Hsiang Lai[1,*] and Pin Chieh Wu[1]

[1]Department of Photonics, National Cheng Kung University, Tainan 70101, Taiwan
*Corresponding author: a0905919411@gmail.com

***Abstract*—In this work, we present a 940nm metalens designed for integration with CCDs, enabling a significant reduction in system volume. The proposed metalens features a wide field of view of 93° while maintaining high modulation transfer function (MTF) performance. This ultra-compact solution enhances light collection efficiency for near-infrared optical receivers.**

***Keywords*— metalens, metasurface optics, optical receiver, wide-angel optics, ray-tracing and wave optics co-design.**

I. Introduction

Recently, the rapid development of optical sensing and communication systems has driven a strong demand for compact and highly integrated optical receivers. For these systems, achieving high optical collection efficiency over a wide field of view (FoV) is a critical requirement. However, conventional refractive or diffractive optical components often suffer from bulky form factors, limited FoV, and increased aberrations under large-angle incidence, which significantly constrain system-level integration and performance.

Metasurface lens (Metalens) provides a promising solution to overcome these limitations by enabling subwavelength wavefront manipulation within an ultrathin platform. Through spatially engineered phase responses, metalenses can achieve compact focusing functionalities that are difficult to realize with traditional optics. In particular, metalenses designed for a single operating wavelength offer enhanced flexibility in phase control, making them attractive candidates for wide-angle optical reception while maintaining high numerical aperture (NA). Nevertheless, realizing a wide-angle metalens at 940 nm that meets the practical requirements of optical receiver applications remains challenging, especially when off-axis performance and system-level efficiency must be simultaneously considered.

In this work, we present a wide-angle metalens operating at 940 nm, specifically optimized for optical receiver applications [1][2]. Our design framework integrates ray-tracing analysis with wave-optics-based metasurface modeling, allowing both geometric light collection behavior and electromagnetic wave effects to be consistently accounted for during the optimization process. Ray-tracing is employed to define the target phase profiles and evaluate angular response at the system level, while full-wave simulations are used to refine the meta-atom geometry and ensure accurate phase and amplitude control of metalens under oblique incidence. By combining these two complementary approaches, we demonstrate a metalens design that maintains stable focusing behavior and high reception efficiency across a wide FoV. The proposed methodology highlights an effective pathway for bridging system-level optical design and nanoscale wavefront engineering, offering practical insights for next-generation near-infrared optical receiver systems.

II. Methods

To meet the significant requirements of a compact optical receiver, a top-down hybrid design strategy was employed. This process consists of two stages: macroscopic optimization based on ray-tracing analysis, followed by physical implementation using Rigorous Coupled-Wave Analysis (RCWA).

A. Macroscopic Optimization via Ray Tracing

To model the properties of the metasurface, a binary 2 phase surface was utilized. The phase profile $\varphi(r)$ is defined by a rotationally symmetric polynomial expansion:

$$\varphi(r) = \sum_{i=1}^{N} A_i \left(\frac{r}{R_{norm}}\right)^{2i} \quad (1)$$

where R_{norm} is the normalization radius, and A_i is the aspheric phase coefficients. These coefficient (A_i) was set as variables in the optimization process. A merit function was constructed to minimize the root-mean-square spot size under various conditions of incidence and wavefront error while satisfying specific optical targets.

B. Physical Realization via RCWA

Based on the ray-tracing optimization, the optimized continuous-phase profile was discretized and mapped to physical nanostructures using the RCWA method. The meta-atoms consist of symmetric square nanopillars, ensuring polarization-independent optical response, making the device suitable for unpolarized light sources commonly used in

practical applications.

III. Results and Discussion

The macroscopic performance of the designed metalens was first evaluated using ray-tracing simulations. Figure 1 illustrates the ray-tracing optimization results of the metasurface. The system is optimized for a center wavelength of 940 nm with an effective focal length (EFL) of 1.513 mm and an F-number of 1.3. As shown in the ray trajectories, the metalens effectively focuses incident light across the entire field of view. The design supports a FoV of 93°. The distinct colored rays represent different field angles, confirming that the optimized phase profile successfully suppresses off-axis aberrations and directs light onto the sensor's active area.

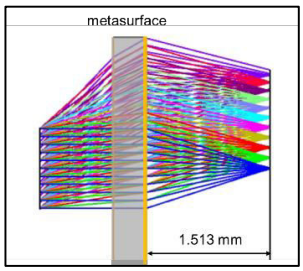

Fig. 1 optimization results of the 940-nm metalens system. The schematic shows the realized FoV of 93°, demonstrating effective focusing on the sensor plane.

Based on the ray-tracing optimization results of the metasurface, we subsequently use the RCWA method to design meta-atoms. Figure 2(a) depicts the schematic of the unit cell. The structure consists of amorphous silicon (a-Si) nanopillars on a SiO_2 substrate. Figure 2(b) shows the resulting transmittance (left) and phase shift (right) maps as functions of incident angle and width W. The transmittance map reveals that the unit cell maintains high efficiency across a broad range of widths, and the phase shift covers the full 2π range, satisfying the requirement for complete wavefront control.

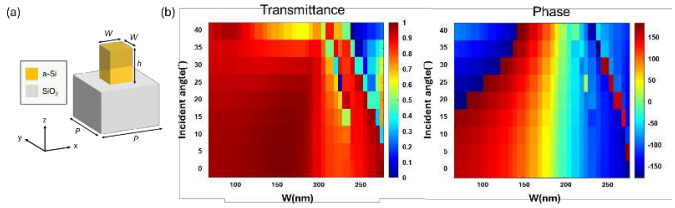

Fig. 2 (a) Schematic of the designed metasurface unit cell. The geometric parameters are defined as the lattice period P = 400 nm, pillar width W, and height h. (b) Simulation of transmittance and phase colormap of the unit cell as a function of nanopillar width W and incident angle at λ = 940 nm.

To strictly evaluate the imaging capability of the integrated metalens, we analyzed the intensity distribution and contrast transfer function at the sensor plane. Figure 3 presents the simulated focal spot intensity distributions for different incident angles. As the incident angle increases, slight coma and astigmatism develop, leading to a lateral spread of the spot profile. However, as shown in the intensity colormap, the optical energy remains highly concentrated within the central lobe. This confirms that the metalens effectively focuses light onto the active pixel area even at large field angles, ensuring sufficient signal-to-noise ratio (SNR) for optical sensor.

To further quantify the image quality, the modulation transfer function (MTF) was calculated, as shown in Fig. 4. The results demonstrate tangential and sagittal performance across the entire field of view. At a higher frequency of 100 cycles/mm, the MTF values for both on-axis and off-axis fields are maintained above 0.3. This indicates that the metalens design is successful for sensing applications.

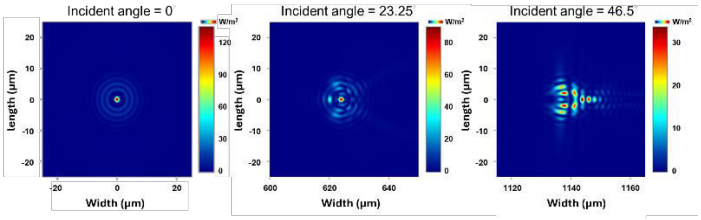

Fig. 3 Simulated point spread functions on the sensor plane for incident angles of 0°, 23.25°, and 46.5° at λ = 940 nm.

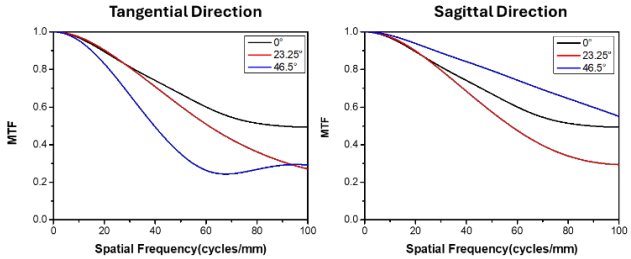

Fig. 4 Simulated MTF of the metalens for tangential and sagittal direction at λ = 940 nm, with incident angles of 0°, 23.25°, and 46.5°.

IV. Conclusion

In this work, we presented compact, high-performance metalens operating at 940 nm for optical receiver applications. By employing a hybrid design strategy combining macroscopic ray tracing with microscopic RCWA, we realized a polarization-independent device with a wide field of view (93°). The design ensures robust detection of unpolarized light with excellent focusing capabilities and superior MTF performance. Consequently, it offers a practical, scalable solution for next-generation space-constrained devices.

Structural Coloring via Hyperuniform Arrays of Tapered Si Nanostructures on Glass

Hanna Kylhammar[1, *], Mikko E. Kjellberg[1], Srinivasan Anand[1]

[1]Department of Applied Physics, KTH Royal Institute of Technology, Sweden
*Corresponding author: hannaky@kth.se

***Abstract*— High□index dielectric nanostructures provide a route to structural coloration without pigments. Here, we demonstrate color tuning in hyperuniform arrays of amorphous silicon (a□Si) nanodisks by controlling the nanodisks' sidewall angle, which results in a shift in the spectral position of the resonant scattering. Charged sphere lithography enables scalable hyperuniform pattern generation.**

***Keywords*— structural colors, all-dielectric metasurfaces, hyperuniform disorder, Mie resonators, charged sphere lithography**

Structural colors produced by dielectric nanostructures have emerged as a sustainable alternative to pigment□based coloration, which often relies on environmentally harmful chemical processes.[1] Beyond their ecological advantages, all□dielectric metasurfaces offer robust functionality for applications such as solar energy harvesting, decorative coatings, sensing, and display technologies.[2-6] Previous work has shown that tuning the size and geometry of high□index Mie resonators enables vivid colors. Beyond the size parameters, the tapering angle of nanostructures has recently been identified as a powerful degree of freedom for tailoring scattering responses in nanostructures.[7]

To translate coloured metasurface concepts into practical technologies, scalable and CMOS□compatible fabrication routes are essential. Silicon offers a low□loss, abundant, and CMOS□compatible platform, enabling scalable fabrication and seamless integration with established semiconductor processes. Here, we demonstrate structural colours generated by tapered amorphous□silicon (a-Si) nanodisks arrays on glass substrates. By systematically varying the taper angle, we demonstrate it as a parameter for colour tuning. The proposed methodology provides a scalable pathway toward high□performance dielectric colour metasurfaces.

The nanodisk arrays are fabricated using charged sphere lithography combined with reactive-ion etching. The a-Si/glass substrate is covered with a positively charged layer (PDDA). Negatively charged nanospheres are diluted in deionized water and drop-casted on the a-Si/glass substrate and bind electrostatically to the surface. Charged sphere lithography produces nearly hyperuniform disordered patterns (Fig. 1). We control the pattern density by increasing the ionicity of the charged sphere suspension.

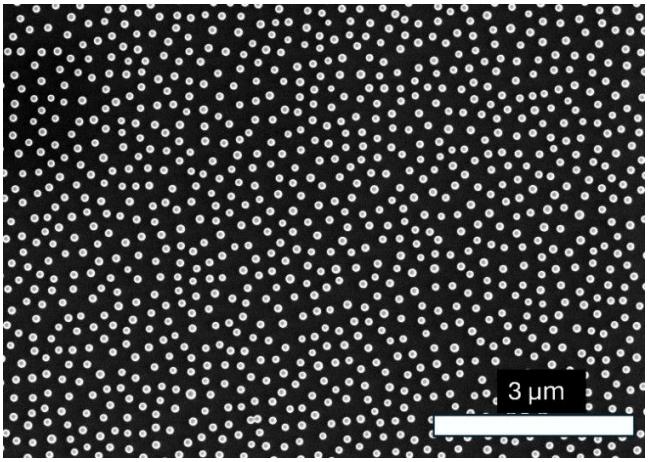

Fig. 1 SEM image of the top view of 100 nm diameter nanodisks as patterned by charged sphere lithography.

The nanostructures are etched in the a-Si are by reactive-ion etching using SF_6/C_4F_8 chemistry. Outward tapering of the structures is achieved by decreasing the gas ratio.[8] In Fig 2. the profiles of nanodisks etched with 30:80 SF_6/C4F8, with a sidewall angle of 90°, and nanodisks etched with 17:80 SF_6/C_4F_8, with a sidewall angle of 80°. We compare arrays of nanodisks of a-Si and c-Si to determine how material properties influence the fabrication of tapered nanodisks as well as the overall impact on structural color generation.

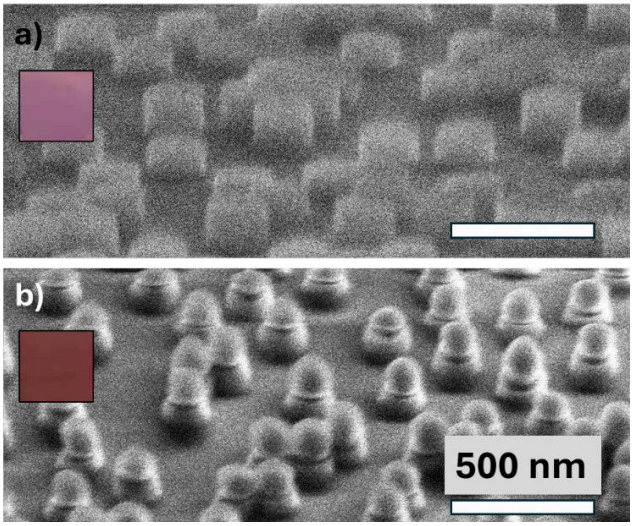

Fig. 2 SEM image of 200 nm top diameter nanodisks with a) 90° sidewall angle, etched with 30:80 SF_6/C_4F_8 and b) 80° sidewall angle, etched with 20:80 SF_6/C_4F_8. Inset are the reflected colours of the metasurfaces, photographed when placed on a black surface.

The scattering of the nanodisks is studied through finite-domain time-difference simulations and analysed by multipolar decomposition. [9,10] We show that the tapered geometry strongly influences the electric/magnetic dipole modes, shifting the spectral position of the resonant scattering which allows for continuous tuning across the visible spectrum.

Beyond the nanodisk geometry, we also investigate the impact on the colour appearance of the hyperuniform disordered arrangement. The disorder in the array results in stronger insensitivity to incident angle than for periodic arrays. The specular and diffuse reflectance and transmittance of the fabricated samples are measured.

The proposed coloured metasurfaces relies on low□cost, self□assembled patterns and that are compatible with large□area processing, opening pathways toward scalable coloration in a wide range of photonic devices.

***Abstract*— We present an analytically guided coupling engineering framework that maps coupling parameters to spectral characteristics in a resonator with a drop waveguide. By designing wavelength dependent coupling trajectories, we realize broadband uniform resonance output at the drop port and broadband critical coupling at the bus port.**

***Keywords*— Optical resonator, coupling trajectory, spectral response**

I. Introduction

Optical microring resonators are fundamental components in photonic integrated circuits because they provide compact and spectrally selective functionalities. Their performance in filtering, wavelength multiplexing, and on chip signal processing is determined by their resonance spectrum. In many practical systems, stable and predictable spectral characteristics over a broad wavelength range are required. However, spectral response exhibits strong wavelength dependence due to the dispersive coupling between the waveguides and the resonator, which leads to variations in resonance intensity, extinction ratio, and quality factor across the operating bandwidth.

In this work, we adopt a coupling centric perspective and establish an analytically guided framework that directly relates coupling parameters to spectral response. We explicitly analyze how the waveguide resonator coupling coefficients govern key spectral quantities. To extend the accessible coupling space, we consider a resonator coupled to both a bus and a drop waveguide. The presence of two independent coupling channels enables systematic exploration of a two-dimensional coupling parameter space and provides additional degrees of freedom for spectral engineering.

Within this framework, spectral design can be reformulated as trajectory engineering in the coupling parameter space. Desired spectral responses correspond to analytic conditions that define contours in this space. Broadband stabilization is achieved when the wavelength dependent evolution of the coupling parameters follows these contours. We formulate the coupling–response relation explicitly and show how target spectral characteristics can be predictively determined from analytic conditions.

II. Methods

To demonstrate the validity of the framework, we aim to realize the broadband uniform resonance output at the drop port as a first example. We first clarify the physical parameters that govern the spectral response. Figure 1a-1c present the physical model establishing the connection between the coupling parameters and spectral response. By analyzing how variations in coupling parameters influence the spectral response through the mapping, desired target response can be predictively designed from proper coupling engineering. The resonance output at the drop port is:

$$T_{drop,\max} = \frac{\alpha(1-t_1^2)(1-t_2^2)}{1+(\alpha t_1 t_2)^2 - 2\alpha t_1 t_2} \tag{1}$$

Therefore, the coupling parameter space can be directly mapped to the response. This mapping enables the derivation of the coupling trajectory which satisfies uniform resonance output at the drop port with enhanced stability of the quality factor. (Fig. 1d and Fig. 1e)

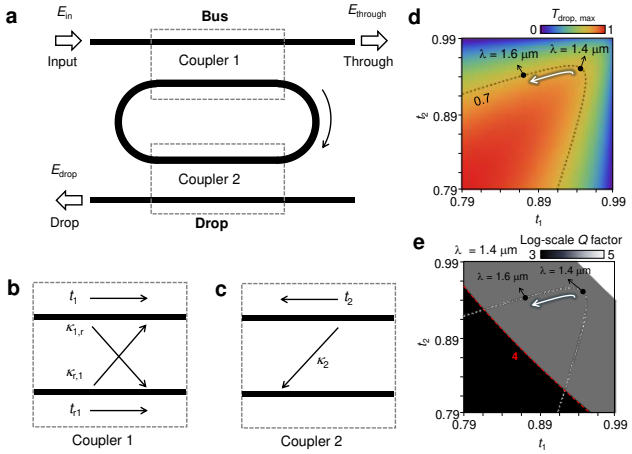

Fig. 1 Coupling system of a resonator with a drop waveguide to realize the broadband uniform resonance output at the drop port.

III. RESULTS

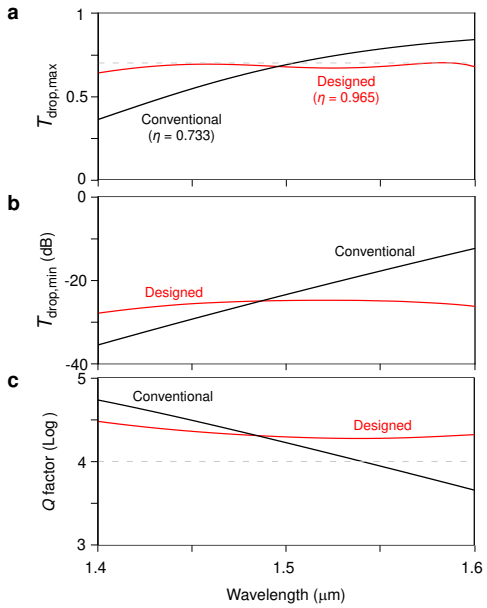

Fig. 2 Analytic calculation of the resonance output.

We calculate the resonance output and the quality factor from the coupling parameters from the given trajectories. Figure 2 illustrates the resonance output of the designed and conventional model. The designed model exhibits a nearly uniform resonance output, nearly constant in the 1.4 to 1.6 um wavelength range. Additionally, resonance dip of the designed model remains nearby -30 dB, with enhanced extinction ratio and uniform signal-to-noise ratios. Furthermore, quality factor of the designed model remains more than 10,000 in wide bandwidth. On the other hand, conventional model exhibits considerable fluctuation of the spectral responses in the same wavelength range.

We realize the broadband critical coupling at the bus port for the second example (Fig. 4). Using the same framework, the coupling trajectory which the critical coupling occurs can be derived. Figure 4 illustrates the physical analysis for realizing the broadband critical coupling at the bus port. The target model (Fig. 4c) shows that the critical coupling occurs in the broad wavelength range, 1.4 to 1.6 um. On the other hand, the conventional model (Fig. 4d) exhibits a narrow wavelength range of approximately 30 nm in which the resonance dip falls below -30dB.

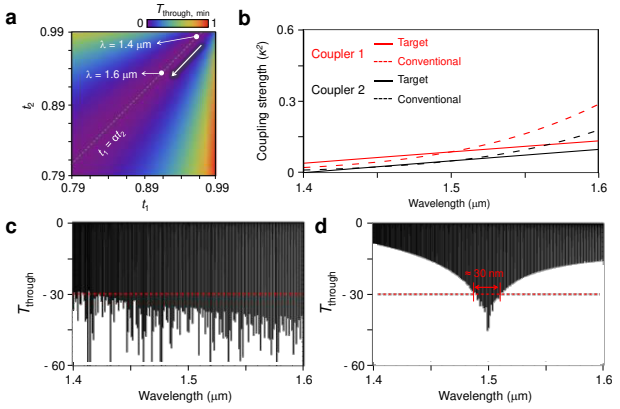

Fig. 3 Analysis of the broadband critical coupling at the bus port

IV. CONCLUSION

We verify the effectiveness of the proposed framework from realizing two representative examples, broadband uniform resonance output at the drop port, and the broadband critical coupling at the bus port. This work demonstrates that the proposed framework provides a general and predictive approach for designing a model with desired device performance.

***Abstract*— Precise control of thermal infrared emissivity is critical for thermal management. Here, a single-layer zigzag metallic glass film fabricated by glancing angle deposition is demonstrated to provide precisely tunable emissivity. The structure induces strong optical anisotropy, enabling continuous emissivity modulation and effective thermal infrared camouflage of heated objects.**

***Keywords*— metallic glass, zigzag-type structure, anisotropic optical property, glancing angle deposition, thermal management, thermal infrared camouflage.**

I. Introduction

Precise control over thermal emissivity is essential for emerging applications in energy conservation, heat dissipation, and thermal infrared camouflage technologies. Effective modulation of emissivity enables regulation of radiative heat transfer and suppression of infrared signatures, which are critical for objects operating under elevated temperatures and variable environmental conditions.

Thin film metallic glasses possess intrinsically lossy optical characteristics arising from their amorphous atomic structure, which distinguishes them from conventional crystalline metals. Glancing-angle deposition enables the fabrication of anisotropic metastructures with well-defined geometry through self-shadowing, leading to pronounced optical anisotropy. However, the application of glancing-angle-deposited structures for precise control of thermal infrared emissivity remains largely unexplored.

In this work, we demonstrate a single-layer zigzag metallic glass film fabricated by glancing angle deposition that enables precisely tunable thermal infrared emissivity. The incorporation of a zigzag pattern enabled tunable optical behavior, enabling the film to adapt effectively to diverse thermal-infrared camouflage conditions. The lossy nature of metallic glass was leveraged to produce marked differences in thermal IR emissivity. By exploiting structure-induced optical anisotropy the thermal radiation of heated objects can be modulated, enabling stable thermal infrared camouflage under varying operating conditions.

II. Methods

Metallic glass films were deposited on silicon (Si) wafers via DC magnetron sputtering to fabricate the zigzag-type structure. To fabricate the zigzag structure, the first branch was deposited on the substrate at an α angle of 75°. Afterward, the substrate was rotated 180°, enabling the second branch to be deposited with the same α angle of 75°. This procedure was repeated to form the third and fourth branches. Thermal infrared images of the samples were captured with a thermal camera (FLIR T340) operating over a wavelength range of 7.5–13 μm.

III. Results and Discussion

Figure 1 schematically illustrates the zigzag-type metallic glass structure fabricated by glancing angle deposition and the experimental configuration used to characterize its thermal infrared response. Figure 1(a) depicts the atomic structure of a representative metallic glass (FeCrCoMoCBSi), which features a random and disordered atomic arrangement. This disordered structure leads to frequent electron scattering and increased conduction losses, resulting in the intrinsically lossy optical properties of metallic glass.

Figure 1(b) shows the zigzag-type structure based on FeCrCoMoCBSi. The zigzag pattern plays a key role in controlling the metastructure's optical anisotropy in the infrared. It significantly enhances the tunability of in-plane emissivity, enabling modulation of thermal emission under varying conditions.

To probe the angle-dependent optical behavior, a polarizer was introduced during the measurements, and three rotation angles, φ, θ, and ψ, were defined to describe the orientation of the zigzag structure relative to the incident radiation, as shown in Fig. 1(c). The angle φ is defined by the relative orientation between the transmission axis of the polarizer and the zigzag plane, while θ and ψ describe out-of-plane tilting of the sample. By adjusting these angles, the thermal infrared absorptance and emissivity of the zigzag-type metallic glass film can be effectively modulated.

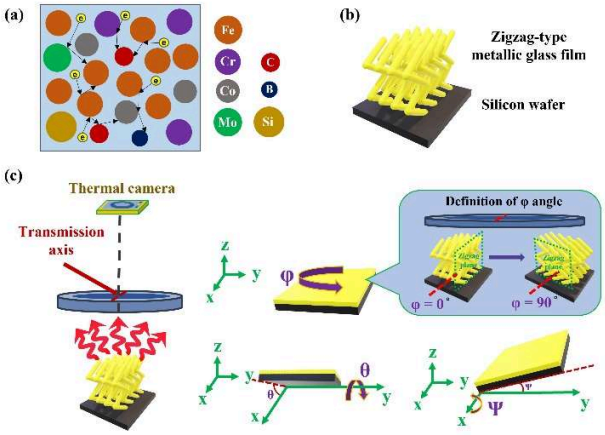

Fig. 1 (a) Atomic arrangement and free electron movement within the metallic glass (FeCrCoMoCBSi). (b) The zigzag-type structure of metallic glass can achieve tunable absorptance. (c) The schematic of the experimental setup for placing the zigzag-type film. For the two-parameter angular measurements

To further investigate this effect, a thermal camera was employed to capture the apparent temperature of the film at different φ, θ, and ψ angles, and thermal infrared images were analyzed to compare the corresponding emissivity. As shown in Fig. 2(a), the setup included a zigzag-type metallic glass film, a reference blackbody tape placed on a heated copper plate, and a polarizer positioned above. Fig. 2(b–g) illustrate the thermal emissivity at an object temperature of 73 °C, with emissivity values of 0.67, 0.59, 0.52, 0.40, 0.30, and 0.17, respectively. The zigzag-type metallic glass film exhibited significant changes in emissivity with variations in φ, θ, and ψ, demonstrating a continuously tunable thermal infrared response enabled by angular control.

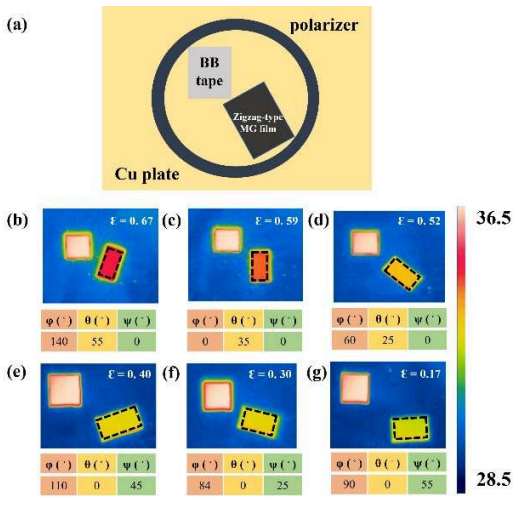

Fig. 2 (a) The schematic diagram and (b-g) thermal infrared images of zigzag-type metallic glass film at (φ, θ, ψ) of (b) (140°, 55°, 0°), (c) (0°, 35°, 0°), (d) (60°, 25°, 0°), (e) (110°, 0°, 45°), (f) (84°, 0°, 25°), and (g) (90°, 0°, 55°) at a blackbody tape apparent temperature of 73 °C.

As shown in Fig. 3(a), the experimental setup consisted of the zigzag-type metallic glass film and a reference blackbody tape placed on a heated copper plate, with soil and leaf used as background materials and observed through a polarizer.

Fig. 3(b–d) present thermal infrared images captured at different object temperatures. By selecting appropriate angular configurations, the apparent temperature of the zigzag-type metallic glass film can be adjusted to closely match that of the surrounding soil and leaf backgrounds, resulting in effective thermal infrared camouflage. In contrast, the copper plate remains clearly distinguishable from the background under the same conditions, highlighting the role of the tunable emissivity provided by the zigzag-type metallic glass structure.

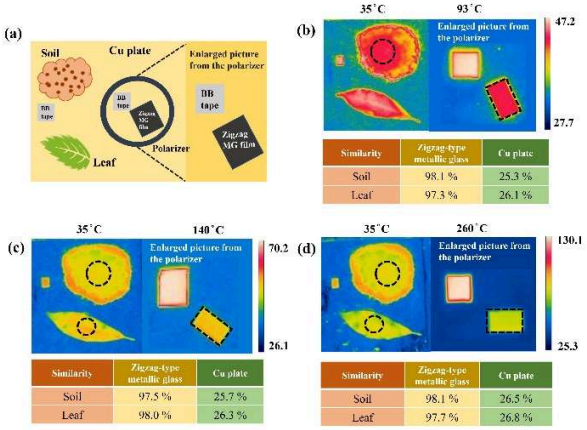

Fig. 3 (a) Schematic diagram of the experimental setup. Thermal infrared images and similarity with different heating temperatures of the samples, the temperatures of the blackbody tape are (b) 93 ˚C, (c) 140 ˚C, and (d) 260 ˚C.

IV. Conclusion

A zigzag-type metallic glass film fabricated by glancing-angle deposition is shown to enable controllable thermal infrared emissivity via angular tuning. The film's thermal radiation can be effectively modulated and applied to thermal infrared camouflage under various thermal conditions. These results highlight the potential of single-layer metallic glass metastructures as a practical platform for tunable thermal radiation control.

***Abstract*—We present a combined experimental-theoretical study of third harmonic generation (THG) in plasma-etched silicon nitride metasurface gratings. Compared to a planar membrane, the resonant structures exhibit polarization-selective TE and TM responses. Under ultrafast near-infrared excitation, strong electromagnetic field localization enables two orders of magnitude THG enhancement, enabling efficient visible-to-UV upconversion.**

***Keywords*— nonlinear optics, silicon nitride, third harmonic generation, ultrafast laser, dielectric metasurface.**

I. Introduction

Silicon nitride (Si_3N_4) is a CMOS-compatible, wide-bandgap ($\sim 5eV$) dielectric with a moderately high refractive index ($n \approx 2$) and very low optical loss. A new generation of tunable metasurfaces, recently enabled by high-index semiconductor materials in their transparency windows, provides a versatile and efficient platform to simultaneously manipulate the near-field and far-field electromagnetic (EM) waves. In contrast to plasmonic systems with high thermal losses due to absorption, high index dielectric resonators can realize multipole electric or magnetic resonances with negligible thermal loss in their operating wavelength range. High-index dielectric resonators can realize near-field and far-field manipulation of EM waves with a high degree of freedom and thus provide a versatile high-performance platform to engineer the EM waves, such as manipulating the chirality, coherence, and topology of light [1]. On the other hand, nonlinear Si_3N_4 photonics offers unique abilities to generate, manipulate, and detect optical signals in nano-devices, with applications based on field localization and large third-order nonlinearity. These properties make it ideal for integrated nonlinear optical applications [2,3], especially in the in the near-infrared and telecom wavelength range, where its common adversary silicon suffers from two-photon absorption.

This study focuses on the third-order nonlinear optical properties of Si_3N_4, experimentally retrieved and quantified through THG from two distinct periodic nanogratings. The nanoscale gratings are fabricated by plasma etching from a planar Si_3N_4 membrane. Although intrinsically limited by subwavelength interaction lengths and very low nonlinear conversion efficiency, the flat membrane serves as a reference to quantify THG enhancement from the structured surfaces. We design and fabricate two types of resonant dielectric metasurfaces, exhibiting polarization-selective resonances under transverse electric (TE) and transverse magnetic (TM) polarizations. When driven by ultrafast near-infrared pulses under resonant conditions, these gratings strongly confine the EM field within the bulk of the structure, enhancing light–matter interaction and significantly increasing THG in the UV. Their characteristic resonances yield THG enhancements of more than two orders of magnitude. Our planar architectures are fully transparent, operate at normal or near-normal incidence, and provide a flexible design platform for the upconversion of visible light into the ultraviolet (UV) and deep-UV regimes with enhanced efficiency.

II. Methods

The nonlinear light-matter interactions in the thin film membrane is simulated using a microscopic, hydrodynamic model of linear and nonlinear optical properties of semiconductors that accounts for surface, magnetic and bulk nonlinearities extracted from equations of motion arising from free (Drude model) and bound electrons (Lorentz model) [5,6]. By fitting the THG characteristics of the planar membrane, we retrieve the wavelength dependent datasets of $\chi^{(3)}_{\omega}$ and $\chi^{(3)}_{3\omega}$, for our pump intensity and fixed laboratory environment. These datasets are then introduced into Comsol FEM platform as Si_3N_4 material properties, to simulate the linear transmission and the nonlinear transmitted THG from the structured materials. The linear transmission, E and H field localization maps are solved by the Maxwell's equation, while the THG conversion efficiencies are calculated by introducing the nonlinear polarization term into the same.

For experimental measurements, The pump used as a source for nonlinear wavelength dependant experiments is a femtosecond (fs) pulsed laser, wavelength tunable in the range of 650 nm - 2500 nm, with pulse width of 180 fs, pulse repeatition rate of 60 KHz, peak energy of $6\mu J/pulse$ and a maximum average power of 400 mWatt. The pump beam is focused on the sample plane using a plano-convex lens of f = 20 cm, in order to achieve intensities of $\sim 10GW/cm^2$. The transmitted signal is passed through a series of wavelength

selective optical elements such as a UV enhanced collimating lens, two "ultrafast harmonic separator" mirrors and a narrow bandpass filter centered at the THG frequency [4]. A Wollaston polarizer separates the TM and TE polarized THG signal and a photomultiplier tube is used to detect the harmonic signals. A detailed calibration procedure enables us to precisely quantify the THG conversion efficiencies, which are of the order of 10^{-6} down to 10^{-12}, and corroborate with our theoretical predictions in terms of shape, spectral width, and maximum amplitude of the spectral response.

III. Results and Discussion

The study begins with a Si_3N_4 membrane of thickness 380 nm (Fig.1(a)) which shows a Fabry-Perot resonance around 800 nm (Fig.1(d)). The corresponding THG spectral response, shown in Fig.1(g), gives a peak conversion efficiency of $\eta_T H = \frac{P_{THG}}{P_{Pump}} = 9 * 10^{-9}$.

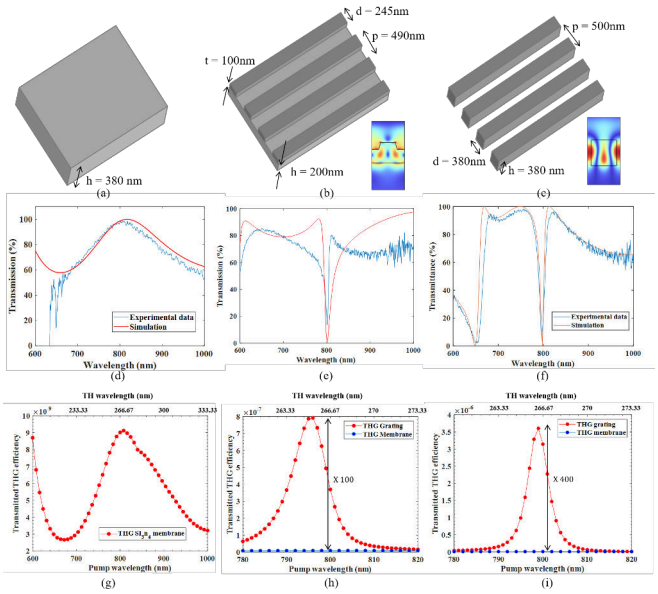

Fig. 1. Schematic diagram of the (a) Suspended membrane of Si_3N_4 (b) Suspended grating in Si_3N_4 and (c) Shallow etched grating. Linear transmission map of (d) Suspended membrane of Si_3N_4 (e) Suspended grating in Si_4N_4 and (f) Shallow etched grating. (g)-(i) Resonant THG spectral response and enhancement peak corresponding to each type of resonances.

The membrane is partially etched to fabricate a grating with corresponding design parameters indicated in Fig.1(b). This grating is designed to sustain a guided mode resonance at or near 800nm (Fig.1(e)). In this case, we achieve a resonant EM field localization (inset of 1(b)) due to the guided mode resonance, whose spectral position is highly dependant on the periodicity of the structure. Under TM polarized illumination, the EM mode field localization results into a THG spectral variation as theoretically predicted and shown in Fig1(h) with a peak enhancement factor of ~ 100 times, with respect to the flat membrane.

On the other hand, the membrane is fully etched to fabricate a second grating with dimensions as shown in Fig1(c), suspended in air. This grating is designed to sustain a characteristic Mie type resonance at or near 800nm (Fig.1(f)), under TE illumination, and the dip in the transmission spectra is once again a result of light localization in the bulk of the material (inset of 1(c)). This strong light localization corresponds to a resonant THG spectral variation as theoretically predicted, and shown in Fig.1(i), with a peak enhancement factor of ~ 400 times, with respect to the flat membrane.

IV. Conclusion

We report third-harmonic emission from two Si_3N_4 metasurfaces, comparing their resonant field localization and THG efficiencies with a flat Si_3N_4 membrane. Resonant, polarization-selective designs enhance conversion by over two orders of magnitude, with strong agreement between theory and experiment. The two gratings can be compared in terms of spectral properties of their characteristic resonances, resonant EM field localization, tunability and rebustness of the fabricated structure.

This study maps an important step towards understanding and showcasing Si_3N_4 metasurfaces as efficient, broadband photonic platforms operating from UV to IR and compatible with on-chip integration. Understanding their resonant properties and nonlinear dynamics enables compact UV/DUV/EUV light sources. With low losses, CMOS compatibility, high power handling, and hybrid integration (e.g., with InP), they support diverse applications from sensing to quantum technologies across an unprecedented spectral range.

***Abstract*—Non-perturbative light–matter coupling in quantum nanophotonic platforms enables control of decay, dissociation, and electromagnetic confinement beyond geometry. We illustrate this across atomic, molecular, and nanophotonic systems, highlighting how structured multi-mode coupling provides new handles for controlling quantum optical functionality and spatial field distributions.**

***Keywords*— polaritons, quantum nanophotonics, ultrastrong coupling, photostabilization, nanophotonic waveguides, superstrong coupling.**

I. Introduction

Quantum nanophotonics exploits confined electromagnetic fields, tailored photonic environments, and strong light–matter interactions to engineer optical functionality at the nanoscale. In the non-perturbative regime, coupling to multiple photonic modes can modify intrinsic properties of both matter and light beyond what geometry alone determines. Here we present three realizations spanning atomic, molecular, and solid-state settings: (i) resonant laser driving stabilizes ionizing electronic transitions via AC Stark level repulsion [1]; (ii) multi-mode cavity coupling to a dissociative vibrational continuum suppresses photodissociation in diatomic molecular cations; and (iii) co-localized superstrong coupling (SSC) between an exciton and multiple photonic modes in visible nanophotonic waveguides provides direct control over real-space electromagnetic field distributions [2].

II. Results and Discussion

Laser-stabilized ionizing transitions

Resonant pumping of an ionizing transition above a critical intensity creates a metastable discrete resonance via AC Stark level repulsion—a semiclassical counterpart of the photon-bound exciton observed in microcavity-embedded doped quantum wells [3]. Unlike the Mollow triplet of a bound-to-bound transition, only two of the four emission channels survive; their spectral weights encode the hybridization with the continuum, and the state decays through two-photon ionization [1]. This demonstrates how structured light coupling can reshape decay pathways in an open quantum system.

Multi-mode photostabilization of molecular photodissociation

Extending the Lee–Friedrichs framework to diatomic cations (H_2^+, K_2^+), multi-mode cavity coupling to the dissociative vibrational continuum reshapes polaritonic potential energy surfaces. Franck–Condon overlaps with continuum modes, together with the coupling-strength dependence of the lower polariton energy, define a threshold above which cavity-induced stabilization suppresses photodissociation. These results show that quantum photonic environments can be used to control molecular instability and reaction channels through continuum engineering.

Co-localized superstrong coupling in visible nanophotonic waveguides

Co-localized SSC is the nanophotonic counterpart of multi-mode matter coupling: rather than one photon hybridizing with multiple matter excitations, one exciton hybridizes simultaneously with multiple photonic modes [2]. Because these modes possess distinct transverse field profiles, exciton-energy tuning becomes a direct handle on the spatial distribution of electromagnetic energy. Planar grating-coupled waveguides realize this mechanism in the visible range: restricting a 2D hybrid organic-inorganic perovskite active layer to 30% of the waveguide core yields full modal overlap between TE_0 and TE_1, producing multi-mode polaritons. RCWA simulations fitted with a generalized Hopfield model [2] confirm a characteristic S-shaped dispersion; coupling the lowest-order modes yields up to 44% higher coupling strength than higher-order pairs, and exciton tuning continuously switches the electromagnetic energy distribution between the bulk and the surface of the waveguide. This provides an in-situ route to field-profile engineering in integrated visible nanophotonic architectures.

III. Conclusion

These results frame non-perturbative multi-mode coupling as a resource for quantum nanophotonics. Across atomic, molecular, and waveguide platforms, coupling to a structured continuum enables control over decay, dissociation, and spatial field localization beyond conventional geometric design. This points toward nanophotonic strategies for quantum optical

devices based on continuum engineering, polaritonic mode shaping, and programmable electromagnetic confinement.

***Abstract*—We study TE-TM splitting effects on resonantly driven spinor exciton-polariton bistability. TE-TM coupling modifies thresholds, hysteresis, and spin composition, suppressing circular polarization under elliptical pumping. Pump momentum and dispersion curvature govern nonlinear regimes. The intermediate branch is unstable but can show slow growth, enabling long-lived transient switching dynamics.**

***Keywords*— exciton-polaritons, microcavities, TE-TM splitting.**

I. Introduction

Exciton–polaritons are hybrid light–matter quasiparticles formed through the strong coupling between quantum-well excitons and cavity photons in semiconductor microcavities. Owing to their photonic component, polaritons possess an extremely small effective mass, while their excitonic component provides strong nonlinear interactions. This unique combination enables rich driven–dissipative nonlinear phenomena, including optical bistability, soliton formation, superfluid-like flow, and polarization multistability. Under coherent resonant pumping, interaction-induced blueshifts dynamically modify the effective detuning between the pump and the lower polariton mode, giving rise to S-shaped input–output characteristics and hysteresis behavior.

Beyond scalar nonlinear effects, polaritons carry a spin (polarization) degree of freedom associated with the cavity photon polarization. Spin-anisotropic interactions produce nonlinear polarization switching and multivalued steady states. An additional key mechanism affecting spin dynamics in planar microcavities is transverse-electric-transverse-magnetic (TE-TM) splitting. TE-TM splitting originates from polarization-dependent photon dispersion and introduces a momentum-dependent linear coupling between polarization components, effectively acting as a spin–orbit interaction for polaritons. While TE-TM splitting is known to play a central role in phenomena such as the optical spin Hall effect and spin textures, its systematic influence on bistability structure and dynamical stability in spatially homogeneous resonantly driven systems has not been fully clarified.

In this work, we investigate how TE-TM splitting reshapes bistability, polarization properties, and dynamical stability in a homogeneous spinor exciton–polariton system under continuous-wave resonant pumping. We demonstrate that TE-TM splitting strongly modifies switching thresholds, hysteresis width, and spin composition of steady states. Furthermore, although the intermediate branch of the hysteresis loop remains linearly unstable, its instability growth rate can be substantially reduced in certain parameter regimes, leading to long-lived transient dynamics.

II. Methods

We consider a one-dimensional, spatially homogeneous spinor exciton–polariton system described by coupled mean-field equations for the cavity photon field E_σ and exciton field Ψ_σ, where $\sigma = \pm$ denotes circular polarization components. The model incorporates photon dispersion, exciton–exciton nonlinear interactions, dissipation, coherent pumping, and TE-TM-induced spin mixing. The TE-TM contribution appears as a term proportional to $\beta\partial_x^2 E_{\bar{\sigma}}$, where β denotes the normalized TE-TM splitting strength and $\bar{\sigma}$ is the opposite spin component. Under plane-wave steady-state solutions at pump momentum k_p, this term scales as βk_p^2, explicitly showing that spin mixing increases quadratically with in-plane momentum.

Steady-state solutions are obtained by solving the coupled algebraic equations for fixed pump power P, detuning Δ, ellipticity χ, and pump momentum k_p. The spin-resolved exciton densities determine the degree of circular polarization (DoCP),

$$\mathrm{DoCP} = \frac{|\Psi_+|^2 - |\Psi_-|^2}{|\Psi_+|^2 + |\Psi_-|^2}.$$

In addition to full nonlinear numerical calculations, we derive an analytical linear-response expression for DoCP, demonstrating that the leading TE-TM-induced suppression scales as $(\beta k_p^2)^2$.

To determine dynamical stability, we perform a Bogoliubov analysis by linearizing the dynamical equations around steady states and constructing the corresponding non-Hermitian excitation matrix. The instability growth rate is defined as

$$\Gamma = \max_{j,q} \mathrm{Im}\, \mu_j(q),$$

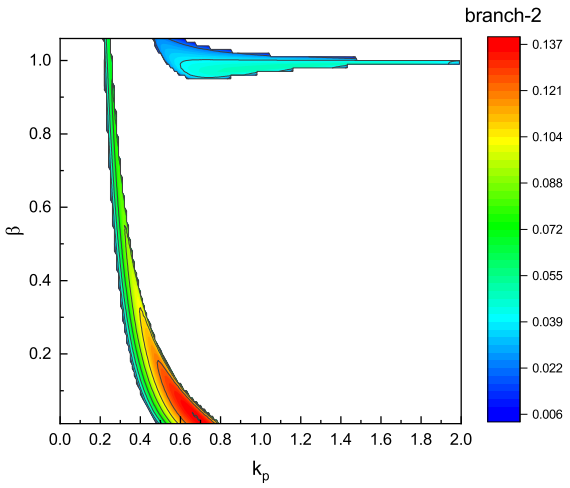

Fig. 1. Two-dimensional map of the growth rate Γ of branch-2 as a function of k_p and β. The slight jaggedness near the boundary originates from the finite parameter step size and data-boundary constrained interpolation, rather than physical discontinuities. Parameters: $\chi = 0.5$, $\gamma_{ph} = \gamma_{ex} = 0.1$, $\Delta = -0.32$, $P = 1.18$.

where $\mu_j(q)$ are Bogoliubov eigenvalues. The inverse growth rate $\tau_{\rm inst} = \Gamma^{-1}$ characterizes the instability timescale.

III. Results and Discussion

Our results show that TE-TM splitting substantially reshapes the nonlinear response of the system. In the absence of TE-TM splitting, bistability arises from interaction-induced renormalization of the effective detuning between the pump and the lower polariton mode. Finite β does not generate bistability by itself but significantly modifies switching thresholds and hysteresis width by introducing momentum-dependent spin mixing.

The pump momentum k_p plays a crucial role through its connection to the curvature of the lower polariton dispersion. Below the dispersion inflection point, interaction-induced blueshifts efficiently reduce the effective detuning, lowering bistability thresholds. Above the inflection point, bistability shifts toward higher pump powers and becomes narrower. This curvature-dependent behavior explains the strong momentum dependence of the hysteresis structure.

A central finding of this work is the strong suppression of circular polarization induced by TE-TM splitting. At normal incidence ($k_p = 0$), the DoCP is determined solely by the pump ellipticity and is independent of β. For finite momentum, however, TE-TM-induced spin mixing scales as βk_p^2, progressively reducing polarization contrast. At sufficiently large β or k_p, the steady states become nearly spin balanced even under elliptically polarized pumping. This behavior reflects competition between interaction-induced longitudinal spin splitting and TE–TM-induced transverse effective fields. At low β, interactions stabilize polarization on the lower branch, whereas at large β, transverse spin mixing dominates across all branches.

The pump detuning Δ further reshapes the bistability landscape. Near resonance, broad hysteresis regions appear over a wide momentum range. As the detuning becomes more negative, the bistable region shrinks and becomes increasingly sensitive to pump momentum. This behavior can be understood from the effective detuning

$$\Delta_{\rm eff}(n, k_p) = \omega_p - E_{\rm LP}(k_p) - gn,$$

where density-dependent energy shifts dynamically restore resonance. The efficiency of this restoration depends on dispersion curvature and detuning depth.

Although the intermediate branch of the hysteresis loop is always linearly unstable, the magnitude of the instability growth rate Γ varies significantly across parameter space. For certain combinations of moderate pump momentum and TE–TM splitting, Γ becomes much smaller than the intrinsic polariton decay rate. In these regimes, the instability develops over long timescales, and the system can transiently remain near the intermediate solution for experimentally relevant durations. TE–TM splitting modifies the Bogoliubov excitation spectrum and can substantially reduce instability growth rates without rendering the branch linearly stable. This demonstrates that TE–TM splitting provides a mechanism for controlling instability timescales and transient dynamics.

IV. Conclusion

We have systematically analyzed the influence of TE-TM splitting on bistability and nonlinear spin dynamics in resonantly driven spinor exciton-polaritons. TE-TM splitting modifies hysteresis thresholds and polarization properties through momentum-dependent spin mixing proportional to βk_p^2. The interplay between interaction-induced energy renormalization, dispersion curvature, and TE-TM coupling governs both steady-state structure and dynamical stability. While the intermediate branch remains linearly unstable, its instability growth rate can be dramatically reduced in selected parameter regimes, leading to long-lived transient states. These results establish TE-TM splitting as a powerful control parameter for nonlinear optical response and spin dynamics in polariton systems, with potential implications for polariton-based optical switching and spin-dependent photonic devices.

I. Introduction

Long-range coherent energy transfer between spatially separated dipoles plays a central role in many physical, chemical and biological systems[1],[2]. In conventional electromagnetic environments, dipole–dipole interactions are typically limited to subwavelength distances due to radiative losses and rapid field decay[3]. Overcoming these constraints is essential for realizing scalable platforms for information processing, sensing, and energy routing. Metasurfaces provide a versatile framework for tailoring light–matter interactions through subwavelength structuring of electromagnetic resonators. By engineering collective resonances and symmetry properties, metasurfaces can support bound states in the continuum (BICs), which are nonradiative modes embedded within the radiation spectrum[4]. Owing to their symmetry protection or parameter tuning, BICs exhibit vanishing radiation loss and theoretically infinite quality factors in ideal structures, enabling strong field confinement and enhanced local density of optical states[5],[6].

Recent studies have shown that BIC-enabled metasurfaces can substantially enhance spontaneous emission[7], nonlinear optical processes[8], and near-field interactions[9]. However, the role of BICs in mediating long-range coherent energy transfer between spatially separated dipoles remains largely unexplored, particularly in the terahertz (THz) regime. The long wavelengths and weak intrinsic light–matter coupling at THz frequencies pose additional challenges for achieving efficient and controllable interactions. In this work, we investigate dipole–dipole energy transfer in a gold metasurface supporting BIC modes using a custom THz near-field microscope. By employing dipolar microprobes, we reveal millimeter-scale, highly anisotropic coherent energy transfer enabled by long-range collective resonances, highlighting the potential of BIC metasurfaces for low-loss and directional THz photonic technologies.

II. Methods

Terahertz (THz) near-field measurements were performed using a custom-built time-domain microscopy system, as illustrated in Fig.1(a). An ultrafast femtosecond laser (780 nm) was split into pump and probe beams using a beam splitter. The pump beam was focused onto a photoconductive-antenna microprobe to generate THz radiation, which served as the emitter. The probe beam, delayed by a mechanical delay stage, was focused onto a second microprobe for coherent detection. Both emitter (E) and detector (D) microprobes were mounted on independent three-dimensional translation stages, allowing precise control of their positions relative to the metasurface sample. The sample was mounted on an additional three-dimensional stage, enabling accurate alignment and scanning of the measurement region. Dipole-dipole interaction measurements were conducted using the two THz microprobes positioned on the metasurface, as shown in Fig. 1(b). The separation between the probes was systematically varied along the longitudinal (L_x) and transverse (L_y) directions. The THz electric field polarization was aligned parallel to the long axis of the metallic rods to selectively excite the relevant resonant modes. During measurements, the emitted THz near field from the source probe interacted with the metasurface and was detected by the receiver probe. The time-domain THz signals were recorded and Fourier-transformed to obtain spectral information. A camera system was used to monitor the relative positions of the probes and the sample in real time (Fig. 1(c)), ensuring stable alignment throughout the experiments. This setup enabled high-resolution mapping of spatiotemporal THz fields and direct characterization of long-range dipole-dipole energy transfer mediated by BICs.

The metasurface studied in this work consists of a periodic array of gold (Au) rod dimers fabricated on a substrate. Each unit cell contains two identical rods separated along the longitudinal direction, with a designed periodicity chosen to support symmetry-protected BICs. The metasurface is a square

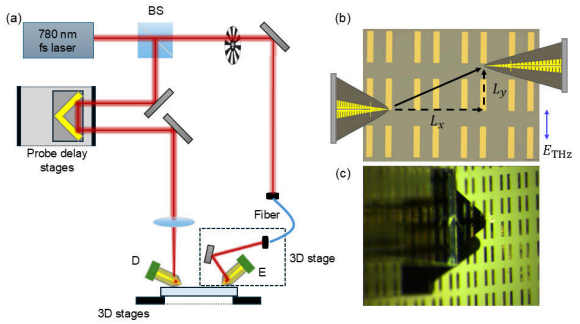

Fig. 1. (a) Illustration of the THz near-field microscopy setup. THz radiation is generated and detected by focusing ultrafast optical laser pulses onto photoconductive-antenna microprobes, which serve as the emitter and detector. The positions of the emitter and the measurement region on the sample are independently and precisely controlled using dedicated three-dimensional translation stages. (b) Conceptual schematic of dipole–dipole interaction measurements on a metasurface enabled by two THz microprobes, with the THz electric field oriented parallel to the long-axis direction of the rods. (c) Camera view of the sample and probes during the measurements.

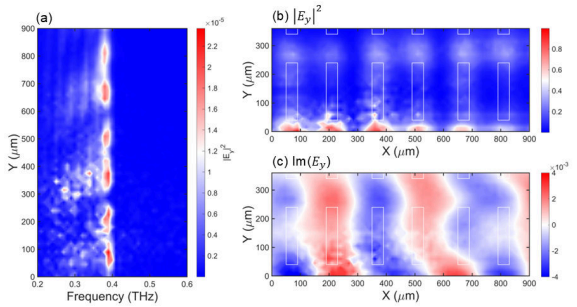

Fig. 2. (a) Two-dimensional color plot of the THz intensity $|E_y|^2$ as a function of frequency and relative displacement L_x between the emitter and the detector. (b) Spatial distribution of the THz intensity $|E_y|^2$ along L_x and L_y at the BIC frequency. (c) Spatial distribution of the imaginary part of the THz electric field, $\mathrm{Im}(E_y)$, as a function of relative displacement along L_x and L_y at the BIC frequency.

lattice with a lattice constant of 300 μm. Each rod has a length of 200 μm and a width of 40 μm, with a lateral separation of 120 μm between the two rods in one unit cell as shown in Fig. 1(b) and (c).

III. Results and Discussion

Fig. 2(a) presents the two-dimensional map of the THz intensity $|E_y|^2$ generated by the dipolar emitter and measured by the dipolar detector as a function of frequency and relative displacement L_x. A pronounced intensity enhancement is observed near 0.39 THz, corresponding to the BIC mode of the metasurface. Notably, this mode persists over a wide range of L_x, indicating robust long-range energy transfer between the emitter and detector probes mediated by the BIC mode. The localized intensity maxima along L_x demonstrate that energy transfer remains efficient over several hundred micrometers, far exceeding the typical near-field interaction range. Figure 2(b) shows the spatial distribution of $|E_y|^2$ in the L_x–L_y plane at the BIC frequency. The intensity is strongly confined and periodically modulated along the longitudinal direction L_x, following the arrangement of the rod dimers. In contrast, the field decays rapidly along the transverse direction L_y, revealing a highly anisotropic energy transfer behavior. This directional confinement reflects the collective nature of the BIC mode.

The phase characteristics of the energy transfer are further illustrated in Fig. 2(c), which displays the imaginary part of the electric field, $\mathrm{Im}(E_y)$, at the BIC frequency. A clear alternating phase pattern is observed along L_x, indicating coherent oscillations of the electromagnetic field across multiple unit cells. This extended phase correlation confirms the presence of long-range spatiotemporal coherence supported by the BIC mode. Meanwhile, the rapid phase variation along L_y further evidences the suppression of coupling in the transverse direction.

Together, these results demonstrate that the BIC resonance enables millimeter-scale coherent dipole–dipole energy transfer with strong directional selectivity. The simultaneous enhancement of field intensity and preservation of phase coherence along L_x indicate that the metasurface supports collective modes that effectively channel electromagnetic energy over long distances. This behavior stands in sharp contrast to conventional near-field interactions and arises from the nonradiative nature of the BIC mode.

IV. Conclusion

In conclusion, we have demonstrated millimeter-scale coherent dipole–dipole energy transfer in a terahertz metasurface mediated by nonradiative bound states in the continuum. Using a custom-built near-field time-domain microscopy system, we directly mapped the spatial evolution of THz fields and revealed highly anisotropic, long-range coherence along the longitudinal direction of the rod dimers. The pronounced intensity enhancement and preserved phase coherence confirm that BIC modes enable efficient and directional energy transfer far beyond conventional near-field limits. The demonstrated control of long-range coherent energy transfer opens new opportunities for the development of low-loss THz communication, sensing, and integrated photonic devices based on BIC-enabled metasurfaces.

***Abstract*—We report a universal approach to the colloidal synthesis of high-quality pentatwinned plasmonic nanoparticles with tailored optical properties.**

***Keywords*— gold nanoparticles, colloidal synthesis**

I. Introduction

Plasmonic nanoparticles with five-fold symmetry offer an important advantage over their single-crystalline analogs due to their superior structural stability at elevated temperatures. Although the family of pentatwinned nanoparticles is relatively rich, current experimental approaches can produce three main shapes: decahedra, rods, and bipyramids (Fig.1)

Gold decahedra are nearly isotropic, composed of five tetrahedral subunits sharing a common axis and joined along 111 twin planes, giving an overall ten-faceted shape. All exposed faces are of low-energy, making this morphology energetically favorable within a certain size range compared with single-crystal shapes.

Gold nanorods feature high synthetic tunability, allowing their longitudinal dipolar plasmon wavelength to be adjusted from the visible to the mid-infrared region by varying their aspect ratio.[1] They exhibit highly polarization-dependent absorption and scattering cross sections, large extinction cross sections, and intense electromagnetic field enhancement at their ends.

Finally, gold bipyramids are elongated nanoparticles composed of two pentagonal pyramids, base-stacked symmetrically.[2], [3] Unlike gold nanorods, which typically have rounded or flat ends, bipyramids have two sharp tips that facilitate the so-called ”lightning rod effect,” generating extremely large local electric-field enhancements and significantly larger optical cross-sections. Bipyramids exhibit highly tunable longitudinal dipolar plasmon resonance wavelengths that can be adjusted by aspect ratio. Gold bipyramids exhibit a narrower ensemble plasmon band, making them superior for surface-enhanced spectroscopies, and their nearly 100% photothermal conversion efficiency is critical for efficient catalysts for plasmon-powered chemical reactions.

Typically, regardless of shape, the concentration of Au seeds is the sole factor determining the size and/or aspect ratio, and thus the optical properties of the nanoparticles. That is, the fewer the seeds, the larger the nanoparticles. As a result, varying nanoparticle volumes while keeping their optical spectra unchanged remains a synthetically non-trivial task. Therefore, there is a need to simplify and unify current procedures to ultimately provide an experimental framework that enables facile tuning of structural properties. Here, we expand the chemical space for the synthesis of highly monodisperse penta-twinned gold nanoparticles (bipyramids, nanorods, and decahedra) and achieve yields approaching 100%. In particular, we found a unique role of bromide ions in tailoring the aspect ratio of gold bipyramids.

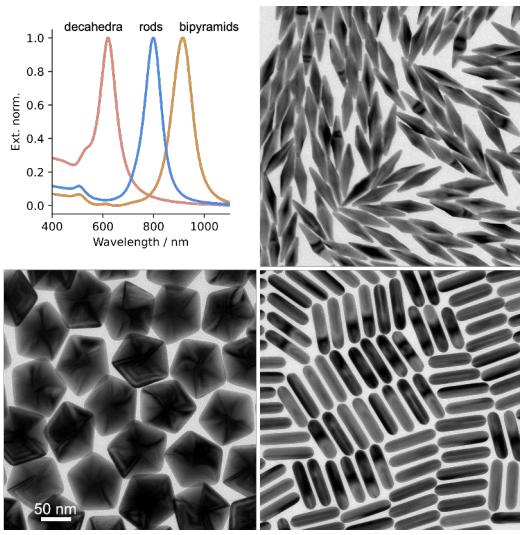

Fig. 1. Example of three types of pentatwinned gold nanoparticles, decahedra, rods, and bipyramids.

II. Methods

Our approach builds on our previous method, which starts with the synthesis of thermally aged 6 nm seeds with pentatwinned symmetry.[5] By further seeded growth in the presence of additives such as silver bromide or silver nitrate, we control the kinetics of gold precursor reduction, thereby producing nanoparticles of the desired shape and size. The final nanoparticles are characterized by UV-Vis-NIR spectroscopy and Transmission Electron Microscopy.

III. Results and Discussion

We expanded the parameter space for the synthesis of gold bipyramids, showing that both bromide ions and seed

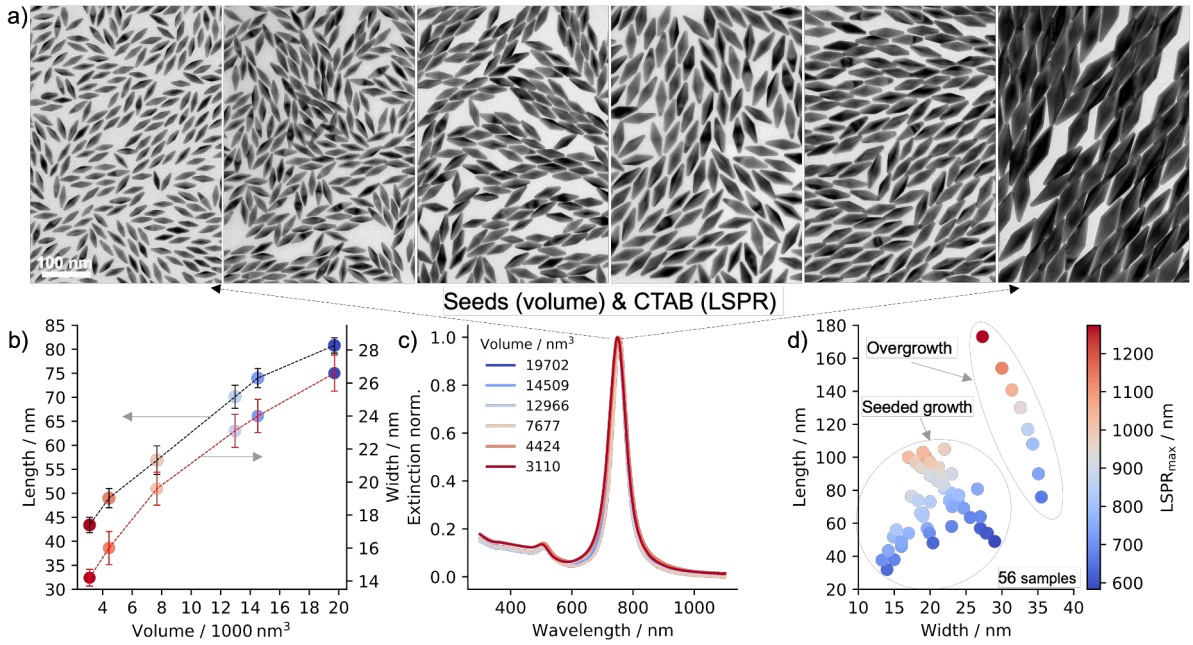

Fig. 2. Controlling the volume of gold bipyramids at constant position of longitudinal plasmon band. a) TEM images of nanoparticles featuring volumes ranging from 3110 to 19702 nm3 (from left to right) at constant aspect ratio. b) Change of length and width of nanoparticles demonstrating 6 fold reduction of volume at constant aspect ratio. c) UV–vis–NIR spectra of gold bypiramids featuring a constant plasmon band position at 750 nm. d) a collection of samples of gold bipyramids (56 in total) obtained through our new method.

concentration play complementary roles in tuning nanoparticle dimensions and thus their optical properties (Fig.2).[6] As a proof-of-concept experiments, we synthesized gold bipyramids with a fixed position of plasmon band at 750 nm and varying nanoparticle volume, a property that is not readily achievable with conventional methods. While the seed concentration was used to vary the volume of the final nanoparticles - the primary experimental parameter -, the bromide concentration was used to fine-tune the plasmon band position to the desired wavelength - the secondary experimental parameter. By carefully tuning these two parameters, we obtained six samples with the longitudinal surface plasmon band in nearly the same position. The same approach can be used for other nanoparticle shapes.

IV. Conclusion

We have expanded the chemical space in the synthesis of gold nanoparticles with pentatwineed symmetry. By carefully adjusting bromide and seed concentrations, we were able to produce nanoparticles with different dimensions but the same aspect ratio, thereby fixing the position of the plasmon bands. Our method unlocks the structural diversity of plasmonic nanoparticles, making them a suitable playground for evaluating plasmonic performance on the ensemble or single particle level.

Nanoparticles significantly enhance molecular Raman peaks, enabling sensitive, on-chip detection and potential chiral sensing. Guided measurements show with TM polarization 1.5× stronger than TE.**

***Keywords*— plasmonics, Nanoparticle on a Mirror (NPoM), guided Raman spectroscopy**

I. Introduction

Raman spectroscopy is a powerful optical technique used to probe the vibrational modes of molecules. By measuring the inelastic scattering of light, it provides detailed chemical fingerprints, enabling identification of molecular structures, composition, and interactions.

A nanoparticle-on-mirror (NPoM) consists of a metallic NP positioned above a metallic film, separated by a nanometer-scale gap. This configuration strongly confines light in the gap, creating intense electromagnetic hotspots that greatly enhance optical signals such as Raman scattering. NPoMs are ideal for single-molecule detection and nanoscale spectroscopy applications.

To make a compact design NPoM structure can be waveguide-coupled allowing the integration into photonic circuits, paving the way for portable, high-throughput sensing devices and lab-on-a-chip technologies that combine optical spectroscopy with microfluidics or other on-chip analytical tools. This structure would allow enantiomeric detection if it used with enantiomeric molecules and chiral nanoparticles [1].

We demonstrate waveguide-integrated Raman spectroscopy based on a nanoparticle-on-mirror (NPoM) plasmonic nanocavity fabricated directly on a silicon nitride waveguide. The NPoM nanogap, formed by a gold nanoparticle separated from a gold patch by a molecular monolayer, enables strong electromagnetic confinement and enhanced Raman scattering under guided excitation. Numerical and experimental results show that TM-polarized guided modes efficiently couple to the plasmonic cavity via evanescent excitation, producing significantly stronger nanogap-enhanced Raman signals compared to TE modes. Experimentally, TM excitation yields ~1.5× higher Raman intensity than TE polarization. The presence of the NP results in pronounced enhancement of the molecular vibrational peaks, confirming the critical role of nanogap formation for on-chip detection. This hybrid dielectric–plasmonic platform provides a compact architecture for sensitive integrated Raman spectroscopy and opens new opportunities for scalable molecular and potentially chiral sensing within photonic circuits.

II. Methods

The structures used in this study are composed of a silicon substrate and a strip silicon nitride waveguide (300 nm x 500 nm). Then a gold patch with 500 nm x 5 µm dimensions is placed on top of the silicon nitride waveguide. The gold surface is functionalized with a self-assembled monolayer (SAM) of biphenyl-4-thiol (BPT), finally using soft-lithography [2] a gold nanosphere with a diameter of 150 nm is deterministically transferred on top of the SAM. The NP enables the formation of a nanogap or even a picogap, between the two metallic structures, strongly confining the electromagnetic field and allowing highly sensitive molecular detection, potentially down to the single-molecule level [3]. The gold patches are placed on top of the waveguide, so we can couple light into the NPoM via evanescent field under TM-polarized guided modes, whose field components strongly overlap with the metallic nanostructure. The novelty on this configuration resides in enabling Raman spectroscopy through both reflection and transmission channels of the waveguide, allowing dual interrogation of the plasmonic nanocavity within a fully integrated configuration. This approach enables a systematic comparison between reflection and transmission channels, allowing us to evaluate their relative efficiency for Raman excitation and signal collection within the integrated platform. In figure 1, it is shown a scanning electron microscope (SEM) image of the mentioned structure.

The simulations are performed using finite-difference time-domain (FDTD) methods implemented in RSoft. We evaluate the enhancement factor (EF), defined as

$$EF(r, \lambda) \equiv |E(r, \lambda)|^2 / E_0(r, \lambda)|^2 \qquad (1)$$

where $E(r, \lambda)$ represents the electric field at position r in the presence of the complete metallic structure and $E_0(r, \lambda)$ corresponds to the field at the same position in the absence of the resonator structure (with the metal fully removed) [4].

We further define the waveguide transmission in Eq. (2) for the configuration including the gold patch, enabling quantitative evaluation of the insertion losses introduced by the plasmonic structure.

$$T(dB) = -10\, log_{10}\left(\frac{P_{in}}{P_{out}}\right) \qquad (2)$$

.

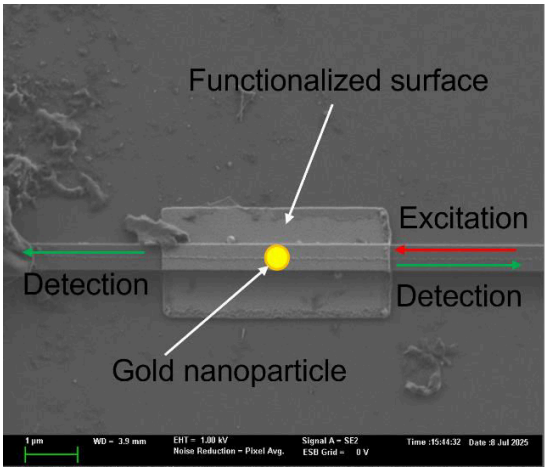

Fig. 1. SEM image. Example of the NPoM structure with gold patch on top. The gold surface is functionalized with a SAM of BPT, a gold nanosphere is placed on top to create the nanocavity. A SiN waveguide is used to excite and detect molecules.

For the Raman characterization of measurements is used a commercial Raman spectrometer from *WiTec.* The sample is placed vertically on a holder to couple light into the waveguide using the x100 microscope, as can be seen in fig 2.

Fig. 2. Optical microscope image of the experimental setup for guided Raman spectroscopy, showing the waveguide-coupled sample measured using a commercial Raman system.

III. Results and Discussion

III. a) Transmission and Enhancement Factor of the waveguide and the NPoM

The initial results are presented in Fig. 3, which shows the supported guided modes of the silicon nitride waveguide. The waveguide is designed to sustain TM-polarized modes that enable more efficient coupling into the NPoM cavity, as the plasmonic structure is positioned directly on top of the SiN core. The simulations are performed under continuous-wave excitation at 633 nm. A full spectral analysis will be addressed in future work.

Further optimization studies will investigate the influence of waveguide width, patch length, nanogap size between the nanoparticle and the gold film, and nanoparticle positioning. In the present study, however, the geometrical parameters are selected based on prior optimizations reported by our group [4,5].

For this configuration, the waveguide is designed to preserve the TM mode with less losses than the TE mode.

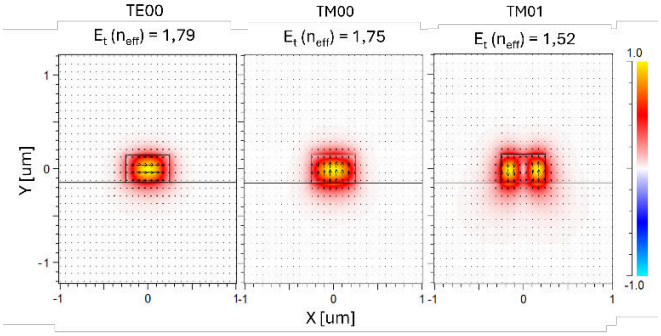

Fig. 3. Simulated transverse electric field profiles of the supported modes in the silicon nitride waveguide: TE00 (left), TM00 (center), and TM01 (right).

Table 1 summarizes the results from *full-wave* simulations, where the previously computed guided modes are used as the input field, to evaluate both propagation losses and field enhancement for the ideal configuration shown in Fig. 1, with the nanoparticle positioned above the waveguide. The simulations indicate that TE-polarized modes exhibit lower propagation losses than TM modes, as their electric field interacts only weakly with the gold patch. In contrast, TM excitation produces significantly stronger coupling to the plasmonic structure. The calculated enhancement factor is seven orders of magnitude higher for the TM mode compared to the TE mode, confirming that TM polarization more efficiently excites the plasmonic response of the patch due to its stronger evanescent field overlap with the metal interface.

	Transmission (dB)	EF
TE	0,73	0,0000001
TM	0,46	1,42

Table 1. Transmission and enhancement factors computed for the two polarizations.

III. b) Raman characterization of the NPoM

The structure is first characterized under free-space excitation. Figure 4(a) shows an optical microscope image of the fabricated NPoM, where the dark spot indicates the presence of a gold NP positioned on the metallic patch.

Figure 4(b) presents a Raman intensity map acquired at 1580 cm^{-1}, revealing a localized hotspot at the NP position. This enhanced signal originates from electromagnetic confinement within the nanogap cavity, which amplifies the Raman response of the molecular monolayer.

Figure 4(c) displays a representative Raman spectrum of the BPT monolayer within the nanogap. The characteristic vibrational peaks at 1090, 1280, and 1580 cm^{-1} are clearly resolved, confirming effective plasmonic enhancement.

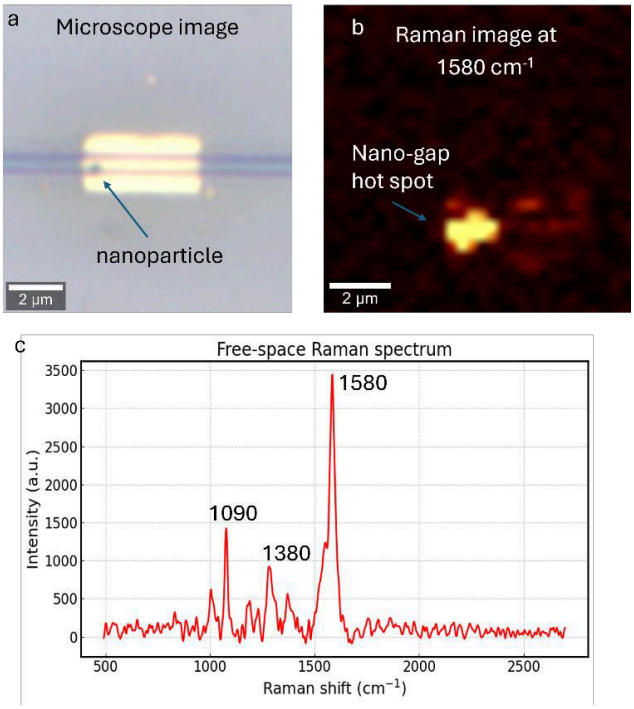

Fig. 4. a) Microscope image of the NPoM structure on top a silicon nitride waveguide. b) Raman mapping of the intensity of the 1580 cm^{-1} vibrational mode of the BPT molecule. c) Free-space Raman spectra of the BPT molecule highlighting the principal vibrational modes at 1090, 1280 and 1580 cm^{-1}.

Figure 5 compares the guided Raman spectra obtained from the complete NPoM structure and from a gold patch without the NP, where no nanogap is formed. In the absence of the NP, the vibrational peaks at 1090 and 1280 cm^{-1} are not detectable, and the intensity of the 1580 cm^{-1} mode is significantly reduced. When the nanogap cavity is created, the 1580 cm^{-1} peak increases by approximately a factor of three, clearly demonstrating the critical role of plasmonic nanogap formation in enhancing the Raman response [6].

This behavior is consistent with the expected operation of the NPoM cavity: without the NP, the electromagnetic field is not strongly confined, and the Raman signal from the BPT monolayer remains weak.

Although the guided Raman signal is lower in intensity compared to free-space measurements, it remains sufficiently strong to clearly resolve the characteristic molecular peaks. This confirms that the waveguide-coupled configuration enables effective on-chip Raman detection despite reduced excitation power and collection efficiency relative to free-space illumination.

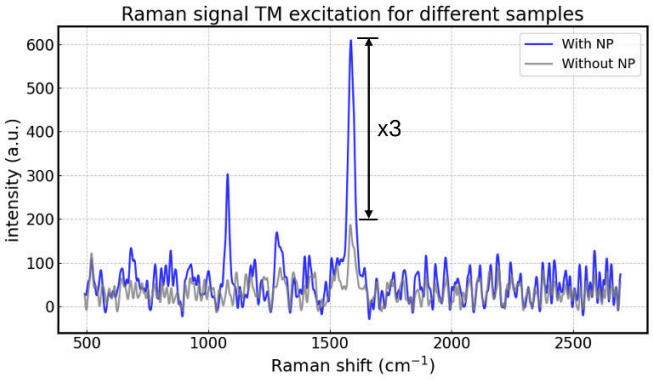

Fig. 5. Guided Raman signal of the NPoM structure measured with TM polarization (blue) vs the guided Raman signal of only gold patch with TM polarization (grey).

Figure 6 compares the guided Raman response under TE and TM excitation. Experimentally, TM polarization yields approximately 1.5× higher Raman intensity than TE, consistent with stronger coupling between the TM mode and the gold patch. This behavior can be attributed to the enhanced overlap of the TM mode's electric field component with the metallic structure, leading to more efficient plasmonic excitation of the nanogap cavity. However, in contrast to the simulations, which predict negligible enhancement for TE polarization, the experimental results show that TE excitation still produces a measurable Raman signal.

This discrepancy may arise from the fact that practical waveguide modes are not perfectly pure in polarization; a quasi-TE mode can retain non-negligible longitudinal or vertical field components that interact with the metallic patch. Additional full-vector and broadband simulations will be required to fully understand this behavior.

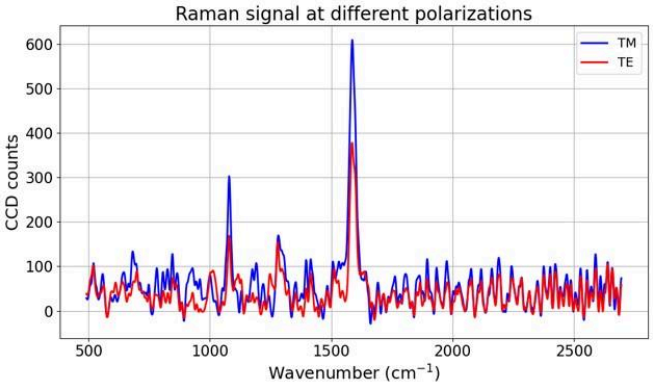

Fig. 6. Guided Raman signal of the NPoM structure measured with TM polarization (red) and TE polarization (blue).

IV. Conclusion

In this work, we have demonstrated both numerically and experimentally a novel waveguide-integrated configuration for Raman spectroscopy based on a NPoM nanocavity fabricated on top of a silicon nitride waveguide. Simulations confirm that TM-polarized guided modes efficiently couple to the plasmonic structure, producing strong local field enhancement within the nanogap. Although TE modes are predicted to exhibit weaker interaction with the gold patch, experimental results show that they still provide sufficient coupling to excite the nanocavity and detect the molecular signal.

Experimentally, guided Raman measurements collected through the waveguide clearly resolve the characteristic vibrational peaks of the BPT monolayer, demonstrating the viability of fully integrated excitation and collection. The formation of the nanogap via deterministic NP placement leads to a substantial increase in Raman intensity compared to a gold patch without NP, confirming the critical role of plasmonic confinement.

These results establish the NPoM–waveguide platform as a compact hybrid dielectric–plasmonic architecture for on-chip Raman spectroscopy, with strong potential for highly sensitive molecular detection and future implementations in chiral and enantiomeric sensing using engineered nanostructures.

***Abstract*— We demonstrate the first inverse-designed multi-port splitter for cladding-free photonic crystal waveguides, achieving 99.99% transmittance with 30:39:30% power splitting across three outputs within a 1.4 × 4.2 μm^2 footprint. Adjoint-based topology optimization with fabrication-aware projection filtering maintains 50 nm minimum feature size, enabling ultra-highdensity photonic integration without cladding layers.**

***Keywords*— Photonic Crystal, Adjoint Optimization, Inverse Design, Photonic-Integrated Circuit**

I. Introduction

Ultra-high-density photonic integrated circuits (PICs) require the elimination of every unnecessary spatial overhead. Recently, cladding-free photonic crystal (PhC) waveguides based on anisotropic rectangular lattices achieved zero-spacing waveguide arrays with negligible crosstalk by exploiting shifted spatial dispersions [1]. Unlike conventional waveguides that rely on total internal reflection or photonic bandgap cladding, this platform achieves mode isolation through deliberately mismatched iso-frequency contours between adjacent channels. Each waveguide simultaneously functions as a transmission channel and an effective cladding for its neighbors, completely removing micrometer-scale cladding layers and enabling unprecedented integration density.

However, functional circuit components, particularly multi-port power splitters have not been explored on this platform. A simple junction connecting one input to three output waveguides demonstrates limited transmission performance, achieving approximately 85% transmittance with a 17:66:17 power distribution [1], where the center channel dominates due to direct in-line coupling while the side channels receive minimal power.

Adjoint-based topology optimization has emerged as the leading method for compact, high-performance photonic device design [2], [3]. Recent advances include fabrication friendly frameworks guaranteeing design-rule compliance [4], broadband multi-port splitters on silicon [5], and silicon nitride platforms [6]. However, extending these capabilities to the cladding-free PhC platform presents unique challenges due to the anisotropic unit cell geometry and the fundamentally different waveguiding mechanism based on dispersion mismatch rather than index contrast.

In this work, we apply adjoint-based topology optimization to design the first inverse-designed 1×3 beam splitter on the cladding-free PhC platform, overcoming the severe limitations of intuitive junction designs.

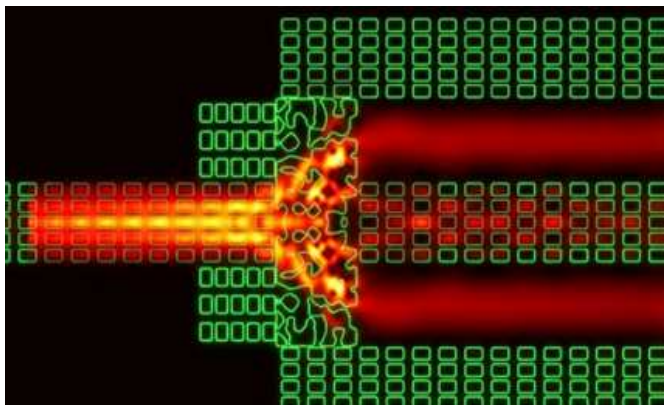

Fig. 1 *Schematic of the cladding-free photonic crystal 1×3 beam splitter. The rectangular dielectric rods ($\varepsilon = 12$) form an anisotropic lattice with periods a and $b = 0.6a$. One input waveguide (left) connects to three output waveguides (right) through the inverse-designed junction region. Green outlines indicate the PhC rod structure.*

II. Methods

A. Cladding-Free Photonic Crystal Platform

The PhC structure follows Ref. [1]: rectangular dielectric rods (ε = 12) in a rectangular lattice with horizontal period a and vertical period b = 0.6a. At a ≈ 460 nm, the operating frequency f = 0.2962(c/a) corresponds to λ ≈ 1.55 μm. The

anisotropic lattice shifts the iso-frequency contours of adjacent channels in momentum space, providing mode isolation without physical cladding [1]. The device consists of one input PhC waveguide connecting to three output waveguides through a 3a × 15b (≈ 1.4 µm × 4.2 µm) design region (Fig. 1). All simulations are performed in 2D for the TM polarization (Ez), consistent with the rod-type PhC operating within the first photonic bandgap.

B. Topology Optimization Framework

The design region is parameterized by a continuous density field ρ(x) ∈ [0, 1] mapped to permittivity: ε(x) = 1 + ρ(x) (εrod −1). The objective function jointly maximizes total transmission and splitting uniformity:

$$\mathcal{J} = \sum_{i=1}^{3} T_i - \alpha \sum_{i=1}^{3} (T_i - \bar{T})^2$$

where T_i is the transmitted power in port i, $\bar{T} = \frac{1}{3}\sum T_i$ is the mean, and α penalizes imbalance. Gradients are computed via the adjoint method in MEEP [2], requiring only two FDTD simulations per iteration regardless of the number of design variables.

As shown in Fig. 2, each iteration runs forward and adjoint simulations whose field overlap yields the sensitivity map. A gradient-based optimizer (Adam) updates the density, which is processed through a conic spatial filter and hyperbolic tangent projection:

$$\tilde{\rho} = \frac{\tanh(\beta\eta) + \tanh\big(\beta(\bar{\rho} - \eta)\big)}{\tanh(\beta\eta) + \tanh\big(\beta(1 - \eta)\big)}$$

where $\bar{\rho}$ is the filtered density, $\eta = 0.5$ is the projection threshold, and β controls binarization strength. A multi-stage β schedule (β: $1 \rightarrow 64$) gradually increases projection sharpness, allowing free exploration at low β before converging to a binary structure with minimum feature size ≥ 50 nm (Fig. 2, bottom).

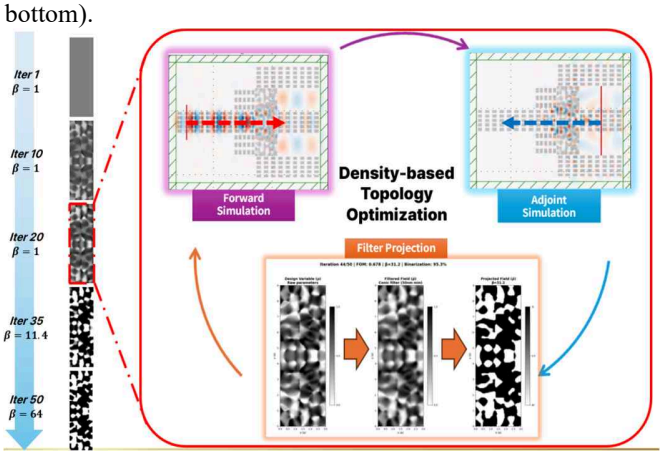

Fig. 2 *Density-based topology optimization workflow. Forward and adjoint FDTD simulations (top) compute gradients across the design region. The projection filter (bottom) progressively binarizes the design from grayscale ($\beta = 1$) to binary ($\beta = 64$), enforcing minimum feature size constraints.*

III. Results and Discussion

Performance Comparison with PhC-Based 1×3 Beam Splitters

Design	Trans.	Split Ratio	Feature	WG Pitch	Method
Ref. [1] (unopt.)	~85%	17:66:17	—	0.6a†	Manual
Jin *et al.* [7]	>96%	33:33:33	~100 nm	≥3a*	Simplex
This work	**99.99%**	**30:39:30**	**50 nm**	**0.6a†**	**Adj. TO**

†Cladding-free: zero-spacing waveguide array /
*Requires cladding rows between adjacent waveguides

- **99.99% total transmittance** with 30/40/30% power splitting
- **~5× higher channel density** than conventional PhC splitters (WG pitch 0.6a vs. ≥3a)
- **50 nm minimum feature size** maintained throughout the fully binarized design
- **Strong field confinement** with minimal scattering loss at the junction (Fig. 1)

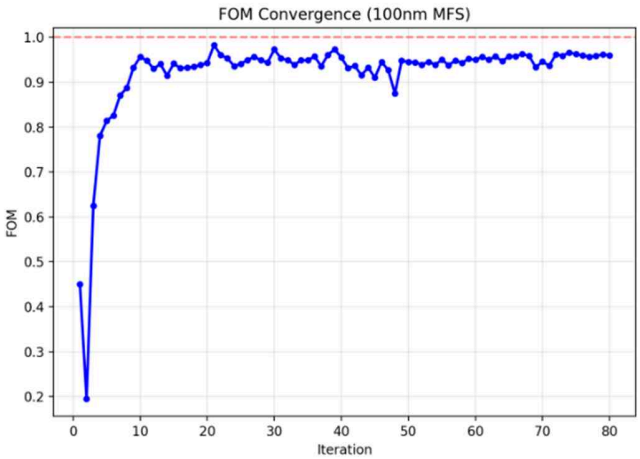

Fig. 3 *FOM convergence over 80 iterations. The dashed red line indicates the theoretical maximum.*

Fig. 3 shows the convergence of the figure of merit (FOM) over 80 iterations. The FOM rises rapidly during the initial low-β phase (iterations 1–10). Oscillations between iterations 20–60 correspond to β increments; each step sharpens binarization, temporarily degrading the FOM before reconvergence. The final FOM stabilizes near 0.97, reflecting high transmittance and improved uniformity with a fully binarized structure.

The 30:39:30 splitting ratio reflects the inherent T-junction geometry where the center channel receives slightly more power from direct in-line coupling. While not perfectly uniform, this represents a dramatic improvement over the 17:66:17 baseline and is sufficient for practical PIC applications including balanced detection and optical monitoring.

IV. Conclusion

We demonstrated the first inverse-designed multi-port component on a cladding-free PhC platform. The adjoint-optimized 1×3 beam splitter achieves 99.99% transmittance and 30:39:30 splitting within a $1.4 \times 4.2\ \mu m^2$ footprint with 50 nm minimum feature size. This establishes topology optimization as a viable methodology for cladding-free PhC circuits. Future work includes broadband optimization, robustness analysis (erosion/dilation), and experimental demonstration.

***Abstract*— Nonlocal free-electron dynamics have a substantial contribution to the optical nonlinearity in heavily doped semiconductor systems, and is very tunable. We applied hydrodynamic method to explored the tunability third-harmonic generation and optical Kerr bistability.**

***Keywords*— hydrodynamics, mid-infrared, nonlocal optics, nonlinearities.**

I. Introduction

Understanding the nonlinear light-matter interaction at the nanoscale has been a long-standing fundamental target since it guides the design rule for minimized and integrated nonlinear photonic devices. Achieving a strong and ultrafast nonlinear optical response is essential for various fields such as optical information processing and artificial intelligence training. Yet, efficiently manipulating light with light is still challenging, leading to an urgent demand of exploring new physics for higher nonlinear interactions.

II. Methods

Our methodology used hydrodynamic theory to calculate the free-electron nonlinear interactions from the equation of the motion of the free-electron gases with the encapsulated energy functionals:

$$m_e\left(\frac{\partial}{\partial t}+\mathbf{v}\cdot\nabla+\gamma\right)\mathbf{v}=-e(\mathbf{E}+\mathbf{v}\times\mu_0\mathbf{H})-\nabla\frac{\delta G[n]}{\delta n}. \quad (1)$$

It will coupled with the wave equation for the linear and nonlinear optical responses

$$\nabla\times\nabla\times\mathbf{A}_j+\frac{\varepsilon_r}{c^2}\frac{\partial^2\mathbf{A}_j}{\partial t^2}+\mu_0\frac{\partial}{\partial t}(\mathbf{P}_j+\mathbf{P}_d^{\mathrm{NL}})=0. \quad (2)$$

with a field effect on the semiconductor considered by including the Poisson equation:

$$\nabla^2\varphi=-e(p_0(\mathbf{r})-n_0(\mathbf{r})+N_D^+-N_A^-)/\varepsilon_0\varepsilon_r. \quad (3)$$

On the left-hand side of Eq. (3) there is the Laplacian of the band bending φ, whereas the right-hand side accounts for the total charge density, including hole $p_0(\mathbf{r})$ and electron $n_0(\mathbf{r})$ densities, and ionized donor N_D^+ and acceptor N_A^- concentrations. $\varepsilon_0\varepsilon_r$ denotes the permittivity of the semiconductor.

III. Results and Discussion

Free electrons in plasmonic structures can provide extra degrees of freedom in modulating nonlinearities in the system when spatial nonlocality is considered. The hydrodynamic model reveals that the third-order nonlinearity due to the free electrons could even be orders of magnitude higher than that of the conventional bulk susceptibility when the equilibrium electron density is low.

Kerr nonlinearity is a third-order process that supports fascinating phenomena such as optical bistability and self-focusing. A high optical Kerr nonlinearity at the nanoscale is a crucial element in ultrafast optical neuromorphic computation devices as it can enable all-optical nonlinear activation functions. Employing a time-domain simulation within a finite-element framework, we could self-consistently solve electromagnetic wave equation and hydrodynamic formalism

with Kerr nonlinear contributions. We show that heavily doped semiconductor structures can provide strong free-electron Kerr nonlinearities supported by the longitudinal bulk plasmon mode, and is very tunable by the field effect. This high nonlinearity originates from the multibody properties of the free electron gas as the electron-electron interaction can be naturally taken into account in the hydrodynamic theory when proper kinetic energy functionals are considered. It can work as optical modulators in the mid-infrared.

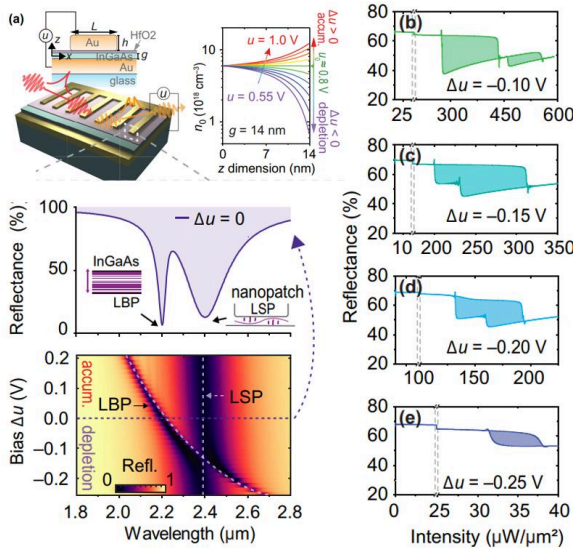

Fig. 1 Surface charge modulation of the heavily doped semiconductors that give rise to exceptional tunabilities for optical modulator in the mid-infrared.

IV. Conclusion

We applied multiphysical calculations involving quantum-corrected hydrodynamic theory with semiconductor and wave optics based on the finite-element method to explore a tunable and significant third-harmonic generation and optical Kerr bistability. We proposed a microscopic mechanism to electrically reconfigure the Kerr nonlinearity by modulating the concentration of free electrons in heavily doped semiconductors under a static bias. Our theory incorporates electrostatic and hydrodynamic frameworks to describe the electronic dynamics, demonstrating electrically tunable linear and nonlinear modulations. The power threshold of achieving optical bistability shows unprecedented tunability over 2 orders of magnitude. Varying biases, a charge depletion will significantly decrease the power threshold of the bistability from thousands of down to tens of $\mu W/\mu m^2$. On the contrary, charge accumulation will give rise to a wide (>70%) and high-contrast ($\sim 40\%$) bistability with a still decent threshold of several $mW/\mu m^2$. Moreover, we unveil that the often-neglected cascaded contributions in the Kerr effect can also be dominant in this system. Our findings open a viable avenue for active ultrafast nonlinear devices with low power consumption.

These findings offer insights into understanding and actively controlling Kerr nonlinearities, paving the way for efficient refractive-index engineering as well as the development of advanced linear and nonlinear electro-optical modulators

***Abstract*—We report a five- layer gold and polymer dispersed liquid crystal multilayer metamaterial exhibiting sub unity permittivity in the optical regime. Using spectroscopic ellipsometry and effective medium theory, we characterize this Epsilon near zero phenomenon. This architecture serves as a foundational platform for thermally switching the system towards hyperbolic dispersion.**

***Keywords*— Epsilon near zero, Active metamaterials, Hyperbolic metamaterial, Topological phase transition, Liquid crystal photonics.**

I. Introduction

Photonic metamaterials with Epsilon-Near-Zero (ENZ) and hyperbolic dispersion offer extraordinary control over light-matter interaction. However, many plasmonic-dielectric stacks are static[1]. By incorporating Polymer Dispersed Liquid Crystals (PDLC) as the active dielectric layer, we introduce a temperature-dependent refractive index into the system. This work focuses on the characterization of an Au/PDLC multilayer stack, identifying the specific spectral regions where the parallel permittivity component vanishes, marking the onset of the ENZ regime.

II. Methods

The system consists of a 5-layer stack (Au/PDLC/Au/PDLC/Au) on a glass substrate (Fig. 1). Au and PDLC layers were fabricated by sputtering and spin coating respectively. The PDLC was prepared with a mixture of nematic liquid crystal E7 and NOA68 in the ratio 70:30. After spin coating, the film was photo-polymerized with UV irradiation to form a polymer layer. The formation of PDLC was confirmed by polarizing optical microscopy. Nominal layer thicknesses are d_m = 55 nm for gold and d_d = 110 nm for PDLC. The layer thickness was confirmed by stylus profilometry. Spectroscopic ellipsometry was performed to collect Ψ (Psi) and Δ (Delta) parameters at three different incident angles, 65°, 70° and 75°. Data analysis was performed using the PyElli Python library, employing a multilayer model to fit the experimental Ψ and Δ profiles. Uniaxial Effective Medium Approximation (EMA) based on Maxwell-Garnet approach was employed to extract the permittivity[2]. The parallel and perpendicular permittivity components were calculated as:

$$\varepsilon_{\parallel} = \rho\varepsilon_m + (1-\rho)\varepsilon_d \quad (1)$$

$$\varepsilon_{\perp} = \frac{\varepsilon_m \varepsilon_d}{\rho\varepsilon_d + (1-\rho)\varepsilon_m} \quad (2)$$

where, ε_m and ε_d are permittivity of Au and PDLC layers, and ρ is the fill fraction of Au.

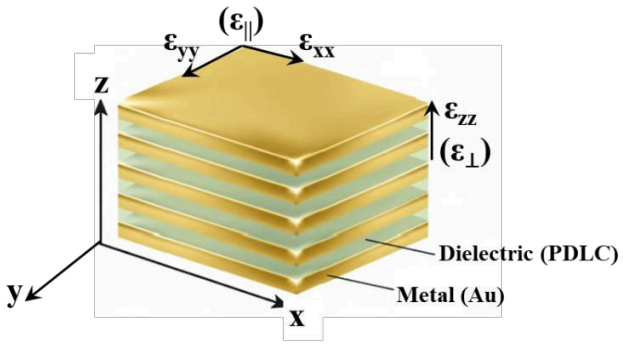

Fig. 1 Schematic representation of the Au/ PDLC multilayer metamaterial system.

III. Results and Discussion

The optical response of the five-layer Au/PDLC stack was characterized using spectroscopic ellipsometry. The extracted parallel and perpendicular effective permittivity components, $\varepsilon_{\parallel}$ and parallel $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ perpendicular reveal a strong uniaxial anisotropy inherent to the multilayer geometry[3]. As shown in

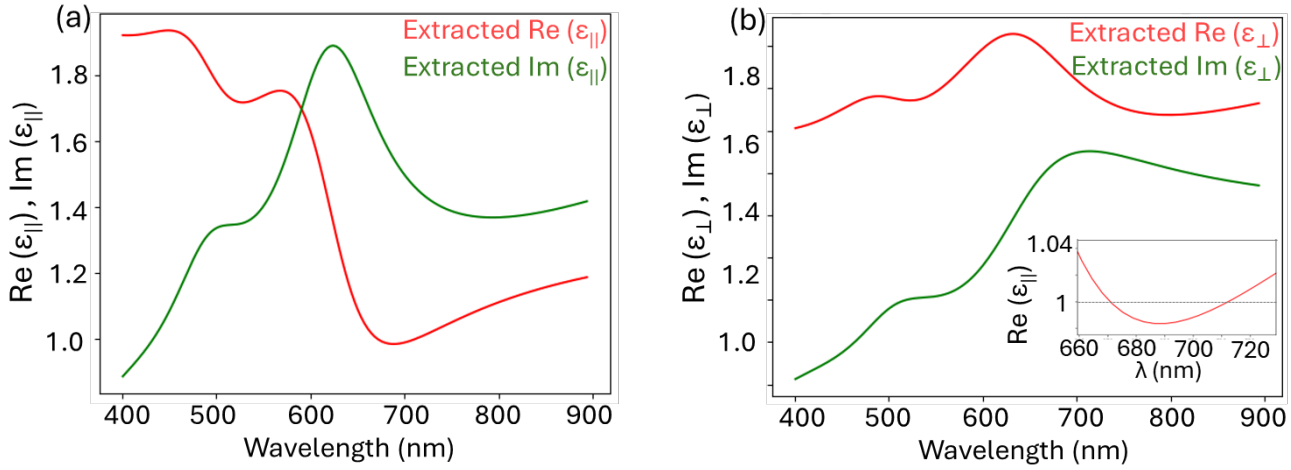

Fig. 2 Extracted Real and Imaginary permittivity of the Au/PDLC multilayer system in the direction (a) parallel to the layers and (b) perpendicular to the layers. Inset to (b) shows the Re $\varepsilon_{\parallel}$ drops below 1, thus exhibiting an ENZ behaviour

Fig. 2, the real part of $\varepsilon_{\parallel}$ (i.e., Re $\varepsilon_{\parallel}$) exhibits a significant decrease across the visible spectrum, reaching a sub-unity minimum of 0.98 at ~ 685 nm. This sub-unity value of $\varepsilon_{\parallel}$ signifies that the system is effectively acting as an Epsilon-Near-Zero (ENZ) medium, while the extent and wavelength range of ENZ is tunable by the nematic liquid crystal.

The proximity to zero indicates a highly balanced ratio between the plasmonic contribution of the gold layers and the

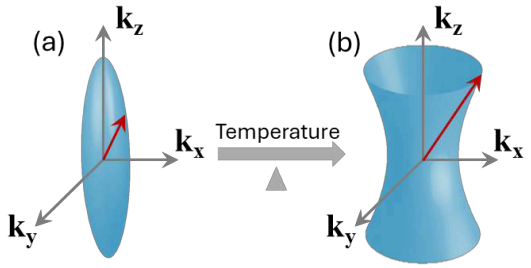

Fig. 3 Schematic representation of the Iso frequency surfaces representing the (a) ENZ behaviour exhibited by the Au/ PDLC multilayer system, (b) Hyperbolic metamaterial behaviour expected in the system upon increasing the temperature. The red arrow represents the direction of propagation of the k- vector

dielectric response of the PDLC. At this specific wavelength, the system operates at the topological threshold. The iso-frequency surface is currently an extreme prolate ellipsoid but is positioned to transition into hyperbolic dispersion[3]. The stability of this near-zero state validates our design and the accuracy of the effective medium approximation (EMA) for a five-layer metamaterial system. Unlike static metal-dielectric stacks, the current results represent a "pre-transition" state. Because the refractive index of the PDLC layers is highly sensitive to temperature, this Re $\varepsilon_{\parallel} \sim 0.98$ baseline suggests that a modest thermal modulation will drive the permittivity across the zero-axis, triggering a topological transition[4] to a hyperbolic regime (Re $\varepsilon_{\parallel} < 0$) as depicted in Fig. 3. This confirms the stack's potential as a thermally addressable photonic platform.

Conclusion

We have successfully designed, fabricated and characterized a five-layer gold and polymer-dispersed liquid crystal (Au/PDLC) multilayer metamaterial system. Spectroscopic ellipsometry analysis identifies a distinct sub-unity permittivity regime ($\mathrm{Re}(\varepsilon_{\parallel}) \approx 0.98$) in the nematic phase, confirming that the effective medium response is accurately captured by our 5-layer model. The achievement of an Epsilon near-zero state in the optical spectral regime serves as a critical threshold for active topological photonics.

Future work will focus on temperature-resolved ellipsometry to map the topological phase transition as the system crosses the nematic-to-isotropic transition. By thermally modulating the liquid crystal medium, we aim to demonstrate the active switching from an elliptical to a hyperbolic dispersion. This research provides a robust roadmap for the development of high-sensitivity thermal sensors and reconfigurable flat optics.

***Abstract*—These studies explore the potential of Liquid Crystals (LCs) for the realization of security system based on the paradigm of Physical Unclonable Functions (PUFs). By exploiting the self-organizing nature of LCs and their sensitivity to external stimuli, we generate unique optical "textures" through different pathways. In parallel, the optical properties of LC allows to camouflage security system as PUF or Qre code which will be revealed only under specific conditions. Our results demonstrate the potential of LC to realized multi-modal security systems that significantly increase the barrier to unauthorized cloning.**

***Keywords*— physical unclonable function, liquid crystal, image recognition, optical encoding.**

I. Introduction

Traditional anti-counterfeiting measures, such as 2D holograms and RFID tags, often rely on secrets stored in digital memory or reproducible manufacturing patterns, making them vulnerable to sophisticated emulation. Physical Unclonable Functions (PUFs) offer a paradigm shift by deriving security from the inherent randomness of a physical medium.

Liquid crystals (LC), specifically chiral nematics, are ideal candidates for the generation of PUF primitives due to their stochastic self-assembly and sensitivity to stimuli like temperature, pressure, and electromagnetic fields. The obtained textures act as "physical-to-digital" bridges, where the microscopic complexity of molecular alignment provides a unique, non-deterministic signature that cannot be replicated even by the original manufacturer.

II. Results and Discussion

The experimental investigations yielded significant insights into the stochastic generation of liquid crystal textures across various physical configurations, establishing a robust basis for their use as Physical Unclonable Functions. In the first phase of the study, cholesteric liquid crystals (CLC) emulsioned with acqueos or Polydimethylsiloxane (PDMS) matrix were confined within spherical micro-cavities to observe the effects of multi-stimuli interaction. By applying controlled temperature variation, or mechanical stress, we successfully induced a series of highly complex, fingerprint-like textures. The latter were analyzed with image recognition algorithm yealding to identify more than 500 unique features in a single texture.

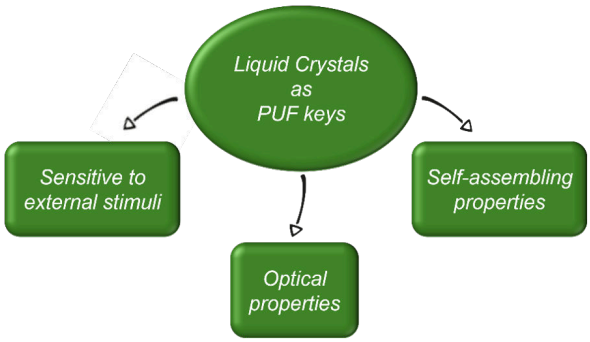

Fig. 1. Schematic of liquid crystal properties for the realization of PUF keys.

In parallel, our research into planar-aligned CLC revealed a critical discovery regarding molecular behavior in the regime immediately preceding the Fréedericksz transition. We observed that the application of sub-threshold voltages triggers a continuous and non-linear molecular rearrangement rather than a binary switch. This subtle movement results in a temporal sequence of unique textures that are governed by microscopic local variations in anchoring energy and field distribution. This phenomenon effectively creates a "kinetic" PUF, where the security key is defined irreproducible the texture's evolution over time. The discretization into different levels of the single unique image leads to the generation of a very large amount of secret key that can be used as One Time Password.

Finally, a polymer-dispersed liquid crystal (PDLC) architectures was optimized to provide a sophisticated method for optical camouflaging. The PDLC was realized on a multilayer structure which provide structural colors which are sensitive to incident and viewin angles. The results indicate that the light-scattering properties of the polymer matrix effectively

mask the underlying secret keys rendering the security device invisible to standard optical inspection. Upon the application of a temperature variation, the PDLC undergoes a transition from an opaque to a transparent state, revealing the key for verification. Furthermore, in the transparent state the structural colors are also visible. This dual-state functionality adds a vital ”stealth” layer to the authentication device, ensuring that the fingerprint is only exposed during the authorized reading phase, thereby significantly reducing the risk of unauthorized cloning or scanning.

III. Conclusion

This research establishes a versatile framework for utilizing Liquid Crystals in the fight against counterfeiting. By leveraging the sensitivity of LC textures to environmental and electrical stimuli, we have developed a suite of PUF keys that are both highly complex and easy to verify through standard optical methods. Furthermore PDLC matrices were optmized to realize a ”camouflage” layer that protects the key from unauthorized scanning. Future work will focus on the automated verification of these textures to ensure rapid, field-deployable authentication.

***Abstract*—Triply Periodic Minimal Surfaces (TPMS) offer lightweight, high-symmetry architectures with tunable mechanical properties. This study computationally investigates deformation coupling in TPMS-based beams under static and dynamic loading. Results reveal morphology-dependent behaviors, with sheet gyroids exhibiting strong bend–twist coupling and solid gyroids showing pull–twist responses. Coupling can be tailored via geometric modifications, enabling multifunctional, shape-adaptive structural design.**

***Keywords*— TPMS, deformation coupling, optimization**

I. Introduction

Triply Periodic Minimal Surfaces (TPMSs) have recently emerged as a versatile class of structured materials due to their high symmetry, exceptional stiffness-to-weight ratio, and large, tunable design space [1], [2]. Defined by smooth, zero-mean-curvature surfaces that partition space into two continuous and equivalent volumes, TPMSs can be efficiently described through parametric formulations and readily modified through grading, hybridization, or by modifying their equations [3] . While some research can be found studying their mechanical properties [4] and wave-propagation characteristics [5], [6], the potential of coupling effects—such as bend-twist and pull-twist interactions—remains comparatively underexplored.

II. Methods

This work investigates the utility of coupling in TPMS-based structures, with particular emphasis on the varying symmetry of the different geometries. Several TPMS-based structures are analyzed using finite element methods (FEM) to explore their deformation coupling in finite structures. The path followed looks at beams under static loading conditions and how the coupling they present can be tuned with a variety of techniques such as modifying the aspect ratio of the unit cells, al-tering their orientation or modifying their iso-surface. To effectively handle the complexity of these geometries in a computationally efficient manner, several geometry and simulation approaches have been used such as voxelization [7].

The testing campaign consists of both static and dynamic tests on polymeric, 3D-printed samples. The behavior of the resulting experiments is compared against the computational models and used to validate them.

III. Results and Discussion

Results demonstrate that different TPMS morphologies exhibit markedly distinct coupling behaviors. Figure 1 includes the static simulation of three different cantilever beams consisting of 1x1x10 unit cells and 20% volume ratio. Two different loading conditions, pure axial and pure bending, were applied to visualize and understand the deformation characteristics. The primitive acts as the control, lacking any type of coupling. On the other hand, the gyroid does couple deformation with a radically different type for the sheet and body variants. Figure 2 illustrates a quantitative measure of different TPMS types. The coupling coefficient, $C = r_{end}/d_{end}$, is a normalized ratio between the rotation and deformation at the end of the beam. it is apparent that different geometries have different coupling coefficients, with the gyroid being the most efficient at coupling bending-rotation, interesting for passively adaptive-airfoils [8].

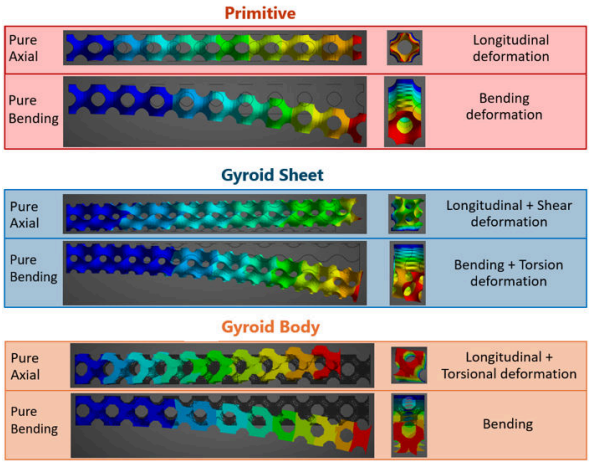

Fig. 1. Deformation coupling of different TPMS structures.

With this information, the finite structures can be modified to eliminate or enhance desired couplings increasing the design space of these types of structures. The impact of increasing the aspect ratio of the unit cells, modifying the iso-level surface of the TPMSs and the orientation of the unit cells have also been explored. These modifications result in different symmetries [7] with their respectively different stiffness

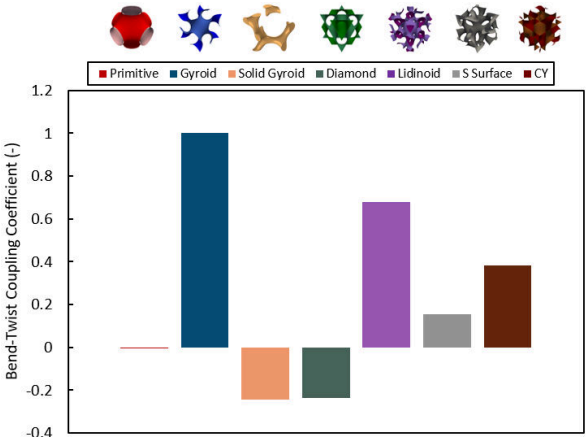

Fig. 2. Bend-Twist coupling coefficient of different geometries.

tensors allowing us to use properties such as anisotropy to our advantage [9]. These findings prove that TPMSs are not only effective structural materials but can also be engineered for multifunctional applications by exploiting coupling effects, such as passive shape-adaptive structures.

IV. Conclusion

This work demonstrates that TPMS-based beams exhibit morphology-dependent deformation coupling under static and dynamic loading. Finite element simulations, validated experimentally, confirm that coupling can be tuned through unit-cell aspect ratio, orientation, and iso-surface modifications. By leveraging symmetry and anisotropy, TPMS architectures can be systematically engineered to enhance or suppress targeted couplings. The gyroid resulted of particular interest for its hight coupling coefficient and tunability. These results expand the functional design space of TPMS structures, highlighting their potential for lightweight, multifunctional, and passively shape-adaptive applications.

Topological Eutectic Heterostructures: Quantification of Their 2D-morphology

Krzysztof Markus[1], Kingshuk Bandopadhyay[1], Andrzej Materna[1], Andriy. M. Gusak[1], Dorota A. Pawlak[1]

[1]ENSEMBLE[3] Centre of Excellence, Wolczynska 133, 01-919 Warsaw, Poland

***Abstract*— Three-dimensional topological insulators (TIs) have attracted considerable attention due to their topologically protected gapless surface states. However, they have some disadvantages that limit their use. Here, we propose utilizing eutectic TI heterostructure composites as a platform for studying junctions between TIs and materials with complementary physical properties.**

***Keywords*— topological insulator, eutectic lamellar heterostructure, materials characterization.**

I. Introduction

The morphology of eutectic heterostructures is strongly influenced by crystal growth conditions. This dependence provides a powerful route to engineer and optimize microstructures for targeted applications. To understand and control these effects, a quantitative description of the relationship between growth parameters and resulting structural features is required. In this work, we investigate the morphological evolution of eutectic topological insulator heterostructures grown under different conditions and develop a methodology for their quantitative analysis.

II. Methods

The analyzed samples consisted of polycrystalline eutectic TI heterostructures, including Sb_2TeSe_2-Sb_2Se_3, Bi_2Te_3-BiTeI, grown using the vertical Bridgman method. For each material system, at least three different growth rates were employed. Samples were sectioned perpendicular to the growth direction and subsequently polished to obtain high-quality surfaces suitable for imaging. Morphological characterization was performed using scanning electron microscopy (SEM) in backscattered electron mode, providing enhanced phase contrast between the constituent materials.

The acquired SEM images were converted into binary matrices representing the two constituent phases. This enabled quantitative analysis using a digital image-processing algorithm developed by Gusak and Abakumov [1]. The algorithm determines structural parameters using two complementary approaches. The first method evaluates the number of phase transitions along image rows and columns, providing information on characteristic spacing and periodicity. The second method utilizes the total area of the minority phase and the interfacial boundary length to quantify phase distribution and interface complexity.

III. Results and Discussion

The analysis reveals a clear correlation between crystal growth rate and structural parameters, including lamellar thickness, interlamellar spacing, and interface morphology for each eutectic composition studied. The results confirm that the characteristic lamellar dimensions are strongly dependent on growth velocity. Increasing the growth rate leads to a significant reduction in lamellar size, enabling the transition from micrometer-scale to nanometer-scale structural features. This demonstrates the possibility of tailoring the microstructure through controlled solidification conditions.

IV. Conclusion

The study demonstrates that SEM imaging combined with the quantitative analysis algorithm developed by Gusak and Abakumov provides a reliable method for characterizing eutectic heterostructures, even when the constituent phases exhibit only small differences in atomic number.

Furthermore, we confirm that the morphology of eutectic topological insulator heterostructures can be systematically controlled through growth conditions. Such control enables the tuning of lamellar dimensions and material combinations, offering opportunities for phonon spectrum engineering and the enhancement of thermoelectric performance [2].

***Abstract*—An all-dielectric slotted-disk metasurface sensor supporting quasi-bound states in the continuum is presented. Symmetry-breaking enables high-Q resonance with strong, external E-field confinement, producing high refractive index sensitivity and figure-of-merit while offering a scalable platform for nanophotonic sensing application.**

***Keywords*— metamaterials, quasi-bound states in the continuum, metasurface, refractive index sensing.**

I. Introduction

Traditional biosensing methods frequently employ plasmonic nanostructures, utilizing localized surface plasmon resonances (LSPRs) for signal transduction. However, these structures often suffer from broad resonance peaks caused by inherent material losses, which lowers their quality factors [1].

The discovery of quasi-bound states in the continuum (q-BIC) resonances in dielectric metasurfaces presents interesting possibilities for sensing applications. q-BICs are sharp Fano resonant states with long optical lifetimes which can be manufactured and controlled by fabricating a small degree of asymmetry in the design of a nanoresonator.

In this work, we present a novel all-dielectric silicon metasurface design based on a slotted-disk nanostructure [2]. Compared to other designs, the slotted-disk is relatively easy to fabricate with enhanced control over the symmetry breaking, enabling very high Q-factors. As the slotted-disk is defined primarily by a single radius, whereas dimer-based metasurfaces specify complex positioning and ellipse requires both the minor and major axes.

This design exhibits a bulk refractive index sensitivity (S) of 450 nm/RIU in the IR spectrum, with a Q-factor $> 10^3$, E-field enhancement of 104 and a Figure-of-Merit (FOM) > 460. The quoted Q-factor is for a slot width of 100 nm offset by 10 nm from the center of the meta-atom. These dimensions fall well within fabrication limits of electron beam lithography and helium-ion lithography. The slot width can be further reduced with possibilities of Q $> 10^5$ achievable with the slotted-disk geometry. This work explores a new design space for advancing BIC-based nanophotonic sensors, which can be used for improved performance in real-world sensing applications.

II. Methods

Finite difference time domain (FDTD) simulations were performed using a commercial FDTD software (Lumerical Inc.) to numerically simulate the reflectance, transmittance and electric field maps of the metasurface using refractive index data. The transmittance spectra shown in Figure 3 can be described by the Fano formula. The Fano parameters are explicitly expressed through the material and geometrical parameters of the metasurface and dimensionless frequency [1].

$$T(\omega) = T_{bg}(\omega) + \frac{T_0}{1+q^2}\frac{(q+\bar{\omega})^2}{1+\bar{\omega}^2} \tag{1}$$

The dimensionless frequency is defined as $\bar{\omega} = \hbar(\omega - \omega_{\text{q-BIC}})/\gamma_{\text{q-BIC}}$, where $\omega_{\text{q-BIC}} = 2\pi c/\lambda_{\text{q-BIC}}$. Here, $\gamma_{\text{q-BIC}}$ denotes the half-linewidth of the q-BIC resonance, q is the Fano parameter, and c represents the speed of light in vacuum. The terms T_{bg} and T_0 correspond to the background contribution from non-resonant modes to the amplitude of the resonant peak and the offset, respectively.

Sensitivity is defined as $S = \Delta\lambda_{\text{res}}/\Delta n$, where $\Delta\lambda_{\text{res}}$ is the resonance shift induced by a refractive-index change Δn. The figure of merit is $\text{FOM} = S/\text{FWHM}$, with FWHM the resonance linewidth.

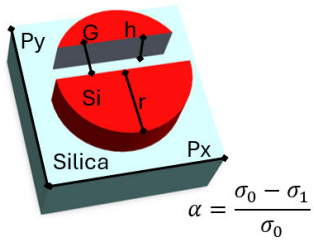

Fig. 1. Schematic of the Si slotted-disk meta-atom on a SOI (SiO_2) substrate. The parameters shown are the width of the slot, G, the radius of the disk, r, the periodicity of the meta-atom in the x and y directions, p_x and p_y, respectively and the height of the disk, h. The array of meta-atoms produces a metasurface that supports a q-BIC resonance. σ_0 and σ_1 are defined as the area of the larger and smaller hemispheres of the disk, respectively, and α is the asymmetry parameter.

III. Results and Discussion

A schematic diagram of the all-dielectric Si slotted-disk meta-atom can be seen in Figure 1, defining the unit cell of the metasurface with periodicity p_x and p_y in the x and y directions, respectively. The unit cell is composed of a cylinder of height h and radius r, with an off-center slot with width G, creating 2 asymmetrical hemispheres. The crucial structural

feature responsible for the realization of the q-BIC resonance is the off-center slot with width, G, between the hemispheres of the disk, as indicated in Figure 2 where the E-field map is shown. As seen in Figure 3, by tuning G, the FWHM of the resonance can be controlled, with a minimum full width at half maximum (FWHM) of 0.12 nm obtained with $r = 300$ nm, $G = 100$ nm, $p_x = p_y = 800$ nm and $h = 220$ nm, indicated by the dark blue line at 1539 nm in Figure 3 achieving a Q-factor $>$ 12,800.

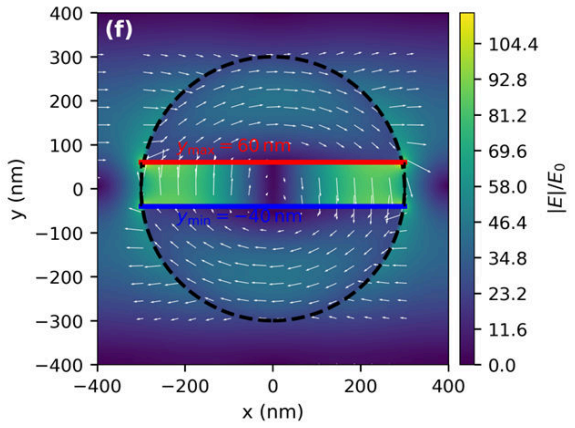

Fig. 2. Simulated electric field enhancement of the resonator, simulating the q-BIC resonance shown in Figure 3 located at 1544 nm with the positions of y_{min} and y_{max} shown.

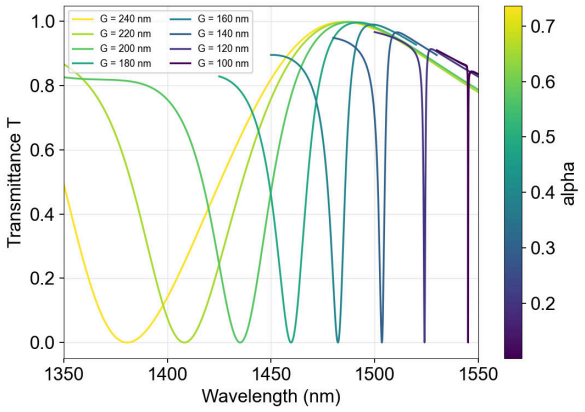

Fig. 3. Transmission spectra for a range of slot widths, with with one slot edge fixed at -40 nm and $r = 300$ nm, $p_x = p_y = 800$ nm and $h = 220$ nm.

The relationship between the slot width, the BRIS, the FOM, and Q-factor of the resonance was explored. It was shown that as the slot width increases, the sensitivity increases along with the FOM while a decrease in the Q-factor is observed. This is expected due to the $Q \propto \alpha^{-2}$ for q-BIC resonances. The sensitivity of the sensor was found to increase with the slot width, due to the increase in volume of the region of enhance dielectric field within the slot.

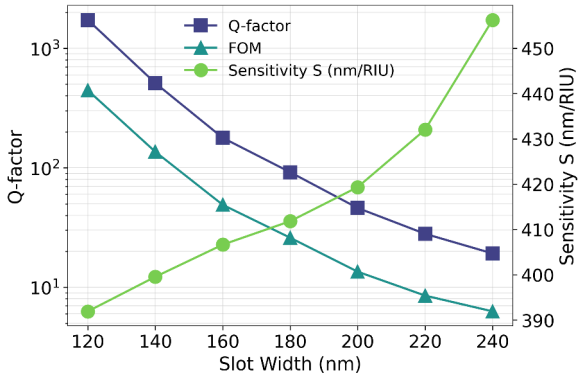

Fig. 4. FDTD simulations showing the FOM and sensitivity as a function of the slot width with $r = 300$ nm, $G = 120$ nm, $p_x = p_y = 800$ nm and $h = 220$ nm with the minimum of the slot kept at -40 nm.

TABLE I
SELECTED SILICON-BASED METASURFACE SENSORS WITH HIGH-PERFORMANCE SENSING METRICS.

Structure	Res.	λ (nm)	FOM	S (nm/RIU)
Dual Ellipses [3]	q-BIC	700–900	72.2	122
Chiral q-BIC [4]	q-BIC	940	163	48
Eight-Shaped [5]	Fano	1350–1550	444	404
Slotted Square [6]	q-BIC	1557	117000	58.9
This Work	q-BIC	1350–1550	450	460

IV. Conclusion

We have demonstrated an all-dielectric metasurface sensor which employs a q-BIC resonance. Table 1 shows a comparison between high performance silicon metasurfaces and our metasurface in a similiar spectral region. The Si slotted-disk metasurface shows the highest reported sensitivity and FOM for the wavelength range/

***Abstract*—We propose a double-resonant mid-infrared plasmonic metasurface for label-free spectroscopic analysis of circulating exosomes in hepatocellular carcinoma. The device is designed to enhance protein vibrational bands and to provide a refractive-index-sensitive readout, as a candidate characterization module for a future exosome-based liquid biopsy platform.**

***Keywords*— plasmonic metasurfaces, mid-infrared spectroscopy, extracellular vesicles, exosomes, liquid biopsy, hepatocellular carcinoma.**

I. Introduction

Mid-infrared spectroscopy provides label-free access to vibrational fingerprints of nucleic acids, proteins, and lipids, making it highly attractive for biosensing and cancer diagnostics. Its use in complex biofluids, however, is limited by weak biomolecular absorption cross-sections and strong water background, which reduce sensitivity and restrict in-liquid measurements. Surface-enhanced infrared absorption using plasmonic metasurfaces has emerged as an enabling technology to overcome mid-infrared limitations, by exploiting lithographically defined metal nanoantennas to concentrate the electromagnetic field and amplify selected vibrational modes. In parallel, recent studies have demonstrated that similar double-resonant metasurface architectures can also be applied to real-time monitoring of live cells under drug treatment, further supporting their robustness and versatility. Extracellular vesicles (EV), and exosomes in particular, are nanoscale lipid vesicles secreted by most cell types that carry molecular cargo reflecting the physiological or pathological state of their parental cells. They are abundantly released in blood and other fluids and are increasingly recognized as promising biomarkers for liquid biopsy in oncology, including hepatocellular carcinoma.

In this work we present a double-resonant gold nanoantenna metasurface tailored for mid-infrared characterization of circulating exosomes from hepatocellular carcinoma patients. We show how our nanoantenna based device enhances diagnostically relevant amide bands, provides a refractive-index-sensitive readout for monitoring immunocapture, and fits as the core characterization module of future multifunctional platform for exosome isolation and machine-learning-driven spectral classification

In a future implementation, this metasurface module could operate alone or downstream of an exosome isolation unit (e.g. ZnO-nanowire based microfluidic module) and be coupled to machine-learning analysis of mid-IR spectra for automated classification of healthy, cirrhotic, and HCC samples.

II. Methods

The sensing platform is based on a double-resonant gold nanoantenna array fabricated on CaF_2 and optimized for mid-IR operation in liquid. The chip is conceived for reflection measurements on a commercial FTIR spectrometer using back-side illumination: the mid-IR beam impinges on the dry

side of the CaF_2 substrate at an oblique angle and is reflected by the nanoantennas in contact with the liquid sample. This geometry minimizes direct interaction with water, maintains exosomes in a hydrated environment, and enables large-area probing of the metasurface.

Gold nanoantenna metasurfaces are patterned on a 1 mm-thick CaF_2 substrate by electron-beam lithography using a 300 nm thick PMMA resist layer. The unit cell of the pattern includes two parallel rod types: long rods ($L \approx 1.8$ μm) resonant in the Amide I–II region, and shorter rods ($L \approx 1.0$ μm) responsible for a sharp reflectance dip around 1900 cm^{-1}. After PMMA exposure and development, a 10 nm Cr / 80 nm Au bilayer is deposited by e-beam evaporation and lifted off, leaving the rod array directly on CaF_2. Final cleaning involves organic solvent rinses and brief oxygen plasma to remove resist residues. Exosomes are isolated from plasma of healthy, cirrhotic, and HCC subjects using polymer-based precipitation and are characterized by TEM and NTA to confirm vesicle size and morphology. The gold metasurface is functionalized with a biotin-PEG thiol layer, NeutrAvidin, and biotinylated antibodies to enable selective immunocapture of exosome subpopulations directly on the antennas.

III. Results and Discussion

Mid-IR analysis of extracellular vesicles isolated from plasma of cirrhotic and HCC patients evidences that discriminative information is concentrated in the vesicle fraction rather than in bulk plasma.

The double-resonant nanoantenna architecture is designed to enhance exactly these diagnostically relevant regions and to introduce an additional refractive-index-sensitive observable. Long antennas are tuned to the Amide I–II bands, maximizing near-field enhancement for protein-related vibrations, while shorter antennas generate a sharp reflectance dip around 1900 cm^{-1} in a spectral interval with negligible intrinsic biomolecular absorption. This configuration enables a dual-mode readout: i) enhanced vibrational absorption in the amide bands, suitable for extracting spectral markers such as the 1538 cm^{-1} feature; ii) a mass- and refractive-index-sensitive shift of the reflectance dip, which can be used to monitor the extent and kinetics of exosome immunocapture on the metasurface. Our results show differences in EV-enriched samples between cirrhotic and HCC patients, revealing tumor-related changes and identifying key spectral targets.

In the context of the proposed platform, the metasurface and the EV measurements are therefore conceived as a single integrated system: EV spectroscopy defines the relevant bands for HCC vs cirrhosis discrimination, and the antenna design is optimized to amplify those bands and to add a quantitative surface-binding metric. Subsequent integration with dedicated isolation modules and machine-learning-based analysis is foreseen as a future development.

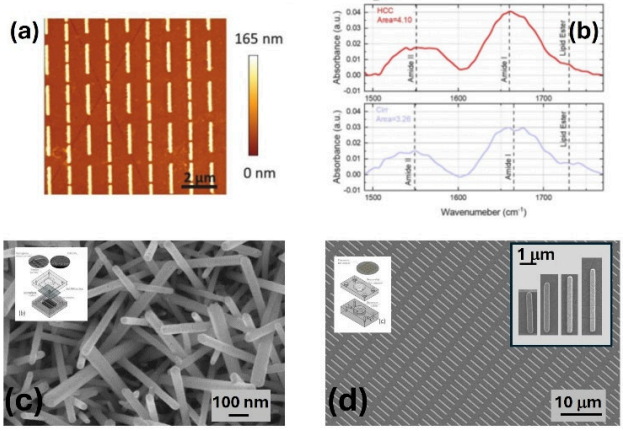

Fig. 1. (a) AFM image of double-resonant gold nanoantenna array on CaF_2. (b) Representative Amide I–II spectra of EV-enriched samples from cirrhotic (blue) and HCC (red) patients. (c) SEM image of ZnO nanowires used in the isolation module (shown in the inset), (d) SEM images of DNA/RNA-resonant nanoantennas, with the plasmonic characterization module shown in the inset.

IV. Conclusion

We have presented a design concept for a mid-infrared double-resonant plasmonic metasurface intended for label-free spectroscopic analysis of circulating exosomes in hepatocellular carcinoma. The device targets simultaneous enhancement of amide bands and refractive-index-sensitive monitoring of immunocapture on a commercial FTIR spectrometer.

In future developments, the double-resonant platform will be engineered to address both protein and DNA/RNA bands, to increase sensitivity towards tumour-specific molecular targets. Within this conceptual framework, the plasmonic metasurface is envisioned as the core characterization element of a modular platform that will also include a ZnO nanowire-based isolation/elution unit, essential to enrich and purify clinically relevant exosome subpopulations and to deliver them in a controlled manner to the metasurface, and machine-learning-assisted spectral analysis for exosome-based liquid biopsy.

***Abstract*—We demonstrate that, using colloidal lithography with carboxyl-functionalized polystyrene particles, we can control the correlations in the particle arrangement and tune the pseudo-period between 260 and 980 nm. Such correlated disordered nanostructures show promise in enhancing light scattering outside the escape cone and effectively trapping light in solar cells.**

***Keywords*— Colloidal lithography, correlated disorder, light trapping, self-assembly**

I. Introduction

Disordered photonic structures have emerged as a promising strategy to increase light trapping in ultrathin silicon solar cells [1]. Self-assembly processes such as colloidal lithography allow fabricating disordered structures on large surface areas. Previous works on PMMA (poly(methyl methacrylate)) [2] and PS (PolyStyrene) [3] particles have already shown homogeneous patterns with correlated disorder and studied how to vary the arrangement parameters. However, one aspect that has been overlooked in the literature is the impact of particles functionalization.

In this study, modifying the functionalization of the particle surface allows us to obtain an homogeneous arrangement for rather large nanoparticles (200 and 500 nm), while maintaining a simple process. We showed that using different strategies, we can tune the pseudo-periods between 260 nm and 980 nm, thereby opening the way to tailored optical properties for enhanced light-trapping in the visible and near-infrared range in a wide range of applications, and in particular solar energy conversion.. This tunability is achieved through a simple process based on PS particles and the control of particle and salt concentration. We discuss an in-depth investigation of the impact of experimental conditions on correlated disorder based on the pair correlation function and structure factor, which are directly related to the scattering optical properties.

II. Methods

A. Colloidal lithography:

A 0.2 wt% PDDA (poly(diallyl dimethylammonium chloride)) solution was deposited via dropcasting for 30 seconds, and then rinsed for 30 seconds on clean p-type silicon substrates. PS-Latex beads (0.2 wt%) were deposited using the same dropcasting method. Adsorption times were optimized based on bead diameter: 2 minutes for 0.2 µm beads and 7 minutes for 0.5 µm beads, following a protocol adapted from Hanarp et al. [4]. Before nitrogen drying, the sample was rinsed with boiling water for 1 minute, followed by an IPA (IsoPropyl Alcohol) rinse to reduce aggregation [5].

B. Image analysis

SEM (Scanning Electron Microscope) images are used to detect particle centers and diameters through custom Python-based image processing. We then calculated several metrics to analyze the particle arrangements (% aggregates, density of particles). We calculated the pair correlation function g(r) [6] to assess the pseudo-period of the particle arrangement. We used the plots of the static structure factor and its angular average [7] as qualitative tools to study the correlated disorder in the particle arrangement.

III. Results and Discussion

A. Functionalization of particle surfaces

Most studies on colloidal lithography use polystyrene particles with sulfate functionalization [4], [3]. In this study, we tested alternative functionalizations on the particle surface: carboxyl and CML.

Figure 1(a-c) shows the SEM images of the arrangement obtained with the three functionalizations used in our study, and the associated structure factor in Figure 1 (d-f). Firstly, we note that the CML (modified carboxylate) functionalization does not exhibit a correlated arrangement anymore, as observed in the SEM images. This is confirmed by the absence of the correlation ring found in sulfate et carboxyl functionalization, which we seek to preserve. The pseudo-periods of our two arrangements, calculated using the pair correlation function, are similar: 352 nm for the sulfate and 362 nm for the carboxyl. The main difference observed is the percentage of aggregates. The calculated aggregate percentage is 11% for the arrangement with sulfate functionalization and 3.8% for carboxyl. Carboxyl functionalization therefore allows us to obtain more homogeneous and reproducible arrangements.

B. Tuning the pseudo-period

As highlighted in Figure 2(c), we investigated different strategies to tune the pseudo-period on a wide range of values.

Fig. 1. Impact of surface functionalization on the arrangement obtained by colloidal lithography (a-c) SEM images of the arrangement obtained with (a) sulfate, (b) carboxyl and (c) CML particles functionalization. (d-f) 2D-plots of structure factor for the arrangement obtained with (a) sulfate, (b) carboxyl and (c) CML particles functionalization.

Fig. 2. Impact of tuning the pseudo-period with addition of ions or dillution of the colloidal suspension. (a-b) SEM images of the arrangement obtained with 200 nm diameter carboxyl-functionalized particles (a) with the addition of NaCl and (b) dilution of the colloidal suspension. (c) Pair correlation function of different arrangements made with 200 and 500 nm particles, with the addition of NaCl, or with dilution of the colloidal suspension.

On one hand, the addition of NaCl to reduce the pseudo-period, studied for sulfate functionalization, has not been studied for carboxyl functionalization. We prepared samples with an addition of 4mmol/L and 40mmol/L of NaCl in the suspension of carboxyl-functionalised particles. In Figure 2 (a), the SEM image shows the arrangement obtained by adding NaCl (4 mmol/L) to the colloidal suspension. Our results matched our expectations, with a clear reduction in the pseudo-period from 360 nm to 262 nm (with an addition of 40 mmol/L of NaCl).

On the other hand, we have investigated the dilution of the colloidal suspension as a way to increase the pseudo-period. We prepared 4 samples with 4 different colloidal concentrations ranging from 0.1 to 0.02 wt%. Figure 2 (b) shows the arrangement obtained with carboxyl-functionalized particles (200 nm diameter) at a concentration of 0.05 wt%. Through this dilution, we successfully increased the pseudo-period from 362 nm to 556 nm. However, this increase in pseudo-period was accompanied by a reduction in particle surface density, which may be detrimental for application to light trapping.

IV. Conclusion

In conclusion, we have demonstrated the potential of carboxyl surface functionalization of polystyrene particles, not previously reported in the literature, in order to obtain homogeneous arrangements. We demonstrated our ability to tune the pseudo-period of the particle arrangement between 260 nm and 980 nm, see Figure 2 (c), which allows for a wide range of possible applications. In this study, modifying the functionalization of the particle surface allows us to obtain an homogeneous arrangement for rather large particles (200 and 500 nm), while maintaining a simple process.

***Abstract*—Metasurfaces demonstrate unprecedented advantages in multi-functional imaging, but their tunability is still severely limited in the visible band. Joint optimization of metasurfaces and liquid photonic devices can enable tunable, multifunctional imaging, opening new avenues for metasurface development.**

***Keywords*— metasurfaces, liquid photonic devices, tunability, imaging.**

I. Introduction

Three-dimensional imaging is a key technology for capturing the three-dimensional information of objects and is widely applied in fields such as machine vision, medical plastic surgery, and cultural heritage protection. Although the structured light projection based on the metasurface offers a large field of view and a large depth of field, its spatial sampling rate is fixed after fabrication and cannot be improved, which limits reconstruction resolution. To solve this problem, this work proposes a meta-device with tunable point-cloud projection, composed of an mmeta-lens array and a tunable focus objective lens, for collaborative optimization. This meta-device can dynamically adjust the distribution of the projected point cloud, thereby achieve multiple samplings of the object's spatial information and effectively improving the spatial resolution of three-dimensional reconstruction.

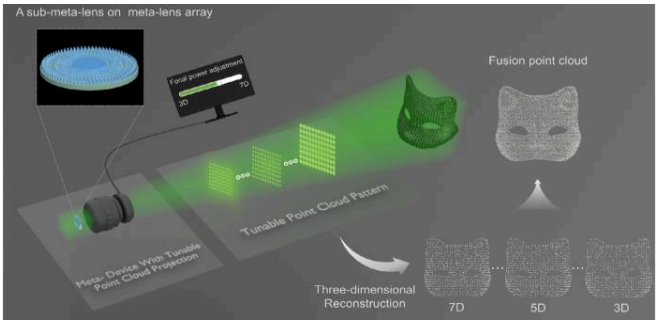

Fig. 1 Schematic of the proposed meta-device.

II. Methods

The proposed meta-device consists of two main parts: a diffraction-free meta-lens array that generates approximately 3600 focal points to form the initial points pattern; and a variable-focus projection objective based on a liquid lens, used to zoom and project the point cloud. By adjusting the optical power of the liquid lens, the point cloud pattern can continuously change radially, achieving multiple sampling of the object surface without introducing defocus blur. The system adopts a binocular stereo vision architecture, combining the Hough transform to extract point centers, epipolar-line constraint-based matching, and depth calculation based on the triangulation principle. Finally, it fuses the multi-focus point clouds to achieve high-density three-dimensional reconstruction.

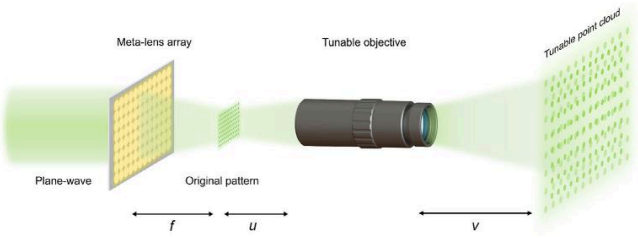

Fig. 2 Working principle of tunable point cloud projection based on the meta-device.

III. Results and Discussion

Figure 3 illustrates the experimental process of high-resolution depth estimation using a binocular stereoscopic imaging system based on meta-devices. Figure 3a is a schematic diagram of the experimental setup, including the laser illumination, the meta-device, and the binocular cameras. Figure 3b shows the images captured by the left and right cameras under different focal lengths. Figure 3c matches the point clouds in the left and right views through epipolar constraints. Figure 3d presents the contraction of the projected point cloud patterns and the extraction results of the center point as the optical focal length changes. Figure 3e compares the point cloud density of a single optical focal length with that after multi-focus fusion, verifying the effectiveness of the fusion strategy in improving spatial resolution.

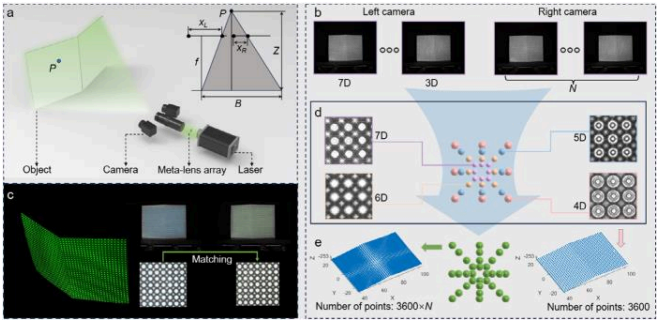

Fig. 3 High-resolution depth estimation of 3D objects.

To evaluate the depth perception capability of the proposed meta-device in three-dimensional imaging, this study first used a standard ceramic flat plate as the test object and conducted multi-position quantitative accuracy experiments, as shown in Fig.4. In the experiment, the plate was placed at four radial positions, and point cloud images at different optical focal lengths were collected using a binocular system, and depth information was calculated using the triangulation principle. The results showed that the reconstruction error distribution at each position was highly consistent, with root-mean-square errors (RMSEs) of 0.0365 mm, 0.0320 mm, 0.0353 mm, and 0.0356 mm, respectively, and an average accuracy of 0.035 mm. This high precision was mainly attributed to the system's longer baseline (128.8 mm) and its sub-pixel-level point-center extraction capability. Moreover, because the point cloud pattern remained focused across different optical focal lengths, the system could still stably output high-precision depth information while maintaining a large depth-of-field characteristic, verifying its consistent and reliable imaging performance across the full field of view.

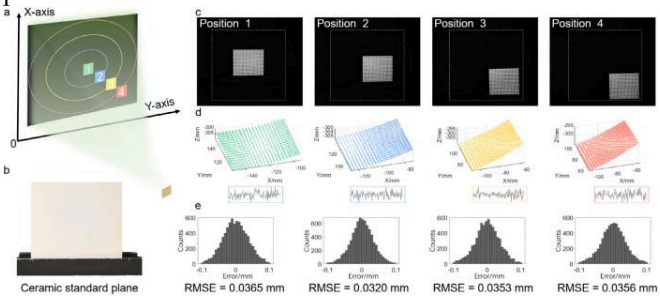

Fig. 4 3D imaging of a standard ceramic plate at four positions.

To further verify the improvement in spatial resolution from adjustable-focus projection, the experiment selected complex-shaped head portrait sculptures as test objects, as shown in Fig. 5. By adjusting the liquid lens's optical power, the system successively collected point clouds at multiple focal states and merged them into a high-density point cloud model. The experimental results showed that the point cloud in a single optical power could only reconstruct the rough outline of the object, with a large amount of surface details missing; while after fusing multiple optical power point clouds, the model details were significantly enhanced, especially in areas such as facial contours and hair textures, showing a higher geometric fidelity. Taking the head portrait sculpture as an example, the point cloud density increased to 3600×17 points, and the spatial sampling rate increased by approximately 17 times.

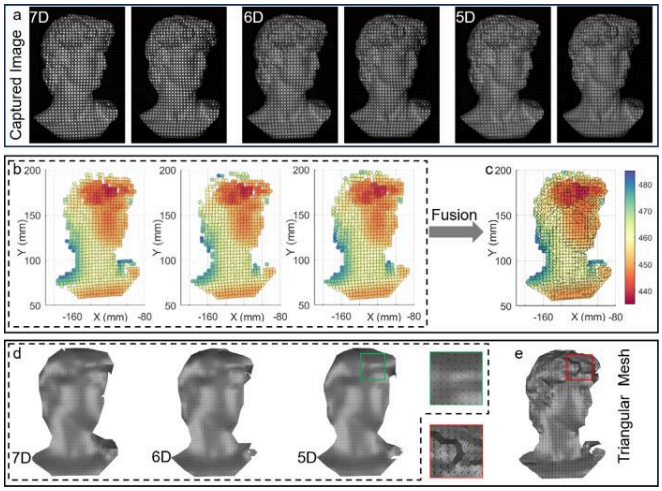

Fig. 5 3D reconstruction results of the head statue.

IV. Conclusion

We present a tunable point-cloud-projection meta-device, designed collaboratively as a meta-lens array and a liquid lens. It achieves high-resolution three-dimensional imaging without mechanical movement, wide spectral adaptation, and large depth of field. The system maintains a small footprint while significantly improving spatial and depth resolution, achieving a reconstruction accuracy of 0.035 mm. It provides a new technical path for fields such as augmented reality, face recognition, and human-computer interaction.

***Abstract*—We demonstrate nonreciprocal acoustic scattering by using weakly nonlinear self-oscillators whose internal synchronization state controls the system behavior, without bias, modulation, or strong nonlinearity. The meta-atom scattering is modeled by modified nonlinear coupled mode theory and validated experimentally. A two meta-atom unit cell yields directional transmission and reflection.**

***Keywords*— acoustic scattering, synchronization, limit cycle.**

I. Introduction

Reciprocity in passive linear wave media dictates that source and receiver are interchangeable under the assumptions of (microscopic) time-reversal symmetry and time-invariance, implying that an unidirectional transmission (e.g. diodes, insulators, circulators, etc.) requires bias or nontrivial material properties. Specific strategies to break reciprocity have been classified [1] into: (i) momentum bias (breaking time-reversal) [2], (ii) spatio-temporal modulations (breaking time-invariance) [3], and (iii) structural asymmetry with nonlinearity (breaking linearity) [4].

We propose a fundamentally different approach (Fig. 1), which relies on weakly nonlinear self-oscillators and their internal synchronization state rather than bias, spatio-temporal modulation, band topology, or conventional nonlinearity. Specifically, we employ autonomous, saturable-gain elements, whose individual steady state is a stable limit cycle emitting a single dominant frequency, which can be phase- and frequency-locked by an external drive [5], or another such element [6], inside a subset of amplitude–frequency space (i.e., the synchronization region or Arnold tongue [7, Chap. 3.1.2]).

Crucially, the two self-oscillators do not need to be precisely adjusted, it is sufficient that the driving frequency-amplitude pair is in the range of the joint synchronization region, and importantly, the self-oscillators lock to the injected signal, hence, phase relations are fixed. This mechanism is generic to systems supporting weakly nonlinear limit cycles and is compatible with the modified temporal coupled mode theory (TCMT) developed next.

II. Results

A nominally stable shear layer is able to amplify acoustic perturbations at certain frequencies and the coalescence of the Helmholtz mode with this amplifying frequency range is the physical mechanism driving the self-sustained cavity oscillations in our system [Fig. 1(a)]. However, this behavior eventually saturates due to nonlinear effects and the systems flips from finite linear gain at low amplitudes to finite linear loss at high ones. To model this phenomenon we utilise a saturable gain given by $(1+a^2)^{-1}$, hence, the nonlinear temporal coupled mode theory (TCMT) describing the scattering at a single meta-atom reads [5]

$$\frac{\mathrm{d}a}{\mathrm{d}\tau} = \left(i\frac{1-\Omega^2}{2\Omega} + \frac{\mu}{2}\frac{1-|a|^2}{1+|a|^2}\right)a - \frac{i}{2\Omega}\left\langle\kappa\middle|s_j^+\right\rangle , \tag{1}$$

$$\left|s_k^-\right\rangle = \left|s_j^+\right\rangle S_{kj} + |\kappa\rangle\, a\,, \tag{2}$$

where $\mathrm{d}/\mathrm{d}\tau$ represents the derivative with respect to time, normalized by the self-oscillation frequency $\tau = f_0 t$, i denotes the imaginary unit, and $a = A\exp i\varphi$ is the complex envelope of the normalized limit cycle [normalized pressure inside the whistle in Fig. 1(a)]. Additionally, μ incorporates the radiation and viscous losses, $\langle\kappa| = \kappa\,\langle 1| + \kappa\,\langle 2|$ stands for the coupling matrix and $\left|s_j^+\right\rangle = s\,|j\rangle\cos\Omega\tau$ represents the injected signal,

Fig. 1. Schematic representation of (a) the experimental setup and (b) the scattering process of a single meta-atom. The (acoustic) limit cycle is implemented as a whistle, which is arranged as a side branch of a one dimensional waveguide. The latter results in a fully transmissive direct process.

Fig. 2. Scattering matrix of (a) the passive resonator and (b) the (reciprocal) self-oscillating meta-atom. Markers represent experimental measurements and lines are predictions of Eqs. (1)–(2). Blue and red colors correspond to transmission and reflection, respectively. Note that the behavior transitions from fully transmissive in the passive case (a) to fully reflective when waves are scattered by the limit cycle (b).

Fig. 3. Schematic representation of (a) the experimental setup and (b) the scattering process of the unit cell consisting of two coupled nonlinear self-oscillators. The (acoustic) limit cycles are arranged as side branches of a one dimensional waveguide and are separated by approximately quarter of a wavelength. The fully transmissive direct process in combination with a relative phase shift of about $\pi/2$ between them results in unidirectional radiation. The phase shift can be controlled by tuning the air flows $\dot{Q}_1$ and $\dot{Q}_2$.

with s being the normalized magnitude and $\Omega = f/f_0$ the ratio of injected to self-oscillation frequency. $\mathbf{S}$ denotes the (reciprocal) scattering matrix of the direct process [cf. Fig. 1(b)], with S_{11} and S_{21} being reflection and transmission, respectively.

Note that Eqs. (1)–(2) are evolving in a time dependent reference frame, and contain terms deviating from classical temporal coupled mode theory. Specifically, we perform asymptotic averaging in a coordinate system moving in-phase with the incident wave, i.e., $|s^+\rangle = |1\{2\}\rangle\, s$ with $s = \text{const}$, which introduces an asymmetric detuning term, $j(1-\Omega^2)/2\Omega$, and multiplicative forcing factor, $j/2\Omega$ [5]. With the aforementioned modifications we can qualitatively and quantitatively capture the physical processes involved as shown in Fig. 2.

Next we introduce a second self-oscillator, and as a consequence of the mutual synchronization between the two the scattering behavior is governed by the relative phase of the locked limit cycles (Fig. 3). In particular, by separating the whistles by about quarter of a wavelength [Fig. 3(a)] and detuning them via the air flows $\dot{Q}_1$ and $\dot{Q}_2$ as to achieve roughly $\pi/2$ phase difference, we establish a synchronization state heavily favoring one of the propagation directions. Specifically, since the physical separation introduces a $\pi/2$ phase delay, radiation from the limit cycle which is $\pi/2$ radians behind will accumulate a phase of π as it reaches its counterpart, hence, resulting in destructive interference in this direction. Conversely, the self-oscillator which is $\pi/2$ radians ahead will get delayed by quarter of a cycle as it reaches its counterpart, resulting in a constructive interference in the opposite direction [Fig. 3(b)].

Since opposite injection ports can favor or resist the stable synchronization branch, waves incident from opposite directions experience dramatically different transmission, i.e., destructive interference in one direction yet not in the other [Fig. 4]. The resulting synchronization pattern governs the reciprocity breaking, where the bandwidth is set by the width

Fig. 4. Scattering matrix of the (nonreciprocal) self-oscillating unit cell. Markers represent experimental measurements with blue and red colors corresponding to transmission and reflection, respectively. Shaded regions indicate the synchronization bandwidth where high nonreciprocity is achieved. The data itself illustrates a highly nonreciprocal behavior, with superradiant transmission and negligible reflection in the direction favored by the synchronization sate and vice versa in the opposite direction. The depicted magnitude measurements reveal transmission ratios of up to $(|S_{21}|/|S_{12}|)_{\max} \approx 50$, which corresponds to $(|S_{21}|^2/|S_{12}|^2)_{\max} \approx 2500$ in terms of power.

of the joint synchronization region, while the weak nonlinearity filters out small perturbations. Even for the simple setup in Fig. 3(a) this effect readily achieves transmission ratios of up to $(|S_{21}|/|S_{12}|)_{\max} \approx 50$ in terms of magnitude, or alternatively $(|S_{21}|^2/|S_{12}|^2)_{\max} \approx 2500$ in terms of power.

Finally, we can model this behavior by a temporal coupled mode theory similar to Eqs. (1)–(2)

$$\frac{\mathrm{d}a_1}{\mathrm{d}\tau} = \left(i\Delta_1 + \frac{\mu}{2}\frac{1-|a_1|^2}{1+|a_1|^2}\right) a_1 - \frac{i}{2\Omega}\left\langle\kappa\middle|s_1^+\right\rangle + \frac{1}{2\Omega}\left\langle\kappa\middle|s_{\mathrm{in}}^-\right\rangle, \tag{3}$$

$$\frac{\mathrm{d}a_2}{\mathrm{d}\tau} = \left(i\Delta_2 + \frac{\mu}{2}\frac{1-|a_2|^2}{1+|a_2|^2}\right) a_2 - \frac{i}{2\Omega}\left\langle\kappa\middle|s_2^+\right\rangle + \frac{1}{2\Omega}\left\langle\kappa\middle|s_{\mathrm{in}}^+\right\rangle, \tag{4}$$

$$\left|s_1^-\right\rangle = \left|s_1^+\right\rangle S_{11} - i\left|s_{\mathrm{in}}^-\right\rangle S_{21} + |\kappa\rangle\, a_1\,, \tag{5}$$

$$\left|s_{\mathrm{in}}^+\right\rangle = \left|s_1^+\right\rangle S_{21} - i\left|s_{\mathrm{in}}^-\right\rangle S_{11} + |\kappa\rangle\, a_1\,, \tag{6}$$

$$\left|s_{\mathrm{in}}^-\right\rangle = \left|s_2^+\right\rangle S_{21} - i\left|s_{\mathrm{in}}^+\right\rangle S_{11} + |\kappa\rangle\, a_2\,, \tag{7}$$

$$\left|s_2^-\right\rangle = \left|s_2^+\right\rangle S_{11} - i\left|s_{\mathrm{in}}^+\right\rangle S_{21} + |\kappa\rangle\, a_2\,, \tag{8}$$

where a_1 and a_2 are the complex envelopes of the normalized pressure of the first and second meta-atom, respectively [Fig. 3]. Additionally, $\Delta_1 = (1-\Omega^2)/2\Omega$ and $\Delta_2 = (\delta - \Omega^2)/2\Omega$, with $\delta = f_{0,1}/f_{0,2}$ being the frequency detuning between the two self-oscillators.

III. Conclusion

We introduce a reciprocity-breaking mechanism for acoustic scattering that is rooted in the internal synchronization state of weakly nonlinear self-oscillators rather than external bias, spatio-temporal modulation, topological edge states, or strong nonlinearity, and which is fundamentally different from the synchronization topology approach reported in [6]. Using self-oscillating meta-atoms implemented as "whistling" side branches of a one-dimensional waveguide, we show that a modified nonlinear TCMT with saturable gain captures the experimentally observed scattering of a single reciprocal element. Subsequently coupling two such limit-cycle meta-atoms illustrates highly nonreciprocal transport, where mutual phase locking sets a stable relative phase that, together with a quarter-wavelength separation, enforces constructive interference in one propagation direction and destructive interference in the other. The resulting unit cell exhibits strongly asymmetric transmission and reflection over a bandwidth governed by the joint synchronization region, while remaining robust to small perturbations due to the weakly nonlinear, saturated dynamics. These results establish synchronization as a generic and tunable route to nonreciprocal acoustic devices and provide a predictive TCMT framework for scaling toward more complex active metamaterial architectures.

Abstract: We implement a synthetic discrete photonic lattice based on a dual fiber loop system and construct dynamically reconfigurable temporal metasurface within this platform. By introducing electro-optic linear phase modulation at temporal interfaces, we experimentally realize discrete-light temporal refraction and perfect imaging. We further observe refraction and reflection in spatial and spatiotemporal metasurfaces, where phase gradients evolve in space or vary jointly in space and time.

Main results:

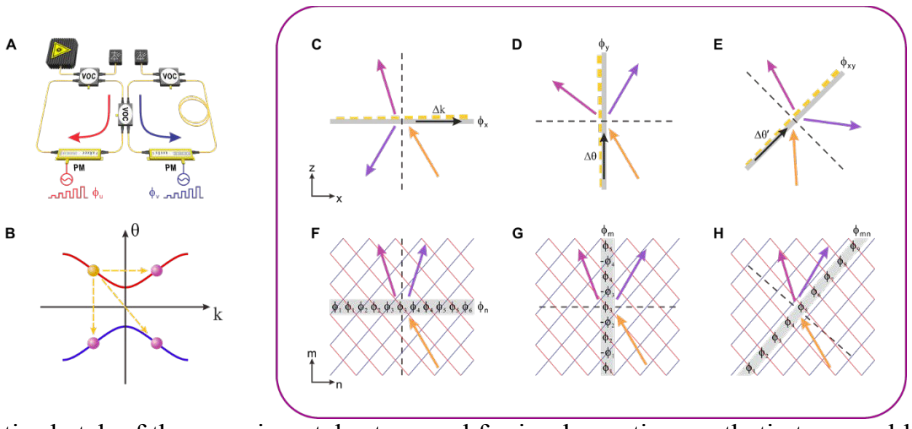

Fig. 1. A. Schematic sketch of the experimental setup used for implementing synthetic temporal lattice. **B.** Schematic diagram of the band structure. **C-E.** Refraction and reflection in the spatial coordinate system. **F-H.** Refraction and reflection in the spatiotemporal coordinate system.

As illustrated in Fig. 1, applying electro-optic linear phase modulation to the long and short fiber loops induces temporal metasurface in the synthetic temporal lattice, leading to the change in momentum within the Floquet bands. Similarly, spatial metasurface and spatiotemporal metasurface influence the evolution of the light beam through the tangential momentum generated at the corresponding interfaces.

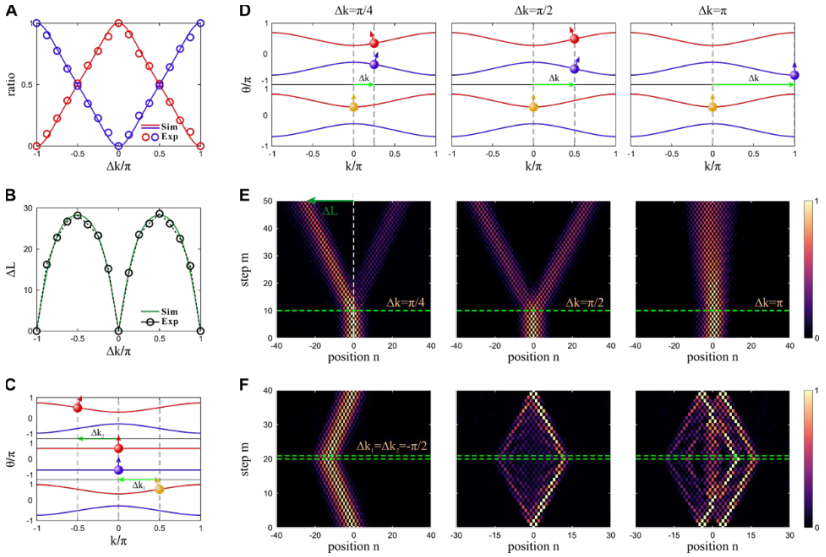

Fig. 2. A. Measured (circle) and theoretical (solid line) upper band (red) and lower band (blue) occupancies versus Δk as the wave packet crosses temporal metasurface. **B.** Measured (circle) and theoretical (solid line) splitting distance ΔL versus Δk as the wave packet crosses temporal metasurface. **C.** Band structures schematic of the sandwich configuration, the structure consists of two cascaded temporal metasurfaces and a flat band. **D,E.** Band structure schematic and the corresponding pulse intensity evolutions for $\Delta k = \pi/4$, $\pi/2$ and π. **F.** Measured pulse intensity evolutions for a wave packet incidence and n-site excitation.

Based on the discrete-time photonic lattice discussed above, we first introduce an electro-optic linear phase modulation $\phi(n) = \Delta k \cdot n$, which varies linearly with the space position "n", at a specific time step "m" to construct temporal metasurface. We observe discrete time refraction and reflection in a single-layer temporal metasurface, and then extend to double-layer configurations to realize negative refraction and perfect imaging.

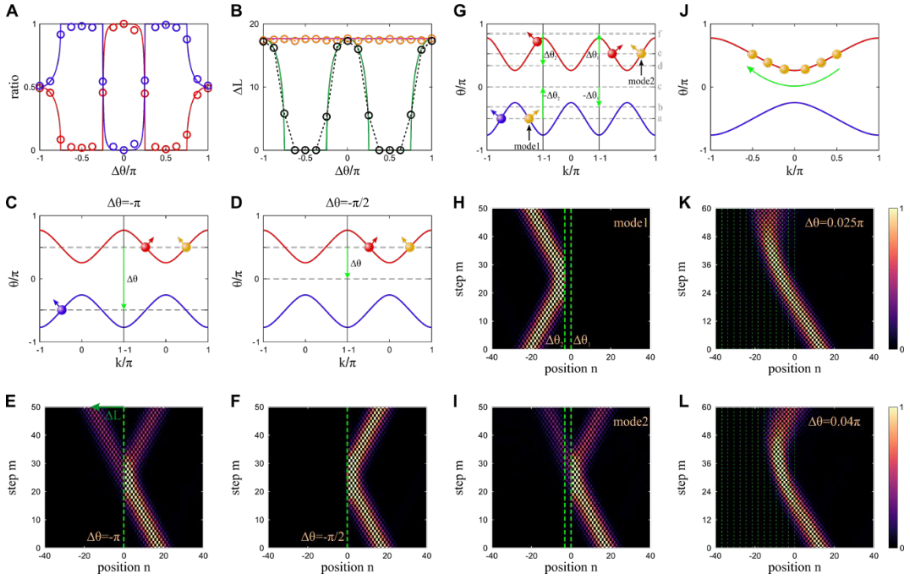

Fig. 3. A. Measured (circle) and theoretical (solid line) upper band (red) and lower band (blue) occupancies versus $\Delta\theta$ as the wave packet crosses spatial metasurface. **B.** Measured (circle) and theoretical (solid line) splitting distance ΔL versus $\Delta\theta$ as the wave packet crosses spatial metasurface. **C-F.** Band structure schematic and the corresponding pulse intensity evolutions for $\Delta\theta = -\pi$ and $-\pi/2$. **G.** Band structure schematic of two cascaded spatial metasurfaces. **H,I.** Measured pulse intensity evolutions for different incident modes. **J.** Band structure schematic of mode translation in multilayer spatial metasurfaces. **K,L.** Measured pulse intensity evolutions for $\Delta\theta = 0.025\pi$ and 0.04π at each layer of the metasurfaces.

We extend this concept to spatial metasurface, which is constructed by applying the gradient phase modulation $\phi(m) = \Delta\theta \cdot m$ in the time evolution direction. To be more precise, we create an equivalent temporal interface between $n = -1$ and $n = 0$. We experimentally demonstrate discrete spatial refraction and reflection in a single-layer spatial metasurface, followed by the implementation of multilayer configurations to achieve asymmetric transmission and beam bending.

***Abstract*—Optical skyrmions exhibit structured polarization textures, but extended side lobes hinder spatial isolation. We design a compact silicon metasurface generating a spatially confined skyrmion using a truncated Bessel target and full-wave adjoint optimization. The device achieves field overlap above >88% and a skyrmion number $N_{\mathrm{sk}} \approx 0.97$ at $\lambda = 1550$ nm.**

***Keywords*— optical skyrmion, metasurface, inverse design, adjoint optimization, topological photonics.**

I. Introduction

Optical skyrmions are vector fields carrying structured polarization textures that have attracted growing interest in topological photonics [1], [2], [4]. These textures have been observed in free-space beams, surface plasmon fields, and guided modes, offering a route toward compact polarization-based field encoding [1], [3], [4]. Dielectric metasurfaces are well suited to shape such textures with subwavelength control [13].

However, confining these textures within a clear radial boundary remains difficult. Many skyrmion generators rely on vortex-type modes, including Bessel beams, whose oscillating side lobes extend well beyond the main lobe [5]. The ambiguous boundary that results limits applications where multiple skyrmion channels must coexist without crosstalk.

Here, we design a metasurface that produces a skyrmion field confined within a spatial boundary. We define a target field that vanishes outside a chosen radius and optimize a compact silicon structure using full-wave adjoint methods [6], [7].

II. Methods

Figure 1(a) illustrates the simulation schematic. A normally incident Gaussian beam (beam waist $w_0 = 1.15\,\mu$m) at $\lambda = 1550\,$nm illuminates a silicon metasurface on a silica substrate. The metasurface consists of a $1\,\mu$m thick silicon layer patterned within a $6.0\,\mu$m diameter disk. The transmitted field is recorded on a focal plane located $1.55\,\mu$m from the metasurface exit.

The target field is composed of two circularly polarized Bessel-mode components of different orders. The RCP channel follows a zeroth-order Bessel profile J_0, exhibiting a bright central lobe with nearly uniform phase, while the LCP channel

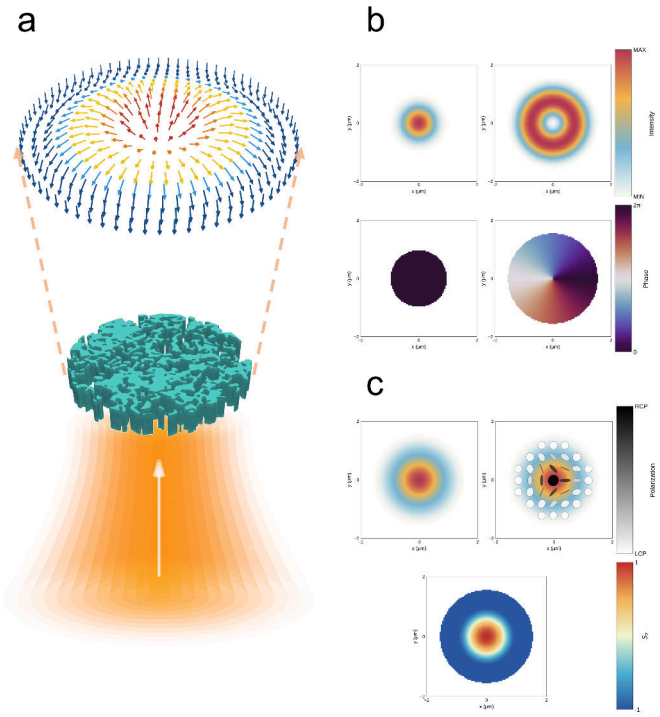

Fig. 1. Simulation schematic and desired field definition.

follows a first-order profile J_1, forming a ring-shaped intensity with a 0 to 2π azimuthal phase winding [Fig. 1(b)]. Both components share a numerical aperture $\mathrm{NA} = 0.61$, giving a radial wave vector $k_r = 2\pi\,\mathrm{NA}/\lambda \approx 2.47\,\mu\mathrm{m}^{-1}$. To enforce spatial isolation, both profiles are truncated by a radial mask at $r_1 = j_{1,1}/k_r \approx 1.55\,\mu$m, where $j_{1,1} \approx 3.832$ is the first zero of J_1. In polar coordinates (r, φ), the target reads

$$\mathbf{E}_{\mathrm{tar}}(r,\varphi) = \left[J_0(k_r r)\,\hat{\mathbf{e}}_R + J_1(k_r r)\,e^{i\varphi}\,\hat{\mathbf{e}}_L\right]\Theta(r_1 - r), \quad (1)$$

where $\hat{\mathbf{e}}_{R/L}$ are circular basis vectors and $\Theta(\cdot)$ is the Heaviside step function. This truncation removes the extended side lobes of ideal Bessel beams [5], confining both the amplitude and polarization texture within a compact disk.

From the coherent superposition of the two channels, we evaluate the total intensity, the polarization ellipse map, and the normalized spin density [Fig. 1(c)]

$$S_z = \frac{|E_R|^2 - |E_L|^2}{|E_R|^2 + |E_L|^2}, \tag{2}$$

which equals $+1$ for pure RCP and -1 for pure LCP. The polarization ellipse map visualizes the local circularity consistent with S_z, where the background shading reflects local intensity.

We quantify the topological quality through the skyrmion number [1], [3], [4]

$$N_{\mathrm{sk}} = \frac{1}{4\pi} \iint \mathbf{n} \cdot \left(\frac{\partial \mathbf{n}}{\partial x} \times \frac{\partial \mathbf{n}}{\partial y} \right) dx\, dy, \tag{3}$$

where $\mathbf{n}$ is the normalized Stokes vector.

The metasurface is optimized through three-dimensional FDTD simulations (Meep) [8] with the adjoint gradient method [9], [10]. The spatial resolution is 50 pixels/μm. The permittivity distribution is iteratively updated using the Adam optimizer, and fabrication constraints are enforced through spatial filtering and threshold projection with a minimum feature and gap size of 80 nm [11]. The objective function is a normalized overlap between the simulated and target fields evaluated inside the truncation radius r_1.

III. Results and Discussion

Simulation results show:

- Field overlap integral of 95 percent between the simulated output and the truncated Bessel target inside r_1 (Fig. 2)
- Skyrmion number $N_{\mathrm{sk}} \approx 0.97$, indicating near-unity topological purity
- Field leakage of 8 percent outside the region of interest ($r > r_1$), confirming effective spatial isolation

After optimization at $\lambda = 1550\,\mathrm{nm}$, the resulting metasurface is a compact, aperiodic silicon pattern in which the smallest features and gaps satisfy the 80 nm fabrication constraint. Figure 2(a) shows the top view of the optimized binary structure within the 6.0 μm diameter disk, where black regions denote silicon and white regions denote air. The pattern exhibits a spiral-like, freeform topology that is characteristic of adjoint-optimized metasurfaces and cannot be reduced to a periodic unit-cell description.

The simulated output field on the focal plane is decomposed into its circularly polarized components in Fig. 2(b). The RCP component displays a compact central intensity lobe with a nearly flat phase front, closely reproducing the target J_0 profile. The LCP component forms a ring-shaped intensity distribution with a clear 0-to-2π azimuthal phase winding, consistent with the target $J_1\, e^{i\varphi}$ profile. In both channels, the field amplitude drops rapidly near the designed boundary at $r_1 \approx 1.55\,\mu$m, with negligible intensity outside this radius compared to the central region. This confirms that the truncated target successfully suppresses the side lobes characteristic of ideal vortex-type modes [5].

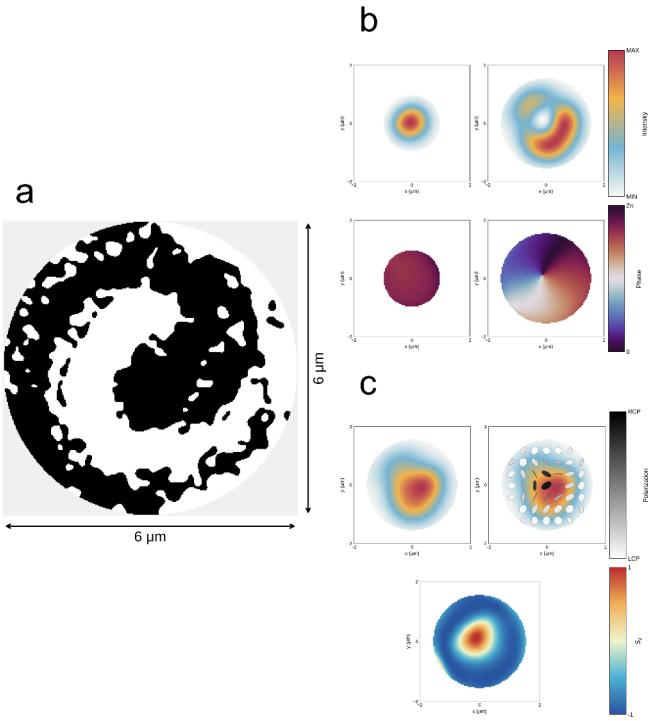

Fig. 2. Optimization result and output skyrmion characterization.

Figure 2(c) presents the skyrmion properties of the output field. The total intensity profile shows a well-confined distribution that vanishes smoothly at the target boundary, demonstrating effective spatial isolation. The polarization ellipse map reveals a continuous texture that winds from right-circular polarization at the center to left-circular polarization in the outer ring, reproducing the intended skyrmion topology. The normalized spin density S_z transitions from $+1$ (pure RCP) at the core to -1 (pure LCP) at the periphery, in agreement with the target defined in Eq. (1) and consistent with prior optical skyrmion reports [3], [4].

Although a strict radial truncation can in principle introduce diffraction artifacts, the freeform nature of the inverse-designed metasurface allows near-field coupling and multiple scattering to suppress the field outside the target radius while preserving fidelity inside the disk [6], [7].

IV. Conclusion

We have designed a compact silicon metasurface that generates a spatially isolated optical skyrmion with a well-defined edge. The design uses a truncated target built from two circularly polarized Bessel-mode components and is realized through full-wave adjoint optimization. The resulting 6.0 μm device achieves a field overlap above 88% and a skyrmion number of 0.97 within the target region. This approach may benefit dense photonic architectures such as optical communication arrays or holographic multiplexing, where crosstalk between neighboring channels must be minimized.

***Abstract*— This paper studied the optimization of Helmholtz resonator arrays to achieve broadband high absorption. The interaction between adjacent resonant cavities was studied using finite-element methods. Then genetic algorithm combined with the theoretical model helps optimize arrays of nine resonators. A 0.95 averaged absorption was observed in the 300-490 Hz range.**

***Keywords*— Acoustic metamaterials, Helmholtz resonator, genetic algorithm.**

I. Introduction

Acoustic Metamaterials (AMs) are materials consisting of designed artificial microstructures that can manipulate acoustic waves. AMs are currently studied to control the reflection, transmission, and absorption of sound [1]. Helmholtz resonators (HRs) are one of the commonly used microstructures in AMs [2-4]. An HR contains a cavity and a neck connecting the atmosphere and the cavity. By modifying the geometric sizes of HRs, the resonant frequency of air inside the cavity changes, and thus HR absorbs sound of different tones. HRs with different sizes may have the same resonant frequency, and a small HR can absorb low-frequency sound with a high absorption rate, so it has received attention and a lot of research in recent years.

In fact, an HR only has a narrow absorption frequency bandwidth; therefore, array structures were proposed to extend the high absorption frequency range. Designing a proper HR array actually consumes much computation. Thus, this paper studies the optimization of designing a wide-band and high absorption HR array.

II. Methods

We studied the absorption spectrum of and interaction between adjacent resonant cavities by finite-element method (FEM) firstly. A model of an HR in an impedance tube was defined in COMSOL as shown in Fig. 1(a). The HRs with an extended neck in Fig. 1(b) are used in this study. Then the absorbing coefficient α can be evaluated based on the instruction in ASTM-E-1050-08.

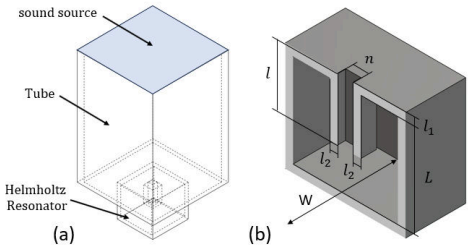

Fig. 1 (a) The model to evaluate absorption in FEM. (b) Geometry of the extended neck HR.

The theoretical resonant frequency of a single HR has be studied [2-3] and can be estimated as

$$f_r = \frac{c}{2\pi}\sqrt{\frac{A_0}{l_0 V_0}}, \tag{1}$$

where c is the sound velocity, A_0 the cross section area of the neck, l_0 the length of the neck, and V_0 the volume of the cavity.

Then the AM made of an HR array can be defined. Fig. 2 shows an example consisting of nine HRs to expand the absorption frequency range. To form a high-performance AM, these HRs should have discrete resonant frequencies in the high-absorption range.

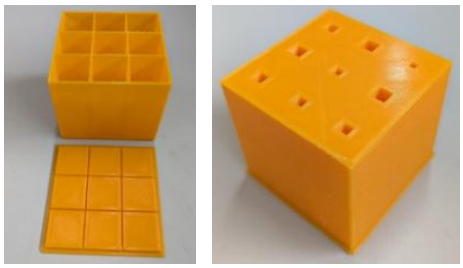

Fig. 2 The AM made of nine-HR array.

However, the adjacent resonant cavities interact with each other and change the spectrum. Therefore, the genetic algorithm was adopted to search for the design of high-performance HR arrays. To accelerate the process, we proposed a two-phase

optimization method. Firstly, we use Eq. (1) to build the cases of the initial population and find the geometric sizes of every single cavity in the array. Then the results in the first phase became the initial population of the nine-cavity array and the best design was evaluated at the end of the second phase. Finally, a specimen of an array with nine HRs was fabricated and the experimental absorption was measured to verify its performance.

III. Results and Discussion

In the FEM simulation, we observed that the interaction of two or more HRs is complex. There can be constructive or destructive results in the absorption spectrum. Therefore, optimization is a considerable issue in designing an HR-array AM.

In the optimization of the HR-array, we give the nine cavities the same W=19mm and L= 50 mm (defined as shown in Fig. 1(b)), and let the algorithm search for the best dimensions for l and n. The value of l is limited between 3 and 6 mm, and n is between 4 and 48mm. The requested high absorption range is 300-480 Hz. In the GA, the initial population is set as 40 after several trials. We first let GA optimize 18 dimensions synchronously. After 40 generations, the average absorption is 0.9, shown as the case "General GA" in Table 1. To accelerate the process, the two-phase GA as mentioned was executed. In the first phase, the target frequencies are 300, 310, 320, 340, 370, 400, 430, 360 and 490 Hz, respectively. All of them reached 0.85 absorption after 10 generations. Using the results as the initial population, the second phase GA gets a higher absorption of 0.95 after 5 generations. The total time is obviously less than the General GA. The final performance is shown in Fig. 3.

Table 1. Acceleration of two GA method

Method	Freq. (Hz)	$\alpha_{ave.}$	Time (h.)
General GA	300–480	0.9	189.8
Two-Phase GA	300–490	0.95	68.9

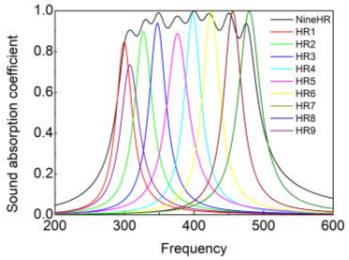

Fig. 3 The absorption spectrum of the HR array optimized by the two-phase GA. The absorption of individual HR are also shown.

After the GA optimization, we fabricated the specimen (as shown in Fig. 2) and then measured the absorbing coefficient α according to ASTM-E-1050-08. We also measured the absorption of a porous material, a sponge, with the same thickness. The spectra were plotted in Fig. 4, and the result shows a high absorption in a wide frequency range. Further, the thickness of this AM is only 1/20 of the wavelength of the lowest frequency sound.

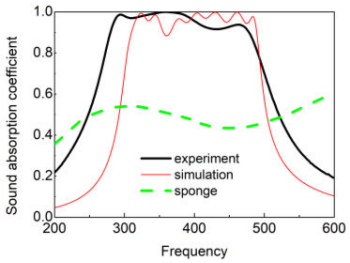

Fig. 4 The experimental result of HR array comparing to the numerical result.

IV. Conclusion

We have demonstrated the optimization of designing a broadband sound absorber based on Helmholtz resonators. The interaction of HRs in an array is complex, and thus an optimization algorithm is necessary. GA was adopted in this research, and further, a two-phase method was proposed and examined. The result shows more efficient optimization and a better design in a shorter time. This paper shows the potential of using an HR-array as an AM to absorb low-frequency noise. Future work will extend the design to minimize the thickness of AM devices.

***Abstract*—We introduce a new framework for quantizing radiative nanophotonic systems with arbitrarily positioned quantum emitters. The framework produces free-space propagation and decay terms, enforcing causality. Applying our framework to spherical nanoparticles captures position-dependent, non-Markovian dynamics, providing a complete picture of near- and far-field interactions essential for designing quantum nanophotonic devices.**

***Keywords*— Quantum Photonics, Non-Markovian Physics, Quantum Light-Matter Interactions.**

I. Introduction

Recent advances in quantum nanophotonics have enabled quantum light sources to be coupled to increasingly compact and complex radiative nanophotonic structures operating at deeply subwavelength scales. In the strong-coupling regime [1], these systems offer promising platforms for integrated quantum technologies operating under ambient conditions [2]. However, designing these systems requires precise control over radiative losses and open quantum dynamics. It is therefore crucial to develop an accurate theoretical understanding of radiative nanophotonic systems. However, the strongly radiative nature of these systems presents a fundamental challenge in obtaining a full description of the quantum dynamics that govern their light-matter interactions.

Recently [3], we introduced an *exact* and *complete* framework for describing the quantum dynamics of radiative nanophotonic systems using a second quantization approach that preserves the often-overlooked non-Markovian contributions. Here, we extend this framework to nanophotonic systems coupled to a Quantum Emitter (QE) positioned within the free space continuum, revealing additional terms corresponding to free-space propagation and decay. Our formulation enforces causality intrinsically, without requiring externally imposed conditions, which we demonstrate through its application to a nanophotonic system consisting of a spherical nanoparticle. By comparing emitter dynamics at different spatial positions relative to the nanoparticle surface, we show how these terms reduce to known expressions for free space decay while revealing tail effects characteristic of non-Markovian dynamics. Finally, we demonstrate how these additional terms impact the quantum dynamics of radiative nanophotonic systems.

II. Methods

Second quantization is a formalism which describes a system by treating its fields as fundamental degrees of freedom. Each mode is represented by creation and annihilation operators that account for discrete energy quanta allowing the full field to be described through their combination. In the case of a closed photonic system, a discrete set of well-defined normal modes can be constructed straightforwardly from boundary conditions. In an open system however, as energy can propagate to a continuum of far-field modes, there is additional complexity in defining a discrete and normalizable set of modes.

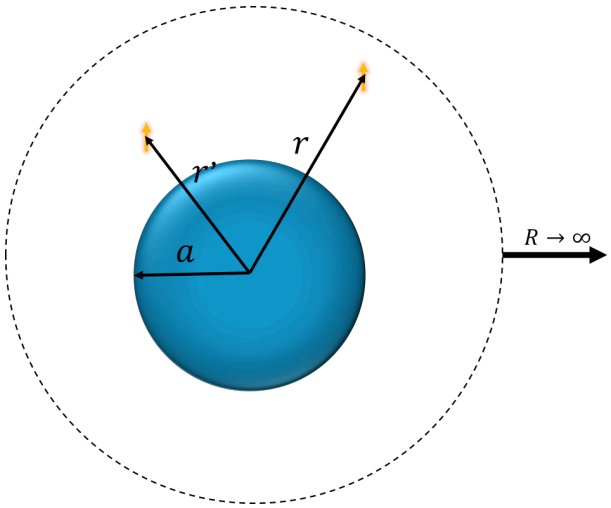

Fig. 1. The layout of the nanophotonic system studied. A spherical nanoparticle of radius a is coupled to a quantum emitter at position $\mathbf{r}$ and detector at $\mathbf{r}'$. The system is enclosed within a spherical boundary which is taken to infinity when convenient modeling radiative losses.

To quantize a radiative nanophotonic system, we start by considering its closed analogue. By enclosing it within a boundary shell matching its geometry, a set of well-defined normal modes, $\mathbf{u}_\xi(k, \mathbf{r})$ can be obtained. To recover a description applicable to an open, radiative system, we let the radius of the boundary tend to ∞. The continuum that arises as a result is handled by transforming [3], [4] the resulting continuous normal modes into a set of complex pseudomodes, $\mathbf{v}_{\xi n}(\mathbf{r})$,

using the generalized pseudomode transformation given (for a time τ) by:

$$\int_0^\infty dk\; k\rho(k)\mathbf{u}_\xi\left(k,\mathbf{r}\right)\mathbf{u}_\xi\left(k,\mathbf{r}'\right)e^{-ick\tau} = \Theta\left(\tau,\mathbf{r},\mathbf{r}'\right)\sum_n z_{\xi n}\mathbf{v}_{\xi n}\left(\mathbf{r}\right)\mathbf{v}_{\xi n}\left(\mathbf{r}'\right)e^{-icz_{\xi_n}\tau} + f_{fs}(\mathbf{r},\mathbf{r}';\tau), \quad (1)$$

where each of the (ξ, n)th pseudomodes resonates at complex frequency $z_{\xi n}$ and the $\Theta\left(\tau,\mathbf{r},\mathbf{r}'\right)$ term introduces a time delay on the pseudomodes ensuring causality. By solving the integral in Eq. 1, we now obtain an additional f_{fs} term when the quantum emitter is positioned away from the nanoparticle. This describes the free space propagation for times prior to light propagating from $\mathbf{r}$ to $\mathbf{r}'$ via the nanoparticle, ensuring causality is preserved for the QE positioned away from the surface.

This generalized transformation allows the full quantum dynamics of radiative system to be described through the coupled equations:

$$i\dot{\tilde{c}}_0(t) = \Theta_1\omega_{fs}\tilde{c}_0(t) + \Theta_2\sum_{\xi,n} e^{i(\omega_0 - cz_{\xi,n})t}\bar{g}_{\xi,n}\tilde{b}_{\xi,n} \quad (2)$$

$$i\dot{\tilde{b}}_{\xi,n}(t) = \bar{g}_{\xi,n}e^{-i(\omega_0 - cz_{\xi,n})t}\tilde{c}_0(t) \quad (3)$$

Here $\tilde{c}_0(t)$ is the scaled probability amplitude of the QE, oscillating at bare frequency ω_0. $\tilde{b}_{\xi,n}(t)$ is the probability amplitude of the (ξ, n)th pseudomode and $\bar{g}_{\xi,n}$ is the coupling strength between the QE and each pseudomode. The free space terms cause an additional complex contribution, ω_{fs}, which modifies the bare frequency of the QE, representing free space propagation and decay. The functions $\Theta_{1,2}$ correspond to Heaviside step functions that ensure relevant terms act either before or after sufficient time has occurred for light to propagate from $\mathbf{r}$ to $\mathbf{r}'$ via the nanoparticle. These terms enforce causality for our description and naturally arise from the solutions to Eq. 1.

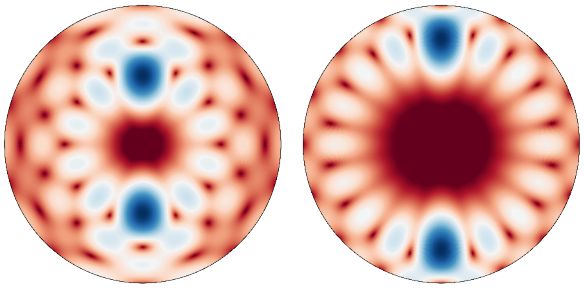

Fig. 2. The intensity of the $(5, 4)$ [left] and $(8, 3)$ [right] pseudomodes within the nanoparticle. Both resonate at the same frequency, w_r and their profiles show remarkable similarity to the normal modes of a spherical system demonstrating the close mapping between the two.

III. Results and Discussion

We apply our framework to a spherical silicon nanoparticle of radius $a = 1\mu m$ coupled with a two-level QE aligned radially so only the TE modes contribute. The quantum dynamics

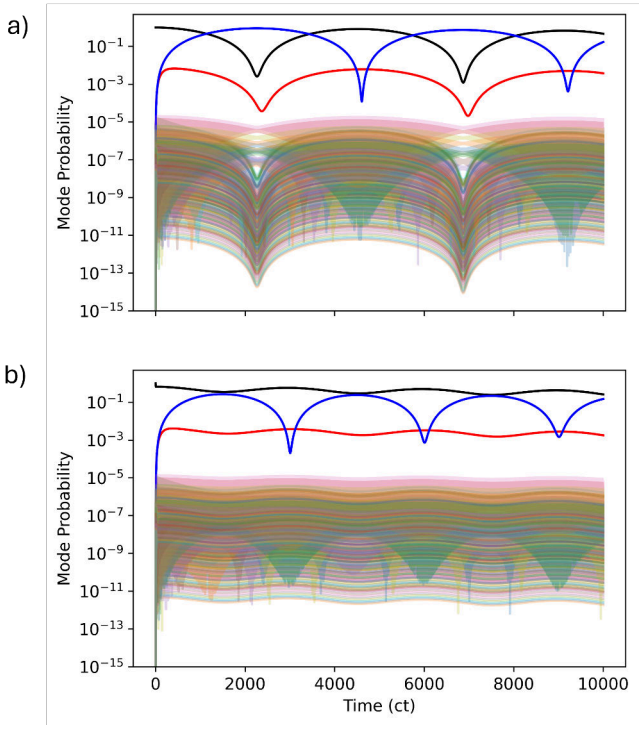

Fig. 3. The population dynamics for the spherical nanoparticle system with a QE placed (a) on the surface and at (b) $2\mu m$ from the $1\mu m$ silicon nanoparticle. The QE is tuned to be on resonance with the $(8, 3)$ mode with a dipole moment $d = 1000D$. The population of the QE is plotted in black, the resonant $(5, 4)$ and $(8, 3)$ pseudomodes in red and blue respectively, with fainter lines showing off resonant pseudomodes.

are calculated for various QE positions both on and away from the nanoparticle surface. Fig. 2 shows the normalized intensity profiles of two pseudomodes ($(\xi, n) = (8, 3)$ and $(5, 4)$) which share a similar resonant frequency, ω_r.

Evaluating Eq. 1 for arbitrary positions of $\mathbf{r}$ and $\mathbf{r}'$ results in solutions containing the previously unaccounted for free-space terms. To compute the pseudomode dynamics, we take the limit $\mathbf{r} \to \mathbf{r}'$ keeping the non-divergent components of f_{fs}. This results in terms that describe the free-space behavior of the QE. The imaginary component of these terms, $Im(f_{fs}) \propto \omega^3 d^2/3\pi c^3\hbar\varepsilon_0$ agrees with standard results predicted by other quantum theories for a dipole decaying in free space. Additionally, position dependent phase shifts of the probability amplitude oscillations arise, affecting the coupling between QE and pseudomodes. Additional tail effects broaden the interaction as light reaches the surface of the nanoparticle demonstrating the non-Markovian effects our framework preserves.

Fig. 3 shows quantum dynamics obtained using our generalized pseudomode framework for two different QE positions. For short times in 3b there is a strong initial decay, occurring before light can return information about the nanoparticle. In this scenario, the real part of f_{fs} shifts the frequencies, enhancing coupling to the radiative channels of the off resonant modes as can be seen. This same shift simultaneously

weakens coupling to the resonant modes resulting in the smaller oscillation amplitudes observed.

At longer times, the dynamics obtained for both QE positions exhibit both Markovian and non-Markovian behavior. The resonant $(8, 3)$ pseudomode exhibits out of phase vacuum Rabi-oscillations, a signature of non-Markovian dynamics, while the $(5, 4)$ pseudomode oscillates in phase with the QE reflecting Markovian behavior.

IV. Conclusion

We have demonstrated a generalized pseudomode framework for the exact second quantization of radiative nanophotonic systems with emitters placed at arbitrary positions. By applying our framework, we have shown it naturally accounts for causality through additional terms representing free space propagation and decay. Using this method, we obtain a *complete* picture of the near- and far-field quantum dynamics that incorporates overlooked non-Markovian effects.

Light emission from metals - photluminescence and electroluminescence

Imon Kalyan[1], Ieng-Wai Un[1], Kaiqiang Lin[2], John M. Lupton[2], Sebastian Bange[2], Yonatan Sivan[1]
[1] *School of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel*
[2] *Institut für Experimentelle und Angewandte Physik, Universität Regensburg, Germany*

Abstract: We provide a single line analytic theory for photoluminescence and electroluminescence from metal nanostructures under CW and pulsed illumination which allows us to explain a long series of seemingly contradicting experimental reports. We then describe the signature of our predictions in old and new measurements.

Photoluminescence (PL) from metals is one of the most fundamental aspects of light-matter interactions – it involves the 2-step process in which an incoming photon gets absorbed in a material, and consequently emitted spontaneously. In the context of metals, this phenomenon was disputed for many decades, with contradicting experimental reports on every possible aspect – the emission statistics (fermionic/bosonic, thermal/non-thermal), its dependence on electric field (polynomial/power law with integer/non-integer exponent), on structure size (grows/decreases with increasing size), its quantum efficiency, the underlying microscopic mechanism (electronic Raman scattering/simple recombination) etc. etc. [1]. These radically different behaviours were not accompanied by a complete theory because of the lack of knowledge of the hard-to-calculate electron non-equilibrium distribution under illumination.

Here, we remedy this problem by providing a complete quantitative theory for this important, decades-old, yet unresolved problem of (nonlinear) photoluminescence (PL) from metals for both continuous-wave (CW) and pulsed illumination. Based on our the *steady-state* non-equilibrium electron distribution in metals [2], we first compute the electron and lattice temperatures and the emission from metals illuminated by *CW* light [3]. This solution reveals what is to our knowledge, the first ever explanation of the dependence of the metal emission on the electric field, and its dependence on the electron temperature; we show that the emission is a primarily *non-thermal* phenomenon, and identify the unique signatures of the deviation from thermal equilibrium on the emission spectra and electric field dependence. The theory is then shown to match experimental data and used to clarify open questions associated with the use of the PL as a temperatre probe.

We then analyze *transient* nonlinear PL following illumination by intense *ultrashort pulses*. Our detailed calculations and a simplified heuristic model enable us to elucidate the crossover from the non-thermal emission characteristic of weak (CW-like) illumination to thermal emission occurring after illumination by strong shorter pulses [4]. Specifically, we identify the characteristics of nonthermal and thermal emission in the transient emission spectra and its dependence on the illumination frequency and intensity. These findings, specifically, the weak 3 photon absorption, were then verified in measurements from various sets of Au rods (see Fig. 1(a)). In that regard, our work puts to rest the many decades-long arguments on the statistics and electric field dependence of the emission [1].

Then, based on the extension of our point-emission theory [3,4] to macroscopic bodies using the extension of the local Kirchhoff's law to non-equilibrium distributions [5], we reconcile seemingly contradicting behaviour of the PL as a function of the metal structure size (for nanospheres and nanofilms), see Fig. 1(b)-(d) [6].

Finally, we describe the analogous theory for light emission under bias voltage (with and without illumination), and discuss our novel findings and their relation to the state-of-the-art theory and to experimental measurements.

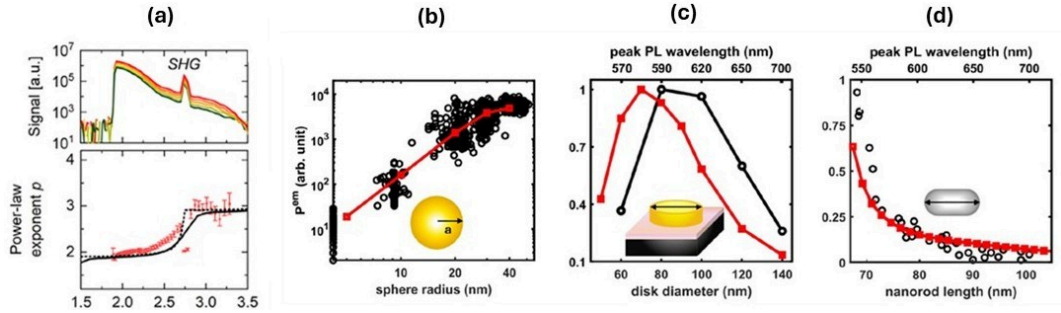

Figure 1: (a,top) Measured spectra at various illumination intensities and (a,bottom) the corresponding power-law exponent extracted from the measured data; an excellent match to the theoretical prediction (black line) is observed. (b)-(d) Measured PL from various different metal nanoparticles (Au spheres, discs, Ag rods), showing opposing size dependence, all explained by our single line quantitative theory (red).

***Abstract*— Reconfigurable spatial filters comprising phase-change materials integrated into extraordinary optical transmission metasurfaces are designed and fabricated. Near-zero transmission in the crystalline state coupled with high amorphous transmission deliver spatial filters that can be written and re-written. Example functionalities of reconfigurable high and low-pass spatial filters are demonstrated.**

***Keywords*— phase-change metasurface, extraordinary optical transmission.**

I. Introduction

Analogue optical computing is experiencing increased attention as a result of inherent advantages it possesses over digital computing, including spatial parallelism, ultra-high bandwidth and low-loss transmission [1]. Previous work in the field has demonstrated both free-space and integrated photonic systems for a range of uses that include optical neural networks [2] and parallelized matrix-vector multiplication [3]. Here we present a design for a reconfigurable spatial filter metasurface within a free-space system. The metasurface utilises phase-change materials (PCMs) to allow for reconfigurability by writing into the spatial filter regions of high and near-zero transmission, corresponding, respectively, to amorphous and crystalline regions of the PCM layer. In this manner, a variety of optical spatial filters can be realized, including high-pass, low-pass, band-pass and band-reject, in a single reconfigurable device.

Our devices are designed to be used in the classic 4f spatial filter arrangement, as shown in Fig. 1a. The reconfigurability of the metasurface is achieved via the integration of chalcogenide phase-change materials into an extraordinary optical transmission (EOT) metasurface. The EOT effect is a phenomenon in which massively enhanced light transmission occurs at the resonant wavelength of a sub-wavelength array of holes in a metallic film [4]. The device developed here consists of a thin film of $Ge_2Sb_2Te_5$ (GST) deposited atop a gold film patterned with an array of sub-wavelength holes (see Fig. 1b). GST offers vastly contrasting optical properties (n and k) between its amorphous and crystalline phases [5]; changing the phase of the GST shifts the spectral position of the EOT array's resonant wavelength. Switching of the PCM phases can be achieved via a heat stimulus, e.g. by using ex-situ laser excitation or in-situ embedded microheaters [6]. Arbitrary patterns can thus be written into the GST layer of the device such that a variety of reconfigurable spatial filters can be realized by selectively switching desired regions of the PCM-EOT metasurface to deliver, for example, the low-pass, high-pass, band-reject and band-pass spatial filters shown schematically in Fig. 1c.

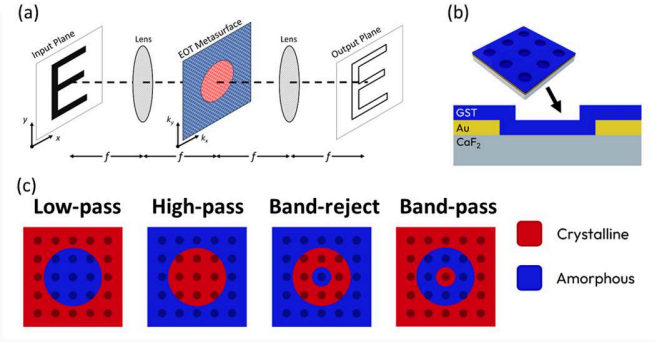

Fig. 1. (a) Schematic of a 4f system with the phase-change EOT metasurface placed at the shared focal point of the lenses; this example shows the metasurface acting as a high-pass filter. (b) A schematic of the phase-change ($Ge_2Sb_2Te_5$, or GST) EOT device design. (c) Schematics of metasurface devices with amorphous (blue) and crystalline (red) regions written into the phase-change layer to produce the spatial filter functionalities of low-pass, high-pass, band-reject and band-pass filters.

II. Results and Discussion

Phase-change EOT devices were fabricated using magnetron sputtering and electron beam lithography. An SEM image of an exemplar device is shown (prior to the deposition of the PCM layer) in Fig. 2a, here with geometric dimensions designed to provide functionality in the mid-infrared waveband. The

transmission spectra of the fabricated devices were measured using Fourier transform infrared spectroscopy (FTIR). Typical experimental transmission spectra are shown Fig. 2b, for the phase-change layer in both its amorphous and crystalline states. As expected, switching the phase-state of the PCM layer shifts to the position of the EOT peak, due to the change in refractive index (n) on switching. An increase in extinction coefficient (k) leads to slight reduction peak transmission in the crystalline case, as compared to that of the amorphous state. It can also be seen in Fig. 2b that the minimum (near-zero) in the crystalline transmission occurs almost directly below the maximum in the amorphous transmission, such that the device demonstrates the desired properties for use as a reconfigurable spatial filter along the lines previously discussed.

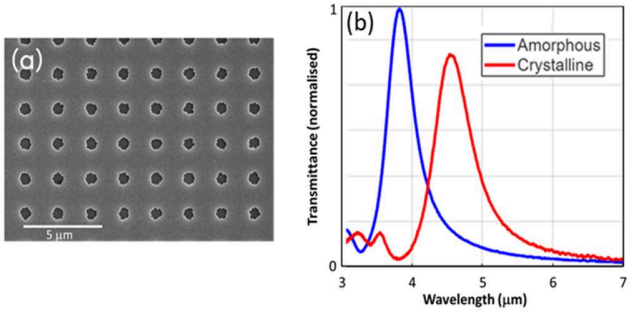

Fig. 2. (a) SEM image of an exemplar as-fabricated EOT array (Au on CaF_2) designed for use in the mid-infrared. (b) Experimental (FTIR) spectra of a phase-change EOT array with the PCM layer in both the amorphous (blue) and crystalline (red) states.

To test the likely performance of the device shown in Fig.2, its operation as a spatial filter in a 4f system, for both high-pass and low-pass filtering, was simulated (in Matlab). The results are shown in Fig. 3 for example cases of high-pass and low-pass filtering. The input image is the letter 'E', and with the PCM layer configured to deliver a high-pass response (central region crystalline, outer region amorphous) the filter emphasizes the edges of the input image, acting as a form of edge detector, so revealing a high-pass functionality (Fig. 3b). With the device reconfigured to provide a low-pass response (central region amorphous, outer region crystalline), the output image shows evidence of smoothing/blurring (Fig. 3c), as expected from a low-pass filter. These functionalities are further clarified in the output image cross-sections shown in Figs. 3d and 3e. These experimental results demonstrate the viability of the PCM EOT metasurface device to function as a reconfigurable spatial filter in the mid-infrared.

III. Conclusion

We have presented device designs based around phase-change extraordinary optical transmission metasurfaces that can provide a form of reconfigurable optical spatial filtering. Experimental transmission results of as-fabricated devices revealed properties suitable for such reconfigurable spatial filtering. Simulations based on experimental transmission responses successfully demonstrated, as a proof-of-concept, both high-pass and low-pass spatial filtering of test images.

***Abstract*— Vanadium dioxide nanoporous films and Au–VO_2 nanocomposites were fabricated by pulsed laser deposition. The nanoporous VO_2 shows anisotropic optical properties and a thermally driven structural-phase and insulator-to-metal transition. Incorporating Au nanoparticles enables photo-thermal activation of the structural-phase transition under continuous-wave illumination, demonstrating a pathway toward switchable VO_2-based photonic devices.**

***Keywords*— vanadium dioxide, phase change material, nanoporous thin films, photo-thermal switching, Au nanoparticles, optical anisotropy.**

I. Introduction

Vanadium dioxide (VO_2) is a phase-change material exhibiting a reversible insulator-to-metal transition (IMT) coupled to a structural phase transition (SPT) at ~68 °C, leading to pronounced changes in its optical and electrical properties. These features make VO_2 highly attractive for photonic, plasmonic, and smart photothermal applications. However, its practical implementation is hindered by the relatively high transition temperature (T_C) and by synthesis challenges arising from the multiple oxidation states of vanadium.[1] Recent studies have shown that nanoscale control of VO_2 thin films—particularly in terms of morphology and doping—enables effective tuning of their thermochromic response. In this context, nanoporous VO_2 has emerged as a promising architecture: the high surface-to-volume ratio can accommodate the structural distortions associated with the SPT, resulting in a reduced T_C.[2] Moreover, the enhanced surface area of nanoporous VO_2 is advantageous for sensing and energy-storage applications. This morphology also facilitates the incorporation of metal nanoparticles (NPs), such as gold. Au-VO_2 nanocomposites have been reported to further decrease T_C through thermoplasmonic heating, nanoantenna effects, and possible carrier injection at the Au/VO_2 interface, although the dominant mechanism remains under debate.[3,4] Furthermore, such Au-VO_2 systems have been mainly investigated under thermal excitation or ultrafast optical pumping, whereas photo-induced phase transitions driven by continuous-wave optical illumination remain less explored.

Therefore, in this work, a pure nanoporous VO_2 thin film and an Au-VO_2 nanocomposite were fabricated by pulsed laser deposition (PLD). The nanoporous VO_2 thin film exhibited a smooth SPT transition from the VO_2 (M1) phase to the VO_2 (R) phase, beginning near 70 °C and ending near 90 °C. Furthermore, the nanoporous VO_2 grew preferentially along the vertical direction, forming a columnar-like structure that displayed optical anisotropy between the in-plane and out-of-plane directions, further tunable with temperature: two positive (dielectric) and negative (metallic) ε_1 values at room temperature and high temperature, respectively. Finally, the Au nanoparticles embedded in the VO_2 nanoporous matrix were shown to be essential for photo-inducing the VO_2 SPT.

II. Methods

The VO_2 thin film and Au-VO_2 nanocomposite were deposited by pulsed laser deposition (PLD). The morphology was investigated by scanning electron microscopy (SEM). The insulator-to-metal transition of the pure VO_2 thin film was investigated by room and high temperature ellipsometric measurements. The thermally induced structural phase transition (SPT) of VO_2 was investigated by variable-temperature Raman measurements using a 532 nm laser with a power <1 mW to avoid thermal contribution coming from the Raman laser. Conversely, the photo-induced SPT of the VO_2 and Au-VO_2 nanocomposite was studied through variable-power Raman measurements at room temperature.

III. Results and Discussion

During growth, the nanoporous pure VO_2 thin film exhibited a preferential vertical growth, forming a columnar-like structure characterized by an approximate uniaxial anisotropy (Fig. 1a). In this case, the dielectric constants are equal in the in-plane directions but differ along the out-of-plane direction (i.e. $\varepsilon_{xx} = \varepsilon_{yy} \neq \varepsilon_{zz}$). The SPT investigated by variable, Raman

temperature measurements is reported in Fig. 1b. The main Raman peaks of the insulating VO_2 (M1) phase progressively decreased in intensity with increasing temperature and completely transformed into the metallic VO_2 (R) phase at 90 °C. The IMT investigated by room temperature (RT) and high temperature (HT) ellipsometric measurements is shown in Fig. 1c and 1d. At RT, the VO_2 film exhibits a dielectric-like behaviour, with different dielectric constants along the in-plane (*xx*) and out-of-plane (*zz*) directions. Conversely, at HT the real permittivity (ε_1) becomes negative in the near-infrared region. The in plane and out-of-plane dielectric functions show different plasma frequencies, hinting at possible hyperbolic behaviour.

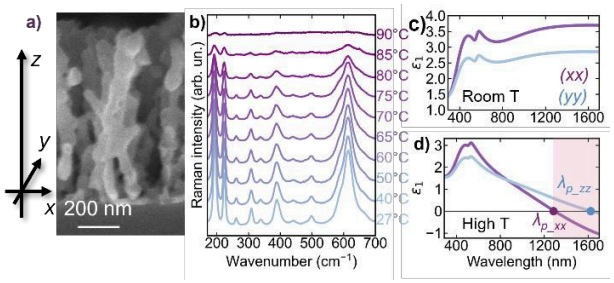

Fig. 1 (a) Cross-sectional SEM image of a nanoporous VO_2 thin film. (b) Temperature-dependent Raman spectra. (c,d) Ellipsometric measurements at room temperature and high temperature.

Subsequently, the nanoporous VO_2 thin film was decorated with Au NPs to photo-induce the VO_2 transition and investigate the role of Au under continuous-wave optical excitation (Fig. 2a). The photo-induced transition was studied using power-dependent Raman measurements with a 532 nm laser wavelength resonant with the Au NPs (Fig. 2b). The Raman signal of the VO_2 (M1) phase initially increases with laser power up to 2 mW. At higher powers, the VO_2 (M1) Raman peaks progressively decrease in intensity and completely disappear for powers >20 mW. This reduction in peak intensity can be clearly observed by focusing on the VO_2 (M1) mode at 190 cm^{-1} (see Fig. 2c). By fitting the peak-intensity trend, the onset of the photo-induced SPT can be identified at the maximum of the curve, around 2.3 mW. In contrast, a pure nanoporous VO_2 thin film does not exhibit any photo-induced transition under the same excitation conditions (here not shown), highlighting the crucial role of Au NPs in triggering the VO_2 phase transition.

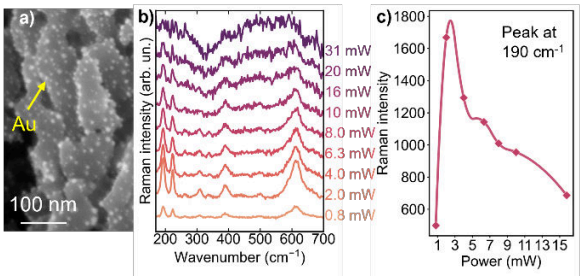

Fig. 2 (a) Cross-sectional SEM image of the Au-decorated VO_2 film. (b) Power-dependent Raman spectra of the Au-VO_2 system. (c) Peak intensity vs power of the VO_2 M1 peak at 190 cm^{-1}.

IV. Conclusion

We successfully deposited a pure VO_2 thin film with a nanoporous morphology, which exhibited anisotropic optical properties and switchable behavior. At room temperature, the film showed a fully positive real permittivity, whereas at high temperature it displayed a negative real permittivity, confirming its insulator-to-metal transition. In addition, we demonstrated that combining the VO_2 thin film with Au nanoparticles enables photo-thermal switching of the VO_2 phase. These results pave the way for the development of VO_2-based devices that exploit morphology-driven properties for active thermal and photo-thermal switching applications.

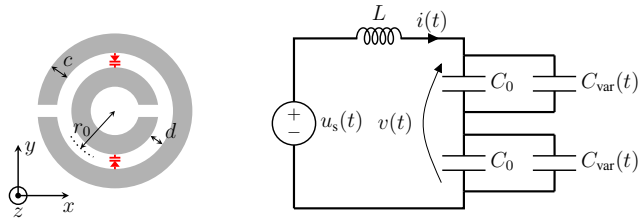
***Abstract*—This paper presents an equivalent circuit model of a time-varying Edge-Coupled Split-Ring Resonator. Time modulation is imposed by a varactor diode connected between the two rings of the scatterer and enables the generation of scattered wave harmonics, as predicted by the provided circuit model.**

***Keywords*— space-time metamaterials, time-varying media, electromagnetic modeling, polarizabilities, scattering**

I. Introduction

Time-varying metasurfaces have recently gained considerable interest due to their broad range of applications. These include photonic time crystals [1], [2], frequency mixing [3], absorbers [4], power combing [5], filtering and isolation [6], beamforming [7] and more. A common method the analysis of a metasurface is by modeling the multipolar response of its constituting scatterers [8]. However, this process is quite difficult for time-varying metasurfaces due to the complex nature of their respective time-varying scatterers. Therefore, the analytic calculation of polarizability/T matrices of time-varying scatterers is possible only for simple geometrical shapes via Mie theory [9]. As a result, the dipole response of the time-varying resonators is usually approximated via equivalent circuit models [10]. Nevertheless, those circuit models for more complicated time-varying resonator setups are still unavailable, and their development would expand the design and optimization processes for time-varying media.

This work proposes a circuit model for the time-varying Edge-Coupled plit-ring resonator (EC-SRR). The EC-SRR is modulated by means of two varactors diodes, corresponding to a time-modulated capacitance. Afterwards, a well-known equivalent RLC-circuit approach for the computation of the (dipole) polarizability matrix in the passive or stationary case [11] is expanded to incorporate the time modulation provided by the varactors [10]. Assuming a periodic capacitance modulation with an instantaneous response, the current induced along the rings can be derived from the voltage across the rings and, consequently, from the external excitation, enabling the calculation of the polarizabilities. Due to the periodic time modulation, the current is expressed in terms of its harmonic components, leading to a matrix formulation of the problem. Then, the generation of harmonic frequencies by an illuminated time-varying EC-SRR is demonstrated and, eventually, the presented results are validated by rigorous and demanding time-domain numerical simulations.



(a) (b)

Fig. 1. (a) Geometry of the time-varying EC-SRR, where $r_0 = 2.3$ mm, $c = 0.8$ mm and $d = 0.2$ mm. All metallic parts are considered, in this work, as PEC. The origin of the axes O(0,0,0) is placed at the center of the EC-SRR. (b) The RLC equivalent circuit of the resonator under study.

II. Equivalent Time-Varying Circuit Model

A time-modulated EC-SRR, as shown in Fig. 1(a), consists of two metallic circular strips of equal thickness c connected through two varactors, placed perpendicularly along the y-axis. The scatterer is modeled as a series connection of two halves, so the use of two varactors is necessary for the analysis to hold. Assume that the largest dimension of the EC-SRR, i.e. its diameter, remains electrically small, below $\lambda/5$. Thus, the response of the particle can be represented as an equivalent assortment of only electric/magnetic dipoles. Under this dipole approximation, the scattered fields of an EC-SRR can be modeled by two electric dipole moments p_x, p_y and a magnetic dipole moment m_z. Due to the geometry of the particle, the induced dipoles are connected with the incident fields on the particle via five non-zero polarizabilities, through [11]

$$\begin{bmatrix} p_x \\ p_y \\ c^{-1}m_z \end{bmatrix} = \begin{bmatrix} a_{\mathrm{ee}}^{xx} & 0 & 0 \\ 0 & a_{\mathrm{ee}}^{yy} & a_{\mathrm{em}}^{yz} \\ 0 & a_{\mathrm{me}}^{zy} & a_{\mathrm{mm}}^{zz} \end{bmatrix} \begin{bmatrix} \varepsilon_0 E_{x,\mathrm{i}} \\ \varepsilon_0 E_{y,\mathrm{i}} \\ c^{-1}H_{z,\mathrm{i}} \end{bmatrix}. \quad (1)$$

The particle is modeled, herein, as an equivalent RLC-circuit, as shown in Fig. 1(b). Each capacitance branch consists of a static capacitance C_0 (the capacitance between the rings in the absence of varactors), and a time-varying capacitance due to the varactor C_{var} placed in parallel. The total capacitance is therefore the sum of two terms: $C_{\mathrm{t}}(t) = \frac{1}{2}\left[C_0 + C_{\mathrm{var}}(t)\right]$. As the capacitance of a varactor can be expressed as the sum of constant and a modulated component, the total capacitance of the time-modulated EC-SRR can be expressed as $C_{\mathrm{t}}(t) = \frac{1}{2}C_{\mathrm{s}}[1 + M\cos(\Omega_{\mathrm{p}}t)]$. Here, Ω_{p} is the modulation frequency, M the modulation strength value, and C_{s} is the stationary capacitance consisting of the capacitance of the half ring, C_0, and the constant capacity of the varactor.

From circuit theory the following equation holds: $u_{\mathrm{s}}(t) = R\,i(t) + L\frac{\mathrm{d}i}{\mathrm{d}t} + v(t)$ [10], [11], with L the system inductance, $R = 0$, as losses are neglected, and $v(t)$ the voltage on the total capacitance C_{t}. In the time-invariant case, $M = 0$ and the analysis is straightforward, as the induced current is linearly related to the derivative of the voltage between the rings: $i(t) = \frac{C_{\mathrm{s}}}{2}\frac{\mathrm{d}v(t)}{\mathrm{d}t}$. However, when the capacitance is temporally modulated, the current turns to $i(t) = \frac{\mathrm{d}}{\mathrm{d}t}\left[C_{\mathrm{t}}(t)v(t)\right]$. In this case, a frequency-domain relation can be found between the current $I(\Omega)$ and the capacitance voltage $V(\Omega)$ [10]:

$$I(\Omega) = \frac{j\Omega}{2\pi}\int_{-\infty}^{+\infty} C_{\mathrm{t}}(\omega, \Omega-\omega)\,V(\omega)\,d\omega. \tag{2}$$

Assuming that the periodic time-modulation is instantaneous (i.e., the absence of frequency dispersion), the capacitance is expressed as a series of harmonics,

$$C_{\mathrm{t}}(t) = \sum_{m=-\infty}^{+\infty} c_m e^{\,jm\Omega_{\mathrm{p}}t}, \tag{3}$$

where, due to the cosine dependence defined above, the only non-zero terms are $c_0 = C_{\mathrm{s}}/2, \quad c_1 = c_{-1} = MC_{\mathrm{s}}/4$, yielding a discrete Fourier spectrum. Assuming a time-harmonic voltage source, the voltage can be expressed as an expansion of exponential functions as

$$v(t) = \Re\mathrm{e}\left\{\sum_{n=-\infty}^{+\infty} V_n\, e^{j\Omega_n t}\right\}, \tag{4}$$

which allows the current in the ring in (2) to be written in discrete form [10] as a series:

$$I = \sum_m \sum_n j\left[\Omega_0 + (n+m)\,\Omega_p\right] c_m\, V_n. \tag{5}$$

Having established the relationship between the current and voltage in the frequency domain, the current in (5) can be rewritten for arbitrary excitation in a matrix form as

$$[I] = -j\,[\Omega]\,[K]^{-1}\,[\Sigma] \tag{6}$$

where the matrix $[K]$ is

$$[K] = \begin{bmatrix} \Omega_{-N}^2 L - q_{11} & -q_{12} & \cdots & -q_{1n} \\ -q_{12} & \Omega_{1-N}^2 L - q_{22} & \cdots & -q_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ -q_{1n} & -q_{2n} & \cdots & \Omega_N^2 L - q_{nn} \end{bmatrix} \tag{7}$$

q_{ij} being entries of the inverse of the matrix relating the voltage and current from (5), and the matrix $[\Omega]$ being a diagonal matrix containing the harmonics Ω_n in (4). It should be noted that the a finite truncation of harmonics must be performed, introducing a negligible inaccuracy, provided that the number of harmonics considered is large enough.

Having established the relation between the current and the excitation, the polarizabilities can be found, following a similar approach as done in [11], as

$$[a_{\mathrm{mm}}^{zz}] = -\mu_0\,\pi^2\,r_0^4\,[\Omega]\,[K]^{-1}\,[\Omega] \tag{8a}$$

$$[\alpha_{\mathrm{ee}}^{xx}] = \frac{16}{3}\,r_{\mathrm{ext}}^3 \tag{8b}$$

$$[a_{\mathrm{em}}^{yz}] = 4j\,\eta_0\,r_0^2\,d_{\mathrm{eff}}\,[K]^{-1}\,[\Omega] \tag{8c}$$

$$[a_{\mathrm{me}}^{zy}] = -4j\,\eta_0\,r_0^2\,d_{\mathrm{eff}}\,[\Omega]\,[K]^{-1} \tag{8d}$$

$$[a_{\mathrm{ee}}^{yy}] = [\alpha_{\mathrm{ee}}^{xx}] - \frac{16\,d_{\mathrm{eff}}^2}{\varepsilon_0\pi^2}[K]^{-1} \tag{8e}$$

where r_0 is the mean radius of the scatterer, $r_{\mathrm{ext}} = r_0 + \frac{d}{2} + c$ is the exterior radius and $d_{\mathrm{eff}} = c + d$.

A scatterer must satisfy the condition of energy conservation for the system. For passive scatterers, this requirement is known as the Sipe–Kranendonk condition [12]. In time-varying systems there is additional energy actively pumped into the balance. However, this pumped energy is expressed by the calculated moments and so it is present in the power absorbed and radiated by the scatterer. In order to correctly add the radiation term into the quasi-polarizability calculated in (8), as in [12], a new, dynamic polarizability $3(N+1)\times 3(N+1)$ matrix, N being the number of retained harmonics, is constructed. It contains every polarizabilty tensor for all frequencies considered, as well as their mutual coupling induced by the time modulation. This way, the quasi-static polarizability matrices $[a]_{\mathrm{st}}$ can be inversed in order for the dumping term to be added, resulting in the dynamic polarizability matrix to be found as

$$[a]_{\mathrm{dyn}}^{-1} = [a]_{\mathrm{st}}^{-1} + \frac{j}{6\pi}[k]^3. \tag{9}$$

III. Results and Discussion

A full-wave simulation was performed via the transient solver of COMSOL Multiphysics [13], in order to validate the equivalent circuit model that was presented above. An SMD capacitor was inserted into the simulation setup, with a periodic electric permittivity variation, $\varepsilon = \varepsilon_{\mathrm{s}}[1 + w\cos(\Omega_{\mathrm{p}}t)]$ with ε_{s} the static permittivity and $w = MC_{\mathrm{s}}/C_{\mathrm{var}}$ the SMD's modulation strength, in order to emulate the behaviour of a varactor. The capacitance value of the SMD was first evaluated with the AC/DC solver of COMSOL, and two such identical capacitors were then placed between the rings of the scatterer [see Fig. 1(a) and its caption for the relevant coordinate system]. The subsequent modulated EC-SRR was excited by an elementary electric dipole, located in the zx plane at the point $A = (a, 0, a)$ with $a = 1$ cm, and its scattered field calculated at an observation point in the xy plane at the point $B = (-b, b, 0)$ where $b = 3.54\,r_0$. A modulated Gaussian pulse is used at the source electric dipole, centered at $f_{\mathrm{c}} = 4.5$ GHz with a spectral deviation set to $\sigma = 1/(1.5f_{\mathrm{c}})$. Additionally, for the purpose of verification, a fast modulation frequency of $\Omega_{\mathrm{p}} = 2\pi f_c/3$ was chosen. The electric permittivity was defined with $\varepsilon_s = 10$ and $w = 0.5$, resulting in the system's total modulation strength $M = 0.125$. Finally, in order to compare the two models, the scattered field at the observation point B is normalized by the spectral peak value of the incident field at B, as

$$\text{normalized } E_{\mathrm{sc}}(f) = \frac{|E_{\mathrm{sc}}(f)|}{\max_f\left\{|E_{\mathrm{i}}(f)|\right\}} \tag{10}$$

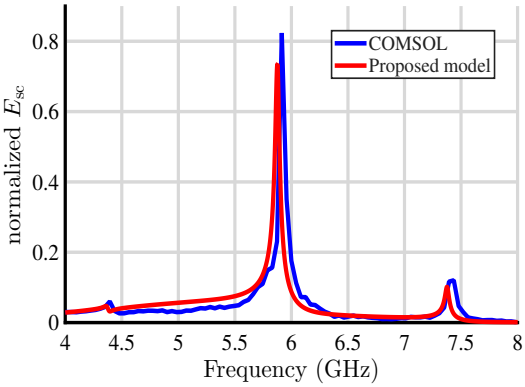


Fig. 2. Comparison of circuit equivalent and numerical results for the scattered field by a time-varying EC-SRR.

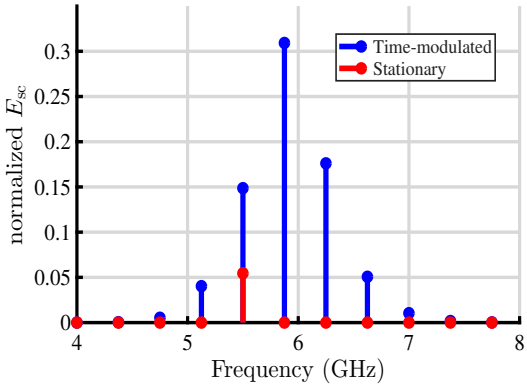

Fig. 3. Normalized scattered fields from a time-varying EC-SRR via the proposed method for a monochromatic excitation.

The comparison, seen in Fig. 2, shows good agreement with a slight frequency shift and a small amplitude deviation. The frequency shift is primarily influenced by small discrepancies in the capacitance value of the SMD capacitor when finally inserted in the EC-SRR setup, i.e. parasitic capacitances or inadequate local mesh density. Moreover, one can also notice the generated resonances. The central one corresponds to the resonance frequency of the EC-SRR, while the others are the harmonics, as indicated in the analysis of the previous section.

As outlined above, the time-varying EC-SRR is generally expected to generate harmonics obtained through the mixing of the modulation and the illumination frequencies. To evaluate this behaviour, the scatterer is excited by a modulated Gaussian pulse centered at $f_c = 5.5$ GHz with a very narrow frequency spectrum, in order to emulate a monochromatic excitation or almost delta function in frequency domain. Additionally, a slow modulation was investigated with $\Omega_p = \Omega_c/14.6$ GHz, while the modulation strength is $M = 0.125$. If we maintain the same points A and B for the dipole source and observation points respectively, the calculated polarizabilities from (8) and (9) lead to the normalized scattered field depicted on Fig. 3, along with the results for an unmodulated or stationary EC-SRR. The creation of harmonics is clearly visible, with some having greater amplitude than the central one, due to being closer to resonant frequency of the EC-SRR. Finally, Fig. 3 shows significantly more powerful scattered waves, reaching approximately four times when comparing with the central scattered frequency without modulation. This behavior is attributed to the time-varying capacitance pumping energy into the system, as an active circuit.

Regarding the numerical validation procedure, a finer mesh density of the numerical simulation will possibly lead to better agreement between the two models. Nevertheless, the COMSOL simulations lasted for about 12 hours running on 128 Gigabytes of RAM, in contrast to the equivalent circuit developed above needing approximately 1 minute.

IV. Conclusion and Future Work

In this paper, an efficient equivalent circuit model of a time-varying EC-SRR was presented and validated. Future work will build on the proposed model by incorporating it into the analysis of time-varying metasurfaces. Finally, the same analysis framework can be applied to other geometries of time-varying resonators, whose equivalent circuit can be determined in the passive case.

***Abstract*—We present a machine-learning-driven inverse design framework that replaces heuristic cavity design with boundary-shape optimisation to engineer three-dimensional microwave resonators supporting large electromagnetic helicity. This approach systematically explores complex parameter spaces, revealing non-intuitive high-helicity geometries, and is demonstrated on smooth, edge-free cavity families using two gradient-free optimisation strategies.**

***Keywords*— inverse design, microwave cavities, electromagnetic helicity, genetic algorithm, Bayesian optimisation, robustness.**

I. Introduction

Electromagnetic helicity, $\mathscr{H}$, defined as the projection of electromagnetic spin onto linear momentum [1], [2], [3], [4], provides a quantitative measure of field handedness. Modes with non-zero $\mathscr{H}$ enable strong coupling to chiral matter, offering versatile platforms for enantioselective microwave spectroscopy [5], [6], axion dark-matter searches [7], [8], and chiral quantum sensing [9].

Although microwave cavities supporting non-zero $\mathscr{H}$ have been demonstrated using heuristic design principles [8], [10], [11], [12], such approaches offer limited guidance for systematically maximising $\mathscr{H}$. The $\mathscr{H}$ figure of merit (FoM) depends on the full three-dimensional field distribution and can be highly sensitive to small boundary perturbations. These challenges motivate the adoption of inverse-design methodologies.

Over the past decade, inverse design has transformed nanophotonic device development, shifting from intuition-driven geometries to algorithmically optimised structures that maximise prescribed performance metrics. By coupling flexible geometric parameterisations with rigorous electromagnetic solvers and optimisation engines [13], [14], [15], these methods enable systematic exploration of large design spaces.

Here, we extend these principles to fully three-dimensional microwave cavity resonators. Metallic boundary shapes are optimised to maximise a $\mathscr{H}$-based FoM evaluated via finite-element eigenmode analysis. Gradient-free optimisation techniques, genetic algorithms (GA) and Bayesian optimisation (BO), enable systematic discovery of strongly helical cavity modes. The framework is applied to multiple cavity families composed of smooth, edge-free components compatible with metal additive manufacturing and electropolishing.

II. Methods

A. Helicity Figure of Merit

For a monochromatic resonant mode i, the global electromagnetic helicity is

$$\mathscr{H}_i = \frac{2\,\mathrm{Im}\left[\int \vec{\mathbf{E}}_i(\vec{r}) \cdot \vec{\mathbf{H}}_i^*(\vec{r})\, dV\right]}{\sqrt{\int \vec{\mathbf{E}}_i \cdot \vec{\mathbf{E}}_i^* dV \int \vec{\mathbf{H}}_i \cdot \vec{\mathbf{H}}_i^* dV}}, \tag{1}$$

where $\vec{\mathbf{E}}_i$ and $\vec{\mathbf{H}}_i$ denote the electric and magnetic fields.

For a parameterised geometry $\mathbf{x} \in [-1, 1]^d$, eigenmodes are computed and the fitness is defined as

$$F(\mathbf{x}) = |\mathscr{H}_m|, \tag{2}$$

where m denotes the most helical mode.

B. COMSOL–Python Optimisation Loop

Each cavity family is implemented in COMSOL Multiphysics®. A Python routine generates $\mathbf{x}$, maps it to physical parameters, injects them via the Java API, performs an eigenfrequency study, and computes $\mathscr{H}_i$. Non-convergent simulations are penalised to prevent propagation of invalid designs. This is demonstrated in the block diagram in Fig. 1.

To compare families, models are scaled to maintain constant surface-to-volume ratio. Surface-loss performance is quantified using the geometric factor

$$\tilde{G}_i = \frac{\iiint_V \mu_0 |\mathbf{H}_i|^2 dV}{\mu_0 \iint_S |\mathbf{H}_i^\tau|^2 dS}. \tag{3}$$

C. Optimisation Strategies

Two gradient-free optimisers are employed:

Genetic Algorithm (GA): A population-based evolutionary algorithm that iteratively refines cavity parameters via selection, crossover, and mutation to maximise $F(\mathbf{x})$.

Bayesian Optimisation (BO): A Gaussian Process surrogate model is trained on COMSOL results to guide evaluations toward promising regions, reducing the number of required simulations.

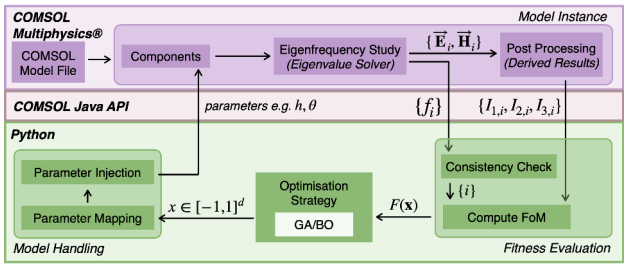

Fig. 1. Inverse-design loop linking Python optimisation to COMSOL eigenmode analysis. A normalised design vector $\mathbf{x} \in [-1,1]^d$ is mapped to geometric parameters, simulated in COMSOL, and scored via the $\mathscr{H}$-based fitness $F(\mathbf{x}) = |\mathscr{H}_m|$ for the most helical mode. The post processing integrals are $I_{1,i} = \int \vec{\mathbf{E}}_i \cdot \vec{\mathbf{H}}_i^* \, dV$, $I_{2,i} = \int \vec{\mathbf{E}}_i \cdot \vec{\mathbf{E}}_i^* \, dV$, $I_{3,i} = \int \vec{\mathbf{H}}_i \cdot \vec{\mathbf{H}}_i^* \, dV$.

TABLE I
OPTIMISED PERFORMANCE METRICS ACROSS CAVITY FAMILIES.

Cavity	f (GHz)	$\mathscr{H}$	$\tilde{G}$ (mm)	$\mathcal{R}$
EF twisted linear (GA, baseline)	8.57	1.03	5.26	1.02
EF twisted linear (BO, baseline)	9.15	1.02	4.57	—
EF twisted linear (GA, expanded)	9.42	1.10	6.32	0.635
EF twisted ring (GA)	9.99	1.47	14.2	1.29
Prism intersection (GA)	12.0	−0.900	8.27	0.735
Sphere-subtracted cyl. (GA)	17.1	−0.958	3.83	0.707
Sphere-subtracted cyl. (BO)	6.23	−0.750	7.38	—
Param. surface (GA)	20.0	−0.673	2.90	0.113

D. Mesh Convergence and Robustness

The optimal cavity geometry is validated through mesh-refinement analysis, in which the maximum element size is progressively reduced until relative changes in $F(\mathbf{x})$ fall below a stringent convergence threshold.

Fabrication tolerance is assessed by independently perturbing design parameters with Gaussian uncertainty and sampling the resulting space using Latin hypercube sampling. We report the mean $\bar{F}$, standard deviation σ_F, 5th percentile $F_{0.05}$, minimum $F_{\min}$, and robustness index $\mathcal{R} = \bar{F} - 2\sigma_F$, which penalises sensitivity to geometric variation.

III. RESULTS

A. Cavity Families and Optimised Performance

We investigated multiple smooth, edge-free cavity families suitable for additive manufacturing, including globally twisted cavities (linear and ring), orthogonal prism intersections, sphere-subtracted cylinders, and parametrised surface resonators.

A concise comparative summary of representative optimised cavities is given in Table I. Across explored design spaces, the EF twisted family consistently achieved the largest $|\mathscr{H}_i|$, with the ring configuration emerging as the top-performing geometry across $\mathscr{H}_i$, $\tilde{G}_i$, and $\mathcal{R}$ metrics.

B. Mechanisms for Large Helicity

Two mechanisms emerge:

Local-feature-driven helicity: Sharp curvature can create strong local helicity hotspots but is highly sensitive to geometric perturbations and may degrade surface-loss performance.

Global-twist-driven helicity: Smooth, continuous twist maintains constructive overlap of electric and magnetic fields throughout the volume, enabling robust $\mathscr{H}_i$ enhancement.

The EF twisted ring benefits from global twist and the absence of endcaps, improving $\mathcal{R}$ and $\tilde{G}_i$.

IV. CONCLUSION

We demonstrate that machine-learning-driven inverse design provides a systematic approach to engineering microwave cavity resonators with large electromagnetic helicity, surpassing previously studied heuristic twisted geometries. Rather than relying on physical intuition and incremental geometric adjustments, this framework systematically identifies smooth, edge-free resonator geometries that support strongly helical modes. In contrast to most inverse-design efforts in quasi-two-dimensional photonics, our method operates on fully three-dimensional metallic microwave cavities compatible with additive manufacturing.

The framework can be readily extended to alternative or composite figures of merit, such as field-gradient enhancement or joint optimisation of $|\mathscr{H}_i|$ and $\tilde{G}_i$, offering a flexible pathway for tailored chiral-field engineering. Machine learning thus provides a general and scalable route for designing highly chiral, low-loss microwave resonators with complex yet manufacturable three-dimensional metallic boundaries, enabling applications in enantioselective spectroscopy, parity-violation experiments, axion haloscopes, and beyond.

***Abstract*—We investigate polarisation control of an infrared beam reflected off the surface of a hyperbolic crystal. We illustrate the mechanism using calcite as our example material. We calculate the reflection coefficients using the 4×4 transfer matrix method, and from this obtain the Stokes vector which characterises the reflected beam.**

***Keywords*— hyperbolic dispersion, infrared, polarisation.**

I. Introduction

The control of the polarisation of radiation is a critical in many established and emerging technologies, from the original BB84 protocol, to edge enhancement imaging using vector vortex beams [1], [2]. Recently, metamaterials have been used as an alternative to traditional optical components, to provide tailored polarisation control for a variety of applications, including structured light, integrated circuits, and polarisation imaging [3], [4], [5]. However, these are often highly specific to polarisation states, where device parameters must be changed in order to tune the output, or rely on expensive nanofabrication techniques [6], [7], [8].

Here, we suggest the use of anisotropic crystals exhibiting hyperbolic behaviour, such as calcite, for polarisation control. In this crystal, hyperbolic behaviour emerges from infrared-active phonon resonances, which drive the principal components of the dielectric tensor to opposite signs. As a result, phenomena such as negative refraction, surface polaritons, and cross polarisation conversion can emerge [9], [10], [11]. For cases where the incident beam comprises both TE- and TM-polarised components (or where there is cross-polarisation conversion), these polarised components will interact differently with the dielectric tensor components, resulting in a change of phase difference between them and, as a consequence, lead to an overall polarisation state change.

II. Methods

We investigate polarisation changes that occur on reflection from an infrared beam in the xz plane incident on a semi-infinite anisotropic crystal as shown in Fig. 1, and where the crystal's optical axis is defined relative to the x, y, and z directions, and lies parallel to the x direction. We consider a general incident polarisation, described as a linear combination of the TE- and TM-polarised components with respect to the incidence plane, also referred to as s- and p-polarisation, respectively. In our case the incident beam contain equal s- and p-polarised components. Therefore, the total reflectance R can be obtained using a 4×4 transfer matrix method and can be expressed in terms of the reflectivity components for each polarised output as:

$$R = \frac{|r_{pp}|^2 + |r_{ps}|^2 + |r_{sp}|^2 + |r_{ss}|^2}{2}, \tag{1}$$

where r_{pp} is the reflection coefficient of the p-polarised components, r_{ss} is the reflection coefficient of the s-polarised component, and r_{ps}, r_{sp} are the reflection coefficients of the crossed polarised components (p-polarised to s-polarised and s-polarised to p-polarised respectively).

Assuming fully coherent radiation, the polarisation of the incident radiation can be represented by either a Jones vector or a Stokes vector. The Jones vector can be defined as any two complex electric field components that are mutually orthogonal with the propagation direction. Here we use the

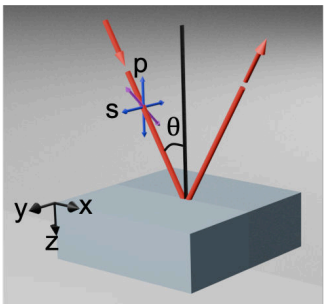

Fig. 1: Diagram showing crystal geometry of incidence in the xz plane, where θ is the angle of incidence, the p- and s-polarised components are shown by blue arrows (that lie in the yz plane) and the incident polarisation is +45° (with respect to the p- and s-polarised components) shown by a purple arrow.

s- and p-polarised components (2) as this allows for the calculation of the Jones matrix of the crystal without additional rotational matricies. The Jones vector of the incident radiation propagating along the $xz-$plane can be defined as:

$$\hat{\mathbf{E}}(\hat{\mathbf{d}}, t) = \begin{bmatrix} E_s \\ E_p \end{bmatrix} \tag{2}$$

where $\hat{\mathbf{d}}$ defines the propagation direction, E_s is the electric field of the s-polarised component (parallel to the crystal surface and referred to as the horizontal direction), and E_p is the electric field of the p-polarised component (perpendicular

to the crystal surface and referred to as the vertical direction). The Jones matrix (Equation 3) is calculated for the crystal, from which the Jones vector of the reflected ray can be calculated as $\hat{\mathbf{E}}_{\text{reflected}} = \hat{\mathbf{J}} \cdot \hat{\mathbf{E}}_{\text{incident}}$, where:

$$\hat{\mathbf{J}}_{\text{crystal}} = \begin{bmatrix} r_{ss} & r_{sp} \\ r_{ps} & r_{pp} \end{bmatrix}. \tag{3}$$

As the Jones vector includes the phase of both electric field components, it cannot be directly determined by intensity measurements. Therefore, we use the Stokes vector to allow for experimental verification. The Stokes vector is defined by four intensity measurements of the form:

$$\hat{\mathbf{S}} = \begin{bmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{bmatrix} = \begin{bmatrix} I_0 \\ I_{\text{horizontal}} - I_{\text{vertical}} \\ I_{+45} - I_{-45} \\ I_{\text{right-circular}} - I_{\text{left-circular}} \end{bmatrix}, \tag{4}$$

where I_0 is the total reflected intensity, $I_0 = RI_{\text{incident}}$ for a case where the incident polarisation has s- and p-polarised components.

The Stokes vector to be calculated from our Jones vector as:

$$\hat{\mathbf{S}} = \begin{bmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{bmatrix} = \begin{bmatrix} |E_s|^2 + |E_p|^2 \\ |E_s|^2 - |E_p|^2 \\ 2\ \mathrm{Re}(E_s {E_p}^*) \\ -2\ \mathrm{Im}(E_s {E_p}^*) \end{bmatrix}. \tag{5}$$

This allows the incident Jones vector to be defined and the experimentally measurable stokes vector to be calculated.

Stokes vectors can be graphically represented using the Poincaré sphere, where each unique polarisation state is determined by polar angle (ψ) and azimuthal angle (ϕ), and the radius $r = S_0$. When the Stokes vectors are normalised with respect to S_0, all polarisations states correspond to a position on the resultant sphere surface, where σ determines the ellipticity and ϕ determines the rotation angle of the major axis of the polarisation ellipse. This means that all linear polarisation states lie along the $S3 = 0$ axis of the sphere, and right and left circularly polarised states correspond to the $S1, S2 = 0, S3 = \pm 1$ axis respectively.

III. Results

The 4×4 transfer matrix method is used to obtain the Fresnel reflection coefficients for the s- and p-polarised components [12], [13], from which the reflected Stokes vector is calculated based on a chosen incident Jones vector. Calculations are performed with the optical axis along x as defined in Fig. 1, an incident polarisation of +45° with respect to the p- and s-polarised components and an angle of incidence of $\theta = 30°$, for wavenumbers in the range 800−1700 cm^{-1} (corresponding to 12.5−5.88 μm). The normalised Stokes vectors are plotted onto the Poincaré sphere which is shown in Fig. 2, where the stokes vector for each wavenumber is represented by a different colour. We can see that in the regions of 875−900 cm^{-1} and 1545−1570 cm^{-1}, small changes in wavenumber result in large changes in polarisation – this is a direct consequence of hyperbolic behaviour.

At a wavenumber of 800 cm^{-1}, the reflected polarisation remains linear, however is rotated to an angle of 18.8° [shown in inset (a)]. Increasing the wavenumber rotates the rotation angle. When nearing the phonon resonance the ellipticity is introduced, and the polarisation starts to rapidly change. Between 875−900 cm^{-1} the ellipticity goes from −7.8° to −8.2° and the rotation goes from −77.0° to −26.4°, passing through a minimum ellipticity of −16.0° (with corresponding rotation of −86.7°) which is shown in inset (c). The polarisation returns to linear at 1005 cm^{-1}, with a rotation of −37.7° shown on inset (f). In the second hyperbolic region, ellipticity is introduced, with a maximum ellipticity of −14.8° (with corresponding rotation of 0.7°) shown in inset (e), and a minimum ellipticity of −30.7° (with corresponding rotation of 38.1°). We then return close to a linear polarisation with a rotation of −77.1° (with corresponding ellipticity of 0.7°), increasing the wavenumber range would allow a linear polarisation to be reached.

It can be seen from Fig. 2, outside of the regions of hyperbolic dispersion, polarisation changes are dominated by amplitude differences between the reflected s- and p-polarised components, and there are only small phase changes that occur, resulting in the reflected polarisation state being of similar type to the incident state, but rotated to a new rotation angle. However within the regions of hyperbolic dispersion the introduced phase difference between the s- and p-polarised components results in elliptical polarisations, (with greater ellipticity in the larger wavenumber band due to larger dielectric tensor components). Larger changes in the amplitudes of the s- and p-polarised components also results in much larger rotation changes than in the non-hyperbolic regions.

IV. Conclusion

We have shown how the polarisation state of a reflected beam can be drastically modified by a hyperbolic crystal. Such changes could be exploited for polarisation control or sensing applications, and more complex crystal geometries could increase the control over the polarisation states. The full characterisation of these interactions is also vital when utilising hyperbolic crystals in polarisation sensitive systems.

***Abstract*—This work proposes a polarization modulator in the infrared range, exploiting optomechanical interaction of Bound-states-In-the-Continuum (BICs) electromagnetic resonances and vibrational modes in MicroElectroMechanical Systems (MEMS). BICs topological nature, forming polarization vortices in the reciprocal space, enables rapid polarization switching through controlled mechanical tilting of the device.**

***Keywords*— optomechanics, Bound states In the Continuum, MEMS, polarization modulation, infrared photonics**

I. Introduction

In recent years, optical metasurfaces have revealed powerful control over all the parameters of electromagnetic radiation. Among the others, interesting topological modes can be designed by patterning semiconductor slabs: Bound-states-In-the-Continuum (BICs) are a prime example of this, since their far-field radiation forms polarization vortices in the reciprocal space, making them suitable for quasi-static control and manipulation of the polarization of light [1]. Combined with their high Q-factor, this makes the use of these modes very appealing for advanced light manipulation. Albeit flexible-by-design, standard operation of optical metasurfaces offers static control, whereas dynamical effect would be favorable for advanced applications. To address this issue, optomechanical polarization modulators based on optical metasurfaces have been recently reported [2], opening the route for advanced dynamical control of the rotational degree of freedom of light via mechanical resonances, which can be controlled introducing Micro-Electro-Mechanical Systems (MEMS) actuators [3].

This work proposes a novel concept for a polarization modulator, operating in the infrared range and exploiting the optomechanical interaction of BICs electromagnetic resonances and MEMS vibrational modes. The topological nature of BICs can be exploited to rapidly switch the polarization of its eigenmodes by tilting the suspended resonator via one of its torsional mechanical modes.

II. Methods

Our work towards the realization of a BIC-based optomechanical polarization modulator started with designing the device via numerical simulations. We computed numerical simulations with Comsol Multiphysics, a partial differential equation solver based on the finite element method. Our model was based on Si_3N_4 trampoline membrane resonators, which have revealed exceptional mechanical properties with ultra-high Q-factors [4]. Despite the material reduced refractive index with respect to silicon, silicon nitride thin films can support near-infrared light guided modes, which have been exploited in integrated devices with different functionalities [5].

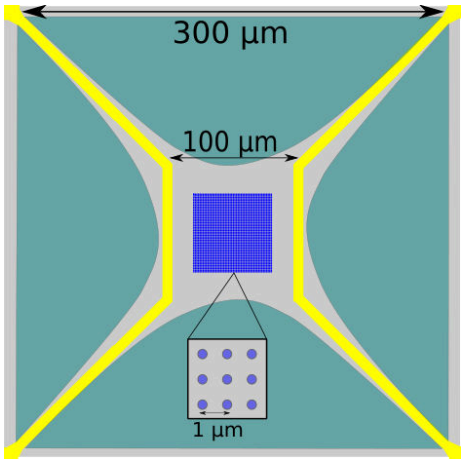

Fig. 1. **Sketch of the hybrid device.** Schematics of the Si_3N_4 trampoline membrane (grey area) composed of a central square pad, on which surface a square array of circular holes with radius $r = 150$ nm (blue circles) is inscribed, and connected to the substrate through four narrow legs on which run the electric contacts (yellow segments).

The sketch of the hybrid device is shown in Fig. 1. It is composed by a square trampoline membrane whose central plate has been patterned with a square lattice of cylindrical holes. Furthermore, we considered a possible deposition of metallic contacts upon the trampoline tethers to exploit Lorentz-based forcing when the device is placed within a planar magnetic field, a standard technique for MEMS resonators [6]. The geometrical parameters of the final device have been identified employing numerical simulations. A frequency-domain analysis of the mechanical motion, upon

Lorentz-force driving a single contact, allowed us to identify the frequency of the first excited eigenmode, which laterally tilts the membrane central plate as sketched in the inset of Fig. 2. A quantification of the tilt angle as a function of the applied voltage, assuming a contact resistance of $\sim$ 200 Ω and a homogeneous static field of $\sim$ 200 mT, can be further extracted from the simulation. Final results have been reported in Fig. 2, where we can appreciate a substantial tilt, both considering low-stress and high-stress 300 nm thick silicon nitride films, characterized by a film planar stress of 200 and 900 MPa and a resonance frequency of 885 kHz and 1667 kHz, respectively.

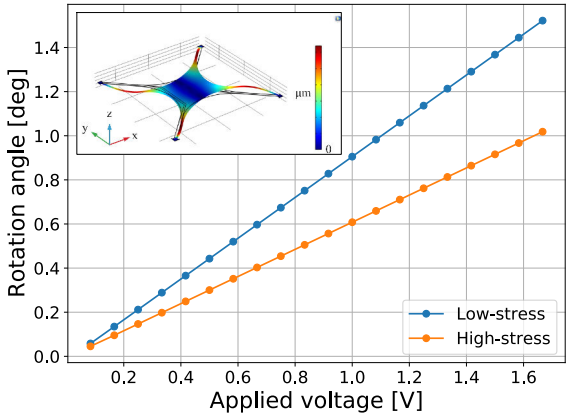

Fig. 2. **Calibration of the trampoline deflection from numerical results.** Plot obtained from numerical results, for both low-stress (blue) and high-stress (orange) Si_3N_4, showing the linear relation between the deflection angle of the trampoline central pad with respect to the driving voltage applied to actuate its torsional mode (inset).

As a second step, we simulated the photonic characteristics of an optical metasurface designed by patterning the central plate of the trampoline membrane. We performed photonic eigenfrequency simulations considering the unit cell of a square lattice of cylindrical holes; sweeping the Bloch periodic conditions at the cell outermost edges we can obtain the photonic band structure. The best set of parameters, reported in Tab. I, give two BICs within the range of the available NIR laser; their frequency dispersion around the Γ point can be seen in Fig. 3 (a). One of the hints towards their BIC nature can be seen by evaluating their radiative Q-factors, reported in Fig. 3 (b), which diverge at the Γ point as expected by symmetry-protected BICs.

While these results have been obtained by considering a one-dimensional path in the reciprocal space crossing Γ along k_x, the topological nature of the BICs can be unveiled by considering their polarization in the far-field at different wavectors in the k_x-k_y plane. Employing a real dielectric constant for the material slab and a $\hat{z}$-symmetric device, we constrain the far-field polarization to be linear. The polarization vectors with their own orientation have been plotted in the quiver plots of

III. Results and Discussion

Mechanical and optical designs can be combined in a hybrid optomechanical device such as the one shown in Fig. 1. Combining typical driving voltages around 1 V_{RMS} to excite the first excited mode, which tilts the membrane in the $\hat{x} - \hat{z}$ plane with static tilting along the orthogonal plane $\hat{y} - \hat{z}$, one can expect a $\pi/2$ polarization rotation at MHz frequency, strongly competing with commercial polarization modulators based on macroscopic moving optical elements ceiling at an operating frequency of $\sim$ 1 kHz.

As a preliminary step before the realization of the final device, we combined the designed photonic structure with a

trampoline membrane resonator. To this end, we prepared a Si_3N_4/Si/Si_3N_4 chip with thicknesses 300nm/250μm/300nm, by spin-coating AR-P 6200 resist (CSAR). The resist layer has been exposed by an Electron Beam Lithography (EBL) to a 30 keV accelerated electron beam to define the desired mask. The silicon nitride layer has been removed by a Reactive Ion Etching (RIE) with an Inductively Coupled Plasma (ICP) step based on SF_6 and performed by a private company (CamGraphic). The final step was performed by wet etching with an hot KOH 30% solution which completely suspended the device by removing the silicon underneath. A Scanning Electron Microscope (SEM) image of the sample after this final step is reported in Fig. 4.

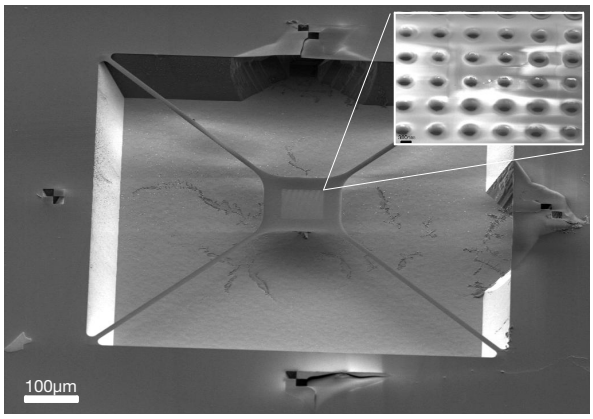

Fig. 4. **SEM image of the final device.** Released structure of the trampoline resonator, composed of a square central pad suspended through four narrow legs, and a portion of the photonic pattern of nanometric circular holes etched on its central pad (inset).

While the combination of mechanical and optical structures is promising for the realization of the final device, which would also include electrical contacts, the possibility of exploiting geometrical mechanical nonlinearities such as the Duffing one makes the metal-free membrane also interesting. By driving the fundamental membrane motion via a piezo-actuator well into the nonlinear regime, it is possible to couple higher order modes which would determine a metasurface tilt resulting in polarization modulation through BICs control.

IV. Conclusions

This work aimed at developing a device able to dynamically modulate the polarization of light in a controlled way.
The numerical results demonstrated the potential of the device as a linear polarization modulator, showing large deflection angles, when exciting the first excited vibrational mode of the square trampoline, and BIC states hosted by the photonic pattern realized in the material of the final device. The fabrication process, which followed to realize the desired device, resulted in an overall yield of about 30%, which is a promising starting point to obtain a device working in the right frequency range. As a future perspective, we plan to fabricate the final sample combining interesting photonic structures with trampoline resonators, which can be actuated in a versatile fashion using embedded metallic contacts.
Although the achievable membrane tilts are small, the extreme sensitivity of BICs is expected to ensure strong effects. Furthermore, mechanical vibrations in the MHz range would make this system highly attractive for fast polarization control, far surpassing macroscopic optical elements limited to ~ 1 kHz. Finally, the possibility of exploiting geometrical mechanical nonlinearities makes the metal-free membrane also interesting, since it makes it possible to couple higher order modes determining a metasurface tilt which would result in polarization modulation through BICs control.

***Abstract*—We present a controllable and scalable approach for fabricating tunable photonic structures based on patterned PDMS and angle-dependent PVD deposition. The optical response of structures can be tailored across the hyperspectral range by applying mechanical strain after fabrication. This strategy enables precise control of properties and supports versatile optical devices.**

***Keywords*— PDMS, slot-die coating, metamaterials, wrinkled plasmonic metastructures, elastic polymers, self-organization, tunability.**

I. Introduction

Tailoring the optical properties of a photonic structure over a wide wavelength range holds significant potential for industrial applications, for example, in passive radiative cooling. However, large-scale structuring is often costly, and post-fabrication tuning of the optical properties remains challenging. We propose a mechanism based on an elastic polymer with periodic metasurfaces, which would allow for mechanical modifications of the optical properties of the structure throughout the hyperspectral range.

In our approach, large-scale patterning is enabled by combining mechanical strain and oxygen plasma treatment. When PDMS is exposed to oxygen plasma, reactive oxygen species attack methyl groups on the surface. Further oxidation leads to the formation of silanol ($Si-OH$) groups. The mechanical properties of treated PDMS differ from those of the untreated polymer. Silanol groups have a glass-like structure, making the topmost oxidized layer stiffer and more brittle. Thus, treated samples exhibit substantial differences in Young's modulus between the surface and the inner part, causing mechanical stress at the interface [1], [2]. To relieve this tension, the surface of the polymer buckles, forming a sinusoidal pattern. In order to ensure that the wrinkles are parallel to each other, mechanical strain is induced during the plasma treatment.

Theoretically, the period of the wrinkles depends on the thickness of the topmost glass-like film h_f and on Young's moduli of this stiff film E_f and of unoxidised PDMS E_s:

$$\lambda = 2\pi h_f \left(\frac{E_f \left(1-\nu_s^2\right)}{3E_S \left(1-\nu_f^2\right)} \right)^{\frac{1}{3}}. \tag{1}$$

The Poisson's ratios of the stiff layer ν_f and pure PDMS ν_s are sometimes also taken into account, although they are often neglected for simplicity [3], [4]. According to this model, the wrinkle period should scale linearly with the thickness of the oxidized topmost layer. Consequently, it is expected to increase with plasma treatment time, although the relationship between oxidation time and layer thickness is not necessarily linear. The Young's modulus of PDMS depends on the concentration of the curing agent and the polymerization conditions [5].

The wrinkle morphology can be further tuned after fabrication by applying mechanical strain to the elastomeric substrate. Stretching the material modifies the wrinkle amplitude and wavelength, providing an additional degree of control over the optical response of the structure. However, this approach alone is insufficient to enable tuning across the full spectral range. Therefore, a viable mechanism for tailoring the optical response of the samples involves utilizing the shadow effect to deposit metal-oxide layers on the hills of sinusoidal wrinkles (see Fig 1).

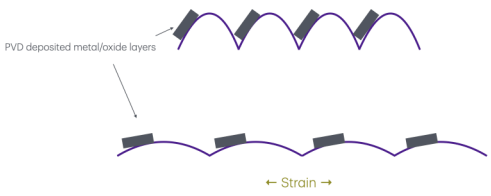

Fig. 1: Tunability scheme.

Stretching of the polymer leads to reorientation of the deposited layers, which changes the optical response of the structure. However, for this mechanism to be efficient, the deposited structure must exhibit a strong angular dependence of the optical response, preferably occurring simultaneously

in different spectral ranges. Therefore, resonant structures are favored, as their optical response relies strongly on the constructive interference of incident light. The optical path inside the structure depends on the angle of incidence, which can either promote or suppress constructive interference. Moreover, structures with well-defined resonance peaks are easier to investigate using optical methods.

II. Methods

Polydimethylsiloxane (PDMS) was prepared using the Sylgard 184 Silicone Elastomer Kit according to the manufacturer's instructions. The structuring process consisted of several steps. First, the PDMS solution was coated onto a glass substrate. The sample was then placed in a vacuum furnace and polymerized for 24 h at $80\,^{\circ}\mathrm{C}$. After polymerization, the sample was removed from the furnace and placed in a water bath. The separated polymer film was subsequently mounted in a custom-made stretching apparatus. After applying the desired strain, the sample was clamped between two rigid frames to maintain the deformation. It was then removed from the stretching apparatus and placed in a plasma cleaner (Diener Zepto 200 W) for oxygen plasma treatment. In the final step, the strain was released after plasma treatment, revealing a self-organized wrinkled structure (see Fig. 2). The resulting structural coloration was visible to the naked eye, as the sample exhibited opalescence similar to that of a diffraction grating.

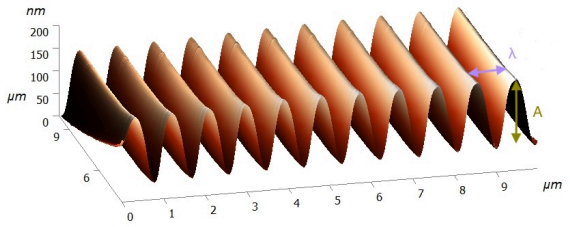

Fig. 2: AFM 3D image of the wrinkled sample. The surface profile can be approximated by a sinusoidal function characterized by the period λ and amplitude A.

The subsequent step involved depositing metal–oxide layers on top of the periodic samples in order to test the proposed tunability mechanism. For this purpose, physical vapor deposition of the following exemplary stack was performed: 40 nm Ag / 160 nm SiO_2 / 25 nm Ag (Kurt J. Lesker PVD75). This coating was chosen due to its resonances in the visible spectral range and its relatively high transmittance. Otherwise, transmittance measurements using an ellipsometer would not be possible, as both coated and uncoated samples exhibit strong scattering and diffraction, while reflectance is difficult to measure accurately without the use of an integrating sphere. The presence of an optical resonance in the visible range enables direct, naked-eye evaluation of the color change induced by mechanical stretching. The samples were placed in custom 3D-printed holders oriented at an angle to achieve the so-called "shadow effect." After the deposition process was completed, the samples were coated with a thin layer of PDMS to secure the metal–oxide layer in place.

The final stage of the study focused on optical measurements of the previously characterized samples. As the RC2 ellipsometer (J.A. Woollam) provides a fast and reliable platform for optical characterization, it was used to perform transmission measurements of the samples. Each sample was measured three times: with the deposited layer, under applied strain, and after releasing the strain, for both horizontal and vertical orientations of the wrinkles.

III. Results and Discussion

Parameters of the periodic structures were found to be controllable and repeatable. The resulting self-organized wrinkles exhibited periods ranging from 300 nm to 1.65 μm and amplitudes between 40 nm and 350 nm, depending on the process conditions. Moreover, the independence of the structural parameters from the sample thickness was established. It is understandable, since according to the literature, they depend on Young's modulus, which is not connected in any way with the dimensions of the sample, but is rather an intrinsic property of the material. Additionally, a relation between said parameters and the percentage of curing agent in the solution was established.

Transmittance measurements, performed using an ellipsometer, were preceded by observations with the naked eye. At first sight, the unstretched sample is red in transmission with strong turquoise hues when the angle is altered (Fig.3a and 3b). Its colours change with the angle of observation because different wavelengths interfere constructively within the metal-dielectric-metal layer relative to normal incidence. The lamp in the background remains clearly visible. Upon applying strain, however, the sample becomes white and opaque (Fig.3c). Scattering from the uneven surface is presumably to account for this behaviour, suggesting the temporary formation of large cracks in the deposited layer. When the strain is released sample looks intact, as the protective polymer overlayer holds the whole structure in place. This particular optical response mechanism is supported by the transmission measurements, confirming the significant reduction of transmitance.

In the case of wrinkled samples deposited at an angle, mechanical deformation led to a substantial reduction in peak intensities and the disappearance of higher-order spectral features. These observations indicate that applied strain modifies the effective geometry of the structure and alters the optical path within the resonant system. The optical response is inherently complex due to scattering, diffraction, and geometric non-uniformities. Nevertheless, the experiments demonstrate that mechanically induced structural changes lead to measurable modifications of the spectral behaviour. The

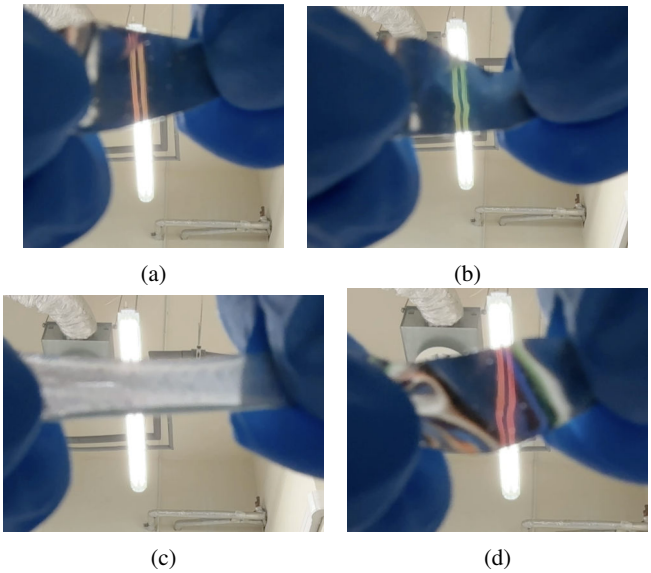

Fig. 3: A photo of PDMS film covered with 40 nm Ag/160 nm SiO_2/25 nm Ag and a protective layer of polymer on top before and during the stretching procedure stages (a) - (d). No damage to the sample was observed after releasing the strain.

colour changes observed in the visible range further support the presence of strain-dependent interference effects.

IV. Conclusion

A systematic investigation demonstrated that the wrinkle period and amplitude depend on plasma treatment time, oxygen concentration, and curing agent ratio, while remaining independent of the overall film thickness. Optical measurements confirmed the feasibility of angle-dependent deposition and revealed the emergence of a shadowing effect above $65\,^{\circ}\mathrm{C}$, enabling controlled modification of the optical response. Optical characterization was performed using ellipsometric transmittance measurements, which showed pronounced angular- and strain-dependent spectral features. Mechanical deformation was found to significantly modify the optical response of the system.

Although complex light–structure interactions were observed in periodically structured samples and require further investigation for a detailed understanding, this study establishes a scalable fabrication route and demonstrates the concept of mechanically tunable optical behaviour in wrinkled PDMS-based systems. The obtained results provide a solid experimental basis for further optimization and modelling of elastomeric photonic structures.

***Abstract*— This research presents a complex amplitude encoded reflective acoustic mirror that integrates super-unit phase encoding with a parabolic geometry to generate ultrasonic needle beams in water at a given focal distance. The mirror, fabricated in PLA with air trapped inside, combines phase-only modulation with geometric focusing, enabling extended depth of focus and controlled beam shaping for ultrasonic underwater imaging applications.**

Keywords— acoustic metamaterials, complex amplitude encoding, parabolic mirror, ultrasonic needle beam, water acoustics.

I. Introduction

Extended depth-of-focus ultrasonic beams are critical for biomedical imaging, nondestructive testing, and underwater sensing. Recently, complex amplitude encoding metalenses (CAEM) have demonstrated the ability to generate arbitrary ultrasonic needle beams using super-unit phase decomposition [1]. Separately, broadband reflective focusing using parabolic mirrors has been modeled through impulse-response formulations treating the mirror as a distributed secondary source [2]. In this work, we merge these two concepts by embedding CAEM phase encoding into a reflective parabolic mirror operating in water. Furthermore, the mirror is realized with plastic, exploiting the so-called trapped-air concept to overcome low impedance mismatch between water and plastic, thus preserving the intended functionality [3]. The objective is to realize a compact, passive, single-sided reflective metasurface capable of generating uniform needle beam for sound manipulation.

II. Methods

A. Complex Amplitude Encoding

The target transmission function is expressed as:

$$T(x,y) = A_0(x,y)e^{i\varphi_0(x,y)} \quad (1)$$

Here both amplitude $A_o(x,y)$ and phase $\varphi_o(x,y)$ are space varying as shown in the Figure 1. Following the CAEM strategy, the complex amplitude is decomposed into two phase-only components:

$$A_o(x,y)e^{\{i\varphi_o(x,y)\}} = 1/2\,A_{max}\,(e^{i\varphi_1(x,y)} + e^{i\varphi_2(x,y)}) \quad (2)$$

Here A_{max} is the maximum amplitude of A_o and such as $\varphi_{1,2}(x, y) = \varphi_0 \pm \theta$ where $\theta(x, y) = cos^{-1}[A_o(x, y)/A_{max}]$. These phase distributions are spatially interleaved using complementary binary masks within super-units, ensuring statistical blending and effective amplitude control [1].

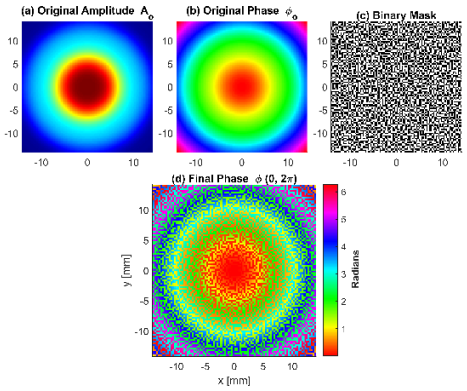

Figure 1: Complex Amplitude Encoding (a) Original Amplitude $A_o(x,y)$; (b) Original Phase φ_o (x,y); (c) Binary Mask (Complementary Mask) for super units and, by combining all of them, the (d) Final Phase φ(x,y)

B. Reflective Parabolic Mirror Model

Unlike transmissive CAEM plates, our design embeds the encoded phase distribution onto a parabolic reflector. The reflected field is modeled using the impulse response method described for plane piston reflection [2].

$$h(\mathbf{r},t) = \int \frac{\delta(t - R/c)}{2\pi R}\, dS \quad (3)$$

Here, $h(\mathbf{r},t)$ denotes the impulse response at position $\mathbf{r}$ and time t, R is the distance between the surface element dS and the observation point, c is the speed of sound, and $\delta(\cdot)$ is the propagation delay [2]. Each point on the mirror acts as a secondary source as shown in Fig.2, and the desired reflected pressure distribution is obtained via superposition of

appropriate phase delays, obtained by realizing different path-length between the mirror surface and the trapped air volume, according to the profile of Fig.1(d).

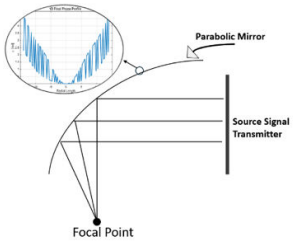

Figure 2: Schematic Diagram of the Parabolic Modulated Reflector

The geometric parabolic condition ensures equal optical path to the focal axis, while the encoded phase introduces additional spatial phase modulation to generate extended needle beam. In addition, a clever trapping of an air layer inside within the parabolic profile ensures the mirror to act as a rigid acoustic reflector in water [3].

III. Results and Discussion

Results were obtained via FEM simulations in COMSOL using full-wave acoustic modeling. The acoustic field produced by the proposed device operating in water was analyzed for input planar pressure fields with frequencies from 100 kHz to 1 MHz. The results show a focus condition over an extended frequency range, fully agreeing with the results shown in [2]. On top of that, a uniform ultrasonic needle beam is generated along the optical axis, as illustrated in Figure 3, because of the additional coded phase delay [1]. Note that at the present stage, the needling behavior is simulating by modulating the pressure field to reflect the desired phase delay. The design also demonstrates suppression of sidelobe oscillations through super-unit phase blending, as shown in Figure 4, which improves beam quality and reduces unwanted acoustic interference. The beam length can be tuned by optimizing the distribution of focal positions in the complex amplitude encoding process. Compared to purely geometric focusing, this approach enables programmable beam shaping while maintaining a compact passive structure. The design supports both single and off-axis needle beams without requiring multiple transducers or active arrays. Full simulations including explicit phase encoding on the mirror surface will be addressed in the extended version of this work.

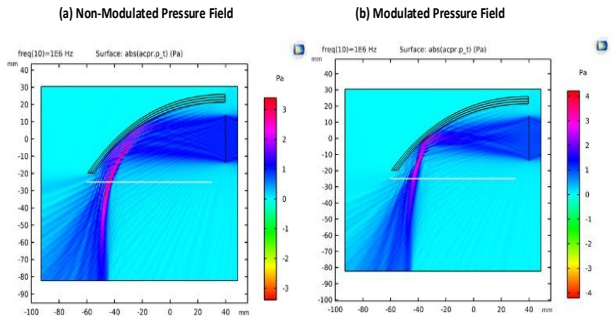

Figure 3: FEM of parabolic reflector (a) without and (b) with the complex amplitude encoded pressure. The white line is the reference cut baseline for Fig.4.

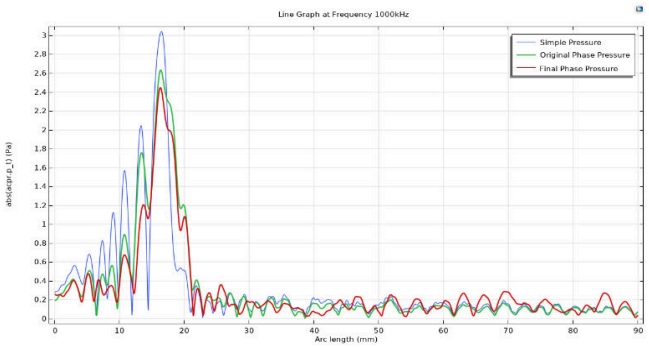

Figure 4: Line graph of Pressure field obtained at the cut-line using the different pressure field input, as per Fig.1.

IV. Conclusions

A hybrid reflective acoustic metasurface integrating complex amplitude encoding with a parabolic mirror geometry is proposed. Operating in water and fabricated in PLA exploiting the trapped-air concept, the structure enables programmable ultrasonic needle beam generation. This approach bridges transmissive acoustic metalenses and reflective focusing systems, opening pathways toward compact underwater imaging systems and single-sided broad-band pulse-echo applications. Future work includes experimental validation, ultra broadband optimization, and integration with single-element transducers for medical and underwater imaging.

***Abstract*—Auxetic materials are increasingly used in biomedical and aerospace applications. Fibre Bragg grating sensors are well-known in non-destructive testing for their precision. This work simulates a tensile test of two auxetic specimens with embedded sensors and compares the results with experimental data to validate the model.**

***Keywords*— metamaterials, auxetic, NDT/SHM, FBG sensor.**

I. Introduction

Auxetic materials are a class of metamaterials that, as a defining feature, have a negative Poisson ratio [1]. It means that these materials, under tension, expand in the directions orthogonal to the applied load. Conversely, under compression, they collapse in directions perpendicular to the applied load. A schematic of auxetic behaviour compared with normal material under tension is shown in Fig.1 As a consequence

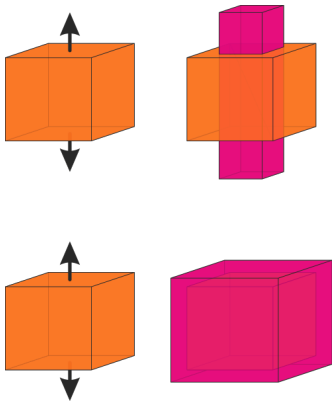

Fig. 1. On top normal material behaviour. Below auxetic material behaviour.

of this peculiar behaviour, these materials exhibit interesting features, such as increased shear, indentation and fracture resistance; synclastic behaviour, which means that if these structures are subjected to an out-of-plane bending moment, they show a dome shape; moreover, due to their deformation method, it is possible to exploit them as a variable permeability [2]. Fibre Bragg Grating (FBG) sensors are composed of an optical fibre in which a grating is inscribed. To obtain the grating, the refractive index of the fibre is modified to form a periodic pattern. As a result, this structure can reflect light with a specific wavelength. It is possible to calculate the exact reflected wavelength using the following formula [3]:

$$\lambda_B = 2n\Lambda, \tag{1}$$

in this formula, λ_B represents the Bragg wavelength, which is the reflected wavelength, n is the effective refractive index, and Λ is the periodicity of the sensor. As it is possible to infer from the formula, this kind of sensors are sensitive to deformation. In fact, when the fibre is stretched, the reflected wave shows a redshift (the reflection happens for a higher wavelength). On the contrary, during compression, the reflected wave shows a blueshift (the reflection happens for a lower wavelength). This is caused by the action of the deformation on the periodicity of the grating and on the effective refractive index. Furthermore, these sensors are sensitive to temperature, which is because temperature can also affect the periodicity of the grating through the thermal expansion coefficient and the effective refractive index through the thermal-optic effect. The relationship between the Bragg wavelength, strain and temperature is made explicit in the following formula [4]:

$$\frac{\Delta\lambda}{\lambda_B} = (1-p)(\epsilon + \alpha\Delta T) + \xi\Delta T, \tag{2}$$

where $\Delta\lambda$ represents the shift of the reflected wavelength, λ_B the Bragg wavelength, p the coefficient of the photoelatic effect, ϵ the deformation, α the thermal-expansion coefficient, ΔT the temperature difference, and ξ the thermal-optic coefficient. The possibility of monitoring auxetic materials using FBG sensors could have some potential due to the increasing importance of auxetic materials and the interesting features of FBG sensors. Nevertheless, this possibility is still poorly explored in the literature. In this paper, we want to investigate the possibility of simulating the behaviour of an FBG sensor attached to the surface of an auxetic material for measuring the stretching of the structure.

II. Methods

In previous work [5], it was demonstrated that it is feasible to attach a Fiber Bragg Grating (FBG) sensor to the surface of an auxetic structure without significantly altering its mechanical behaviour. Building upon this foundation, the present study aims to develop a comprehensive numerical model of an FBG sensor using COMSOL Multiphysics, with the objective of

simulating the sensor's response under tensile strain. The modeling process will proceed in several steps. First, the FBG sensor will be represented as a discrete element with appropriate material properties and geometrical parameters. a picture on the grating modelled in COMSOL is shown in Fig. 2. Subsequently, the auxetic specimen will be simulated under

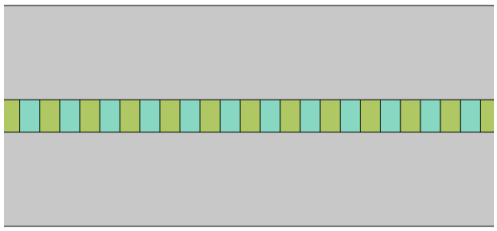

Fig. 2. Schematic of the grating geometry implemented in COMSOL.

controlled tensile loading conditions, providing a detailed map of the strain distribution at the location where the sensor is attached. Using the obtained deformation field, we will then apply the corresponding strain to the FBG model in order to predict the resulting Bragg wavelength shift, based on the well-known relationships that link strain to changes in the optical response of the sensor. This approach enables a direct correlation between the mechanical deformation of the structure and the optical signal generated by the FBG. Figure 3 shows the redshift predicted by the model for a simple tensile simulation, and the blueshift resulting from a compression simulation. Finally, the simulated wavelength shifts

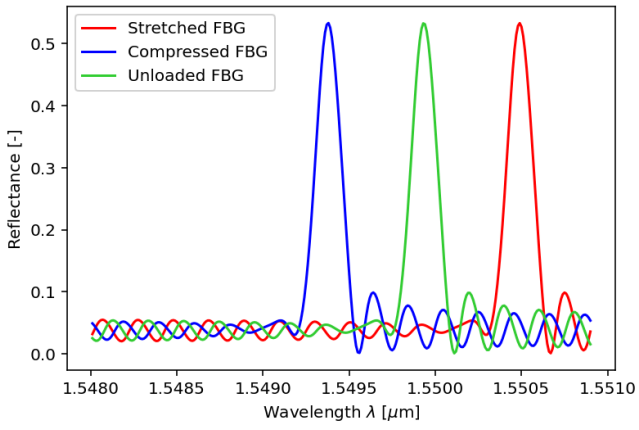

Fig. 3. FBG reflectance peak shifts under mechanical load: compression (blue) causes a blueshift, tension (red) induces a redshift, and the unloaded state (green).

will be processed to calculate the corresponding measured strains. These numerical predictions will be compared with experimental data obtained from physical testing of the sensor-embedded auxetic specimens. Through this comparison, we aim to validate the accuracy of the FBG model. The outcomes of this study will not only provide a validated computational framework for simulating FBG sensors in complex structures but also enhance the understanding of the interplay between auxetic deformation and optical sensing, paving the way for more advanced structural health monitoring applications.

III. Conclusion

This work proposes a numerical approach for simulating the behaviour of a Fibre Bragg Grating sensor attached to an auxetic structure under tensile loading. The developed model, implemented in COMSOL Multiphysics, aims to establish a correlation between the strain field generated in the auxetic material and the corresponding Bragg wavelength shift of the sensor. At this stage, the study focuses on defining the modelling strategy and the procedure that will be used to predict the optical response of the FBG based on the mechanical deformation of the structure. The comparison with future experimental results will allow validation of the proposed framework and assessment of its reliability. The presented methodology represents a preliminary step toward the integration of FBG sensors in auxetic materials for structural health monitoring applications.

***Abstract*—We demonstrate the coexistence of twin Friedrich–Wintgen and Fabry–Pérot bound states in the continuum in a plasmonic metal–insulator–metal double T-cavity. Analytical Green's function formalism and finite-element simulations reveal the existence of multi-BICs and their transformation to Fano resonance for sensing and filtering.**

***Keywords*— FW-BIC, FP-BIC, Plasmonic cavity.**

I. Introduction

Bound states in the continuum (BICs) [1] constitute a special class of resonant modes with infinite lifetimes that remain spatially localized within a structure despite their eigenfrequencies lying inside the radiation continuum. BICs are commonly classified according to their physical formation mechanisms into three main categories [2]: symmetry-protected (or separability-protected) BICs (SP-BICs) [3], Friedrich-Wintgen (FW) BICs [4], and Fabry-Pérot (FP) BICs [5]. More recently, another type, known as twin BICs (T-BICs), has been reported in two-dimensional FP-type resonators [6]. BICs have attracted considerable attention due to their high impact on nanophotonic structures, enabling high-performance sensing platforms through enhanced light–matter interaction at the nanoscale [7]. Recently, increasing attention has been devoted to the interaction mechanisms between FP- and FW-BICs in multi-cavity systems [8]. Among such configurations, the T-shaped cavity has been investigated in photonic and plasmonic platforms to realize FW-BICs [9].

In this work, we show that a plasmonic metal–insulator–metal (MIM) double-T cavity can support the simultaneous existence of FW- and FP-BICs. The MIM waveguide system studied here is composed of two identical T-shaped cavities separated by a distance d_4 (see the illustration of the double T-cavity in Figs. 1 and 2). Each T-shaped cavity consists of two lateral arms with lengths d_1 and d_2, connected to an infinite MIM waveguide by a stub of length d_3.The total length of the horizontal waveguides is kept constant, $d = d_3 = d_1 + d_2$ = 540 nm. The detuning between the two waveguides is defined as $\delta = d_2 - d_1$, which is treated as a tunable parameter. Using both the analytical Green's function formalism [10] and finite-element simulations (COMSOL Multiphysics), we investigate the coexistence and interplay of FW-BICs and FP-BICs in this structure as a function of the geometrical parameters. Each T-cavity supports a FW-BIC, resulting from destructive interference between two resonant modes within the same cavity [9]. The coupling between these FW-BICs in the double T-structure leads to the formation of doubly degenerate BICs, referred to as T-BICs. In addition, FP-BICs appear for discrete values of the separation between cavities, corresponding to a round-trip phase accumulation equal to an integer multiple of 2π. When the BIC conditions are slightly broken, these modes evolve into Fano resonance.

II. Results and Discussion

First, we consider the symmetric case $\delta = 0$ (i.e., $d_1 = d_2$). To examine the coexistence and interaction between T-BICs and FP-BICs, Fig. 1(a) shows the transmission as a function of frequency and the separation d_4. The horizontal line at $f = 198$ THz corresponds to T-BICs, which is independent of d_4. Two additional resonances shift to lower frequencies as d_4 increases and collapse at $d_4 = 540$ nm and $d_4 = 1080$ nm, forming FP-BICs. Their intersection with the T-BICs at $f = 198$ THz results in triple-degenerate BICs. Figures 1(b)–(d) present transmission spectra for selected d_4 values. The analytical results obtained by the Green's function method (blue solid lines) are in good agreement with the numerical results using Comsol Multiphysics (red open circles). For $d_4 = 430$ nm, a Fano resonance appears whose linewidth decreases as d_4 approaches 540 nm. At $d_4 = 540$ nm, the resonance collapses into an FP-BIC, coexisting with the T-BIC and forming a triple-degenerate BIC. Increasing d_4 beyond this value reopens the resonance as a Fano line shape. The spatial magnetic-field distributions corresponding to the T-BIC, FP-BIC, and Fano resonance are shown in Figs. 1(e)–(g) under a local magnetic excitation (red arrow). For $f = 198$ THz and $d_4 = 430$ nm, the degenerate T-BICs (Fig. 1(e)) exhibit strong localization within the lateral arms of the T-cavities without extending into the surrounding waveguides. In contrast, the Fano resonance (Fig. 1(f)) displays significant field leakage throughout the structure, enabling transmission across the system. The field map of the FP-BIC (Fig. 1(g)) reveals a mode tightly confined within the double T-cavity, with no radiation escaping when the excitation is applied in the waveguide of length d_4.

Next, the symmetry of the cavity is broken by setting $\delta \neq 0$. Figure 2(a) shows the transmission as a function of frequency and d_4 for $\delta = 80$ nm. As d_4 varies, the linewidths of

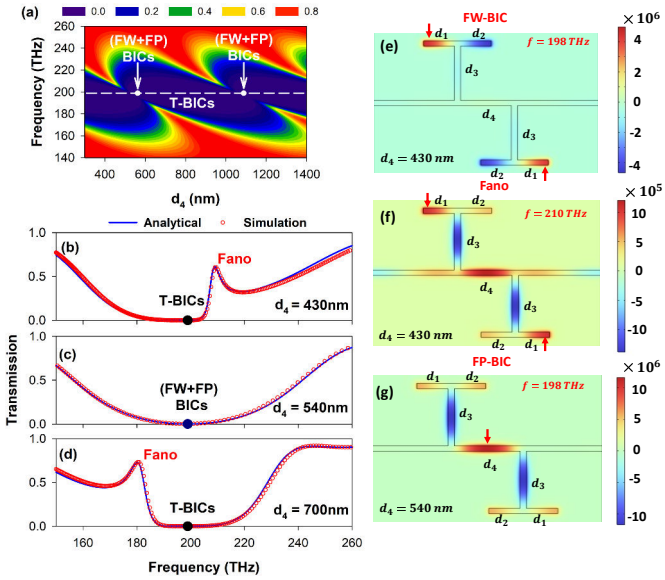

Fig. 1. (a) Variation of the transmission magnitude versus the frequency and d_4, for d_3 = 540 nm and δ = 0 nm. (b)–(d) Transmission spectra as a function of the wavelength for three values of d_4. The blue and red curves indicate the analytical and numerical results, respectively. Magnetic (H_z) field maps of (e) the FW-BIC, (f) the Fano resonance for d_4 = 430 nm and (g) the FP-BIC for d_4 = 540 nm. The positions of the excitations are shown by the red arrows.

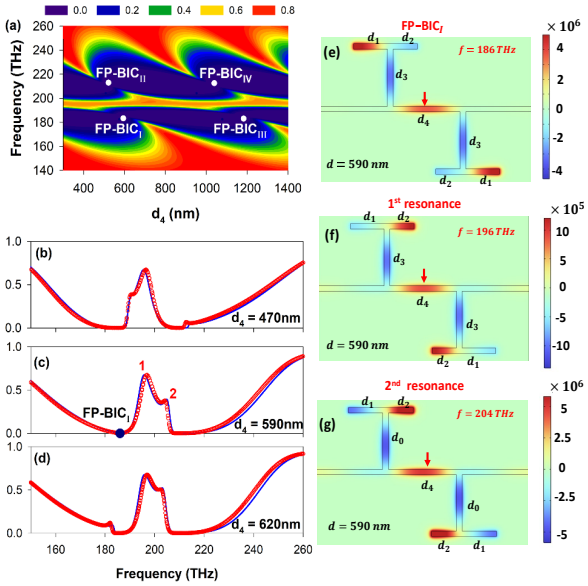

Fig. 2. (a) Variation of the transmission magnitude versus the frequency and d_4. (b)–(d) Transmission spectra at representative values of d_4. Magnetic field maps of (e) FP-BIC$_I$ at $f = 186$ THz and $d_4 = 590$ nm, (f) and (g) of the Fano resonances at $f = 196$ THz (mode 1) and $f = 204$ THz (mode 2) for $d_4 = 590$ nm, under local excitation applied at the waveguide d_4.

the symmetric and antisymmetric FP resonances progressively vanish, leading to the formation of FP-BIC$_I$ and FP-BIC$_{II}$ around $d_4 = d_3 = d = 540$ nm and FP-BIC$_{III}$ and FP-BIC$_{IV}$ around $d_4 = 2d_3 = 2d = 1080$ nm. Figures 2(b)–(d) show transmission spectra as a function of frequency for selected values of d_4. For $d_4 = 470$ nm (Fig. 2(b)), three resonances appear. The second one, around $f = 200$ THz, is broad and remains nearly unchanged as d_4 varies. In contrast, the lowest Fano resonance at $f = 189$ THz gradually evolves into a FP-BIC$_I$ at $f = 186$ THz Fig. 2(c)). Increasing d_4 further to 620 nm (Fig. 2(e)) reopens the resonance, producing a Fano line shape near $f = 182$ THz. The magnetic field map associated with FP-BIC$_I$ at $f = 186$ THz (Fig. 2(e)) clearly shows that this mode is tightly confined within the double T-cavity. The field map of the two resonant modes 1 and 2 in Figs. 2(f) and (g) are fully excited and propagate through the entire structure, resulting in full transmission.

III. Conclusion

In conclusion, we investigated the coexistence of FW- and FP-BICs in a plasmonic MIM double T-cavity operating in the infrared regime. Analytical Green's-function modeling, supported by finite-element simulations, reveals twin FW-BICs localized in each T-cavity and FP-BICs appearing for discrete cavity separations. Their interaction can produce triple degenerate BICs, while breaking the BIC conditions leads to Fano and plasmon-induced reflection (PIR) resonances [11]. These results provide insight into multi-BIC formation in plasmonic waveguides and highlight their potential for compact sensing and integrated photonic filtering devices. Further, BICs enhance light–matter interaction and can produce strong emission when the BIC condition is slightly broken. Indeed, the transformation from a FW-BIC to a quasi-FW-BIC can lead to far-field enhanced radiation outside the double T-cavity, originating from the coherent collective emission of the leaky modes (for more details, see Ref. [11]).

Auxetic Materials for Biomimicry: Designing for Tendon-Like Behavior

Riccardo C. Moroni*, Katarzyna Majewska

Institute of Fluid-Flow Machinary, Polish Academy of Science, Gdańsk, Poland
*Corresponding author: rmoroni@imp.gda.pl

***Abstract*—Tendon healing is slow and rarely restores full functionality. Studies show that in the toe region, up to 2% deformation, tendons behave as auxetic materials. This work aims to optimize a 2D re-entrant auxetic cell to replicate tendon Poisson ratio and stiffness for improved biomechanical performance.**

***Keywords*—metamaterials, auxetic materials, tendon, biomimicry.**

I. Introduction

The physiological role of tendons is to transmit load from muscles to bones to permit the body movement. They are composed by a hierarchical structure of collagen fibres. The hierarchical structure of the tendon is illustrated in Fig. 1. Over 30 million tendon interventions happened every year

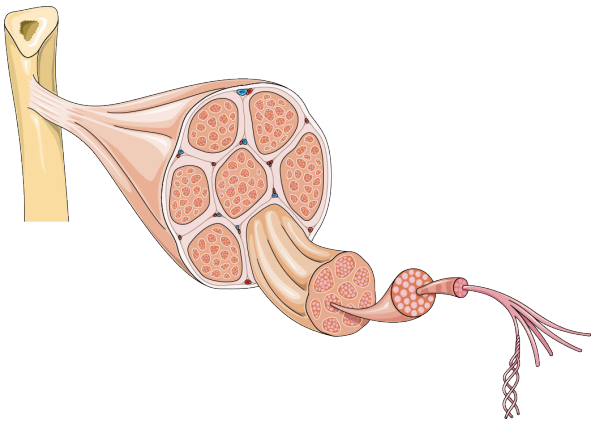

Fig. 1. Hierarchical structure of tendons. Image credit: Smart Servier licensed under CC BY 4.0.

worldwide [1]. Despite the increased possibility of modern medicine, it is still impossible to achieve a full restoration of the pre-injured performance of the tendon, for example the tensile strength of a healed tendon can be 30% less then the healthy one [2]. As a consequence the risk of recurrence is high and the functionality of the tendon can be reduce according to the severity of the residual damage. In 2015 Gatt et al. [3] report that tendons shows an auxetic behaviour. Auxetic material are a class of mechanical metamaterial that present a negative Poisson ratio. Under tensile loading, they expand perpendicular to the applied force, while under compressive loading, they contract laterally. This study focuses on biomimicry, a design approach inspired by natural structures and processes. The term "biomimicry" comes from the Greek words "bios" (life) and "mimesis" (imitation), reflecting the goal of replicating efficient strategies found in nature. Tendon deformation can be divided in three phases. The first one is called toe region (between 0-2% of deformation), in this phase tendon shows a wave-form shape which disappear increasing strain. *In vivo* tendon usually deform in this zone. The second phase is the strain region (between 2-6% of deformation) in this phase collagen fibre are no more crimped and they are strained by the applied load. The third phase is associated with the tendon rupture [4]. Fig. 2 provides a schematic representation of the stress–strain behaviour of tendons. Specifically, Gatt et al. demonstrate that in the toe region Achilles tendon exhibit a negative Poisson ratio. Integrating auxeticity in the design of artificial substitute can result in a more effective device. The primary objective of this research is to develop

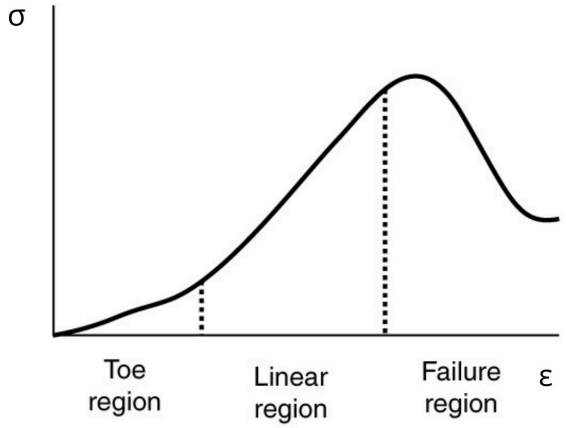

Fig. 2. Schematic representation of the stress–strain behavior of the tendon. Image credit: OpenStax licensed under CC BY 4.0.

and optimize a re-entrant unit cell capable of emulating the characteristic stress–strain response of tendons, particularly in the initial toe region and the subsequent linear elastic region. Achieving this goal could enable the design of bio-inspired auxetic structures that better replicate tendon mechanics and improve the performance of artificial tendon substitutes.

II. Methods

Firstly, among all possible auxetic mechanisms, a re-entrant mechanism was selected due to its simplicity and the fact

that it is the most widely studied and characterized in the literature. Consequently, a 2D re-entrant honeycomb structure was chosen as the basis for optimization. Once the base geometry was defined, the parameters requiring optimization were identified. The study focused on three main objectives: optimizing the Poisson's ratio in the toe region, adjusting the Young's modulus in the linear strain region, and limiting the auxetic behavior to the toe region. The initial geometry was constructed starting from a "Z"-shaped configuration, which provides the characteristic re-entrant profile. The parameters considered for optimization included the length of each rib (L1, L2, L3), the cross-sectional dimensions of each rib (height (H) and base (B) length, assuming a rectangular section), and the re-entrant angle of the cell(α). A schematic representation of the unit cell is shown in Fig. 3. These parameters were chosen because they directly influence the mechanical response, including stiffness, auxeticity, and the transition between the toe and linear strain regions.

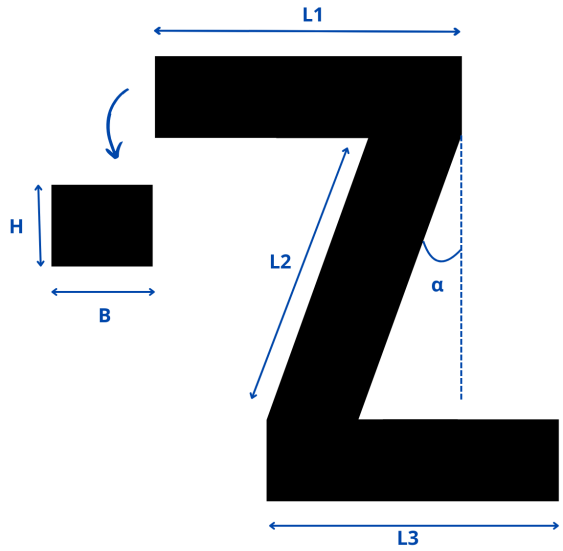

Fig. 3. Schematic representation of the unit cell and the parameter which charcterize it.

III. Conclusion

Tendons play a fundamental role in transmitting loads from muscles to bones, allowing body movement, thanks to their hierarchical structure of collagen fibers. The discovery of auxetic behavior in tendons, particularly in the toe region, opens new possibilities for the design of artificial substitutes. By developing and optimizing a re-entrant unit cell, it is possible to reproduce the tendon's characteristic stress–strain response, controlling both the Poisson's ratio in the toe region and the stiffness in the linear strain region. Implementing these bio-inspired auxetic structures in artificial tendons could improve their mechanical performance, reduce the risk of failure, and bring them closer to the behavior of natural tendons.

***Abstract*— This work presents a fiber Bragg grating (FBG) sensor network for detection and motion analysis of low-slow-small (LSS) unmanned aerial vehicles (UAVs). Spatiotemporal responses of distributed sensors are processed using STFT and FFT to identify drone trajectories and extract propeller micro-Doppler signatures. Experiments demonstrate reliable detection and estimation of rotor rotation characteristics.**

***Keywords*— optical fiber, FBG sensor network, micro-Doppler, drone detection.**

I. Introduction

The rapid growth of UAVs in civil, commercial, and defense domains creates challenges for reliable detection, identification, and classification. Conventional radars, including optical and acoustic [1], are limited by small radar cross-section (RCS), environmental clutter, and others. Both require new approaches to recognize the so-called Low-Slow-Small (LSS) targets, such as small plastic drones used for various delivery and monitoring tasks in the concept of 'smart cities' for a drone swarm delivery, where their concentration in one place is expected to grow over time [2].

Using information gathered from a FBG sensor network, this research suggests a machine learning-based algorithmic framework for LSS UAV detection and trajectory tracing. The suggested method uses the spatiotemporal response patterns of FBG sensors array to infer UAV positioning data and short-term motion dynamics with analysis in time and frequency domains with further prospective involving machine learning.

II. Setup and Frequency Domain Analysis

The block diagram and the appropriate experimental setup-under-test are shown in Fig. 1a, b, respectively. It consists of the consists of FBG sensor network integrated into an optical fiber, each sensor of which is distributed by 100 mm with the reflected wavelength range 1520 to 1565 nm. The fiber is connected to SCN-80 S-line Scan 800 from Sylex measurement tool with sampling rate up to 5 kHz and includes consists of a superluminescent light emitting diode (SLED) as a local oscillator to trig an optical circulator (OC) and transfers light to the FBG sensors via a single mode optical fiber (SMF). The reflected signals are read by the measurement device is fully controlled from a personal computer (PC), allows recording the data after passing the optical spectrometer and digital signal processor (DSP) for each sensor separately. Whole setup is placed over the platform with a 2D coordinate system each cell squared by 200 × 200 mm. – the size is fitted to the size potential drones-under-test (from Crazyflie 2.1+ sized 92 × 92 × 29 mm – was used for this experiment, to DJI Mini 2 sized 131 × 81 × 58 mm).

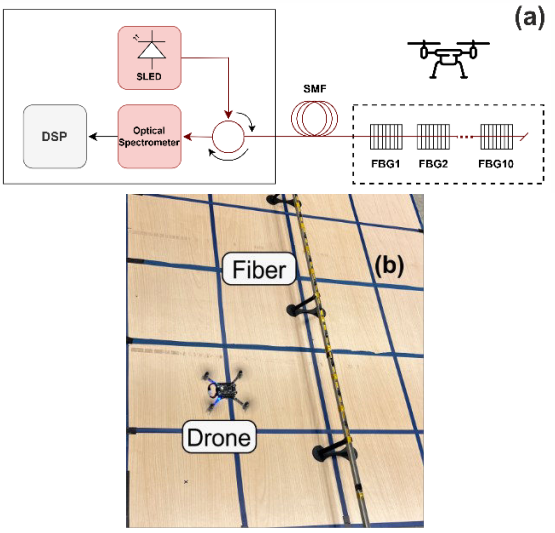

Fig. 1 The block diagram (a) and experimental setup (b) that include an optical fiber FBG sensor network and special measurement tool with full control from a PC.

The first set of assessments engages spectrograms (short-time Fourier transformation – STFT) post-processing analysis. The drone was flying along the fiber back and forth 500 mm over (Fig. 1b). From the normalized STFT diagrams one can clearly see the drone detection and his movement trajectory

where each sensor is trigged one by one (Fig. 2a). The detection process is fully reproducible, considering the STFT of the drone flying in the backward direction where sensors react in reverse order (Fig. 2b) that confirm the measurement system operability.

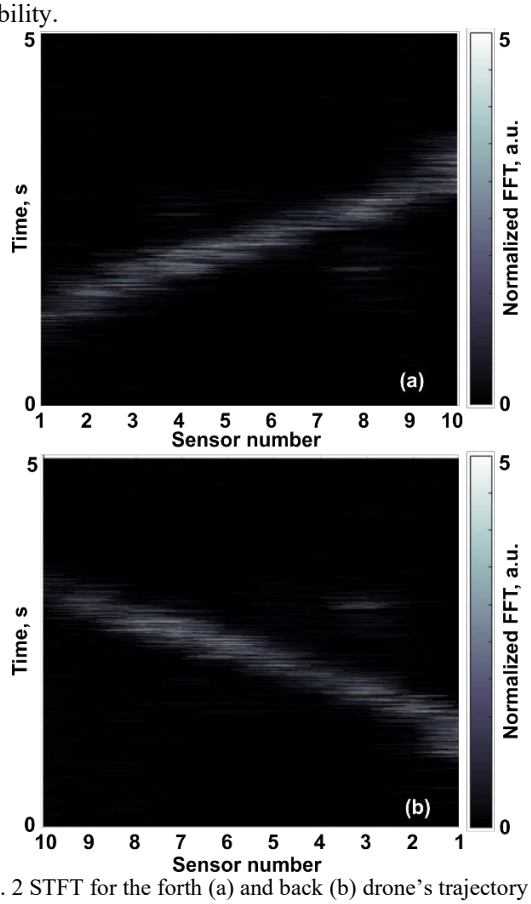

Fig. 2 STFT for the forth (a) and back (b) drone's trajectory flight.

III. Time-Domain Analysis and Micro-Doppler Detection

The analysis in time domain opens a possibility to detect and analyze a unique characteristic of the flying-over drone such as micro-Doppler. It is modern approach in radar technologies for target detection, identification and classification [3-4]. As the LSS UAVs has a very low RCS, their Doppler characteristics is often comparable to birds around [5]. The micro-Doppler combs (appear as a scattering from UAV's propellers) characterization allows such misunderstanding as different UAVs has difference propeller rotation speed, length, material, and so on.

The time series signals, recorded by the used measurement system, are shown in Fig. 3a. It is clearly seen the short 'flashes' of the backreflected signals from each sensor of FBG network for the direct drone flight along the fiber. Meanwhile, the simple Fast-Fourier Transform analysis (Fig. 3b) demonstrate two peaks around 150 and 450 Hz that correspond to the 2nd and 6th micro-Doppler harmonics, thus the speed of propeller rotation can be estimated.

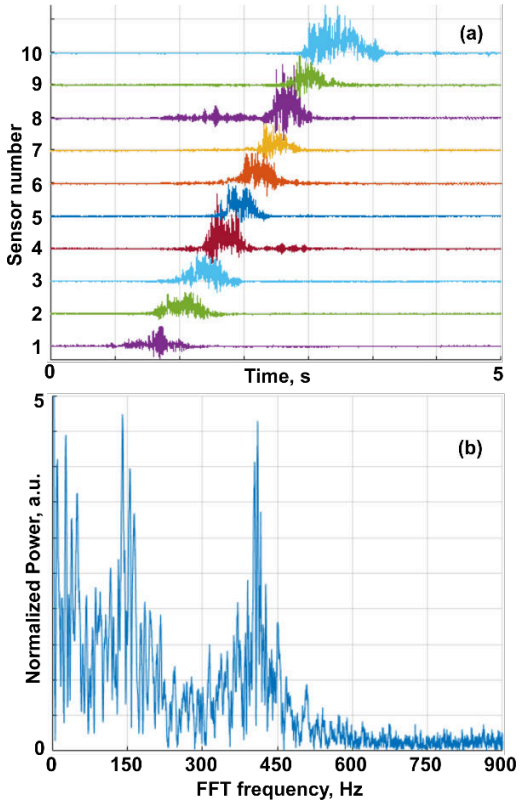

Fig. 3 Time series of the backreflected signals from FBG sensors (a) and the normalized FFT of the measured signal on sensor number 6 (b).

IV. Conclusion

A FBG sensor network was demonstrated as an alternative sensing approach for detection and characterization of LSS UAVs. Spectrogram analysis revealed the drone trajectory through sequential activation of sensors, confirming reliable spatial detection. Time-domain analysis enabled extraction of micro-Doppler signatures associated with propeller rotation. The measured frequency components allowed estimation of rotor rotational dynamics, highlighting the capability of optical fiber sensing systems for UAV monitoring. The proposed approach opens perspectives for integrating machine learning algorithms for improved detection accuracy, classification of aerial targets, and trajectory reconstruction in smart-city environments.

***Abstract*— This work investigated the chiroptical response of chiral plasmonic nanoparticles via structural and substrate design. The plasmonic nanohelix exhibits distinct mode-dependent chiroptical far-field properties. Plasmonic helicoid with high-refractive-index substrate shows remarkable enhancement in g-factor and peak separation between absorption and scattering g-factor spectra, attributed to strong plasmon hybridization.**

***Keywords*— chiral nanoparticles, chiroptical responses, plasmon.**

I. Introduction

Chiral plasmonic nanoparticles enable on-chip CPL devices but rely on substrates. Low-index dielectrics minimally affect their chiroptical properties,[1,2] whereas high-index semiconductors induce image charges similar to NPoM systems. For chiral LSPRs, circular polarization can generate rotating image dipoles that enhance or cancel optical chirality. Substrates strongly modulate chiral signals, with plasmon hybridization and superchiral fields adding complexity.

We systematically simulate dielectric substrates' effects on individual chiral plasmonic nanoparticles using Au helicoids. Increasing substrate refractive index notably amplifies the g-factor and induces an abnormal peak separation between absorption and scattering g-factors.[3,4] This rare phenomenon arises from the enhanced near-field optical chirality confined at the nanoparticle–substrate gap, driven by energy differences between bonding and antibonding quadrupole modes. The mechanism, supported by near-field analysis, is applicable across other metals like Ag and Cu.

II. Methods

The simulations were performed using FDTD Solutions developed by Ansys Lumerical. Two total-field scattered-field plane-waves with orthogonal polarizations and a phase difference of $\pm\pi/2$ were used to generate the RCP or LCP excitation source. Mesh size of 1.0 nm was utilized to calculate the spectra and the electric field enhancement. The dielectric functions of Au, Ag and Cu were set by fitting the measured data of Johnson and Christy, Palik and CRC, respectively.

III. Results and Discussion

To investigate the substrate effect, we performed FDTD simulations on the Au helicoids with an edge length of 150 nm supported by the dielectric substrates with different refractive indexes. For substrates with refractive indexes of $n = 1.5$ and $n = 4.0$, Fig. 1(b) and 1(c) show the scattering and absorption cross-sections under LCP/RCP excitation, along with the resulting g-factor defined as

$$g=2\times\frac{\sigma_R-\sigma_L}{\sigma_R+\sigma_L} \quad (1)$$

where σ_R and σ_L are the cross-sections under RCP and LCP excitation.

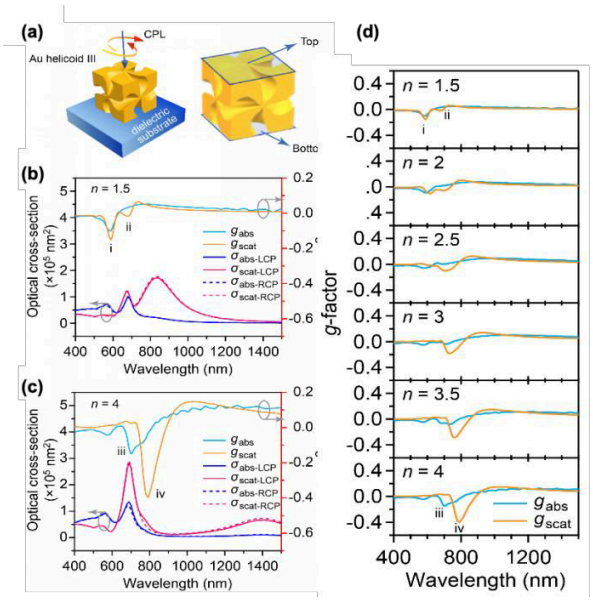

Fig. 1 (a) Schematic of Au helicoid supported by a dielectric substrate under the in-plane CPL excitation. (b),(c) Calculated optical cross-section and g-factor spectra for the substrate with refractive index of $n = 1.5$ (b) and $n = 4$ (c). (d) Calculated g-factor spectra for the substrate with different refractive indexes under the in-plane CPL excitation.

The absorption cross-section shows minor peak shifts but distinct intensity differences for LCP vs. RCP. Scattering

spectra reveal a broad low-energy peak and a sharp high-energy peak. With increasing substrate refractive index, the low-energy peak redshifts and weakens, while the high-energy peak shifts little and strengthens, indicating mode-dependent nanoparticle–substrate coupling.

Moreover, when the Au helicoid is supported by a high-refractive-index substrate, g_{scat} is enhanced from 0.15 to 0.39, and that of g_{abs} also increases from 0.09 to 0.15. Especially, there is a notable separation in the peak positions of g_{abs} and g_{scat}, which is an uncommon phenomenon among various chiral plasmonic nanoparticles.[5–7]

The enhanced chiroptical responses are also evident in the near field. Fig. 2(a) shows the differential optical chirality enhancement ($C_{LCP}/|C_{CPL}|$-$C_{RCP}/|C_{CPL}|$), which indicates the position where the chiral signal is located, and the differential electric field enhancement ($|E_{LCP}|/|E_{CPL}|$-$|E_{RCP}|/|E_{CPL}|$), which is related to the enhancement of the chiroptical response of peaks iii and iv, with the optical chirality enhancement defined by[44]

$$\frac{C(r)}{|C_{CPL}(r)|} = -\frac{c\times \mathrm{Im}[\boldsymbol{E}^{*}(r)\cdot\boldsymbol{B}(r)]}{|\boldsymbol{E}_{CPL}(r)|^{2}} \qquad (2)$$

where c is the speed of light, r is the displacement vector, $\boldsymbol{E}$ and $\boldsymbol{B}$ represent the electric and magnetic field. C_{CPL} and $\boldsymbol{E}_{CPL}$ are the optical chirality density and electric field obtained under CPL excitation without the helicoid, respectively.

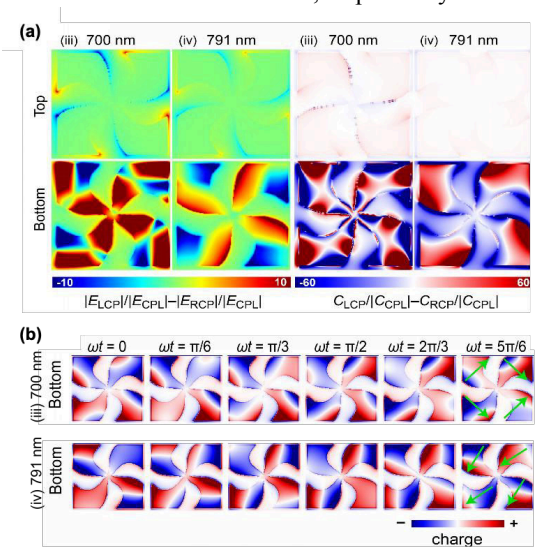

Fig 2 (a) Differential optical chirality distribution and electric field enhancement; (b) Charge distribution contours at different phases and resonance wavelengthsfor the substrate with refractive index of n = 4 under in-plane RCP excitation.

To ascertain the evolution of these chiroptical peaks, we further refine our calculations by varying the substrate refractive indexes from 1.5 to 4 with a step of 0.5. We focus on the in-plane excitation to figure out the physical origins behind the g-factor enhancement and the abnormal peak separation [Fig. 1(d)]. The two g_{scat} peaks i and ii that initially appear for the low-refractive-index substrate of n = 1.5 gradually merge into one dominant peak iv as the substrate refractive index increases. Peak ii gradually redshifts with its intensity largely enhanced, while peak i becomes much weaker even disappears. As the g-factor spectra mainly exhibit negative response, all the charge distributions in Fig. 2(b) are calculated under the in-plane RCP light. For the refractive index of n = 4, the low-energy g_{abs} peak iii is attributed to a bonding quadrupolar mode while the g_{scat} peak iv at 791 nm corresponds to an antibonding quadrupolar mode [Fig. 2(b)]. Symmetry breaking induced by the high-refractive-index substrate enables the excitation of the antibonding quadrupolar mode, leading to the appearance of a bump in the scattering spectrum [Fig. 1(c)]. The observed separation between the g_{scat} and g_{abs} peaks therefore, originated from the mode splitting in the interaction between the Au helicoid and the dielectric substrate.

IV. Conclusion

Chiroptical response modulation is achieved by structural and substrate design. Dielectric substrates with plasmonic helicoid induce symmetry breaking, enhancing chiral response. g_{scat} increases from 0.15 to 0.39 as refractive index rises from 1.5 to 4. Plasmon hybridization of quadrupolar-quadrupolar modes causes separation of gabs and gscat peaks. These findings facilitate precise manipulation of chiral light and facilitate applications in nanophotonics.

***Abstract*— This work demonstrates a plasmonic photonic architecture using an optically inert silica opal framework to confine light efficiently. Spectral alignment between photonic and plasmonic modes amplifies electromagnetic fields, enabling exceptionally high solar driven hydrogen generation without semiconductors or cocatalysts and establishing a general design principle for plasmonic catalysis.**

***Keywords*— plasmonic, slow photons, photonic, hydrogen evolution, photocatalysis**

I. Introduction

The development of efficient solar-driven hydrogen production technologies is a central challenge in the transition toward a sustainable energy economy. Plasmonic catalysis has attracted increasing interest as an alternative to conventional semiconductor photocatalysis, as noble metal nanostructures are capable of concentrating visible light through localized surface plasmon resonance (LSPR) and generating energetic hot carriers that can participate directly in chemical transformations.[1,2] Despite these advantages, standalone plasmonic nanoparticles generally exhibit limited catalytic efficiency, primarily due to weak electromagnetic field confinement and rapid hot-carrier recombination.[3-5]

To enhance light-matter interactions, plasmonic nanoparticles are frequently coupled with photonic crystals, which possess periodic refractive index modulations capable of supporting photonic bandgaps and slow photon effects.[6-7] Nevertheless, many reported plasmonic photonic systems employ photoabsorbing semiconductor backbones, resulting in complex optical competition among photoabsorption, plasmonic scattering, and photonic effects. Such competition often suppresses slow photon formation and diminishes the effective electromagnetic field enhancement. The present work synthesizes a design strategy that mitigates these issues by harmonizing plasmonic and photonic effects through the use of a non-photoabsorbing photonic framework.

II. Methods

Synthesis of silica nanoparticles

The preparation of SiO_2 particles was carried out following the modified Stober's method.[8] Briefly, 37.61 mL of ethanol, 6.75 mL of ultrapure water and 1.2 mL of ammonium hydroxide solution were added in conical flask and stirred at 500 rpm for 15 minutes. Then 1.55 mL, 2 mL or 4 mL of tetraethyl orthosilicate was added dropwise into the ethanolic solution to obtain SiO_2 nanoparticles with diameter of 210 nm, 270 nm, and 400 nm, respectively. The solution was stirred for 6 hours in room temperature. The solution was then centrifuged (8000 rpm, 10 minutes) to obtain the resulting SiO_2 particles. The particles were washed with ultrapure water and ethanol and dried in vacuum.

Fabrication of SiO_2 opal

3D powdered opal was formed by a self-assembly method. Self-assembly of SiO_2 particles was performed by sedimentation aided with centrifugation approach.[9] 1wt% of SiO_2 particles were dispersed in ethanol and sonicated for 10 minutes. The SiO_2 particles was sedimented by long and slow centrifugation process (2000 rpm, 12 minutes). Then, the supernatant was removed and the assembled particles were dried in vacuum. The self-assembled opals were calcined at 300 ºC for 2 hours to strengthen the mechanical stability.

Deposition of silver nanoparticles to form Ag/SiO_2 opal

SiO_2 opal was soaked in 0.1 M sodium borohydride solution for 10 minutes. The excess sodium borohydride solution was removed. Then, 2 mL of 0.2 M silver nitrate solution was added

and allowed to infiltrate the SiO_2 opal under vacuum pressure for 15 minutes for each cycle. This led to in-situ formation of silver nanoparticles deposited on/within the SiO_2 opal. The resulting Ag/SiO_2 opal was washed thrice using ultrapure water.

Photocatalytic hydrogen evolution reaction (HER) using plasmonic photonic opal

The photocatalytic HER setup was carried out by using 12 mL transparent quartz tube secured with septum seal. 15 mg of photocatalyst was placed in the quartz tube in the presence of 3 mL of 10% methanol solution serving as hole scavenger. The reaction solution was purged with argon (Ar) gas for 15 minutes to remove air prior to the reaction. The samples were irradiated with 100 W white light LED (400 - 750 nm) to initiate the HER. The temperature of the photocatalytic setup was maintained at room temperature with a turbo fan. The evolved gas was analyzed by injecting 0.8 mL of the reactor's headspace gas into a gas chromatograph (SRI Multiple Gas Analyzer #5) equipped with a thermal conductivity detector (GC-TCD). All experiments were repeated at least thrice to ensure the reproducibility of the results.

III. Results and Discussion

Our plasmonic photonic architecture consists of a non-photoabsorbing SiO_2 opal backbone integrated with Ag nanoparticles as plasmonic catalysts (Figure 1). Monodisperse SiO_2 nanoparticles with diameters of 210 ± 15 nm, 270 ± 20 nm, and 400 ± 10 nm were synthesized via the Stober method and assembled into three-dimensional photonic crystals by centrifugation-assisted sedimentation. The resulting opal structures exhibit a face-centered cubic arrangement with thicknesses exceeding 10 micrometers, enabling strong multiscattering and pronounced photonic effects. The periodicity of each opal corresponds directly to the SiO_2 particle size, allowing systematic tuning of the photonic bandgap and the spectral region for slow-photon generation. Ag nanoparticles were uniformly deposited throughout the opals using an in-situ reduction approach, yielding spherical Ag particles of approximately 37 nm with consistent size distributions and mass loadings across all samples. Structural integrity of the photonic crystals was preserved after Ag deposition, ensuring reliable comparison of photonic effects.

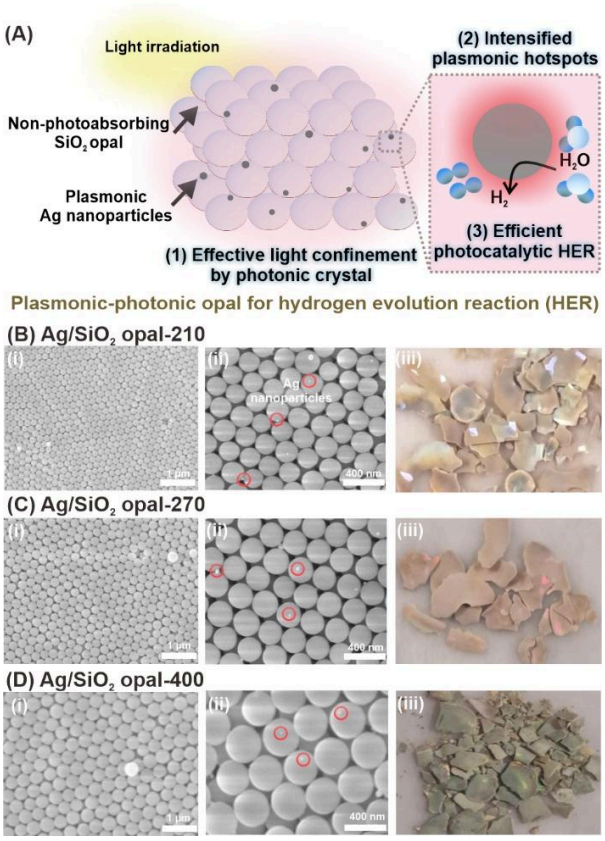

Figure 1. (A) Design of an opal-like plasmonic photonic crystal with superior light concentration ability and its application for efficient photocatalytic hydrogen production. (B – D) Plasmonic photonic crystals composed of Ag nanoparticles deposited onto SiO_2 opal-like structures with nanoparticle diameters of (B) 210 nm (Ag/SiO_2 opal-210), (C) 270 nm (Ag/SiO_2 opal-270), and (D) 400 nm (Ag/SiO_2 opal-400). (i) Overview and (ii) magnified SEM images of various platforms. Ag nanoparticles are highlighted using the red circles. (iii) Digital images showing the distinct color iridescences from the different plasmonic photonic crystals.

Optical characterization confirms that all Ag/SiO_2 opals retain distinct photonic bandgaps, as evidenced by angle-dependent reflectance and diffuse reflectance spectroscopy. The broad photonic features observed arise from random crystal orientation and angle-dependent bandgap dispersion inherent to three-dimensional photonic crystals, enabling access to a wide range of slow-photon wavelengths across the visible spectrum (Figure 2). The localized surface plasmon resonance of Ag nanoparticles is centered near 450 nm and overlaps partially with the photonic bandgaps depending on opal periodicity. Surface-enhanced Raman spectroscopy reveals that Ag/SiO_2 opal-270 exhibits the strongest electromagnetic field enhancement, attributed to concurrent excitation of plasmonic resonance and slow photon modes. In contrast, misaligned photonic bandgaps result in weaker plasmonic enhancement, while standalone Ag nanoparticles show negligible field amplification, highlighting the essential role of the photonic crystal in light confinement.

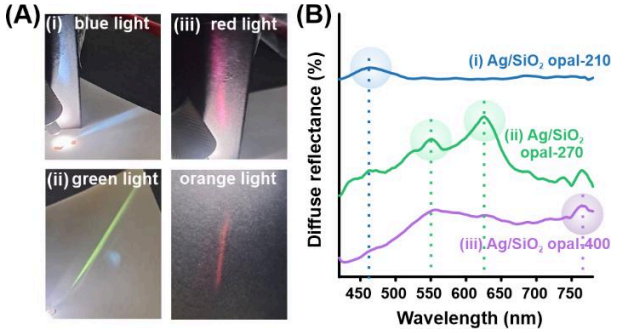

Figure 2. (A) Optical images showing the characteristic stop band reflection of specific light wavelength by various plasmonic photonic crystals upon white light irradiation. (i) Ag/SiO_2 opal-210, (ii) Ag/SiO_2 opal-270, and (iii) Ag/SiO_2 opal-400. (B) Diffuse reflectance spectra recorded from Ag/SiO_2 opal-210, Ag/SiO_2 opal-270, and Ag/SiO_2 opal-400. The dotted line and associated shaded region indicate the position of photonic bandgap (PBG) and estimated slow photons range, respectively. For (A) and (B), the angle-dependent measurement is set at ~40° with respect to the samples.

Application of these architectures to visible-light-driven hydrogen evolution demonstrates that optimized spectral alignment yields hydrogen production rates exceeding 550 mmol $h^{-1}g_{Ag}^{-1}$ under visible light irradiation (Figure 3). Control experiments confirm that neither bare SiO_2 opals nor standalone Ag nanoparticles are effective, underscoring the synergistic requirement of both plasmonic and photonic effects. Disordered Ag/SiO_2 assemblies exhibit significantly lower activity due to the absence of slow photon generation. Further mechanistic analysis indicates that increasing plasmonic nanoparticle loading does not lead to proportional performance gains. Elevated plasmonic content introduces pronounced optical screening and random scattering, which disrupt slow photon formation and reduce light confinement within the photonic crystal. These observations underscore that effective photonic field management, rather than increased photoabsorbing material, governs the efficiency of plasmonic catalysis.

Collectively, these results highlight the critical role of a non-photoabsorbing photonic backbone in harmonizing plasmonic and photonic effects within hybrid architectures, thereby maximizing electromagnetic field enhancement. This conclusion is further supported by apparent quantum efficiency measurements under monochromatic irradiation. The Ag/SiO_2 opal-270 achieves photocatalytic hydrogen evolution rates that surpass most reported systems, outperforming other plasmonic, photonic, and hybrid platforms by up to 280-fold. These comparisons indicate that strengthening photonic effects is more effective for enhancing carrier generation than increasing photocatalyst loading.

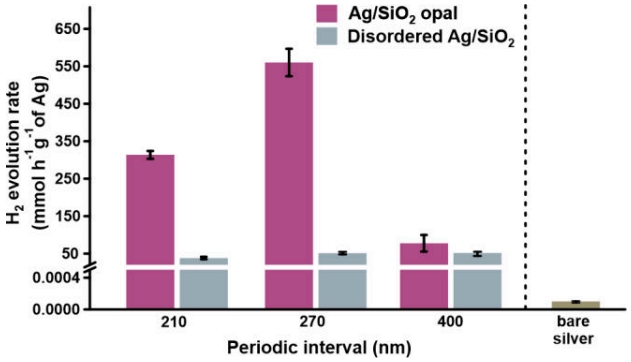

Figure 3. H_2 evolution rate from water when in presence of Ag/SiO_2 opals, disordered Ag/SiO_2 platforms, or bare Ag nanoparticles under light irradiation.

IV. Conclusion

The findings summarized here establish non-photoabsorbing photonic backbones as effective platforms for amplifying plasmonic electromagnetic fields through the preservation and exploitation of slow photons. Deliberate harmonization of photonic and plasmonic effects enables highly efficient visible-light-driven hydrogen evolution without reliance on semiconductor absorbers or additional co-catalysts. The design principles discussed offer broadly applicable guidelines for engineering electromagnetically enhanced plasmonic catalysts and may be extended to a wide range of light-driven chemical and energy-conversion processes.

This paper summarizes previously published work and is submitted solely to meet conference submission requirements. No new experimental data or unpublished results are reported.

Carbon nanodot superparticles were fabricated via emulsion-templated assembly using bare and PEGylated nanodots. PEG functionalization modulates interparticle spacing, leading to emission blueshifts and longer lifetimes. Structural uniformity is confirmed by electron microscopy, while humidity induces emission quenching and structural degradation.

***Keywords*— carbon metamaterials, carbon superparticles, fluorescent carbon dots**

I. Introduction

Carbon nanodots (CDs) are fluorescent carbon-based nanoparticles characterized by tunable optical properties and high photostability making them attractive for optoelectronic and photonic applications. However, aggregation-induced quenching strongly limits their use in solid-state devices.[1]

One promising strategy to overcome this limitation is the hierarchical assembly of CDs into superparticles (SPs), where, similarly to what is observed for other types of nanomaterials [2-3], collective optical properties may emerge from controlled interparticle interactions. Thereby, the successful emulsion-templated assembly of CDs would enable the formation of spherical superstructures with micrometric dimensions and preserved luminescence in the solid state.

In this work, we investigate how surface functionalization with polyethylene glycol (PEG) chains of different molecular weights affects the internal organization and photophysics of CD-based metamaterials. By tuning interparticle distance using PEG400 and PEG3000, we modulate the coupling within the superparticles. Additionally, we explore the stability of these materials under environmental humidity, which is fundamental for real-world application, discovering that the presence of water in the atmosphere compromises the emission properties of the metamaterials.

II. Methods

Carbon nanodots were synthesized by microwave method starting from citric acid and urea, and then purified by column chromatography to obtain a narrow size distribution prior to assembly.[4] Three types of CDs were used: non-functionalized CDs, PEG400-functionalized CDs, and PEG3000-functionalized CDs. To achieve the pegylation of the surface, the non-functionalized CDs were allowed to react in autoclave at 180°C with PEG400 or PEG3000 for 24 hours.

Following a strategy typically used to achieve the self-assembly of semiconductor quantum dots [1], CD superparticles were fabricated via a water-in-oil emulsion-templated self-assembly process in presence of a surfactant (SPAN80) using toluene as the oil phase. The spontaneous evaporation of water droplets induced the hierarchical aggregation of CDs into spherical superstructures.

Morphological characterization was performed using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Optical properties were investigated through steady-state photoluminescence spectroscopy and time-resolved photoluminescence measurements in the ps–ns time range, at the level of individual superstructure. Photobleaching kinetics were measured under controlled atmospheric conditions, comparing dry air and humid environments at level of single superstructure.

III. Results and Discussion

Optical and structural characterization was first performed on isolated carbon nanodots prior to assembly. Bare CDs exhibit an average diameter of approximately 4 nm and show bright photoluminescence in solution. Upon surface functionalization with PEG chains, a small blueshift of the emission band is observed, accompanied by an increase in photoluminescence quantum yield and a longer excited-state lifetime. These effects are likely associated with a screening of the CD surface from the external environment provided by the PEG shell.[4]

After the assembly, morphological study has been performed by SEM and TEM. The images reveal that all types of CDs self-assemble into well-defined spherical superparticles with a quite large distribution of diameters which spans from 150 nm to few um, independent of surface functionalization (examples are

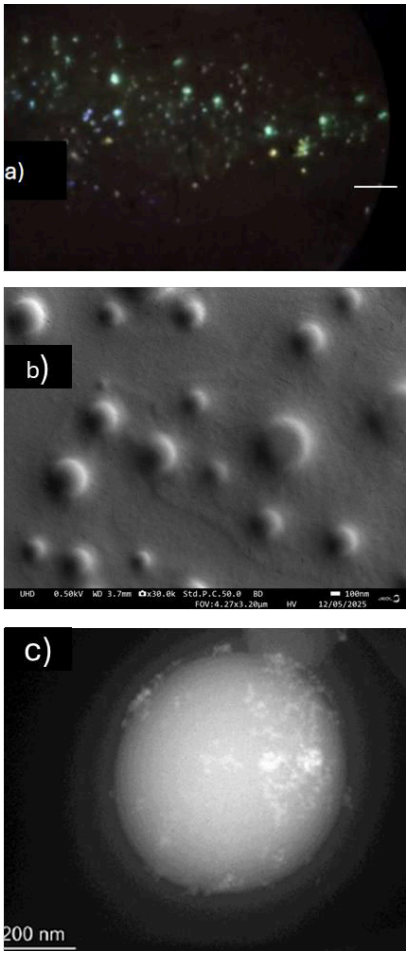

Figure 1: (a) Micrograph of Superstructures deposited on a glass substrate upon 405 nm excitation (the white bar indicates a scale of 50 um). (b) SEM images of non-pegylated superstructures. The scale bar is 100 nm (c) TEM images on a single PEG400-superstructure. The scale bar is 200 nm.

shown in Figure 1). The superstructures appear compact and homogeneous, indicating successful emulsion-templated assembly.

Optical measurements on superstructures deposited on a substrate show that the optical properties of isolated CDs and PEG-CDs are preserved upon self-assembly. PEGylated-CD superparticles display a small but reproducible blueshift of the emission band compared to bare-CD superparticles, but also an increased emission QY and a longer lifetime. Overall, the optical function is preserved (Figure 2a-2b) despite the aggregation of carbon nanoparticles which typically causes a dramatic quenching of the emission. This suggests that a controlled assembly is fundamental to control the structure of microparticles, paving the way to a new family of photoluminescent metamaterials.

We performed environmental stability tests on the optical properties of superstructures. Water vapor has a detrimental effect on the metamaterials. In fact, in humid air, the emission undergoes quenching effect as demonstrated by the photobleaching kinetics in Figure 2c. In contrast, the optical properties are preserved for a longer time in nitrogen atmosphere. This behavior suggests that water penetration disrupts interparticle interactions and partially destroys the superparticle architecture, highlighting the importance of encapsulation strategies for practical applications.

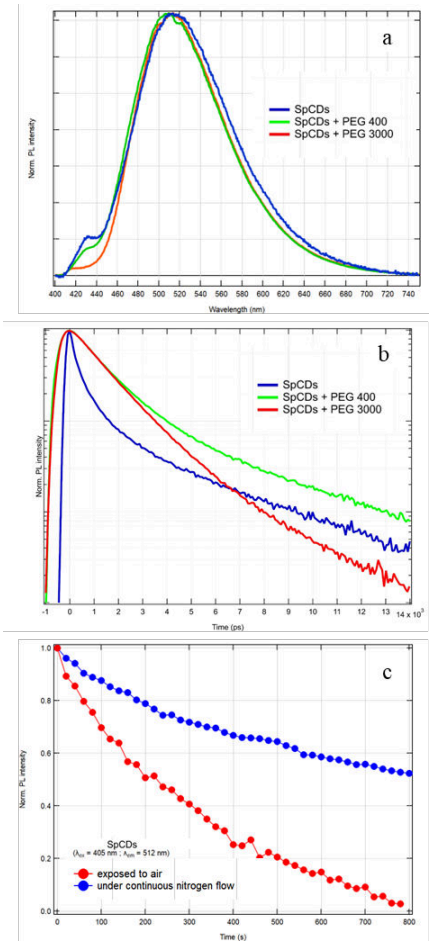

Figure 2: (a) Steady-state emission spectra of single superstructures excited at 405 nm. (b) Emission lifetime of single superstructures excited at 405 nm. (c) Emission photobleaching kinetics of non-pegylated superparticles in ambient air and upon nitrogen atmosphere.

IV. Conclusion

These results demonstrate that emulsion-templated assembly enables the formation of compact CD-based superparticles that retain the intrinsic optical properties of the individual nanodots. PEGylation plays a key role by preserving emissive behavior upon aggregation, leading to higher quantum yield, longer lifetimes, and a reproducible blueshift without aggregation-induced quenching. At the same time, the sensitivity of the superstructures to humid environments reveals that their optical performance is closely linked to the integrity of the assembled architecture.

***Abstract*— We report excitation-controlled lasing from individual CdSe/CdS quantum dot superparticles. By tuning the pump wavelength, reversible selection of whispering-gallery modes is achieved. This provides a purely optical route to dynamically reconfigurable and compact microlasers.**

***Keywords*— Quantum Dot Superparticles; Tunable lasing; Whispering-Gallery Modes Microresonators.**

I. Introduction

Systems combining strong light confinement, optical gain, and tunability are of growing interest in photonics for applications ranging from compact light sources to sensing and adaptive optical components. While high-quality resonances can be readily achieved in dielectric microcavities, their spectral properties are often fixed once the structure is fabricated, limiting dynamic control of their optical response.

Semiconductor quantum dots (QDs) provide a versatile platform for active photonics due to their size-dependent absorption and emission, near-unity photoluminescence quantum yields, and compatibility with bottom-up fabrication. Beyond individual emitters, the self-assembly of colloidal QDs into mesoscale superparticles (SPs) enables collective optical behavior that cannot be attributed to single nanocrystals. In spherical QD SPs, the global geometry supports whispering-gallery modes (WGMs), providing resonant optical feedback coexisting with distributed optical gain.

Lasing from QD SPs has been previously reported, establishing these systems as compact and efficient microlasers. However, dynamic tuning of lasing modes without modifying the physical structure of the resonator remains largely unexplored, even if essential for adaptive and multifunctional photonic platforms.

Here, we present a systematic optical study of lasing in individual SPs assembled from CdSe/CdS core/shell QDs. We show that lasing can be reversibly tuned by controlling the excitation wavelength, owing to the wavelength-dependent penetration of the pump light and the resulting modulation of the spatial overlap between optical gain and WGMs. This mechanism provides a simple and robust route to optical reconfiguration of microlasers.

II. Methods

Superparticle preparation: CdSe/CdS core/shell QDs with thick shells were synthesized to enhance optical gain and suppress non-radiative recombination. Controlled self-assembly yielded spherical SPs with micrometer-scale diameters and smooth outer surfaces, favorable for supporting WGMs with low optical losses.

Optical characterization: Individual SPs were optically excited using pulsed laser source with tunable wavelength. Emission spectra were collected as a function of excitation fluence to identify lasing thresholds and mode structure. Time-resolved photoluminescence measurements were employed to probe emission dynamics and gain evolution below and above the lasing threshold, providing insight into the role of excitation conditions on mode formation.

III. Results and Discussion

Red-emitting quantum dot SPs with diameters of approximately 10 μm were produced via a source-sink emulsion process applied to CdSe/CdS core/shell quantum dots (Fig. 1a). The resulting SPs exhibit a highly spherical morphology and a dense internal packing of emitters, enabling them to act as luminescent optical microcavities (see Fig. 1b). Their circular geometry and refractive index contrast naturally support WGMs, as evidenced by the dense series of narrow peaks superimposed to the photoluminescence spectra of individual SPs (Fig. 1c).

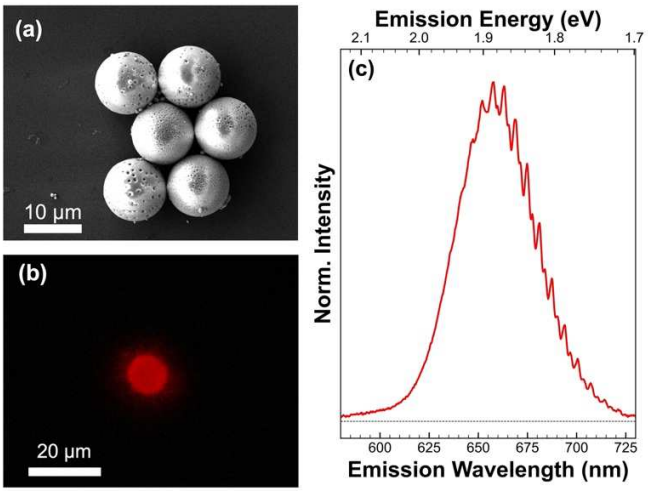

Fig. 1 (a) SEM image of QD SPs. (b) Photoluminescence imaging and (c) spectrum of an individual SP. Adapted from ref [3].

The emission properties of individual SPs were investigated in detail under optical pumping, both below and above the lasing threshold. As shown in Fig. 2, upon increasing excitation fluence, a clear transition from spontaneous emission to stimulated emission is observed, marked by a nonlinear increase in output intensity and the appearance of narrow spectral peaks associated with WGM-lasing. Depending on the specific SP and excitation conditions, single-mode or multi-mode lasing can be achieved, reflecting the balance between gain, cavity losses, and mode competition. Interestingly, lasing spectra are extremely sensitive to the morphology and the environment of each individual SP.

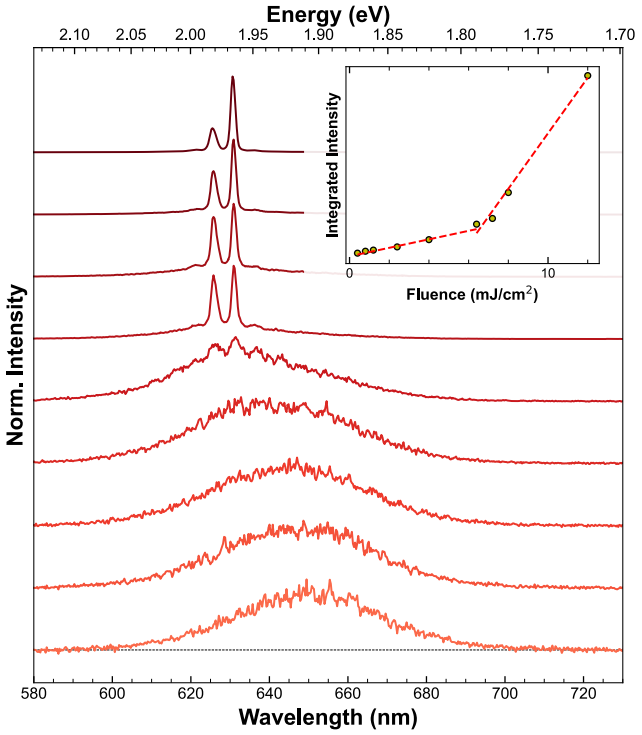

Fig. 2 Single-SP emission spectra for increasing pump fluences. Inset shows intensity of SP emission vs excitation fluence.

A key result of this work is that the lasing emission from individual SPs is spectrally tunable through the excitation wavelength (Fig. 3). By varying the pump wavelength, we observe reversible transitions in the lasing pattern. This tunability arises from the wavelength-dependent absorption profile of the CdSe/CdS quantum dots, which determines whether the optical excitation predominantly addresses the core or the shell region. As a consequence, the spatial distribution of optical gain within the SP is modified, altering the overlap between the gain region and the electromagnetic field profiles of different WGMs.

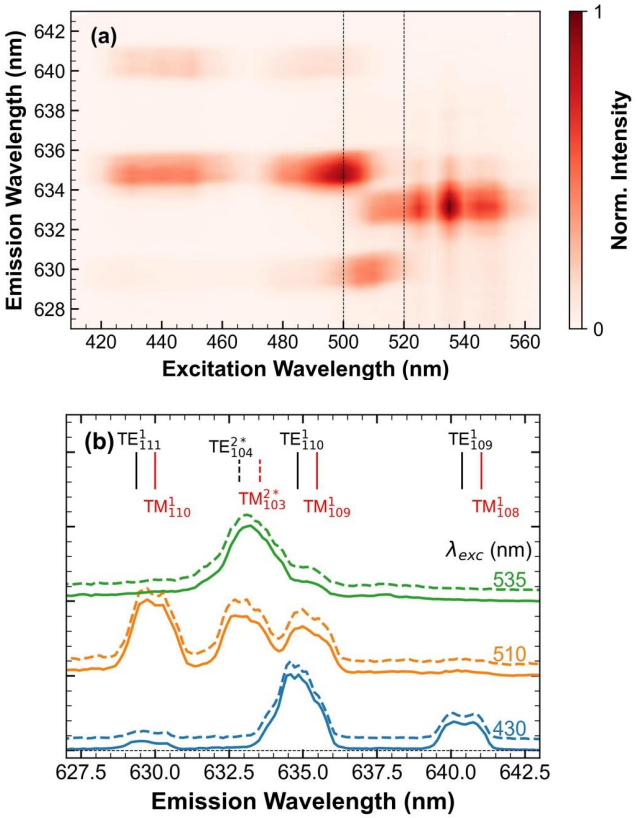

Fig. 3 (a) Lasing excitation-emission map of an individual SP. (b) Lasing spectra at three representative pump wavelength. Adapted from ref [3].

Time-resolved photoluminescence measurements further support this interpretation, revealing excitation-dependent emission dynamics and gain buildup. Shorter-wavelength excitation leads to more localized absorption near the outer regions of the SPs, whereas longer-wavelength excitation penetrates deeper into the structure, activating a larger effective gain volume. Since different WGMs exhibit distinct spatial field distributions, changes in gain localization result in selective amplification of specific modes, enabling excitation-controlled mode selection. This mechanism, corroborated also by numerical simulations, provides a simple and robust route to dynamically reconfigure the lasing response of the SP without modifying its geometry or surrounding environment.

Finally, we achieved both physical and optical coupling to an

optical fiber producing a microlaser that can be easily integrated with existing photonic technologies.

IV. Conclusion

We have demonstrated reversible, excitation-wavelength-dependent lasing in individual CdSe/CdS quantum dot superparticles. The tunability arises from excitation-controlled modulation of the optical gain distribution and its overlap with whispery-gallery-modes, enabling purely optical reconfiguration of micro-resonant emission. Moreover, the strong sensitivity of the lasing spectra to superparticle morphology and environment yields distinctive spectral fingerprints, highlighting potential of these self-assembled microlasers for photonics and optoelectronic applications including sensing and anticounterfeiting.

Increased hot carrier generation and separation in porous golden nanorods

***Abstract*—The enhanced photocatalytic performance of porous gold compared to bulk gold has been examined using atomistic simulations. A correlation has been identified between the larger number of low-coordinated surface gold atoms and an increased generation of hot carriers within the plasmonic nanostructure.**

***Keywords*— hot carrier generation, photocathalysis, gold nanoparticles.**

I. Introduction

Porous gold is known to possess higher catalytic activity than in bulk. This behaviour is commonly attributed to an increased surface-to-volume ratio resulting in a high presence of gold atoms with low coordination numbers, and a higher density of so-called "hot spots," i.e. regions of strongly enhanced electromagnetic field intensity. For certain reactions, the catalytic performance of gold is further linked to the direct transfer of highly energetic charge carriers into the reactants. These carriers arise from the decay of coherent collective electron oscillations, known as plasmons, which are excited in a nanoparticles (NPs). In the present paper, we verify the hypothesis an increased generation rate of hot carriers in porous NPs compared to solid homogeneous NPs.

II. Methods

We investigate the optical and electronic characteristics of porous gold nanorods using Density Functional Theory (DFT) and Real-Time Time-Dependent DFT (RT-TDDFT). All simulations are performed with the GPAW package [1], employing the LCAO scheme for both ground-state DFT [2] and RT-TDDFT [3]. The calculations rely on uniform real-space grids and a finite-difference discretization.

Ground-state properties are obtained using the Gritsenko-van Leeuwen-van Lenthe-Baerends (GLLB-sc) exchange–correlation functional, which offers a substantially improved description of d-electron states in noble metals compared with the conventional Perdew-Burke-Ernzerhof (PBE) functional. The time-dependent response is then evaluated within the adiabatic PBE approximation. Photoabsorption spectra are generated via the δ-kick method [4] in the linear-response regime, using the dipole approximation to describe light–matter coupling. The time-dependent density functional theory (TDDFT) implementation is interfaced with post-processing tools that decompose resonances into electron–hole transition contributions and represent them as transition contribution maps (TCMs) [5]. Hot carrier generation rates are obtained following the procedure of Rossi et al. [6], which enables the analysis of ultrafast plasmon decay through Landau damping in the time domain and yields both the energetic and spatial distribution of hot carriers prior to any electron–electron or electron–phonon scattering.

III. Results and Discussion

We study the optical response of Au nano rods (NRs) with a number of holes inside introduced by systematic removal of chosen atoms (see the insets in fig.1). The geometry of the holes, i.e. size and shape, is kept constant and the number is increased from zero to five.

The TCMs, presented in fig. 1, show a spread of low-energy, in phase plasmonic transitions, into a larger area of energies, i.e., the energy broadening of plasmonic transitions, somewhat similarly as in small metallic clusters like Ag_{55}. There is also a slight increase in single-particle transitions resonant with excitation (transitions resonant with excitation lines on the black diagonal line), suggesting increased damping due to the extended surface of the NR. The out of phase, blue, transitions involving high energetic holes illustrate the contribution from d states present in Au. With an increase in the surface to volume ratio, the contribution of transitions from deep d states decreases. This is accompanied by a shrinking of the width of d-band.

Hot carriers are generated in the process of plasmon decay into single-particle-like transitions, which are resonant with the excitation. In consequence, their energy distribution resembles the density of states (DOS), resulting in highly energetic holes, formed by transitions of the d to sp states. The probability of the total per-atom hot carrier occupation as a function of the excitation energy is shown in fig. 2. Although in a narrow, 5x5 atom wide, NRs hot carrier generation does not follow a systematic evolution, interestingly, in the case of a wider, 7x7 atom wide, NRs we observe a steady increase of carrier per-atom occupation probability. The following analysis of spatial distribution of hot electrons and holes reveals that hot electrons tend to accumulate at the regions of high electromagnetic field intensity, while the hot holes surplus is find at the regions of low electromagnetic field intensity.

IV. Conclusion

The presence of the d states provides a reservoir of electrons that can be promoted to sp states, leading to the formation of high-energy hot holes. The projected density of d states varies

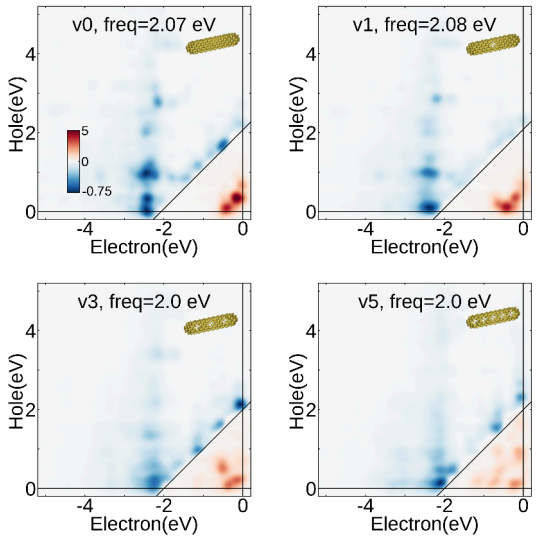

Fig. 1. The TCMs to photoabsorption calculated at the plasmon resonance frequencies for Au NRs with increasing number of pores. The excitation field is aligned with the long axis of rods.

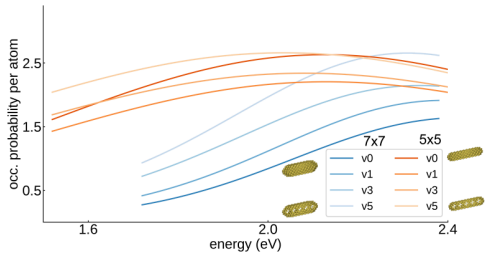

Fig. 2. Hot electron/hole occupation probability per atom as a function of pulse energy.

depending on the arrangement of voids. As the number of pores increases, more distinct electronic transitions contribute to plasmon oscillations, which broaden the energy distribution of hot carriers. Consequently, highly porous NRs produce a larger overall number of hot carriers. Excess hot electrons are concentrated near the NR surface in regions of strongly enhanced electromagnetic fields, whereas hot holes preferentially accumulate at low-coordinated atomic sites in these regions.

***Abstract*— We demonstrate deterministic room-temperature strong coupling between single CdSe/ZnS quantum dots (QDs) and gold nano-bipyramid tips using plasmon-triggered two-photon polymerization. Gold bipyramids are patterned via EBL/drop-casting, then photosensitive QD-loaded resin selectively polymerizes at plasmonic hotspots. Scattering reveals 265 meV Rabi splitting, photoluminescence shows characteristic polariton emission. This reproducible platform overcomes stochastic positioning limitations, and is a potential route to scalable bright nonlinear single-photon sources for integrated quantum photonic circuits and nanolasers.**

***Keywords*— strong coupling, quantum dots, localized sur-face plasmon polaritons, two-photon polymerization, gold nano-bipyramids.**

I. Introduction

Strong light–matter coupling between individual quantum emitters and optical nanocavities is a cornerstone of scalable quantum photonics, enabling hybrid polaritons for single-photon nonlinearities, thresholdless nanolasers, and deterministic entanglement generation.[1,2] Solid-state emitters such as nitrogen-vacancy centers and colloidal quantum dots (QDs) offer photostability and integration potential, yet bare QDs suffer broad linewidths (~50–100 meV) and modest brightness that limit spectral purity and indistinguishability.[3,4] Plasmonic nanocavities offer ultrasmall mode volumes ($V_m \sim 10^{-4}\left(\lambda/n\right)^3$) and room-temperature strong coupling ($g > k, \gamma$) evidenced by Rabi splitting $\hbar\Omega = 2g$ in scattering spectra.[5,6]

Recent advances for plasmonic nanoresonators coupled to single QDs include bow-tie cavities (Ω~100 meV), nanoparticle-on-mirror (NPoM) geometries (Ω~200 meV), and wedge nanogaps (Ω~240 meV), yet stochastic self-assembly or serial nanopositioning hinders scalability.[7,8] Plasmon-triggered two-photon polymerization (P-2PP) offers a deterministic alternative, selectively localizing emitters in plasmonic hotspots *via* near-field enhancement.[9]

Here, we demonstrate room-temperature strong coupling between single CdSe/ZnS QDs and gold nano-bipyramids (BPs)—nanostructures with sharp tips (~4 nm radius) enabling extreme field enhancement [10]. Using P-2PP, we precisely position QDs at a single BP tip hotspot, yielding scattering spectra with clear Rabi splitting, polariton-modified photoluminescence, and verified single-photon emission ($g^{(2)}(0)$=0.3). This hybrid platform provides a reproducible route to bright, nonlinear single-photon sources for integrated quantum technologies.

II. Methods

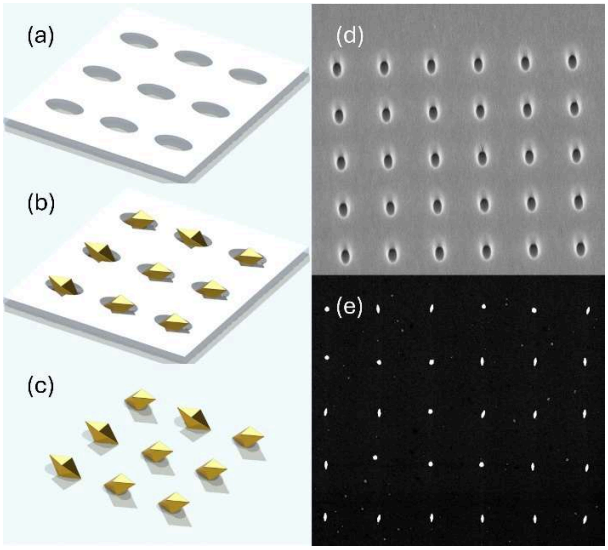

Fig. 1 (a,b,c) Schematic illustration of BPs placement in arrays (d) SEM image of elliptical shaped holes pattern after EBL (e) SEM image of BPs array on silicon substrate.

Our methodology for positioning single excitons at nanoparticle tips consists of two stages. First, we arrange gold BPs into arrays to characterize their plasmonic resonances prior to coupling. Second, we use 2PP to place QDs at the BP tips and achieve strong coupling [11].

The polymer-coated substrate is patterned with elliptical holes by electron beam lithography (EBL) (Fig. 1a,d). A solution of chemically synthesized BPs is drop-cast onto the patterned surface (Fig. 1b), and after solvent evaporation the sample is rinsed in acetone so that only BPs trapped inside the holes remain (Fig. 1c,e).

Next, a solution containing a polymerizable resin with embedded QDs isdeposited onto the BP array. To localize QDs near the tips of the Au BPs, we employ 2PP with the laser power set just below the bulk polymerization threshold, so that polymerization occurs only in regions of locally enhanced intensity due to the plasmonic near field. Finally, the unpolymerized solution is removed, leaving QDs selectively positioned at the BP tips.

III. Results and Discussion

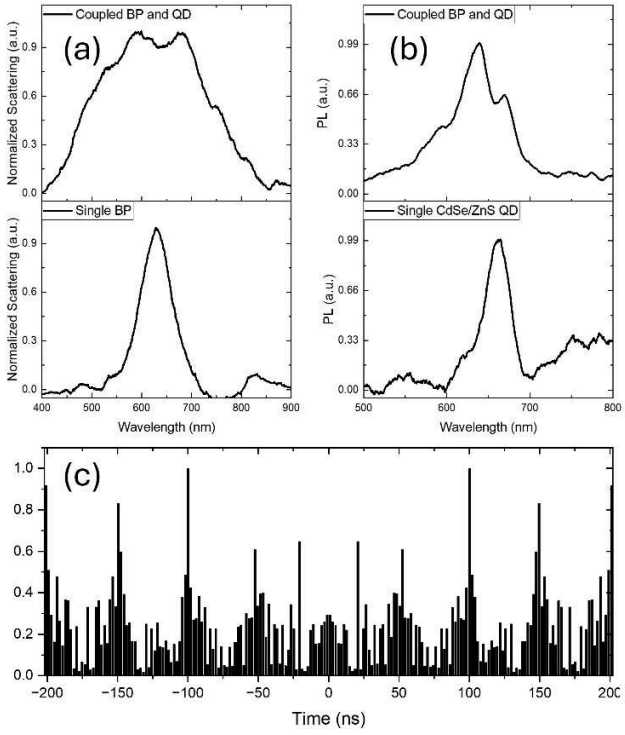

Fig. 2 Strong coupling signatures in QD–BP nanocavities. (a) Scattering: single BP plasmon (black, bottom) vs. Rabi splitting (top). (b) PL: uncoupled QD (bottom) vs. polariton emission (top). (c) $g^{(2)}(0)=0.3$ antibunching from single QD. All measurements are made at room temperature.

The fabricated QD–BP nanostructures exhibit clear optical signatures of room-temperature coupling between the localized surface plasmon mode and the QD exciton. In dark-field scattering, an isolated BP displays a single broad plasmon resonance (Fig. 2a, bottom). When single or few CdSe/ZnS QDs are positioned at the BP tip *via* plasmon-triggered 2PP, the spectra develop characteristic double-peaked profiles with a pronounced central energy dip, revealing Rabi splitting of 265 meV (Fig. 2a, top). This confirms coherent coupling where the exciton–plasmon interaction strength g exceeds the combined linewidths of the uncoupled modes.

Photoluminescence (PL) provides complementary evidence with reduced splitting of 93 meV, as expected from strong coupling theory. An uncoupled reference QD displays a single emission peak (Fig. 2b, bottom), while the coupled QD–BP system exhibits broadened emission redistributed across polariton branches (Fig. 2b, top). The smaller PL splitting (~35% of scattering value) arises because PL probes incoherent spontaneous emission dominated by the lower polariton branch, whereas scattering captures symmetric coupling of both upper and lower branches—a well-established distinction in hybrid nanosystems [12,13].

The single-photon nature of the emitter was independently verified through time-correlated single-photon counting on a reference CdSe/ZnS QD, yielding clear antibunching with $g^{(2)}(0)=0.3$ (Fig. 2c). Together, the 265 meV scattering splitting, 93 meV PL polariton emission, and confirmed single-photon statistics demonstrate deterministic realization of strongly coupled single-emitter plasmonic nanocavities at room temperature.

IV. Conclusion

Our plasmon-triggered two-photon polymerization method transforms gold nano-bipyramid arrays—fabricated *via* EBL-defined elliptical traps—into deterministic single-emitter plasmonic nanocavities. The observed 265 meV Rabi splitting in scattering, alongside polariton-modified photoluminescence, establishes room-temperature strong coupling previously limited by stochastic positioning. This hybrid platform is a route to scalable quantum plasmonic devices with unprecedented reproducibility for next-generation photonic quantum technologies.

***Abstract*— We report on emitter-waveguide modeling results investigating stimulated emission during single photon addition. We design and fabricate a coupled emitter-waveguide device, representing significant progress towards an experimental demonstration of deterministic single photon addition.**

***Keywords*— quantum photonics, 2D materials, quantum emitters.**

I. Introduction

Pushing chip-based nanophotonics to the quantum limit relies on the availability of waveguide-coupled single photons. This is true both for commercializable technologies such as quantum photonic computing and networking and fundamental investigations of non-classical photon interactions. Photon addition, creating a superposition of an initial thermal or coherent state with a Fock state, is a particularly interesting model for both creating non-Gaussian states as a resource for quantum technologies and probing under-studied photon interactions including stimulated emission in a waveguide mode.

Photon addition was theoretically proposed over 30 years ago as a mechanism for generating squeezed light [1]. Today, there are multiple experimental demonstrations of heralded single-photon and multiple-photon addition using probabilistic single photon sources including spontaneous parametric down conversion (SPDC) [2-5] and optical parametric amplification (OPA) [6-8]. The existing work has yielded squeezed light and arbitrary quantum state generation. Further, the authors have proposed that photon addition can be used to amplify the signal to noise ratio (SNR) of weak signals by over 2x the classical limit [9-10].

While probabilistic photon addition is an effective way to generate indistinguishable photons and permits post-processing detected light by single photon events using the heralded photon, it is intrinsically rate limited. As the nonlinear component is pumped at higher powers, the single photon purity degrades [11]. Typical single photon rates from probabilistic sources are on the order of 10 to 100 Hz [7]. Deterministic solid state single photon emitters (SPEs) emit at significantly higher single photon rates. Specifically, hexagonal boron nitride (hBN) is a promising SPE host due to high quantum efficiencies, photon purity, Debye-Waller factors and single photon count rates (>10^6, 10^4x more than common probabilistic sources) [12,13]. hBN SPEs have also been shown to be electrostatically tunable, near lifetime-limited [14], and indistinguishable [15]. Further, hBN emitters have been coupled to nanophotonic structures both in monolithic hBN photonic platforms [16] and hybrid silicon nitride (Si_3N_4) platforms [17].

II. Methods

For our physically robust model, we embed a two-level emitter into the solution for a 1D waveguide (1DWG) in the spatial domain, following a similar derivation to existing models [18,19]. In Eq. 1, derived from considering two excitations in the model, we determine the number of right traveling photons (N_R) at a fixed point by integrating the photon number density (n_R) (defined by Eq. 2) over time.

$$N_R(x) = v_g \int_{t_1}^{t_2} dt\, n_R(x,t) \tag{1}$$

$$n_R(x,t) = |\beta_R(x,t)|^2 + 4\int dx' \left|\gamma_{RR}(x,x',t)\right|^2 + 4\int dx' \left|\gamma_{RL}(x,x',t)\right|^2 \tag{2}$$

$\beta_R(x,t)$ is the complex probability density denoting the combined probability of a single R-traveling photon and the excited state of the emitter. The functions $\gamma_{ij}(x_1,x_2,t)$ represent complex probability densities of the combinations of two photons and the ground state of the emitter. v_g is the group velocity. The limits of integration in Eq. 2 span a detection time gate. Our model of one and two excitations is based upon Ref. 10 and 19. We also include additional number of excitations and perform further statistical calculations.

To advance towards experimental demonstration of deterministic photon addition in a waveguide, we design in simulation an hBN nanowaveguide structure to promote high coupling to a single-mode Si_3N_4 waveguide. Full-wave simulations were performed using a finite difference time domain (FDTD) optical simulation (Tidy3D FDTD). The hBN refractive index was modeled as a custom diagonal anisotropic material using Phillips–van Vechten model and experimental parameter fitting [20]. A downloadable Jupyter Notebook with full simulation details can be found at Ref 21.

To fabricate this device, we first exfoliate hBN flakes onto thin film low pressure chemical vapor deposited Si_3N_4 on a silicon dioxide and silicon substrate. To form SPE defects in the hBN we anneal at atmospheric pressure while flowing argon at 850°C for 30 min. SPEs are characterized with photoluminescent (PL) spectroscopy and second order correlation measurements in a homebuilt mapping confocal microscope. The nanowaveguide pattern is aligned to an individual defect. We use electron-beam lithography and reactive ion etching to fabricate the hBN nanowaveguide and Si_3N_4 waveguide.

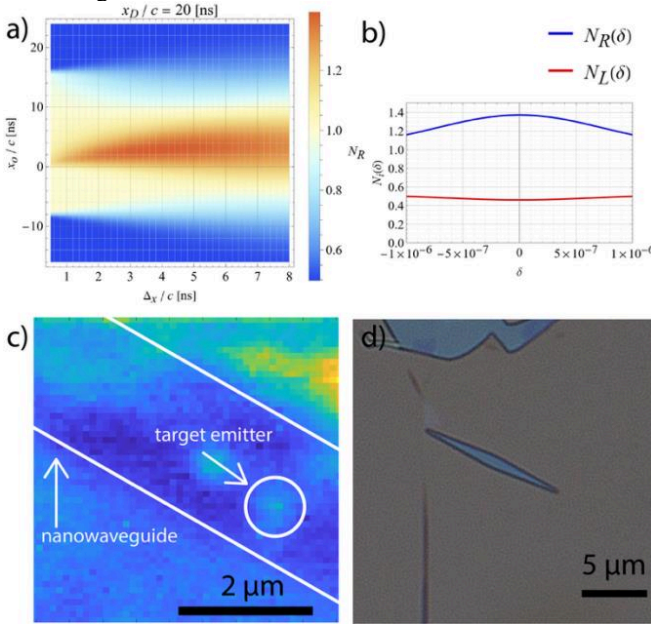

Fig. 1 (a) Parameter plot showing the number of R-traveling photons as integrated through time at a fixed observation point with spatial offset on the y-axis and linewidth detuning on the x-axis. (b) Simulated time-gated photon number measurements for the detuned pulse interacting with the initially excited emitter. (c) PL map of hBN SPE coupled in nanowaveguide. (d) Optical image of patterned and etched active hBN nanowaveguide.

III. Results and Discussion

In this work, we advance the theoretical understanding of stimulated photon addition through the interaction of an emitter and one-dimensional waveguide (1DWG) and make progress towards high coupling between an hBN SPE and a Si_3N_4 waveguide [10]. We use the model described in Methods to simulate photon addition using a nominal case in which the two-level emitter is excited, and a right traveling photon pulse interacts with the emitter. Qualitatively, increasing the spatial overlap between the pulse and emitter significantly alters the emission dynamics with respect to the spontaneous emission case, consistent with stimulated emission. This model can also be integrated into a photon statistic framework like the one used in previous work with a more simplistic numerical model [10]. This allows us to begin addressing questions regarding the ratio of spontaneous to stimulated emission during a deterministic photon addition event, which remains a critical and unanswered question. We also use this model to investigate the effect of detuning the pulse linewidth with respect to the emitter lifetime and the pulse frequency, with the number of right-traveling photons qualitatively relating to stimulated emission. As shown in Fig. 1(a), the emission dynamics and number of right-traveling photons are sensitive to the spatial overlap, showing the greatest number of right-traveling when the pulse is overlaps the emitter by an offset equivalent to around one emitter lifetime of 3 ns. The tolerance increases slightly for wider pulse widths. The dynamics are fairly robust to linewidth detuning (Fig. 1(a)) and frequency detuning (Fig. 1(b)) (only varying by 15% over a span of detuning commensurate with the coupling strength).

Working towards validating these theoretical predictions experimentally, we design and fabricate an emitter-containing a hBN nanowaveguide coupled to a Si_3N_4 waveguide. For a simulated spontaneous dipole emission, this design has 34% coupling in one direction. We have successfully fabricated a passive (no emitter) hBN nanowaveguide on top of a Si_3N_4 waveguide using electron-beam lithography and an active (emitter-containing) hBN nanowaveguide on a Si_3N_4 thin film (Fig. 1(c-d)). Further fabrication of a Si_3N_4 waveguide and grating coupler beneath the active hBN nanowaveguide will yield a favorable platform for experimentally probing deterministic photon addition in a waveguide. Through a robust analysis of photon statistics as we have previously demonstrated with hBN SPEs [22], we will characterize photon addition by examining detected photon distributions for non-classical peaks like those in Ref. 3. Using this device we will validate our theoretical results, particularly those assessing the impact of spatial mode overlap and frequency detuning on the photon addition mechanism and stimulated emission dynamics.

IV. Conclusion

Through our emitter-1DWG modeling and highly coupled emitter-waveguide device design we make significant advancements towards experimental deterministic photon addition. A deterministic photon addition platform provides a foundation for significantly increased experimental photon addition rates. Better photon addition rates enable more

efficient non-Gaussian state generation as a quantum computing or networking resource. Deterministic photon addition is also an ideal system to experimentally demonstrate theoretical predictions for quasi-lossless SNR enhancement of weak signals, whereas probabilistic photon addition may not provide sufficient photon additions to significantly amplify SNR. Finally, the higher photon addition coincidence rate of deterministic photon addition provides a pathway towards multiple sequential photon additions, which enables more exotic state generation and further SNR enhancement. While significant challenges remain in the pursuit of multiple sequential photon additions, with deterministic photon addition this becomes and engineering challenge rather than an intrinsic limitation. As such, the first experimental demonstration will represent a monumental step towards efficient cascaded single photon addition modules.

***Abstract*—The pole expansion of the optical scattering matrix provides a fast and insightful route to investigate nanophotonic systems. However, conventional scattering channels from Mie theory result in matrices that exponentially diverge in the complex frequency plane, preventing simple pole expansions. We discuss different rescaling approaches to regularize the scattering channels.**

***Keywords*— scattering matrix, resonant states, pole expansion, metamaterials**

I. Introduction

In this work, we investigate the optical scattering matrix and its pole expansion in terms of optical resonances for spherical particles. The scattering matrix, which connects the incoming and outgoing waves of a scatterer, plays a central role in describing light-matter interaction at the nanoscale [1]–[7]. Since analytic solutions for the scattering matrix are only available for few systems, theoretical calculations typically rely on computing fullwave simulations of Maxwell's equations. However, such calculations are time-consuming and provide little insight into the underlying physics.

Recently, the pole expansion of the scattering matrix has been established as a powerful tool for replacing full-wave simulations [5], [8]–[14]. This type of expansion based on the optical resonances of the system, also known as resonant states or quasi-normal modes, is not only faster than conventional calculations of the scattering matrix, but also provides additional insight into resonant dynamics [15], [16].

However, to apply the pole expansion the scattering matrix have to satisfy certain prerequisites. This is particularly crucial for the Mittag-Leffler expansion — a variant of the pole expansion that only requires knowledge about poles and residues as well as one background term. While the ML expansion is often successfully applied in literature, its validity is rarely considered rigorously from first principles. Remarkably, the prerequisites for the Mittag-Leffler expansion are not fulfilled for the most-commonly known scattering matrix from Mie theory [17], since this scattering matrix exhibits exponential divergences in the complex plane, as shown in Fig. 1(a) and (b).

Fig. 1. Pole structure in the complex kR plane (left panels) and asymptotic behavior for $kR \to \pm i\infty$ (right panels) of the optical scattering matrix S for different regularizations of the analytic scattering matrices $S^{\mathrm{Mie}}_{\mathrm{TE},\ l=3}$, $S^{\mathrm{R1}}_{\mathrm{TE},\ l=3}$ and $S^{\mathrm{R2}}_{\mathrm{TE},\ l=3}$. The left panels show $|S(k)|$ in the complex plane, where red circles indicate poles originating from optical resonances (Ω_{p}), and black squares indicate poles introduced by the regularization of the channels (Ω_{c}). (a) $S^{\mathrm{Mie}}_{\mathrm{TE},l}$ with channels commonly used in Mie theory. The gray dashed line indicates the cut along the imaginary axis for which $S^{\mathrm{Mie}}_{\mathrm{TE},l}$ is depicted in (b), showing the asymptotically exponential divergence of $S^{\mathrm{Mie}}_{\mathrm{TE},l}$ for $kR \to i\infty$. (c), (d): Asymptotically regularized $S^{\mathrm{R1}}_{\mathrm{TE},l}$ channel that removes exponential divergence. (e), (f): Global regularization $S^{\mathrm{R2}}_{\mathrm{TE},l}$, which also removes the exponential divergence but introduces artificial poles coming from the underlying channels.

II. Results

We demonstrate that a Mittag-Leffler expansion of the scattering matrix becomes possible through an appropriate rescaling of the basis, i.e., the incoming and outgoing waves, and provide a rigorous framework on how this rescaling of the basis affects the scattering matrix. We show that appropriate rescalings make it possible for the scattering matrix $S(k)$ to fulfill the prerequisite of the (first-order) Mittag-Leffler theorem on its asymptotics, which is

$$\lim_{k\to\infty} |S(k)/k| = 0, \tag{1}$$

where k is the wavenumber. We refer to the process of removing divergences of $S(k)$ in the complex k plane as

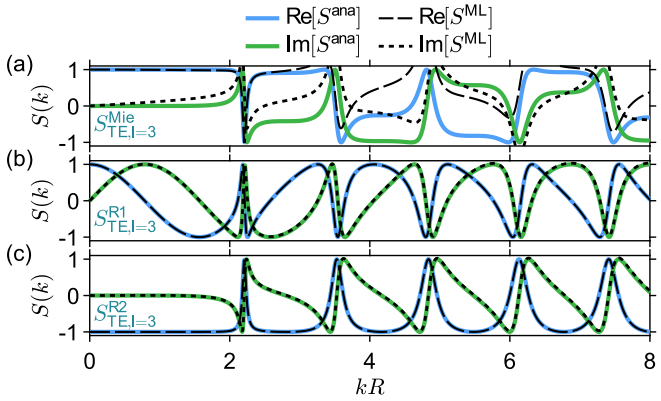

Fig. 2. Real (blue) and imaginary parts (green) of the different analytic scattering matrices $S^{\mathrm{ana}} \in \{S^{\mathrm{Mie}}_{\mathrm{TE},l=3}, S^{\mathrm{R1}}_{\mathrm{TE},l=3}, S^{\mathrm{R2}}_{\mathrm{TE},l=3}\}$ for real kR, compared with the pole expansions S^{ML} (black). Here, S^{ML} denotes the Mittag-Leffler (ML) expansions, where for (a) and (b) only physical poles were used while for (c) additionally the channel poles are used. Note that the residues also differ for the three cases and, thus, both S^{ana} and S^{ML} depend on the channels, so that even the analytic reference differs in all three cases. The pole expansions were computed using 201 physical poles.

regularization and we show that this enables the application of the Mittag-Leffler theorem to the scattering matrix.

Moreover, we demonstrate that the choice of rescaling is not unique and that certain choices can fundamentally alter the analytic continuation of the scattering matrix. We identify the emergence of additional, regularization-dependent poles, referred to as channel poles, that do not originate from the optical resonances of the system, as shown by the black squares in Fig. 1(e). Furthermore, we demonstrate that other regularizations do not require such channel poles, rendering them as a convenient choice in most practicable applications, as displayed in Fig. 1(c) and (d).

Figure 2(a) shows that the Mittag-Leffler expansion fails to describe the real-valued spectra of channels derived from Mie theory, whereas it accurately reproduces the regularized channels, as illustrated in Fig. 2(b) and (c).

III. Conclusion

In conclusion, we have shown that, by rescaling the channels of the scattering matrix, one can modify its analytic continuation to the complex frequency plane in distinct ways. Our results suggest that the regularization of the scattering matrix can enable efficient pole expansion schemes for more complex three-dimensional scatterers, thereby broadening the range of systems accessible to modal analysis in photonics.

***Abstract*—Advances in spatiotemporal material modulation have enabled synthetic motion, emulating electromagnetic responses of moving objects without physical displacement. We assess how faithfully synthetic motion reproduces true motion, using both Galilean and Lorentz protocols. By analysing wave reflection and hybrid real–synthetic motion, we isolate which dynamical effects are genuinely reproduced.**

***Index Terms*—time-varying metamaterials, Galilean and Lorentz synthetic motion, spacetime modulation.**

I. Introduction

Recent work in space-time modulated metamaterials suggests stationary structures can reproduce relativistic phenomena like Doppler shifts. [1] However, it remains unclear in which ways synthetic motion may be electromagnetically equivalent to genuine physical motion. A moving interface alters scattering via frame transformation, whereas synthetic motion relies on explicit modulation of material parameters. Although both generate similar frequency shifts, the underlying mechanisms are distinct. This work compares reflection of a normally incident plane wave from (i) a physically moving surface, (ii) a surface in Galilean synthetic motion and (iii) a surface in Lorentz synthetic motion to determine the limits of this equivalence. Our work lies in parallel to other investigations of spacetime modulation [2] [3].

II. METHODS

We consider a normally incident monochromatic TE plane wave (electric field along $\hat{y}$) impinging on a planar interface at $z = 0$ as in Figure 1. Region 1 ($z > 0$) is vacuum, while Region 2 ($z < 0$) is a non-magnetic dielectric with spatially periodic permittivity

$$\varepsilon_r(x) = \varepsilon_b + \Delta\varepsilon \sin(Kx).$$

Due to the spatial periodicity, the fields are expanded into discrete Floquet diffraction orders. [4] In Region 1, the reflected field is written as a superposition of these orders, with longitudinal components determined by the vacuum dispersion relation, distinguishing propagating and evanescent modes.

In Region 2, Fourier expansion of the permittivity and field converts the Helmholtz equation into a coupled system in diffraction-order space. For sinusoidal modulation, only nearest neighbours couple. The system is written in matrix form and solved via a Bloch eigenvalue problem, yielding the longitudinal propagation constants and modal structure of the periodic medium.

Enforcing continuity of the field and its normal derivative at the interface leads to a linear system for the reflection

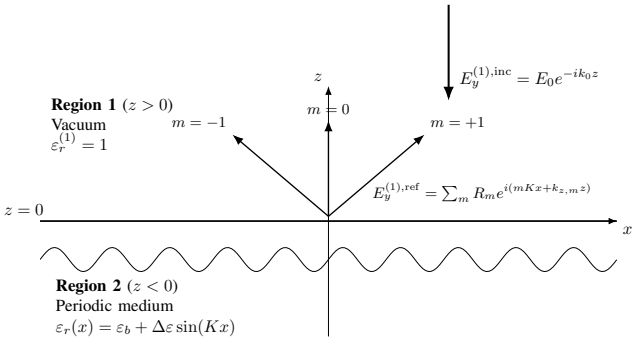

Fig. 1: Normal-incidence TE scattering from a sinusoidally modulated permittivity interface.

amplitudes, from which a closed matrix expression for the reflected-order vector is obtained.

$$\boxed{\mathbf{R} = (M - K_z)^{-1} \left[-(k_0 I + M)\, \mathbf{e}^{(\mathrm{inc})} \right]}$$

Here:

- $K_z = \mathrm{diag}(k_{z,m})$ contains the longitudinal reflected wavenumbers,
- I is the identity matrix,
- $\mathbf{e}^{(\mathrm{inc})}$ has only the $m = 0$ component equal to the incident amplitude E_0,
- M encodes the Bloch-mode response of the periodic medium.

In practice the Floquet expansion is truncated at a finite maximum order to obtain numerical solutions.

Dynamic extensions of the system are constructed directly from the static solution described above. For a surface translating along x, the problem is treated in the instantaneous rest frame of the interface, where the modulation is static and the incidence becomes oblique. The reflected modes are computed using the same formalism and then Lorentz-transformed back to the laboratory frame, yielding Doppler-shifted frequencies and modified reflection angles.

Synthetic motion is introduced through travelling-wave modulation of the permittivity, $\varepsilon_r(x) = \varepsilon_b + \Delta\varepsilon \sin(Kx - \Omega t)$, rendering the system periodic in both space and time. The field is therefore expanded in double Floquet indices, producing a coupled system in spatial and temporal orders derived from Maxwell's equations. In the Lorentz synthetic case, relativistic length contraction is incorporated into the modulation profile,

Fig. 2: The left plot corresponds to the reflected modes in $k-\omega$ space for the case of real physical motion. On the right, the same phase space diagram is plotted for Lorentz synthetic motion. The larger points represent propagating modes and the smaller ones are evanescent. The colours represent the amplitude of the modes.

$\varepsilon_r(x) = \varepsilon_b + \Delta\varepsilon \sin(\gamma K(x - vt)$, while the coupled-mode structure remains formally unchanged.

We introduce a hybrid configuration, where physical motion and synthetic modulation both occur with equal and opposite velocity. The resulting space–time scattering problem is solved in the surface frame and subsequently transformed back to the laboratory frame.

III. RESULTS AND DISCUSSION

Physical and synthetic motion are compared through the spectral structure (Figure 2) and energy distribution of the reflected field. In the frequency–momentum diagrams, the most intense modes produced by Lorentz synthetic modulation follow the same qualitative structure as those of genuine motion, although they do not coincide exactly. In hybrid configurations with equal and opposite velocities, the dominant modes become approximately monochromatic, indicating some form of cancellation for the leading Doppler shifts.

The distinction becomes clearer in the angular and energetic response. Lorentz synthetic modulation captures the principal trends of physical motion more faithfully than the Galilean protocol, yet discrepancies remain in the intensity distribution across diffraction orders. These differences persist in the total reflected power. We also investigate whether synthetic motion may be used for amplification purposes.

IV. CONCLUSION

We have examined to what extent synthetic motion can reproduce the electromagnetic response of genuine physical motion. Although both Galilean and Lorentz protocols reproduce Doppler-like frequency shifts, only the Lorentz construction can combine with physical motion to cancel certain features associated with motion. Even then, the agreement is largely confined to the most intense modes.

Crucially, discrepancies persist in the modal amplitudes and the reflected power. These differences indicate that matching dispersion relations is not sufficient to establish dynamical equivalence. Genuine motion corresponds to a Lorentz-covariant transformation of the full electromagnetic constitutive response, whereas synthetic implementations, so far, have only been able to modulate a scalar permittivity.

Synthetic motion can therefore reproduce certain aspects of moving interfaces, but it does not establish full physical equivalence. These results help delineate both the reach and the limitations of space–time modulation as a surrogate for genuine motion.

***Abstract*—We present strong coupling between excitonic and both localized and delocalized plasmonic modes in the near-field of a multi-resonant nanoparticle-on-mirror array integrated with a WSe_2 monolayer using interferometric time-resolved photoemission electron microscopy.**

***Keywords*— hybrid plasmon-photon modes, transition metal dichalcogenides, strong coupling, plasmonic cavity, photoemission electron microscopy.**

The combination of metallic nanostructures and two-dimensional transition metal dichalcogenides (TMDs) has steadily gained momentum as a robust platform to form hybrid light-matter states by strongly coupling excitons with plasmonic resonances. TMDs are particularly interesting because of their evolution to a direct bandgap at the monolayer level, enabling light absorption and emission through excitonic transitions [1]. When combined with nanostructures, and thus forming metasurfaces, these materials can be tuned to address and manipulate their photoemission by coupling with resonant optical nanocavities and arrays [2], [3], [4]. The tunability of these devices has been of great interest in various fields, such as single photon generation [5], [6], light manipulation [7] and sensing [8], [9], with applications in surface-enhanced Raman spectroscopy (SERS) [10], ultra-fast optical switching [11], [12] and biosensing [13].

In light-matter coupling, we distinguish between weak and strong coupling regimes. The weak coupling regime in monolayered TMD based nanostructures emerges primarily as an increase in photoluminescence intensity without a significant change in the emission spectrum. This enhancement is a result of the Purcell effect, which improves the quantum yield by boosting the local density of optical states [14]. This effect is highly dependent on the nanocavity Q-factor and the effective mode volume V. Gap plasmonic modes, which arise in the nanometric spacers between plasmonic components, are of special interest here due to their ability to achieve extreme field confinement and small mode volumes.

Moving into the strong coupling regime requires overcoming the high dissipative losses inherent in plasmonic cavities. This regime is fundamentally defined by a distinct spectral splitting into upper and lower polariton branches, resulting in a characteristic anti-crossing signature in the energy-momentum dispersion when the exciton and plasmonic cavity modes are in resonance. To address the dissipative challenges in achieving strong coupling, the nanoparticle-on-mirror (NPoM) geometry serves as a particularly interesting architecture [15]. In our NPoM array system [16], the localized surface plasmon (LSP) is created by the intense field enhancement within the sub-nanometer gap between the gold nanoparticle and the underlying metallic film. Simultaneously, the periodic or semi-infinite nature of the mirror surface allows for the excitation of delocalized propagating surface plasmon polaritons (SPPs) that can be tuned via the illumination angle. First, we show LSP-SPP hybridization in our NPoM array that enables both low mode volume (gap mode) and manageable dissipation. Secondly, we integrate a WSe_2 monolayer in this multi-resonant cavity and measure an effective coupling strength of 140 meV between excitons and coupled LSP-SPP, which surpasses Rabi splittings in typical individual nanorod layouts on WSe_2 flakes of approximately 106 meV [17].

To probe these dynamics, we employ interferometric time-resolved photoemission electron microscopy (ITR-PEEM), an advanced imaging technique that bypasses the diffraction limits of traditional optics. While far-field spectroscopy offers an ensemble-averaged view of energy shifts, ITR-PEEM enables a direct way to capture the precise spatial distribution of the electromagnetic fields and thus a direct measure of light absorption. By employing ultra-short laser pulses in an interferometric configuration, we resolve the ultrafast dephasing of excitonic and plasmonic modes with femtosecond timing

resolution, while directly capturing their spatiotemporal propagation dynamics across the surface.

***Abstract*— Room-temperature manipulation of mid-infrared radiation is hindered by weak light–matter coupling and thermal dissipation. We design and fabricate a plasmonic bilayer resonant metasurface that enhances absorption in the mid-IR and enables quantitative evaluation of the resulting temperature rise, offering a pathway toward improved photonic sensing and thermal detection.**

***Keywords*— Metamaterials, Plasmonics, mid-IR detection, SERS**

I. Introduction

The mid-infrared (mid-IR) spectral range (2–20 μm) in the electromagnetic spectrum is of significant importance due to its applications in various fields, including molecular sensing, gas sensing, atmospheric monitoring, biomedical imaging, free-space communication, and energy harvesting. Unlike the visible or near-infrared regions, mid-IR radiation is challenging to detect due to its low photon energy and the influence of thermal noise, which complicates room-temperature detection and limits practical applications.

Recent developments in mid-IR detector technologies, particularly those based on emerging materials and metasurface engineering, offer promising pathways toward more efficient and cost-effective mid-IR sensing solutions and allow wavelength selective detection. Plasmonic Metamaterials are interesting due to their ability to convert light into heat through localized surface plasmons resonance (LSPR) and propagating surface plasmon resonance (PSPR).

Here we designed and fabricated plasmonic Mid-Infrared Disc-Coupled Hole Array (MDHA) system and investigated its mid-IR thermosensing properties using anti-Stokes Raman thermometry.

II. Methods

The MDHA, consisting of array of polymer micropillars with gold disks on the top and a perforated hole-film at the bottom seperated by a dielectric layer (Figure 1), fabricted using two photon polymerization techniques followed by sputtering of gold.

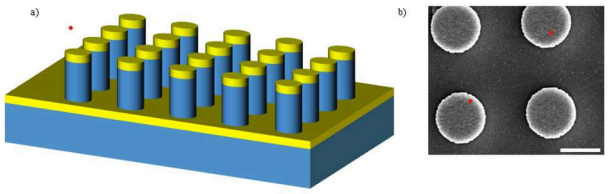

Figure 1: a) Geometry of MDHA The structure consists of a periodic array of cylindrical pillars with a diameter (D) of 5 μm, height (H) of 5 μm, and periodicity (Λ) of 10 μm. b) SEM image of the fabricated structure. The scale bar is 5 μm.

The designed MDHA structure facilitates two channel coupling of mid-IR and NIR light coupling. The mid-IR light (4.6μm) illuminated from the top side couples directly with the MDHM modes whereas tightly focused NIR light at 785nm is coupled through the glass substrate and through the polymer pillar (Figure 2 a). Thus, mid-IR light resonantly gets absorbed on the disc and forms temperature gradient between the top disc layer and the bottom hole film.

The difference in the temperature to top and bottom layer is measured through Surface-Enhanced Raman scattering (SERS) thermometry. The temperature rise induced by the mid-IR laser is estimated from the ratio of the anti-Stokes intensity measured with and without mid-IR excitation using the following equation,

$$\ln\left(\frac{I_m}{I_0}\right) = \frac{\Delta E}{k_B}\left(\frac{1}{T_0} - \frac{1}{T_M}\right) \quad (1)$$

Here T_0 is the refererence temperature, we use $T_0 = 300\ K$ and T_M is the temperature introduced in the presnce of mid-IR, I_m and I_0 are the anti-Stoke intensity with and without the presence of mid-IR radiation, k_B is the Boltzman constant and ΔE is energy difference between incident and scattered photon.

III. Results and Discussion

Upon illumination with the mid-IR laser, a temperature rise (ΔT) of approximately 2 K was observed between the top disc and the bottom film aperture, originating from absorption of the incident radiation by the gold disc. By linearly increasing the excitation power and monitoring ΔT, we find a proportional relationship, indicating that higher mid-IR input leads to greater absorption within the MDHA and a corresponding linear conversion of optical energy into heat.

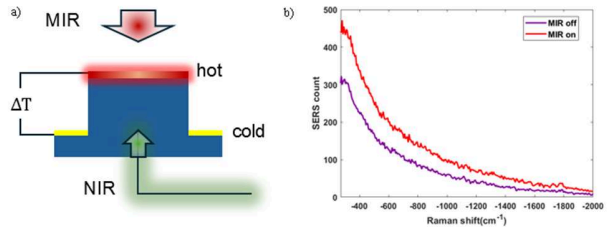

Figure 2: a) Experimental configuration for mid-IR thermosensing measurements using a Raman spectrometer. The MDHA array is illuminated with a mid-IR laser (λ=4.6 μm) from the top metal disc and a near-infrared (NIR) laser (λ=785 nm). b) Anti Stoke SERS spectra with and without mid-IR showing a change in background due to mid-IR absorption.

Under an incident optical power density of $0.727\,\frac{\mu W}{\mu m^2}$, the structure exhibits a detectable temperature modulation corresponding to a thermal response on the order of $10^{-6}\,\frac{W}{\sqrt{Hz}}$, indicating its potential sensitivity at room temperature.

IV. Conclusion

We designed and fabricated a plasmonic bilayer resonant metasurface to enhance mid-IR absorption through engineered optical confinement. The structure supports spectrally selective resonances that increase the interaction between incident radiation and the absorbing layer, leading to a measurable photothermal response under ambient conditions. Local temperature rises induced by mid-IR absorption are quantified using non-contact Raman thermometry, allowing direct evaluation of the thermal response without perturbing the system. Potential applications include thermal imaging, chemical sensing, and mid-IR energy harvesting.

***Abstract*— Periodic plasmonic nanostructures were fabricated on silver, gold, and silver-gold thin films using single ultrashort laser pulses. Grating-coupled resonances exhibit sharp spectral peaks and a high refractive-index sensitivity up to 930 nm/RIU. The Ag-Au nanobump arrays demonstrate enhanced performance stability and repeatability, highlighting their potential for scalable plasmonic sensing platforms.**

***Keywords*— plasmonics, direct laser writing, sensing, periodic arrays.**

I. Introduction

Plasmonic nanostructures arranged in a periodic manner have gained significant attention owing to their distinctive optical response and strong light-matter interaction at the nanoscale. For large-scale applications and integration into practical devices, a reliable, rapid, and highly reproducible method is essential. Conventional lithographic and chemical approaches, while providing high resolution, often suffer from limited throughput, scalability, or multi-step process complexity. Therefore, alternative strategies are actively sought. Direct laser writing (DLW) technique based on single femtosecond pulse exposure of thin metallic films represents a promising single-step approach and is employed in this work for the production of periodic plasmonic arrays with high precision and repeatability [1]. Localized laser irradiation induces melting of the thin metallic films, and subsequent resolidification under strong thermal stresses results in the formation of complex nanostructures, including hemispherical bumps, pyramid-shaped cones, and jets having a sharp spike [2]. Periodic arrangement of these nanostructures results in the excitation and hybridization of several plasmonic modes, leading to the enhanced optical characteristics. Upon interaction with electromagnetic radiation, structures exhibit strong local field enhancement and increased absorption at resonant frequencies. These phenomena are fundamental to application in surface-enhanced Raman spectroscopy (SERS) and plasmonic sensing. Therefore, the fast production with flexible tuning of the properties is in demand.

Plasmonic sensing exploits the sensitivity of nanostructured metallic surfaces to local refractive index (RI) variations near the metal-dielectric interface. Changes in the surrounding RI led to spectral resonance shifts, enabling real-time and label-free detection of DNA, biomolecules, analytes, or liquids [3]. In the latter applications, variations in concentration directly lead to RI changes, allowing rapid and accurate detection of pollutants. Performance of such sensors depends on the plasmonic coupling, therefore strategies aimed at reducing the linewidth of the resonances are actively pursued. Metallic gratings produce sharp and narrow resonant peaks arising from hybridization of plasmonic modes, while also offering device compactness since the bulky prism used in conventional plasmonic sensors is eliminated. By implementing DLW for such platform fabrication, free-form, easily scalable, and large-area sensing zones can be manufactured in a rapid manner with tailored optical responses of required parameters [4]. Here, we present a single-step DLW-based fabrication of a plasmonic sensing platform and its characterization using a glycerol solution of various concentrations.

II. Methods

Ultrafast fs laser (Pharos, Light Conversion) with a 343 nm wavelength was used for nanostructure fabrication in metallic films. Thin gold (50 nm), silver (50 nm), and silver-gold (25-25 nm) layers were deposited on microscopic soda-lime glasses using a magnetron sputter coater. The laser beam was then tightly focused onto the surface using a high-NA objective (NA=0.5) into a spot of 0.8 μm in diameter. Thin films were modified using pulse energies in the range of 0.46-0.55 nJ to produce hemispherical nanobumps. Laser scanning with an implemented pulse picker was employed to produce a square 3×3 mm^2 array with 0.8 μm period. The samples were characterized using a scanning electron microscope and an optical microscope. Finally, the sensing platform (Figure 1a) was finished by attaching an adhesive chamber (HybriWell-FL) over the structured area.

For sensing measurements, ultrapure water and glycerol solution in water of 4 different concentrations were used. Ellipsometric measurements were performed to determine the RI of the measured liquids at 658 nm wavelength, and the Sellmeier equation was used to calculate the dispersions for the whole investigated wavelength range. Sensing performance was determined by measuring the reflection with a spectrophotometer in the range of 600-1400 nm with a step of 1 nm. Response was measured for both s- and p-polarization at

an 8° angle, with additional measurements at 15°, 30°, 45°, and 60°. The whole characterization consisted of a reflectance measurement in an air environment, liquid infusion into a chamber, reflectance measurement in a liquid environment, and a liquid extrusion. Such a cycle was repeated for 3 times to ensure the stability of the platform.

The platform was evaluated by calculating the quality factor of the resonant peaks, as well as the figure of merit (FOM) and sensitivity. The latter was described as:

$$S = \frac{\Delta \lambda_{res}}{\Delta n}, \#(1)$$

where $\Delta\lambda_{res}$ is the resonant peak shift, and Δn is the change in RI. Meanwhile, the FOM was determined by dividing S by the full width of the resonant peak at its half depth.

III. Results and Discussion

The periodic arrays of gold, silver, and silver-gold bilayer nanobumps were produced on 50 nm thick layers with a grating period of 0.8 µm. The geometrical dimensions of the structures were intentionally kept similar to ensure that variation in height and shape would not impact the optical response, thereby allowing a direct comparison of different metallic samples. By measuring the spectral response in air, water, and glycerol solutions of 1.7%, 3.4%, 5.1%, and 6.8%, a clear resonance redshift with increasing RI was observed (Figure 1b). Detailed analysis showed that each diffraction-based resonant peak (m=±1 in *s*-polarization and m=-1 and m=+1 at *p*-polarization) exhibits a slightly different shift and is evaluated individually. Among these, the m=-1 peak demonstrated the highest sensitivity, with values up to 870 nm/RIU. The metal comparison revealed that while silver nanobumps exhibit the largest sensitivity values, the bilayer sample shows intermediate sensitivities, with better performance than gold grating. This suggests that the Ag-Au configuration is optimal for a sensing platform, as the upper gold layer protects the silver from oxidation while the bimetallic combination enhances plasmonic properties. Consecutive measurements confirmed excellent repeatability and demonstrated that the platform provides a stable performance.

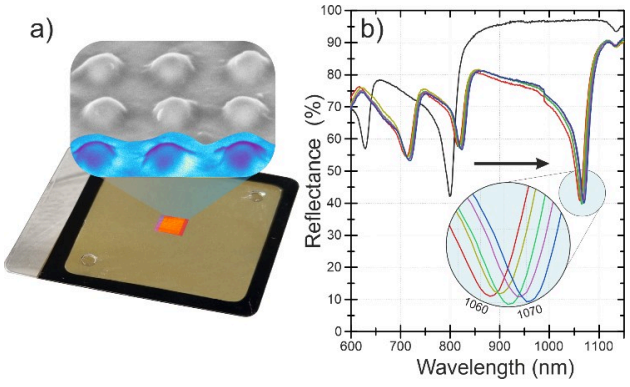

Fig. 1 a) Nanobump sensing platform. b) Reflectance spectrum with a resonance shift.

After determining the optimal metal configuration, additional measurements were carried out for the Ag-Au sample at varying angles of incidence. Since grating-coupled resonances are highly angle-dependent, both resonance position and sensing performance were influenced by this parameter. With increasing angle of incidence, peak qualities, sensitivities, and FOMs either increased or decreased depending on the resonance diffractive origin. For the m=±1 peak, the sensitivity increased up to 933 nm/RIU at 60° angle. However, this was accompanied by peak broadening, resulting in reduced FOM. In contrast, the m=-1 resonance exhibited a slight decrease in sensitivity while maintaining its width with a remarkable redshift, leading to an increase in FOM from 25 RIU^{-1} to 57 RIU^{-1}. It was also observed that, at certain angles, some resonant peaks overlapped with water absorption zones, thus limiting their applicability.

Finally, the durability and reusability of the sample were investigated by performing spectral measurements after 6 months. Despite the storage for a long time, the resonance positions remained unchanged with similar peak sensitivities and highly repeatable results. These findings confirm the robustness of the sensing platform and its suitability for prolonged measurements.

IV. Conclusion

We have demonstrated periodic nanobump arrays fabricated using direct laser writing on gold, silver, and silver-gold bilayer films and evaluated their performance as refractive index sensing platforms. Grating-coupled resonances have pronounced dips in reflectance spectra, which exhibit accurate redshifts with increasing RI of the surrounding medium. Among the investigated structures, the silver-gold bilayer showed the greatest sensing parameters with combined favorable properties of both plasmonic metals. Individual resonant peaks demonstrate distinct sensitivities, which can be improved even more by tuning the angle of incidence. This allows reaching the sensitivity of 933 nm/RIU and FOM of 57 RIU^{-1}. The platform also demonstrates high stability and repeatability of the results over an extended period of time. Overall, the results highlight direct laser writing as a rapid and scalable technique for high-performance plasmonic sensors suitable for environmental and biochemical applications. Future work will extend the platform application for biomolecule binding to the surface and their detection.

Benchmark Study Using Machine Learning Surrogate Models for Predicting Optical Spectra of Tungsten Bronze Nanospheres Based on Mie Theory

Yuanchao Lu[1], Ruixing Li[1,*]

[1]School of Materials Science and Engineering, Beihang University, China
*Corresponding author: 1499149583@qq.com

***Abstract* — We compared three regression models for predicting absorption spectra of tungsten bronze nanospheres with anisotropic dielectric response, approximated by two independent isotropic Mie calculations. The Random Forest achieved higher accuracy than the Multilayer Perceptron and XGBoost under interpolation. All models lost predictive ability when extrapolating beyond the training radius range.**

***Keywords*— machine learning, Mie theory, surrogate model, tungsten bronze.**

I. Introduction

Nanoscale tungsten bronzes (M_xWO_3, M = alkali metal, $0 < x < 1$) exhibit strong localized surface plasmon resonance (LSPR) in the near-infrared region, showing potential for applications in areas such as smart windows, photothermal therapy, and selective absorbers[1]. The optical absorption of nanoparticles is generally sensitive to particle size and morphology[2]. For ideal spherical particles, Mie theory provides an analytical solution to Maxwell's equations and can be used to calculate absorption spectra[3]. In practice, tungsten bronze nanoparticles often exhibit faceted or non-spherical anisotropic morphologies, for which the analytical solution of Mie theory is, strictly speaking, no longer applicable, and numerical methods such as the finite-difference time-domain (FDTD) method are usually needed[4]. On the other hand, if the particle shape is temporarily approximated as a sphere, two independent isotropic Mie calculations can be performed using the dielectric functions along the a-axis and c-axis, respectively. This provides a large amount of accurate analytical training data for benchmarking surrogate models in an exactly solvable system.

Machine learning surrogate models can learn the mapping from structural parameters to spectra from a modest amount of simulation data, significantly accelerating predictions.[5] However, most existing studies test only a single model or report successful cases, and a systematic understanding of the performance differences and applicable ranges of different methods in similar systems is still lacking[6]. Before directly dealing with complex real systems where shape and dielectric anisotropy are coupled, we believe it is necessary to first carry out a comparison within a controllable, analytically tractable, and idealized framework.

Inspired by the experimental practice of separately measuring and averaging spectra under different polarization directions to analyze anisotropic particles, we decompose the dielectric anisotropy of hexagonal tungsten bronze into two independent isotropic Mie scattering problems, phenomenologically defined by the principal dielectric functions: ε_a and ε_c[7]. This gives two independent, noise-free, idealized spectral mapping problems. The two problems follow similar variation trends, yet the distinct principal dielectric parameters introduce subtle differences, together forming a fundamental benchmark for testing the ability of regression models to capture spectral features and generalize. With this simplification, we can clearly evaluate the interpolation accuracy and extrapolation limits of different models on data with zero numerical noise, thereby offering a preliminary reference for future applications of surrogate models in more realistic systems.

In this work, three widely used regression models—Multilayer Perceptron (MLP), Random Forest (RF), and XGBoost (XGB)—are benchmarked. These three models span different algorithm families—neural networks, bagging, and boosting—allowing a comparison of their suitability for spectral surrogate modeling. Using Mie-theory-calculated spectra as the training and test datasets, and considering the optical absorption properties and application requirements of tungsten bronzes, this study is confined to the visible–near-infrared range of 350–2000 nm, with the spectral responses based on the a-axis and c-axis treated separately.

II. Methods

2.1 Dataset Generation

Standard Mie theory calculations were performed using the a-axis dielectric function ε_a and the c-axis dielectric function ε_c, respectively. The resulting absorption cross sections C_{abs} were volume-normalized to give the volume absorption coefficient α_{abs}; this removes the volume scaling effect of particle size on the absorption cross section and highlights the intrinsic absorption strength of the material, making the results more directly comparable with experimentally measured bulk absorption spectra. Calculations were carried out for radii from 1 to 200 nm with a step size of 1 nm, yielding 200 radius samples. The experimental values of ε_a and ε_c were both taken from Ref. [7].

For each radius, we performed Mie calculations using ε_a and ε_c separately, producing two independent spectra. Although in typical experiments an ensemble of randomly oriented nanocrystals yields a polarization-averaged spectrum, we kept these two independent spectra in the training set to capture as much of the intrinsic optical anisotropy of the material as possible. All spectra were initially calculated at 1 nm intervals over the 350–2000 nm range, covering the LSPR of tungsten bronzes and the visible–near-infrared region relevant to applications.

Figure 1 shows the absorption spectra calculated using ε_a at several selected radii. All spectra exhibit a clear absorption peak at around 1100 nm, which is the LSPR peak arising from the collective oscillation of free carriers driven by the incident electromagnetic field. As the particle radius increases from 20 nm to 160 nm, the peak redshifts and its intensity increases, a trend described by Mie theory, while the secondary absorption peaks that gradually appear in the visible region originate from higher-order multipole contributions. The spectra calculated using ε_c have similar line shapes and trends, with only slight shifts in peak position and intensity due to the different dielectric function.

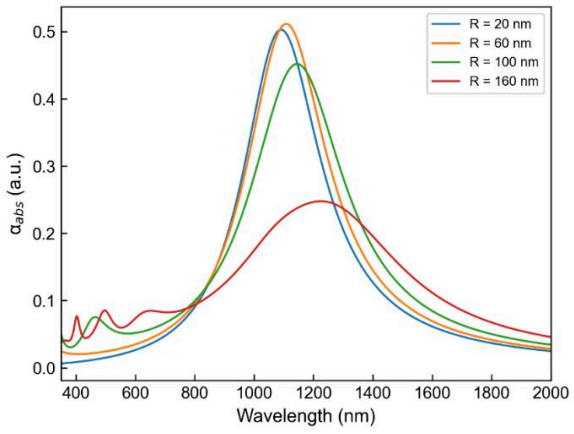

Fig. 1 Volume absorption coefficient spectra of tungsten bronze nanospheres at selected radii calculated using ε_a

2.2 Machine Learning Models

The dataset described in Section 2.1 was used for both interpolation and extrapolation training. For interpolation, the dataset was randomly split into a training set of 160 radii (80%) and a test set of 40 radii (20%). For extrapolation, radii from 1 to 150 nm were used as the training set, and radii from 151 to 200 nm as the test set.

Three regression models were implemented using Python and the scikit-learn and XGBoost libraries:

- **Multilayer Perceptron (MLP).** A feedforward neural network with three hidden layers of sizes 128, 64, and 32, all using ReLU activation. Training used the Adam optimizer with L2 regularization (α = 0.001), early stopping, and a batch size of 32.
- **Random Forest (RF).** An ensemble of 100 decision trees using bootstrap aggregation, with scikit-learn default hyperparameters.
- **XGBoost (XGB).** A gradient-boosted tree model with 100 estimators and a learning rate of 0.1. A multi-output regressor wrapper was used to handle the high-dimensional spectral output.

For all models, the input feature was the nanoparticle radius, and the target was a vector formed by concatenating the a-axis and c-axis absorption spectra (3302 points in total). The input features for the MLP model were standardized; the tree-based models were trained on the raw radius values. Model performance was evaluated using the coefficient of determination (R^2) and root mean square error (RMSE) on the test set. The three models were chosen for their complementarity: MLP represents neural networks that can learn highly nonlinear mappings; RF is generally robust on small datasets; and XGBoost offers another popular boosting-tree scheme.

III. Results and Discussion

3.1 Interpolation test

Table 1 summarizes the predictive performance of the three models on the test set.

Table 1. Performance metrics of the multilayer perceptron (MLP), random forest (RF), and XGBoost models on the test set

Model	Axis	R^2	RMSE($\times 10^{-3}$ m^{-1})
MLP	a	0.9071	6.18
	c	0.9112	11.53
RF	a	0.9991	0.81
	c	0.9993	2.89
XGB	a	0.9966	1.57
	c	0.9973	5.69

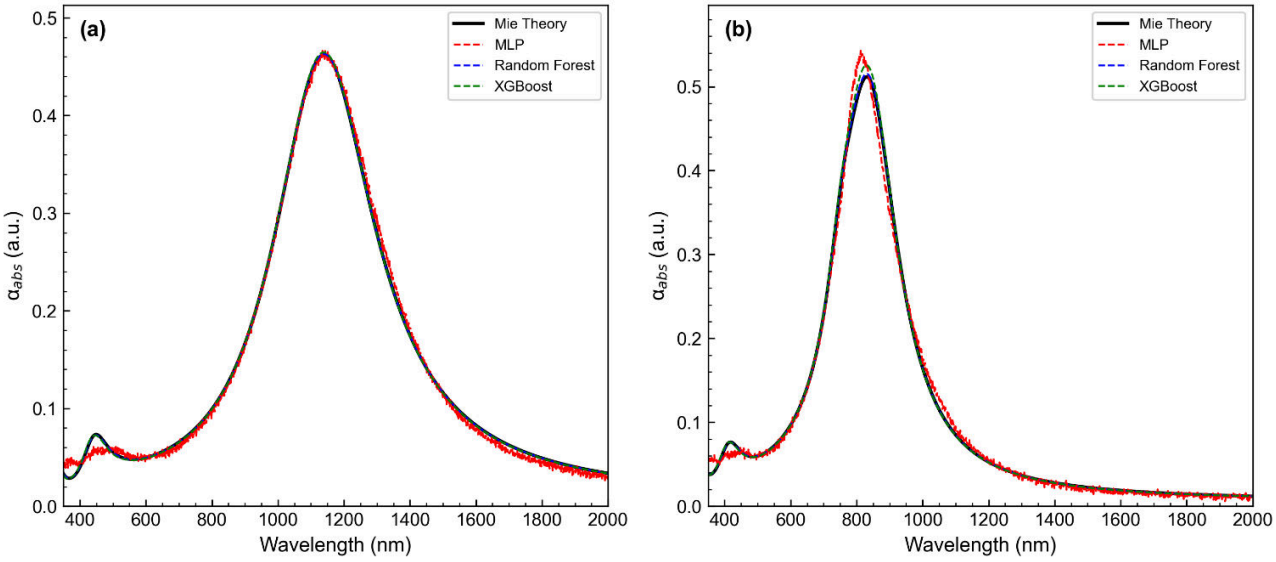

Fig. 2 Comparison of predicted and Mie-theory-calculated volume absorption coefficient spectra for a test radius of 96 nm: (a) a-axis and (b) c-axis

Among the three models, RF performed the best, achieving the highest R^2 and the lowest RMSE for both the a-axis and c-axis directions. XGB followed, also maintaining an R^2 above 0.99. In contrast, MLP, a method commonly used for learning nonlinear mappings, achieved lower accuracy than RF and XGB in this task.

To illustrate the prediction quality visually, a representative sample with a radius of 96 nm is examined. Figure 2 presents the predicted volume absorption coefficient spectra from the three models compared with the Mie theory spectra in the 350–2000 nm range, for both the a-axis and c-axis. The red dashed lines represent the MLP predictions: the agreement at the main LSPR peak around 1100 nm is acceptable, but the accuracy for the c-axis is lower than for the a-axis. The prediction deviations of MLP at the secondary peak near 500 nm are clearly larger than those of RF and XGB. The blue and green dashed lines correspond to the RF and XGB predictions, respectively; both fit the main LSPR peak and the 500 nm secondary peak well, clearly outperforming MLP. The slightly weaker performance of XGB on the c-axis is consistent with its higher RMSE value.

3.2 Extrapolation test

When the models trained on volume absorption coefficient spectra for radii 1–150 nm were applied to the unseen radius interval of 151–200 nm, the R^2 values of all models dropped to negative values, indicating a loss of predictive ability. The R^2 of MLP dropped to -9.91, while those of RF and XGB decreased to -3.56 and -3.40, respectively. The negative R^2 values mainly arise because the models cannot extrapolate features beyond the training range; at the same time, the significantly enhanced contribution of higher-order multipoles in the extrapolation interval further worsens the prediction performance.

IV. Conclusion

This work presents a benchmark study, under interpolation and extrapolation settings, of three regression models—Multilayer Perceptron (MLP), Random Forest (RF), and XGBoost (XGB)—for predicting the absorption spectra of anisotropic tungsten bronze nanospheres based on particle radius. Under interpolation, RF achieved higher accuracy than MLP and XGB. Within the extrapolation interval considered here, none of the models gave valid predictions for radii in the 151–200 nm range (negative R^2), indicating that purely data-driven surrogate models fail to capture changes in physical mechanisms beyond the training parameter space. These results suggest that when applying machine learning surrogate models in nanophotonics, it is important to carefully evaluate their applicable range, and direct extrapolation to unseen parameter regimes should be avoided.

***Abstract*—We demonstrate large strong coupling between a Au bowtie nanoantenna array enabling and monolayer WS_2. Using a PMMA layer to engineer the dielectric environment enhances local fields and increases the Rabi splitting from 84 to 135 meV, visible in both scattering and emission spectra. Experimental results agree well with simulations.**

***Keywords*— Bowtie nanoantenna, Plasmon–exciton interaction, Rabi splitting, Strong coupling.**

I. Introduction

Strong coupling at room temperature between narrow-band excitonic transitions in monolayer transition metal dichalcogenides (TMDCs) and plasmonic modes has attracted significant interest due to its importance for manipulating light –matter interactions in advanced photonic devices [1-3]. In this work, we investigate strong plasmon–exciton coupling in a hybrid system composed of a bowtie nanoantenna array and monolayer WS_2 [4, 5]. Varying the bowtie nanoantenna dimensions enables precise tuning of the plasmonic nanocavity modes, while the sharp tips provide strong near-field confinement, facilitating efficient interaction with WS_2 excitons. The robust excitonic resonance of monolayer WS_2 supports stable room-temperature coupling, resulting in enhanced optical absorption in the hybrid structure [6, 7].

By varying the bowtie geometry, the plasmonic resonance is tuned from 590 to 690 nm, allowing systematic control of the detuning between plasmonic and excitonic modes and leading to the observation of strong coupling at room temperature [8, 9]. A Rabi splitting energy of 84 meV is achieved in the WS_2-coupled Au bowtie nanoantenna. After introducing a PMMA overlayer, the plasmonic resonance exhibits an experimentally observed redshift of approximately 20 nm, accompanied by a pronounced enhancement of the local electric field as seen in the numerical simulations. Experimentally, the Rabi splitting energy increases to 135 meV, in excellent agreement with the simulated value of 138 meV. These results confirm that PMMA layer provides effective dielectric environment engineering and strengthens plasmon–exciton coupling through the enhanced electric field[10, 11].

II. Methods

The bowtie nanoantenna structures are designed and numerically simulated using Lumerical FDTD Solutions. The nanoantennas are fabricated on fused silica substrates by electron-beam lithography (EBL), followed by metal deposition and lift-off [12]. To improve pattern resolution, the sample was developed in a 1:3 MIBK: IPA solution at 0 °C for 30 s using a thermoelectric cold plate with stirring, followed by nitrogen drying. Metal deposition was then performed using a Temescal FC-2000 system. For Au deposition, a 1 nm Ti adhesion layer was introduced, with deposition rates of 1 Å s^{-1} for Ti and 0.5 Å s^{-1} for Au. The patterned structures were transferred to the substrate via lift-off in N-methyl pyrrolidone (NMP) at 55 °C for 45 min, followed by rinsing in acetone and IPA and nitrogen drying. Monolayer WS_2 is obtained from a commercial supplier (Six Carbon Technology) and transferred onto the fabricated nanoantenna arrays using a dry transfer method. A PMMA overlayer with controlled thickness is subsequently deposited by spin coating.

Raman and photoluminescence (PL) measurements are performed using 532 nm continuous-wave laser excitation under ambient conditions. Scattering spectra are collected using an optical microscopy system (Olympus) in a dark-field configuration.

III. Results and Discussion

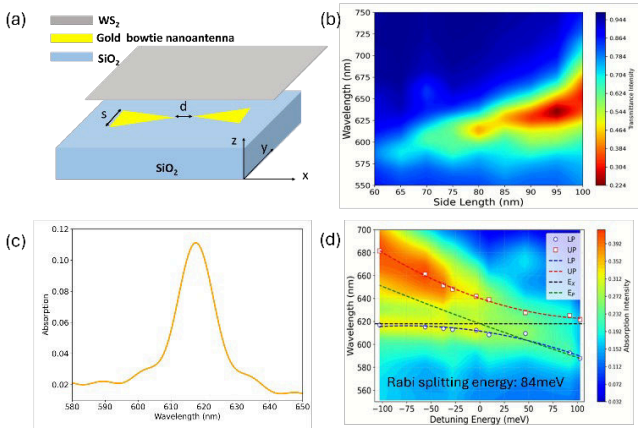

Fig. 1(a) Schematic of the WS_2/bowtie nanoantenna/fused silica hybrid structure. (b) Color map of simulated plasmonic resonance spectra as a function of the bowtie side length. (c) Simulated absorption spectrum of monolayer WS_2. (d) Absorption colormap of the WS_2/bowtie nanoantenna/fused silica system as a function of detuning energy. The horizontal black dashed line denotes the WS_2 exciton energy E_x, while the green dashed line represents the plasmonic resonance energy E_p. The triangle side length s (nm) is varied to tune E_p, yielding an energy detuning $\Delta=E_p-E_x$. The red and blue dashed curves show the fitted dispersion of the lower polariton (LP) and upper polariton (UP) branches obtained from coupled-mode theory (CMT), resulting in a Rabi splitting $\hbar\Omega$ of 84 meV [13].

The schematic of the designed strong-coupling architecture is shown in Fig. 1a, where a monolayer WS_2 is placed on top of a Au bowtie nanoantenna. By varying the side length of the individual triangular elements, the plasmonic resonance can be continuously tuned from 590 to 690 nm (Fig. 1b). As shown in Fig. 1c, monolayer WS_2 exhibits an absorption peak at 616 nm, corresponding to the A exciton peak used for strong coupling with the bowtie nanoantenna mode. The absorption color-map of the WS_2/bowtie nanoantenna hybrid system reveals a clear anti-crossing behavior. By extracting the upper polariton (UP) and lower polariton (LP) branch energies, a Rabi splitting energy of 84 meV is obtained (Fig. 1d).

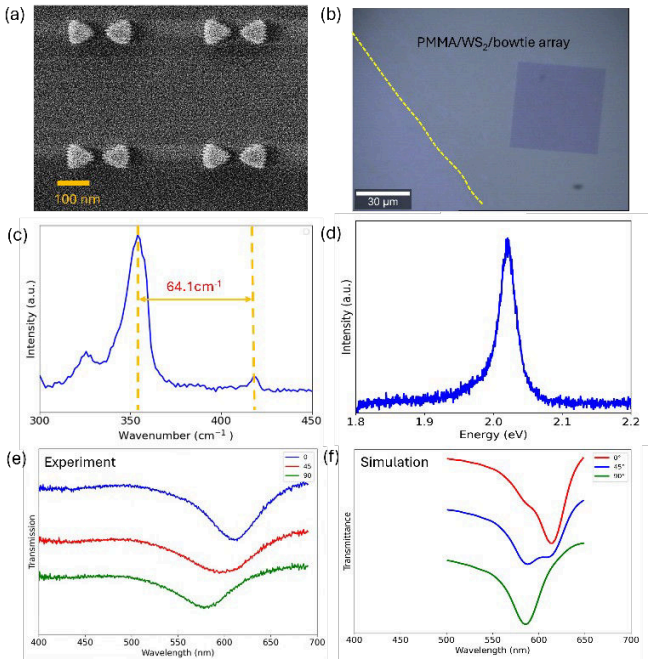

Fig. 2 (a) SEM image of bowtie nanoantennas fabricated by electron-beam lithography (EBL). (b) Optical micrograph of the PMMA/WS_2/bowtie nanoantenna structure. (c) Raman spectrum of monolayer WS_2 showing the E_{2g}^1 and A_{1g} vibrational modes. (d) Photoluminescence (PL) spectrum of monolayer WS_2. Polarization-dependent resonance spectra obtained from (e) experiments and (f) simulations at polarization angles of 0°, 45°, and 90°.

A SEM image of the fabricated bowtie nanoantennas is shown in Fig. 2a. Subsequently, a monolayer WS_2 film was transferred onto the patterned substrate *via* a dry-transfer process (Fig. 2b). The Raman spectrum (Fig. 2c) exhibits two characteristic vibrational modes, with the E_{2g}^1 mode at 353.8 cm^{-1} (red dashed line) and the A_{1g} mode at 417.9 cm^{-1} (green dashed line), with frequency separation $\Delta\approx$ 64.1 cm^{-1} The PL spectrum shows a pronounced emission peak at 2.023 eV, corresponding to the A-exciton transition of WS_2 (Fig 2d). These results confirm the monolayer nature of the WS_2. Polarization-dependent measurements of the bowtie nanoantenna reveal that the plasmonic resonance at 612 nm gradually weakens and eventually vanishes as the polarization angle is varied from 0° to 90° (Fig. 2e), in excellent agreement with the simulated results (Fig. 2f).

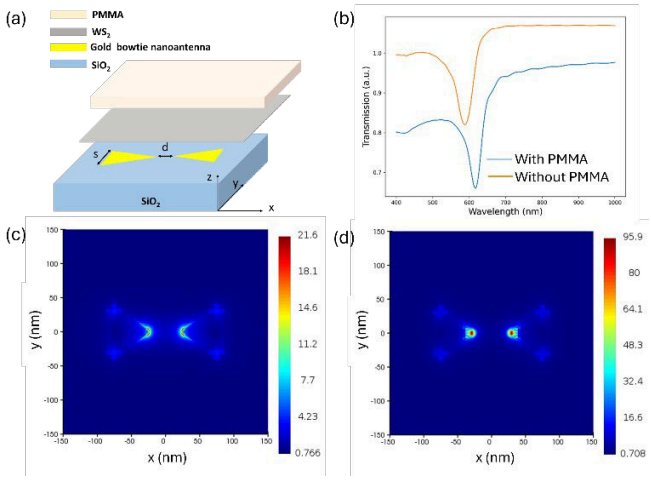

Fig. 3(a) Schematic illustration of the PMMA/WS_2/bowtie nanoantenna/fused silica hybrid structure. (b) Simulated transmittance spectra of the system with and without a PMMA overlayer. (c, d) Simulated in-plane electric field intensity distributions on the top surface of the bowtie nanoantenna (c) without and (d) with the PMMA layer.

To enhance the Rabi splitting energy, a PMMA overlayer was introduced into the hybrid coupling system, as schematically illustrated in Fig. 3(a). After incorporating the PMMA layer, numerical simulations show that the plasmonic resonance of the bowtie nanoantenna redshifts from 598 nm to 617 nm (Fig 3b), and the in-plane (x–y) electric field intensity on the top of the plasmonic is also significantly enhanced, increasing from 21.6 to 95.9 (Fig. 3 c, d).

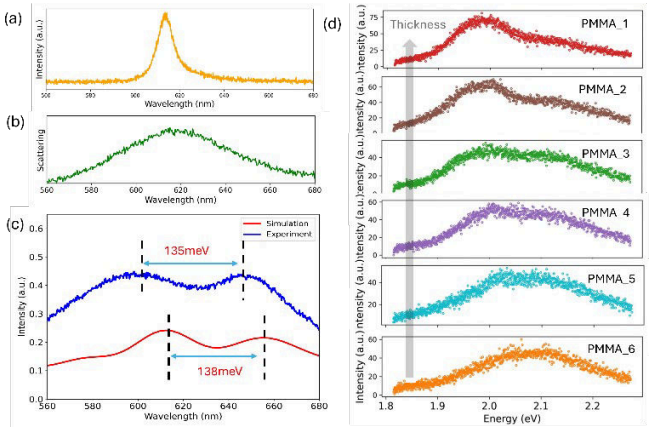

Fig. 4 (a) PL spectrum of monolayer WS_2 and (b) the Au bowtie nanoantenna. (c) Comparison of simulated and experimental scattering spectra of the PMMA/WS_2/bowtie nanoantenna/fused silica hybrid system. The bowtie nanoantenna array parameters are periodicity = 300 nm, side length = 65 nm, thickness = 40 nm, and gap = 40 nm. (d) PL spectra of the PMMA/WS_2/bowtie nanoantenna/fused silica system with varying PMMA thicknesses.

The monolayer WS2 exhibits a peak at 616nm in the PL spectrum, after introducing the PMMA layer (100nm) onto the bowtie nanoantennas array, the plasmonic scattering resonance occurs at 622 nm, see Fig. 4b. The scattering spectrum of the PMMA/WS_2/bowtie nanoantenna hybrid system (blue curve in Fig. 4c) presents a clear splitting, indicating strong coupling, with a calculated Rabi splitting energy of 135 meV. This value is in close agreement with the simulated transmittance-based Rabi splitting of 138 meV (red curve). PL characterization of the hybrid system was further performed (Fig 4d). Different PMMA thicknesses produce distinct PL curves, each showing clear splitting. The Rabi splitting energy extracted from the PL spectra is 135 meV.

IV. Conclusion

In conclusion, a bowtie nanoantenna array was fabricated using electron-beam lithography (EBL). By adjusting the antenna arm length, the plasmonic resonance can be tuned across the visible spectrum. Numerical simulations indicate that strong coupling with a WS_2 monolayer produces a Rabi splitting of 84 meV. Upon capping the structure with a 100 nm PMMA layer, the resonance wavelength redshifts by 20 nm, accompanied by a 4.4 times enhancement of the in-plane electric field amplitude, leading to an increased Rabi splitting of 138 meV. Experimental measurements after PMMA deposition yielded a splitting of 135meV in both the scattering and PL spectra, in excellent agreement with the simulations.

***Abstract*— We demonstrate the vital role of spatial dispersion in the optical properties of planar ordered lattices of plasmonic nanoparticles, which cannot be described by any standard dielectric tensor, and demonstrate the orientational dependence of the optical properties opening a new way for tuning their optical response by the orientation.**

***Keywords*— spatial dispersion, plasmonic nanoparticles, polarizability, effective anisotropy.**

I. Introduction

The properties of any complex system are defined not only by the individual properties of constituting elements but their mutual interactions. In optics such interactions occur via the electromagnetic field generated by a polarizable particle in the place of other particles modifying the local field in relation to the external exciting field [1]. It results in the concept of the local field and effective polarizability.

The external field cannot change the physical polarizability of an individual particle, which is defined by the material, size, and shape of this particle and the dipole moment ($\boldsymbol{P}$) generated on the particle is also an objective physical value independent on the way of its calculation. By definition, it is defined by the physical polarizability (α_0) and the field exciting the particle. However, the exciting field is not the external one ($\boldsymbol{E}_0$) but the unknown local one ($\boldsymbol{E}_{loc}$) at the position of the particle and defined by the external field and fields generated by all other constituting elements. On the other side, it is more convenient to determine the dipole moment via the known external field if we are not interested in the internal field distribution and consider our system as one object. We can do this by introducing an effective polarizability (α_{eff}), which takes into account the interactions between all particles. So, we can write

$$\boldsymbol{P} = \alpha_0 \boldsymbol{E}_{loc} = \alpha_{eff} \boldsymbol{E}_0. \quad (1)$$

Any interaction modifies such effective polarizability via the known canonical expression [1,2]

$$\alpha_{eff}^{n+1} = \frac{1}{\left(\alpha_{eff}^{n}\right)^{-1} - M_n}, \quad (2)$$

where M_n is the matrix element of the corresponding interaction.

It is necessary to note that all interactions are directional meaning that the response of one particle depends on the other particles and fields at their position. So, interactions introduce non-locality in the system, which, in turn, results in spatial dispersion of the resulting optical properties of the system [3], *i.e.* the dependence of optical properties on the wavevector of the exciting light. Such effects of spatial dispersion are proportional to the ratio of the interparticle separation to the wavelength [4], which explains their invisibility in solids.

However, it is worth to note that even optical anisotropy observed for anisotropic materials is the result of spatial dispersion as it stems from interparticle interactions between isotropic objects arranged non-symmetrically in contrary to isotropic materials. Even conventionally used refractive index and dielectric tensor are convenient parameters for the description of the response of media defined by interparticle interactions [5].

II. Peculiar Optical Properties of Planar Systems of Interacting Particles

Even though it is known for more than half a century that optical properties of planar layers of particles depend on the angle of incidence of the exciting light [6], it is usually not taken into account in the treatment of data obtained at different angles of incidence. We attracted attention to this fact and

demonstrated a remarkable dependence of the optical response of lattices of nanoparticles on the angle of incidence, which changes the interactions and effective polarizabilities [1,7]. It was also proven that taking into account the phase retardation reveals the creation of an effective planar optical anisotropy also dependent on the angle of incidence and observed in experiments [8].

However, another effect influencing the optical response of ordered lattices of interacting nanoparticles was demonstrated in Ref. [7], namely the dependence of the optical properties of lattices on their orientation in relation to the plane of incidence.

Considering the direct sum of dipolar fields, it is easy to demonstrate that any two identical particles/dipoles situated symmetrically with respect to the plane of symmetry of the lattice, which coincides with the plane of incidence do not generate any cross-polarized field on particles situated on the plane of symmetry. Analogous considerations but for 4 or 8 symmetrically arranged dipoles were made in Ref. [7].

Recollecting the effective planar anisotropy of such lattices with perpendicular optical axes, the absence of cross-polarization means that the system is illuminated along one of their optical axes. However, square lattices have four planes of symmetry, while hexagonal ones – six. Such a behavior is absolutely peculiar from the point of view of standard crystal optics. According to standard anisotropic considerations, each optically anisotropic lattice has one set of optical axes defined by its Bravais vectors, while symmetrical considerations demonstrate that for planar lattices the number of sets of optical axes is more for the same system.

In contrast to standard ellipsometry determining the two ellipsometric angles Ψ and Δ defined by the Fresnel reflection coefficients for different polarizations [9]

$$tan\Psi e^{i\Delta} = \frac{r_p}{r_s}, \tag{3}$$

Müller matrix ellipsometry allows determining whether cross-polarization is present in the system of interest or not [10] by non-zeroing or zeroing of the values of elements in the non-diagonal block matrices 2x2.

We investigated a number of square lattices of plasmonic nanoparticles prepared by electron beam lithography in dependence on their orientation in relation to the plane of incidence by imaging spectral microscopic ellipsometer Accurion ep4 (Park System). Starting from the orientation of rows of squares along the plane of incidence (angle 0°) the angle was varied up to 90°. The results for the m_{13} element of the Müller matrix for a lattice with a pitch of 350 nm and a diameter of the gold nanodiscs of 260 nm measured at two different angles of incidence (45° and 60°) together with differential spectra of the angle Ψ (*i.e.* in relation to the spectra for the bare substrate without nanoparticles) are presented in Fig. 1.

The main obvious result for the m_{13} element (also revealed for other Müller matrix elements) is the zeroing of its value for any wavelength at illumination along the planes of symmetry of the lattice (0° and 90° correspond to the illumination along columns or rows of squares while 45° to the illumination along a diagonal). This confirms previous symmetry considerations and proves the existence of more than one set of axes of the effective planar anisotropy.

Non-zero values coincide with the spectral position of plasmonic resonances determined by the extrema in the differential spectra of the ellipsometric angle Ψ [11]. It unambiguous demonstrates that interparticle interactions enhanced at plasmonic resonances are responsible for the creation of cross-polarization.

One more result exhibited in Fig. 1 is the hybridization and splitting of different resonances. As the change of the angle of incidence shifts the spectral position of the Rayleigh anomaly it reveals at an angle of incidence 45° a part of a plasmonic mode at about 600 nm (m_0) almost hidden by the Rayleigh anomaly at 60° angle of incidence. Approaching the next plasmonic resonance the Rayleigh anomaly hybridizes with it and changes its spectral position shown by its non-horizontal shape.

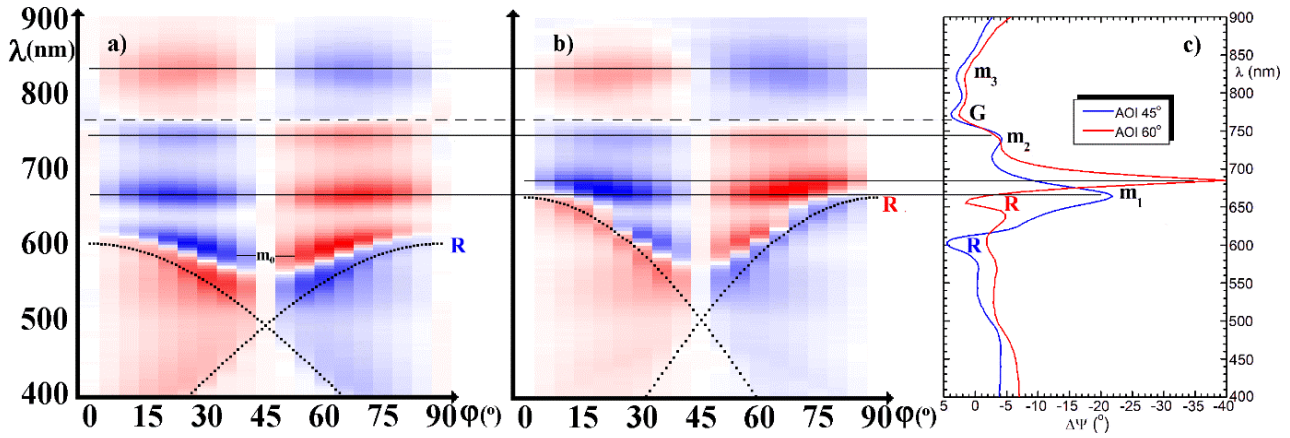

Fig. 1 Color coded value of the m_{13} element of the Müller matrix for a square lattice of gold discs with a period of 350 nm and diameter of 260 nm versus the orientational angle and differential ellipsometric spectra measured at the orientation along the side of squares.

III. Conclusion

We proved experimentally theoretical considerations about the vital influence of interactions leading to spatial dispersion (dependence on the wavevector) in the optical response of planar lattices of interacting particles. The spatial dispersion leads to the creation of a few sets of axes of effective planar optical anisotropy for a nominally isotropic structure.

***Abstract*—We investigate eigenmodes forming in finite, rectangularly periodic 2D arrays, and their effect on the optical response. We experimentally demonstrate optimal far-field coupling and eigenmode engineering that favors Hermite-Gaussian modes over plane waves. Furthermore, we show how traditional band diagrams are discretized to discrete resonance energies in finite structures.**

***Keywords*— metamaterials, surface lattice resonances, finite-size effects, discrete dipole approximation**

I. Introduction

Periodic structures have been used in optical applications for centuries. In recent research, they form the foundation of metamaterials capable phenomena such as lasing, nonlinear optical responses, and beam modulation. Typically, periodicity in these structures is modeled using periodic boundary conditions, which effectively assume an infinitely extended system. This assumption, however, does not accurately represent the physical behavior of real, finite structures. Recent studies have demonstrated deviations in the extinction efficiency of individual particles when compared to predictions based on infinite lattices [1], [2]. Moreover, finite lattices have been shown to support lasing modes that are not captured by periodic boundary condition models [3]. In this work, we investigate both computationally and experimentally the eigenmodes that arise due to the finite size of periodic arrays.

II. Methods

We utilize the discrete dipole approximation (DDA), in which each nanoparticle is modeled as an electric dipole, while higher-order electric and magnetic multipolar contributions are neglected. Within this framework, the optical response of an array is obtained by solving for the dipole moments $\vec{p}$,

$$\vec{E} = \varepsilon_0 \varepsilon_r A \vec{p}, \tag{1}$$

through inversion of the interaction matrix A. We determine the eigenvalues and eigenvectors of this matrix, which reveal the self-consistent spatial distributions of dipole moments supported by the array. Examples of such modes are shown in Fig. 1a.

Furthermore, we extend the DDA framework into the complex frequency plane to identify poles in the eigenvalues (see Fig. 1b). These poles correspond to quasi-normal modes (QNMs), enabling incorporation of mode losses into our analysis. This approach is well suited for inverse design of nanoparticle arrays with tunable degrees of freedom, such as individual particle sizes (and corresponding scattering cross sections) and particle positions, enabling systematic eigenmode engineering.

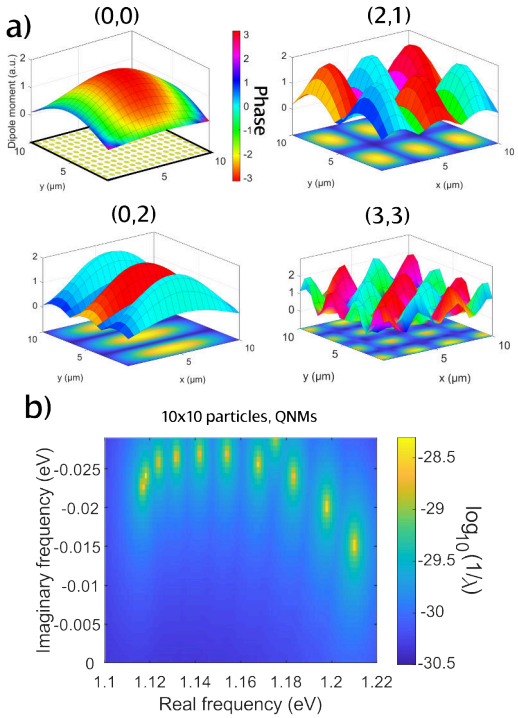

Fig. 1. a) Example eigenmodes found in a 20×20 particle lattice. b) QNM analysis of 10×10 lattice with QNMs from (0,0) to (9,0) for x-polarization shown.

III. Results and Discussion

We experimentally demonstrated selective coupling to distinct finite-size eigenmodes of a lattice by employing Hermite–Gaussian (HG) free-space modes as excitation fields. HG modes were chosen due to their close correspondence and high mode-overlap integrals with the lattice eigenmodes. The results shown in Fig. 2a compare resonance positions obtained under HG-mode excitation with eigenmode resonance energies calculated using DDA, revealing good agreement.

We next measured the quality factor (Q factor) of the lattice under excitation with Gaussian beams of varying waist sizes. Results are depicted in Fig. 2b. As expected, the Q factor increases with increasing beam size, but only up to the physical dimensions of the array. Optimal coupling is achieved when the incident field closely matches the fundamental (0,0) eigenmode of the lattice. Further increasing the beam size leads to a reduction in the Q factor, as additional eigenmodes with nearby resonance energies become simultaneously excited.

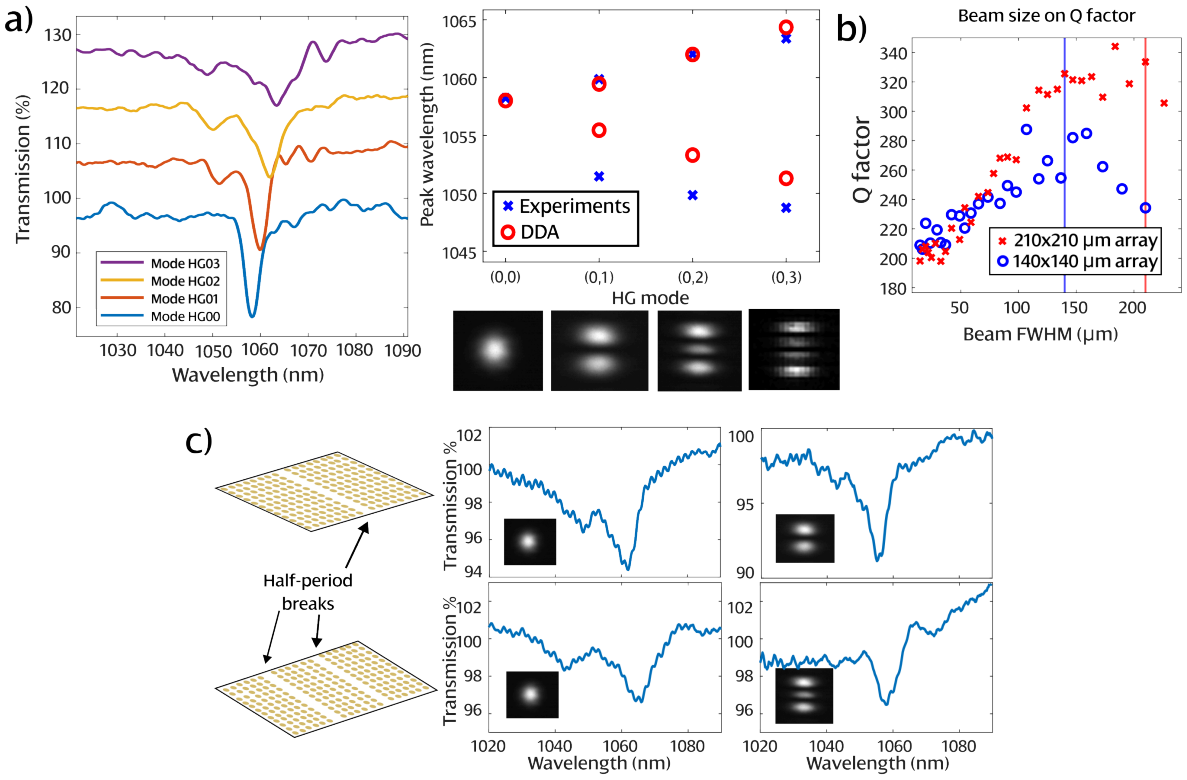

Fig. 2. a) Experiments exciting 210×210μm lattice with different HG modes compared to DDA eigenmode analysis on a lattice of equal size. b) Beam size effect on Q factor on two different-sized arrays. c) Eigenmode engineering using half-period breaks in lattice to favor HG modes over normal Gaussian excitation.

This behavior contrasts with the commonly held assumption that plane-wave excitation provides the optimal coupling to lattice modes [4].

Finally, we experimentally demonstrated eigenmode engineering by introducing half-period defects within the lattice (see Fig. 2c). These defects shift the fundamental eigenmode to exhibit a Hermite–Gaussian–like phase profile while preserving low-loss characteristics. This mode-engineering strategy may enable applications such as mode-cleaning devices and mode-selective flat lasers.

Integration into silicon micro ring resonators confirms their potential as active materials for reconfigurable integrated photonic devices.**

***Keywords*— spin crossover, phase change materials, spin transition, reconfigurable photonics, quadrupole trap, integrated photonics.**

I. Introduction

Reconfigurable nanophotonic platforms require active materials capable of large and controllable refractive index modulation with low energy consumption and high stability. Conventional phase change materials such as chalcogenides or vanadium oxides rely on structural transitions that often introduce optical losses, high switching thresholds, or limited endurance [1].

Spin crossover (SCO) materials provide an alternative molecular mechanism based on reversible electronic transitions between low spin and high spin states. This transition is accompanied by significant volume change and optical contrast while preserving bistability at the nanoscale. Such properties make them promising candidates for integrated photonic switching and nonvolatile optical functionalities [2].

However, the implementation of SCO nanoparticles (SCO-NPs) in photonic circuits requires precise understanding of their behavior at the single particle level. Most previous studies rely on ensembles embedded in matrices or deposited on substrates, preventing accurate isolation of intrinsic optomechanical responses [3,4].

Here, we introduce a substrate free single particle platform based on a quadrupole Paul trap combined with polarization resolved optical scattering, enabling controlled optical and environmental characterization of individual nanoparticles and facilitating their integration into silicon photonic devices [5].

II. Methods

SCO NPs of $Fe(NH_2trz)_3(NO_3)_2$ were synthesized using a reverse micelle method to obtain size-controlled particles between 100 and 300 nanometers [6]. Structural and magnetic characterization confirmed bistable spin transition behavior. SCO NPs were embedded in a polymer matrix to determine their optical constants and refractive index contrast across the transition.

Single particle measurements were then performed using a quadrupole Paul trap integrated inside a vacuum chamber (see Figure 1.c). The SCO-NPs dispersed in ethanol were introduced via electrospray and trapped using radiofrequency electric fields. A polarization resolved multispectral scattering microscope monitored individual trapped NPs under controlled optical excitation.

A blue laser induced the spin transition, while red and near infrared probe beams enabled size dependent scattering analysis. Particle dimensions were extracted by fitting experimental visibilities to Mie scattering calculations. Environmental control was achieved by varying chamber pressure.

For device level validation, a SCO polymethyl methacrylate (SCO/PMMA) nanocomposite was prepared and deposited onto silicon micro ring resonators. Resonance spectra were monitored under controlled temperature to evaluate refractive index driven modulation.

III. Results and Discussion

Magnetic measurements of the Fe(NH2trz)3(NO3)2 compound confirm a thermally driven spin transition with a bistable window of about 10 K between 310 and 320 K (Fig 1.a). This transition produces clear optical signatures, including disappearance of the low spin absorption band near 520 nm and a refractive index contrast measured by ellipsometry of approximately $\Delta n = 0.0123$ in the SCO/PMMA nanocomposite (Figure 1.b). Single particle measurements in a quadrupole Paul

trap reveal optically induced size expansion of approximately 5±1%, corresponding to nearly 10% volumetric change, consistent with typical values for SCO compounds, directly confirming cooperative switching at the nanoscale. We also demonstrate that a pressure reduction to 0.1 mbar induces a 4–6% increase in particle size, highlighting environmental tunability (Figure 1.f).

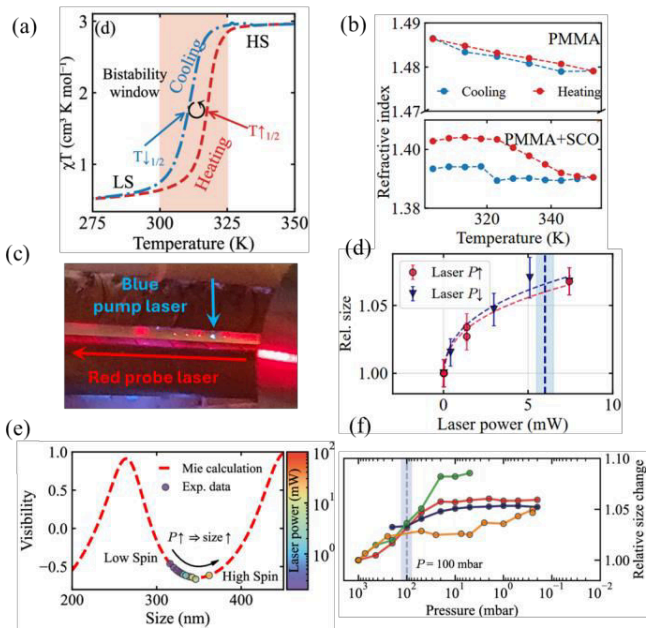

Figure 1: All figures are adapted from Pinilla-Cienfuegos et al., ACS Nano, 2026, under CC-BY license. (a) SQUID measurement of the SCO NPs. (b) Refractive index ellipsometry measurements for the nanocomposite, in comparison to those of a thin film of PMMA. (c) Picture of NPs suspended in the trap. (d) Relative laser-induced size change of trapped SCO NPs as a function of laser power at λ = 488 nm. (e) Visibility of trapped SCO NPs as a function of their size for different laser intensity, plotted over the theoretical Mie calculations. (f) Relative particle size change, as a function of ambient pressure.

Finally, integration onto silicon micro ring resonators demonstrates hysteretic resonance wavelength shifts near room temperature, validating the material as an active platform for nonvolatile and energy efficient photonic switching.

Conclusion

We have demonstrated a substrate free platform for the controlled manipulation and characterization of individual SCO NPs using a quadrupole Paul trap combined with polarization resolved optical scattering. The approach enables three-dimensional metrology, direct measurement of optically induced volumetric expansion, and environmental control at the single particle level.

The observed refractive index contrast and cooperative nanoscale expansion translate into measurable hysteretic resonance shifts when integrated onto silicon micro ring resonators, validating SCO materials as viable active elements for integrated photonics.

These results establish critical operational parameters for implementing molecular phase change materials in reconfigurable photonic architectures and open the path toward energy efficient, nonvolatile optical switching and sensing platforms.

***Keywords*— diffraction, plasmonics, bullseye antenna**

I. Introduction

Plasmonic bullseye antennas—concentric ring arrangements of metallic nanostructures—provide a compact route to shaping emission through the controlled interplay of localized plasmonic scattering and radial phase engineering [1]. Owing to their rotational symmetry, bullseye lattices can convert radiation into a narrow, highly directional beam along the surface normal. In emitter-integrated architectures, this enables enhanced brightness in a target direction, improved collection efficiency, and deterministic control over the far-field pattern without requiring macroscopic optics. Beyond simple collimation, the radial geometry also supports polarization- and wavelength-selective emission features [2], and can be implemented in a planar, lithographically scalable format.

Surface lattice resonances (SLRs) in arrangements of metallic nanoparticles arise from the coherent radiative coupling of localized surface plasmon resonances to diffractive lattice modes near Rayleigh anomalies [3]. This collective coupling strongly suppresses radiative damping relative to isolated nanoparticles, producing spectrally narrow resonances with high quality factors, long-range phase coherence, and pronounced dispersion in angle-resolved spectra. The resulting band structure depends on the array geometry.

Here, we employ the empty lattice approximation to design nanoparticle lattices with exotic dispersions. As a case example, we present the dispersion of a bullseye antenna constructed out of individual nanoparticles. Despite the differences in the underlying physics (surface plasmon polaritons vs. SLRs), a similar beaming property to plasmonic bullseye antennas is uncovered. This paper is a summary of the full work, where we present also other, exotic lattice geometries. [4]. Furthermore, in the full work, we also demonstrate lasing from these arrays [5].

II. Methods

The following description of the methods is paraphrased from Ref. [5]. To calculate the band structures of the investigated lattices, we use the empty lattice approximation, which consists of superposing the dispersion of each diffracted order weighted by its structure factor [6]. The structure factor $S(\mathbf{k})$ of the mode characterized by the wavevector $\mathbf{k}$ is defined as

$$S(\mathbf{k}) = \frac{1}{N^2}\left|\sum_{n=0}^{N-1} e^{i\mathbf{k}\cdot\mathbf{r}}\right|^2 \equiv \frac{1}{N^2}\left|A(\mathbf{k})\right|^2, \tag{1}$$

where N is the number of lattice sites and $\mathbf{r}_n$ denotes the position of the nth lattice site. The choice of the normalization factor N^{-2} ensures that the structure factor takes values between zero and one. The dispersion of light in a homogeneous, linear, isotropic optical background for in-plane modes is

$$E = \frac{\hbar c_0}{n}\sqrt{k_x^2 + k_y^2}, \tag{2}$$

where $\hbar$ is the reduced Planck constant, c_0 the speed of light in vacuum, and n the refractive index of the background medium. In the (k_x, k_y, E) space, this dispersion describes the surface of a light cone emanating from the point $(k_x, k_y, E = 0)$. Thus, modes that can scatter light to a particular point (k_x, k_y, E) lie on a ring centered at (k_x, k_y) with the radius determined by E. The total scattering intensity is thus proportional to the weighted sum of these modes

$$I(\mathbf{k}_\parallel, E) \propto \int S(\mathbf{k}')\delta(|\mathbf{k}' - \mathbf{k}_\parallel| - \kappa)d\mathbf{k}', \tag{3}$$

where the integration is over the k_x-k_y plane, $\mathbf{k}_\parallel = (k_x, k_y)^{\mathrm{T}}$, and $\kappa = \frac{n}{\hbar c_0}E$ is the wavevector magnitude corresponding to the energy E. Numerically, the above integral is computed by discretizing the k space and summing $S(\mathbf{k})$ over the points for which $||\mathbf{k}' - \mathbf{k}_\parallel| - \kappa| \leq \frac{\Delta E}{2}$, where ΔE is the energy discretization parameter.

III. Results and Discussion

We consider bullseye lattice consisting of individual nanoparticles. First, we consider the scattering amplitude [$A(\mathbf{k})$ in Eq. (1)] of a continuous, isotropic 2D distribution $\rho(\mathbf{r}) = \rho(r)$. The scattering amplitude of $\rho(r)$ is given by its Fourier transform:

$$A(\mathbf{k}) = \int \rho(r)e^{i\mathbf{k}\cdot\mathbf{r}}d^2r = \int_0^\infty \int_0^{2\pi} \rho(r)e^{ikr\cos(\theta-\varphi)}rd\theta dr, \tag{4}$$

where $\mathbf{k} = k(\cos\varphi, \sin\varphi)^{\mathrm{T}}$.
On the other hand, the zeroth-order Bessel function of the first kind $J_0(z)$ is defined by

$$\int_0^{2\pi} e^{iz\cos\alpha}d\alpha = 2\pi J_0(z). \tag{5}$$

Because $\rho(r)$ is isotropic, it can be taken outside of the angular integral and Eq. (4) rewritten as

$$A(\mathbf{k}) = 2\pi \int_0^\infty r\rho(r) J_0(kr) dr. \tag{6}$$

Our goal is to construct a lattice that scatters light at a specific wavelength to the normal direction. To this end, we select

$$\rho(r) = \sum_{t=1}^{T} \frac{w_t}{2\pi r_t} \delta(r - r_t), \tag{7}$$

where w_t is a weighting factor for the tth term in the sum. Plugging this into Eq. (4) gives

$$\begin{aligned} A(\mathbf{k}) &= \int_0^\infty \int_0^{2\pi} r\rho(r) e^{ikr\cos(\theta-\varphi)} d\theta dr \\ &= \sum_{t=1}^{T} \frac{w_t}{2\pi r_t} \int_0^\infty \int_0^{2\pi} r e^{ikr\cos(\theta-\varphi)} \delta(r - r_t) d\theta dr \\ &= \sum_{t=1}^{T} \frac{w_t}{2\pi} \int_0^{2\pi} e^{ikr_t\cos(\theta-\varphi)} d\theta = \sum_{t=1}^{T} w_t J_0(kr_t). \end{aligned} \tag{8}$$

The Bessel function $J_0(z)$ has an approximation (Debye asymptotic expansion) for $z \gg 0$

$$J_0(z) \approx \sqrt{\frac{2}{\pi z}} \cos\left(z - \frac{\pi}{4}\right) \equiv D(z). \tag{9}$$

The validity of the approximation for $z \gtrsim 1.2$ is confirmed by Figure 1; we will be interested in values $z \geq 2\pi$.

Inserting this approximant into the expression for the amplitude $A(\mathbf{k})$ yields

$$A(\mathbf{k}) = \sum_{t=1}^{T} w_t \sqrt{\frac{2}{\pi k r_t}} \cos\left(k r_t - \frac{\pi}{4}\right). \tag{10}$$

Next, we set

$$r_t = \Delta r \cdot t, \tag{11}$$

where Δr is the constant spacing between consecutive rings. With this, the amplitude can be written as

$$A(\mathbf{k}) = \sqrt{\frac{2}{\pi k}} \sum_{t=1}^{T} \frac{w_t}{\sqrt{\Delta r \cdot t}} \cos\left(k\Delta r \cdot t - \frac{\pi}{4}\right). \tag{12}$$

The sum is maximized when the cosine terms interfere constructively, i.e.,

$$k\Delta r = m \cdot 2\pi, \; m \in \mathbb{Z}. \tag{13}$$

Finally, to have a maximum in the amplitude (structure factor) at $k = m \cdot k_0, \; m \in \mathbb{N}$, we set

$$\Delta r = \frac{2\pi}{k_0}. \tag{14}$$

This gives a structure factor with concentric rings, which corresponds to scattering of a certain wavelength to the normal direction.

To transform the continuous distribution $\rho(r)$ into a discrete lattice, we generate the lattice by the following algorithm:

1) Select the number of rings T, the lattice constant (ring spacing) R and the number of lattice sites on the first ring N_1.
2) For each ring $t \in [1, \ldots, T]$:
   a) Calculate the number of points as $N_t = \lceil \sqrt{t} N_1 \rceil$ (this, together with the normalization of $1/N$ is the weighting factor w_t).
   b) Set the coordinates of the points as (tR, θ), where θ is a uniformly distributed random number, $\theta \in [0, 2\pi)$.

An example lattice generated by the above algorithm is shown in Figure 2.

Figure 3 shows the dispersion of a bullseye lattice calculated using the empty lattice approximation. It shows a strong feature at the Γ-point. Because of the isotropy of the lattice, by symmetry, the dispersion must be the same along any other line in the k_x-k_y-plane. The lattice thus scatters incident light strongly to the normal direction, similar to the plasmonic bullseye antennas.

The weighting factor that appears in Eqs. (7)–(12) is related to the number of particles in the tth ring over the total number of particles N_t/N, $N = \sum_t N_t$. By choosing $N_t = \lceil \sqrt{t} N_1 \rceil$, we compensate for the $t^{-\frac{1}{2}}$ scaling in the amplitude in Eq. (12).

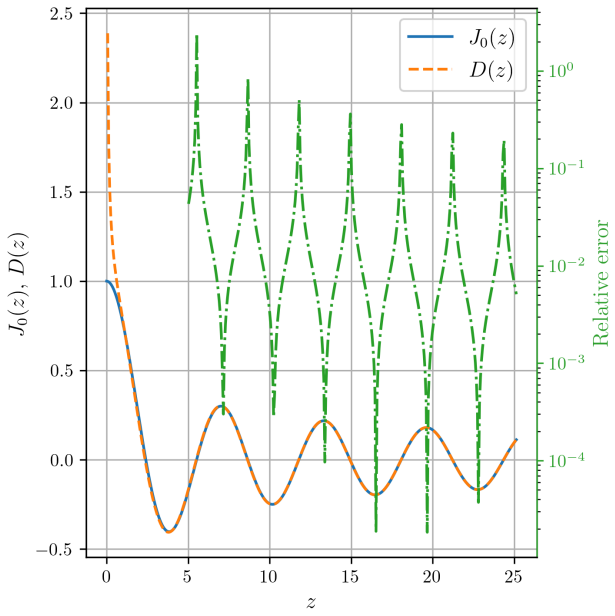

Fig. 1. Plots of the Bessel function $J_0(z)$, the Debye asymptotic expansion $D(z)$ (Eq. (9)) and the relative error. The graph shows that the $D(z)$ approximates $J_0(z)$ well at sufficiently high values of z and away from the zeros of $J_0(z)$.

IV. Conclusion

Using analytical and numerical methods, we have shown that the empty lattice approximation predicts that bullseye

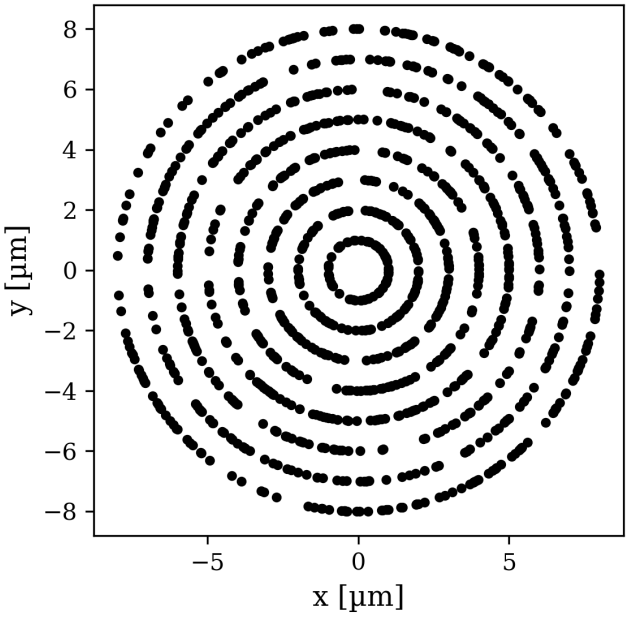

Fig. 2. Example of a bullseye lattice with 1 µm ring spacing.

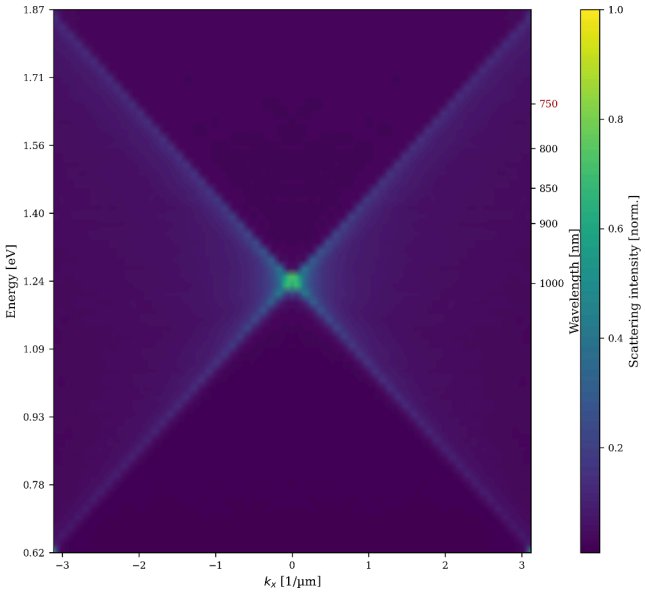

Fig. 3. Dispersion of a bullseye lattice (with more particles than the lattice of Fig. 2). The dispersion shows a strong feature at the Γ point at the wavelength corresponding to the ring spacing of 1 µm with background refractive index $n = 1$.

lattices consisting of isolated nanoparticles have similar beaming properties as plasmonic bullseye antennas consisting of continuous, concentric rings. The work showcases that the empty lattice approximation is useful also for computing the dispersions of exotic and aperiodic lattice geometries.

The collective optical response of plasmonic nanoparticle assemblies is strongly governed by interparticle interactions. Here, we investigate gold nanoparticle superlattices with tunable interparticle spacing, demonstrating that reduced spacing induces a plasmon blueshift and slows electron–phonon relaxation due to enhanced near-field coupling and hot-carrier population.

I. Introduction

Plasmonic metal nanoparticles exhibit localized surface plasmon resonances (LSPRs) arising from collective oscillations of conduction electrons, leading to strong light–matter interactions and enhanced electromagnetic fields.[1] Beyond individual nanoparticles, assembling plasmonic building blocks into ordered superstructures enables access to collective optical phenomena governed by interparticle coupling.[2]

While plasmon coupling in small nanoparticle clusters has been investigated, dense three-dimensional superstructures remain comparatively unexplored, particularly with respect to their ultrafast photodynamics. Interparticle distance is expected to play a critical role, yet systematic studies correlating precise structural control with ultrafast carrier dynamics at the single-superparticle level are scarce.[3]

In this work, crystalline gold superparticles are employed as a model system to investigate how interparticle spacing governs plasmonic spectral features and hot-carrier relaxation dynamics. By combining structural characterization with ultrafast transient absorption microscopy, we elucidate the relationship between nanoscale architecture and collective photophysical behavior.[3]

II. Methods

Gold superparticles (AuSPs) were prepared via emulsion-templated self-assembly by mixing AuNPs in toluene (5 mg mL^{-1}) with an aqueous SDS solution, followed by vortexing and slow solvent evaporation at 30 °C.

Ligand exchange was performed by drop-casting AuSPs onto glass substrates, removing residual SDS by acetonitrile rinsing, and immersing the samples in a 3 mM thiol solution in acetonitrile for 10 min. Samples were subsequently washed, vacuum-dried, and stored for characterization.

Structural characterization was carried out using transmission electron microscopy (TEM) and small-angle X-ray scattering (SAXS). TEM imaging was performed at 120–200 kV, while SAXS measurements were collected under vacuum using an 8 keV X-ray source and analysed to determine lattice symmetry and interparticle spacing.

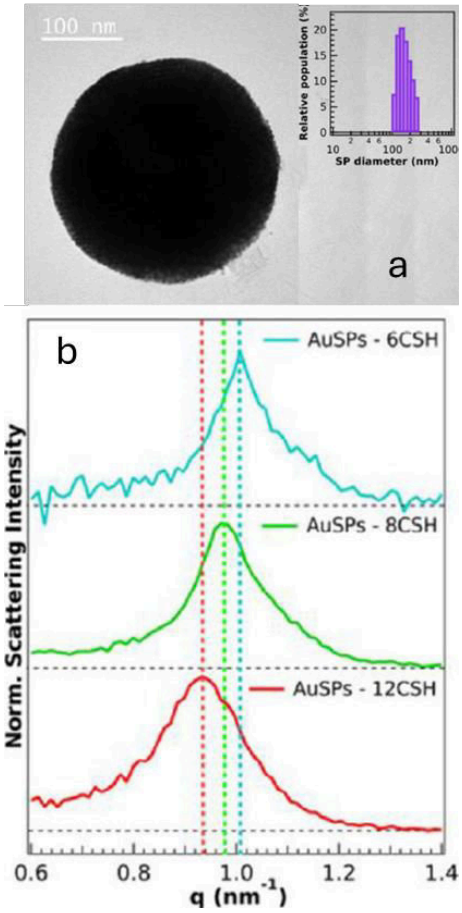
Optical properties were investigated by ensemble UV–vis spectroscopy and ultrafast transient absorption microscopy (TAM). TAM measurements employed 50 fs laser pulses, with a 400 nm pump and broadband probe, achieving ~2 μm spatial and ~80 fs temporal resolution. Kinetic traces were obtained

by averaging multiple pump–probe scans and corrected for dispersion and nonlinear artifacts.

III. Results and Discussion

Gold nanoparticles with an average diameter of ~6 nm were assembled into spherical superparticles via emulsion-templated self-assembly. Transmission electron microscopy (Figure 1a) confirms the formation of compact, highly packed superparticles with diameters around 160 nm. Small-angle X-ray scattering (Figure 1b) reveals a face-centered cubic (FCC) superlattice extending throughout the entire superparticle volume.

Interparticle spacing was systematically tuned through ligand exchange using alkanethiols of varying chain length. Changes in the surface-to-surface nearest-neighbour distance were quantitatively determined from the shift of the FCC (111)



SAXS reflection (Figure 1b). Structural characterization confirms that ligand exchange enables precise control over interparticle spacing while preserving long-range crystalline order. As expected, as the ligand length decreases, the nearest-neighbour distance is reduced, and this could lead to stronger interparticle coupling.

Figure 1: (a) TEM image of a single AuSP; inset AuSPs size distribution.(b) SAXS pattern of AuSPs as a function of ligands.

Optically, assembled superparticles exhibit a blueshift of the static LSPR compared to isolated nanoparticles (Figure 2a) which highlights the interaction between the nanoparticles.

Then, we studied the ultrafast photodynamics using transient absorption microscopy, enabling simultaneous femtosecond temporal resolution and micrometer-scale spatial selectivity, thereby isolating the response of individual superparticles. AuSPs show a systematic redshift of the plasmonic peak when the interparticle distance increases (Figure 2b). These trends indicate that long-range plasmonic interactions dominate the collective response of the superlattice, in contrast to the redshifts typically associated with short-range coupling.

Moreover, transient absorption microscopy kinetics (Figure 2c) reveal pronounced differences in ultrafast dynamics as a function of spacing. Following photoexcitation the electron–phonon relaxation time increases significantly as interparticle distance decreases. This counterintuitive slowdown is attributed to enhanced near-field coupling, which increases the

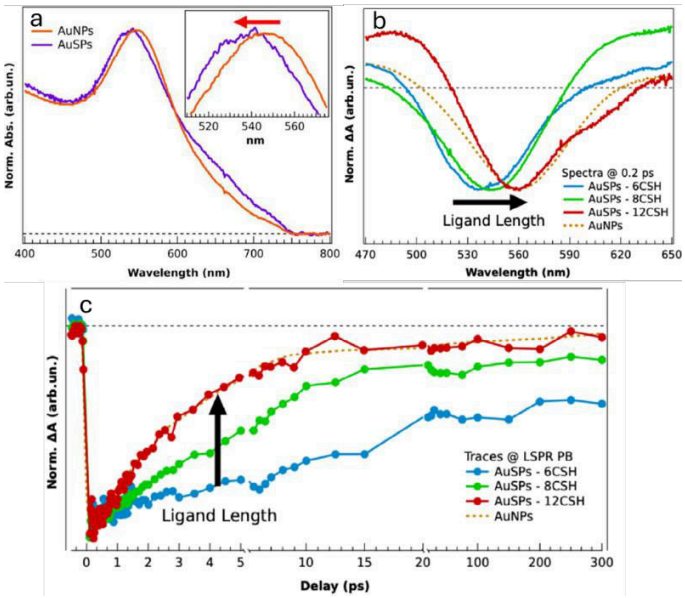


Figure 2: (a) Absorption spectra of Au nanoparticles and AuSPs, the inset highlights the blueshift. (b) Transient absorption spectra of AuSPs as a function of ligands at 0.2 ps. (c) Transient absorption kinetics of AuSPs as a function of ligands on the plasmonic peak.

local population of hot carriers and delays their thermalization with the lattice.

Together, these observations demonstrate that both spectral and dynamical plasmonic properties can be finely tuned through nanoscale structural control.

IV. Conclusion

This study demonstrates that interparticle spacing is a key parameter governing the collective plasmonic response of gold nanoparticle superlattices. Reduced spacing induces a blueshift of the plasmon resonance and significantly slows electron–phonon relaxation due to enhanced near-field interactions. These findings provide fundamental insight into ultrafast

dynamics in dense plasmonic assemblies and offer design guidelines for tunable nanophotonic materials.

***Abstract*—We explore the conversion of a surface plasmon polariton (SPP) into propagating radiation due to a time-varying plasma frequency. We consider a temporal interface using integral transforms and finite-difference-time-domain (FDTD) simulations to benchmark the results. We apply these results to an instantaneous frequency shift in indium tin oxide.**

***Keywords*— time-varying materials, plasmonics.**

I. Introduction

Time-varying metamaterials offers a fascinating counterpart to conventional electrodynamics in static media [1]. In recent years, the field has seen a surge of interest, both theoretical and experimental, driven by the discovery of strong nonlinearities in transparent conducting oxides (TCOs) [2]. Under ultrafast optical pumping these materials undergo rapid and strong electron redistribution, leading to significant modifications to their permittivities.

When the permittivity changes, an initial wave ceases to be an eigenmode of Maxwell's equations and decomposes into a superposition of new eigenmodes. This temporal modulation not only produces refracted and reflected waves, but also breaks frequency conservation. Near-field modes such as surface plasmon polaritons, which are ordinarily confined to interfaces, can convert into propagating radiation that escapes to the far field [3].

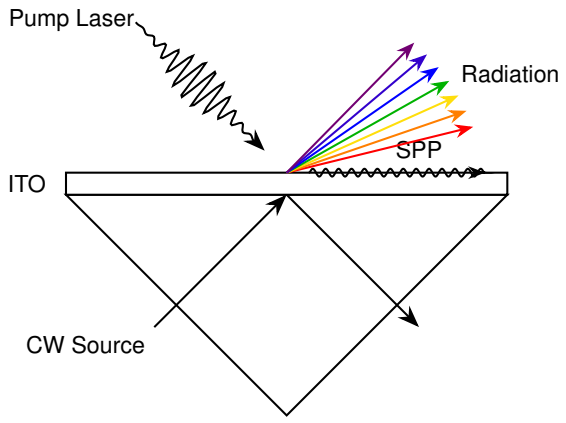

Fig. 1. A surface plasmon polariton (SPP), excited by a continuous wave (CW) source, propagating along an indium tin oxide (ITO)–air interface undergoes mode conversion when the plasma frequency is modified. This temporal perturbation results in the generation of broadband radiation, with frequencies up-shifted from the original SPP frequency.

Here, we consider the idealisation of a rapid plasma frequency change of indium tin oxide (ITO) in the Kretschmann-Rather configuration by considering temporal interfaces. We focus on the characteristics of the far-field radiation in the vacuum half-space. This consists of a continuous frequency spectrum, in contrast to spatial scattering where frequency is conserved, as shown in Fig 1. Our results demonstrate how a temporal interface for an excited SPP undergo conversion under moderate plasma frequencies changes.

II. Methods

Our theoretical model consists of a quasi-1D system where a plane wave in a glass prism with wavevector k_x is incident on an ITO slab (described by a Drude permittivity) with an air half-space above. Excitation by a pump laser redistributes the electrons changing the plasma frequency. We model this by a time-varying effective mass [4]. We solve Maxwell equations with

$$\frac{d\mathbf{J}}{dt} = \epsilon_0 \omega_p^2 f(t)\mathbf{E} - \left(\gamma - \frac{1}{f(t)}\frac{df}{dt}\right)\mathbf{J}, \tag{1}$$

where $f(t) = 1 + \Delta\omega_p^2(t)$ is the modulation function of the plasma frequency.

Time evolving the system, we analyse the conversion to radiation via the total energy emitted in the far-field

$$W_R = \int_{-\infty}^{\infty} dt\, E_x H_y^*. \tag{2}$$

As the parallel wavevector is conserved the radiative frequency ω is directly related to the angle of emission θ.

In the limit that $f(t)$ is much faster than the optical period, the modulation can be treated as stepwise and we can solve the time evolution using the Laplace transform method. We performed FDTD simulations that are in agreement with our analytical results.

III. Results and Discussion

Our system parameters are chosen to model a 6% plasma frequency redshift of which is inline with achievable experimental results for ITO [5]. The Poynting flux as a function of time is shown in Fig 2 showing the coincidence of the analytical and numerical results. Not visible on this scale, but shown in the inset, are oscillations present in the signal; the overall envelope displays a significant peak. By integrating this signal over time, we can calculate the total radiated energy and

compare it to the initial fields giving a conversion efficiency η of about 1%.

Fig. 2. Poynting flux S_z of far-field radiation from surface plasmon polariton conversion under a sudden 6% redshift of the plasma frequency Both the Laplace transform method and numerical method converge. Not visible on this scale are the oscillations present in the flux.

Using the Poynting flux, we can calculate the angular distribution of the far field finding agreement between the numerical and analytical approaches. Both forward and backward propagating radiation can be produced but at the moderate plasma frequencies we consider only the forward fields are present. Furthermore, the angles at which this radiation is produced is shallow suggesting that the bulk of the radiative frequencies are found near the lightline.

IV. Conclusion

We have employed analytical and numerical methods to handle temporal interfaces for SPPs in the Kretschmann-Raether configuration. Working with a moderate change in plasma frequency based on ITO under effective mass modulation, we have analysed the conversion efficiency. We seek to further this work by considering by considering smooth modulations and how this affects both the quantity of radiation and its distribution.

***Abstract*—We report designs for multi-wavelength operation of active metasurfaces, based on guided-mode resonances on tunable electro-optic thin films. We simulate diffractive switching efficiencies of 60% at 625 and 545 nm for titanium dioxide multi-mode waveguides on thin-film barium titanate and demonstrate three-wavelength control through two superposed perturbation pitches.**

***Keywords*— active metasurfaces, electro-optic, guided-mode resonances, multi-wavelength control.**

I. Introduction

Metasurfaces offer a lightweight, versatile approach to complex wavefront control [6]. In many applications which might benefit from such control, such as communication apertures and AR/VR red-green-blue projection, the ability to manipulate light across multiple wavelengths is essential. As such, many approaches—group delay engineering [3], spatial multiplexing [1], or multi-layer stacks [2]—have been used to make either broadband or discrete multi-wavelength passive metasurfaces. However, these solutions fall short when it comes to active metasurfaces. Group delay engineering is incompatible with the use of resonances to amplify the device response to small index changes. Spatial multiplexing increases the challenges of active addressing while reducing either the efficiency by dividing the aperture, or the achievable field of view by interleaving elements. Finally, active metasurfaces tend to be less efficient than passive ones, increasing losses in cascaded systems.

In this work, we report a novel design approach for multi-wavelength, programmable metasurfaces, building on previous work on electro-optically tunable guided-mode resonances [7] [8]. Motivated by recent developments in the fabrication of thin-film barium titanate (BTO) and the material's high Pockels coefficient ($r_{42} \approx 1000pm/V$) [4][9], we consider visible light designs on thin-film BTO. However, our currently on-going fabrication efforts aimed at proving the concepts of this paper will first use lithium niobate (LNO), since it is a more mature and commercially available platform.

II. Methods

GMR metasurfaces locally modify the amplitude and phase of a wavefront through propagation along the waveguide axis, defined here as the y-axis (Fig. 1(a)). We select the wavelength of operation by picking a perturbation pitch in y such that the in-plane momentum matching condition for normally incident light satisfies

$$n_{eff} = a\frac{\lambda_0}{p_y} \tag{1}$$

at the desired wavelength, where $a \in \mathbb{Z}$, n_{eff} is the waveguide effective index, λ_0 is the free space wavelength, and p_y is the period of perturbation along y. Figure 1(a) shows the perturbation as a notch of size (dx, dy).

Our simulated devices shown in Fig.1(a, c) use titanium dioxide (TiO_2) as the waveguide (red), BTO as the active material (light grey), silicon dioxide (SiO_2) to provide the index contrast which localizes the waveguide mode (orange), and a silver backreflector (dark grey). We design our waveguides such that their modes (Fig.1(b)) overlap the electro-optic material. This enables active control of the resonance position through strip electrodes (yellow) which change the refractive index of the electro-optic material. Shifting the resonance changes the local phase and amplitude response of the metasurface. To first order, the target resonance shifts according to

$$\Delta n_{eff} = a\frac{\Delta\lambda_0}{\Lambda} \tag{2}$$

Using the Tidy3D mode solver, we design the metasurface waveguide elements to support two local modes (Fig. 1(b)) with distinct effective indices $n_{eff}(\lambda_0)$. This enables us to satisfy Eqn. 1 at multiple wavelengths, enabling wavelength multiplexing. We also consider an alternate multiplexing scheme in which perturbations of distinct periodicity $p_{y1} \neq p_{y2}$ are superposed onto a single waveguide (Fig. 1(c)).

Finally, approximating the index shift in BTO as uniform within a unit cell, we use Tidy3D's full-wave FDTD simulations to calculate the tunable phase and amplitude response of waveguide elements and simulate diffractive switching.

We also target an initial experimental proof-of-concept demonstration using silicon waveguides on LNO. This effort is currently underway.

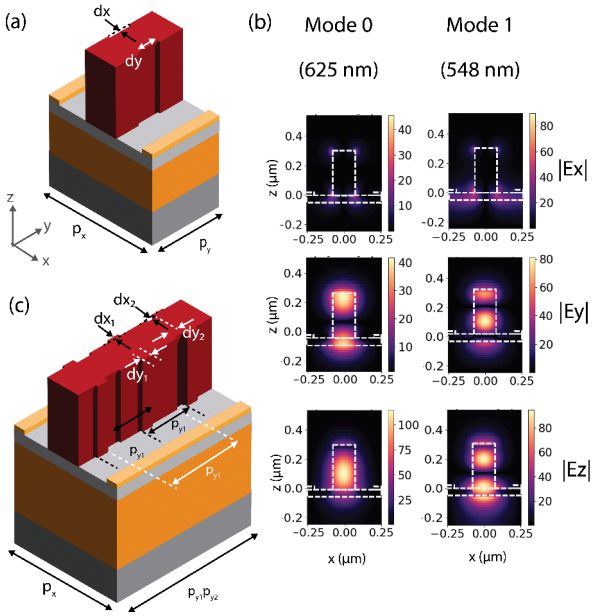

Fig. 1. (a) Guided-mode resonance (GMR) metasurface unit cell. A ridge waveguide (red) is built on an electro-optic material (grey) such that the effective indices of waveguide modes depend on the electrically tuned electro-optic material index. The electrical tuning is applied by the strip electrodes (yellow). p_y periodic perturbations of size (dx, dy) create a momentum matching condition from free space into the waveguide. (b) Two modes which satisfy the momentum matching condition at different wavelengths $\lambda_0^0 = 625nm, \lambda_0^1 = 548nm$. This allows dual-wavelength tunability. The white outline is the xz cross section of the metasurface unit cell. (c) Alternate approach for satisfying the momentum-matching condition at multiple wavelengths, in which two separate perturbation pitches are superposed in a single GMR structure.

III. Results and Discussion

We first confirm in simulation that tuning the BTO index shifts the mode indices at both wavelengths of interest by more than the resonance linewidth. Then, we simulate diffractive switching efficiency in Fig. 2(a) for BTO index shifts of $\Delta n = \pm 0.04$ in adjacent unit cells. We consider three different perturbation sizes, which produce the Q factors noted in the figure, and predict a diffractive switching efficiency of 60% for the lowest Q design.

We simulate devices with different Q factors because the shift in wavelength achieved by index modulation must exceed the linewidth of the resonance to provide significant modulation. Thus, devices with higher Q can be tuned with lower index shifts. Here, we nominally assume an achievable $\Delta n = \pm 0.04$, but these higher Q simulations indicate that our devices will work with smaller index changes, with some efficiency cost. We attribute the lower steering efficiency at higher Q factors to increased inter-waveguide coupling due to longer interaction times between modes in adjacent waveguides [5].

This motivates the use of BTO, with its much higher Pockels coefficient, over lithium niobate (LNO). For a fixed applied voltage, we expect a greater index shift, which in turn enables lower Q, more efficient operation.

Finally, we note that waveguide geometry limits the number of modes and engineering of their dispersion, which limits the number and relative position of tunable wavelengths. In Fig. 2(b), we overcome this limitation and add a third controllable wavelength by introducing a second set of perturbations with a different period, as depicted schematically in Fig. 1(c). The two shorter wavelengths (450 nm, 600 nm) are coupled into mode 1 using two different perturbation periods, and the longest wavelength (640 nm) is coupled into mode 0.

In simulation, the computational cost of large simulations constrains us to periods p_{y1}, p_{y2} which share a small least common multiple. In experiment, we are working towards fabricating silicon on LNO structures with arbitrary periods to demonstrate arbitrary selection of wavelengths of operation.

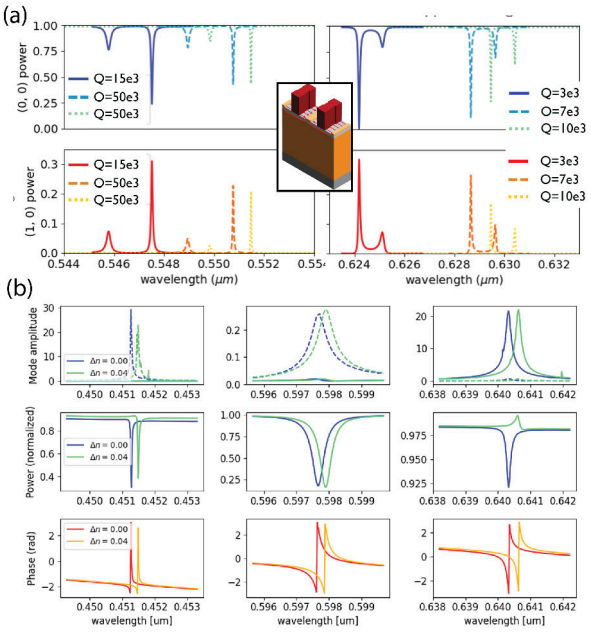

Fig. 2. (a) Simulated diffractive switching at 625 nm and 550 nm, for varying quality (Q) factor resonances. The varying Q factors are produced by varying perturbation sizes (dx, dy), with smaller perturbations corresponding to higher Q factors. Inset shows the effective unit cell used for switching. (b) Shift in resonance with a change of index $\Delta n = 0.04$ in the BTO, at 450 nm, 600 nm, and 640 nm, for a structure with two superposed perturbation pitches.

IV. Conclusion

We present GMR metasurface designs which use thin-film BTO for multi-wavelength active control and steering of light. Unlike previous approaches, these designs do not increase the complexity of electronic addressing, increase the pitch of elements, or decrease efficiency of operation through cascading. We demonstrate diffractive splitting with a simulated efficiency of 60% across both wavelengths and show up to 3 separate tunable wavelengths. We anticipate a first experimental demonstration of these concepts on LNO.

***Abstract* - Selective CO_2 reduction to multi-carbon products requires localized excitation and repeated electron transfer. We present a wavelength-guided plasmonic strategy linking controlled optical modes in gold nanostructures to scalable gold dendritic electrodes. Structure–optical relationships identified in simplified geometries are translated to complex morphologies, enabling optical control of CO_2 reduction processes**

INTRODUCTION

The conversion of CO_2 into value-added chemicals is central to sustainable energy and carbon-neutral manufacturing. While capture technologies continue to advance, selectively reducing CO_2 into multi-carbon (C_2^+) products such as ethylene and ethanol remains challenging. These reactions involve multiple coupled electron and proton transfer steps and must compete with kinetically favored pathways including hydrogen evolution and CO formation under practical operating conditions.

Plasmonic nanostructures offer a complementary route to addressing these challenges by enabling optical control over interfacial reaction environments[1]. Upon illumination, localized surface plasmon resonances concentrate electromagnetic energy into nanoscale regions and generate energetic charge carriers at metal–electrolyte interfaces. These localized excitation conditions can influence adsorption, charge transfer, and reaction pathways in ways that are not accessible through purely thermal or electrochemical activation.

However, achieving selective CO_2 reduction using plasmonic catalysts requires more than increasing light absorption[2]. Reaction outcomes depend on how optical energy is distributed spatially and spectrally, how near-fields are localized, and how these excitation conditions align with the requirements of multi-electron chemistry. Establishing clear structure-optical-reactivity relationships is therefore essential for translating plasmonic concepts into rational catalyst design.

I. Methods and Results

To identify optical excitation conditions relevant to selective CO_2 reduction, we adopt a hierarchical strategy that progresses from simplified plasmonic geometries to complex, scalable dendritic electrodes. Our approach combines electromagnetic simulations (BEM, FEM), nanoscale optical characterization, cathodoluminescence (CL) spectroscopy, and in situ surface-enhanced Raman spectroscopy (SERS) to probe plasmon-mediated excitation and charge-transfer processes.

Gold nanotriangles are employed as a model plasmonic platform to establish wavelength-selective excitation behavior. Their well-defined geometry supports tunable localized surface plasmon resonances, enabling systematic control over resonance energy, near-field localization, and absorption. Electromagnetic simulations are used to correlate triangle dimensions with spectral shifts and field enhancement, providing a controlled

framework for isolating optical effects that are difficult to disentangle in disordered systems.

This simplified-geometry approach is motivated by experimental CL mapping of gold nano-dendrites(Fig. 1 c, d), which reveals that plasmonic hot-spots are strongly localized at sharp tips and high-curvature junctions[3]. These observations suggest that the spectral behavior of dendritic hot-spots is governed primarily by local geometry rather than the full interconnected morphology. Using model structures therefore allows efficient identification of key features controlling near-field localization and wavelength response while capturing qualitative trends observed experimentally.

Raman spectroscopy using molecular probe systems is employed as a sensitive reporter of plasmonic activity and wavelength-dependent excitation effects[4], providing mechanistic insight into plasmon-mediated charge transfer without directly probing CO_2 intermediates. These optical benchmarks establish excitation conditions relevant to multi-electron chemistry and guide interpretation of more complex catalytic measurements.

Building on these insights, we investigate self-assembled gold nano-dendrites fabricated via scalable electrodeposition. These hierarchical architectures exhibit sharp features and complex junctions that support broadband and spatially heterogeneous plasmonic modes. Such excitation landscapes naturally generate localized near-fields and enhanced carrier flux at multiple sites, conditions that are well suited to driving repeated electron-transfer events required for multi-electron CO_2 reduction.

Photocatalytic and photo-assisted electrochemical measurements are used to assess how plasmonic excitation modifies reaction behavior in dendritic electrodes. While wavelength-dependent selectivity can be clearly demonstrated in model plasmonic systems, extending deterministic wavelength control to dendrites remains an active area of investigation due to their multi-mode optical response. Ongoing work focuses on correlating wavelength-resolved excitation with changes in reaction rate and product distribution, guided by optical trends established in simplified geometries.

II. Conclusion

This work establishes a wavelength-guided plasmonic design framework for CO_2 reduction that connects controlled optical modes in simplified nanostructures with scalable gold dendritic electrodes. By using model geometries to identify excitation conditions relevant to complex plasmonic morphologies, we define a clear pathway toward optical control of multi-electron CO_2 reduction. These results position plasmonic dendrites as a promising platform for future wavelength-selective and optically programmable CO_2 conversion.

CdO stands out as the best plasmonic semiconductor in the mid infrared. Here, we evaluate its plasmonic characteristics on two polar substrates, SiC and sapphire, and show large enhancements of the near-field from the interaction between surface phonon polaritons from the substrate and localized surface plasmon polaritons from CdO stripes.

***Keywords*— metamaterials, semiconductors, plasmonics, Oxides.**

I. Introduction

CdO stands out in the mid infrared (IR) range thanks to its low optical losses and high carrier concentration [1]. CdO has a tunable plasma frequency that can be changed with the alloying of other metals like Zn [2]. The possibility to grow it over polar substrates, like SiC and sapphire, together with the recent advances in gap antenna processing [3], opens the door to the coupling of localized surface phonon and plasmon polaritons (LSPhP and LSPP, respectively) leading to very large near field amplifications.

The plasmonic properties of CdO and $Cd_{1-x}Zn_xO$ thin films have been studied in a great variety of substrates. Polar dielectrics, like sapphire, can support surface phonon polaritons, which are highly propagative low-loss modes. When hybridized with the CdO antisymmetric mode in sufficiently thin films, the modes show a large enhancement of the propagation length. [4]. Additionally, in the case of CdO nanostructured thin films over sapphire substrates, the localized surface plasmons can couple with the localized surface phonon polaritons hosted on sapphire, causing significant amplification of the near-field [3].

Unfortunately, sapphire is very insulating, which can be a serious limitation for the integration of CdO on active devices. Hence, a substrate that can host active devices would be most desirable. In this context, SiC is an interesting substrate as it is already present in a variety of commercial devices [5]. Like sapphire, it is a wide-gap polar semiconductor. But, unlike sapphire, its electrical characteristics can be manipulated by doping. In this work we will study the viability of using SiC as a polar active substrate for CdZnO thin films and investigate the near-field amplification in gap-antennas.

II. Methods

$Cd_{1-x}Zn_xO$ thin films were grown by metal organic chemical vapor deposition (MOCVD) on 4H-SiC and r-sapphire. Conventional reflectance and attenuated total reflectance (ATR) in the Otto configuration were performed using a Fourier transform infrared (FTIR) spectrometer.

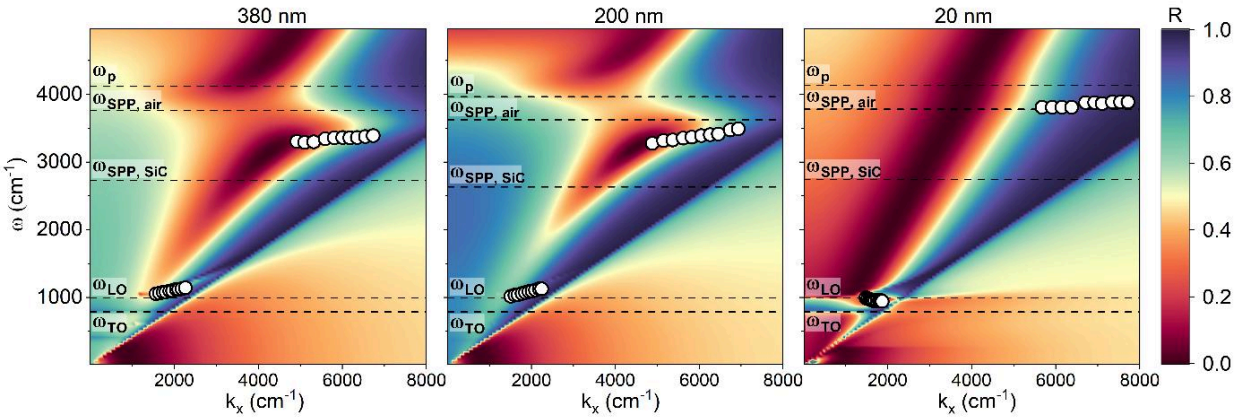

Figure 1: Simulated reflectance contour plots and experimentally determined SPP frequencies (white circles) for CdZnO/SiC structures for different layer thicknesses. The Zn content was 10 % for all three samples.

Gap antennas were processed using standard e-beam lithography followed by ICP etching.

Reflectance dispersion curves on the CdZnO thin films were calculated using a homemade program based on the transfer matrix method (TMM). Near-field amplification maps and surface average amplification in nanostructured CdO stripes were calculated using the commercial software COMSOL Multiphysics.

III. Results and Discussion

Figure 1 shows the simulated ATR contour plots and the experimental SPP resonance frequencies for a series of CdZnO thin films grown on SiC. As seen in previous studies on r-sapphire [4], the dispersion curves show two different polaritonic branches, symmetric and antisymmetric. The decrease in film thickness triggers a repulsion between the two modes. While the symmetric mode is essentially plasmonic in nature and rises to higher frequencies until it reaches the plasma frequency (ω_p), the antisymmetric hybridized mode tends toward lower energies and at low values of k_x remains pinned at the LO-phonon frequency of SiC.

As shown in Figure 2, the plasmonic quality in each of the substrates is quite similar. They both have very low optical losses, but while the symmetric mode behaves similarly in sapphire and SiC, the antisymmetric mode in SiC exhibits lower dispersion throughout k_x and zero group velocity. Overall, these particularities make SiC promising as an epsilon near zero (ENZ) material in the IR range.

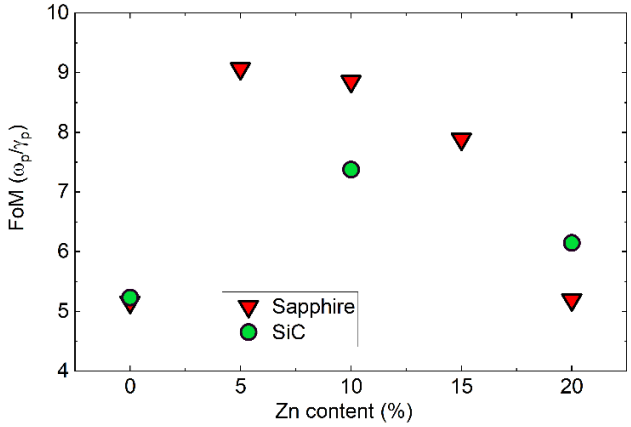

Figure 2:Figure of merit (FoM) of samples with different nominal Zn content. The data for the calculation of the FoM in sapphire substrates was obtained from [6].

In the case of CdO on sapphire our group has recently demonstrated gap antennas [3] with very large near field amplification. This processing technology hence opens the door to reaching very large couplings between the LSPhP from CdO and LSPhP from the polar substrate. As shown in Figure 3, by controlling the stripe size one can tune the LSPP frequency to that of the LSPhP, yielding an anticrossing behavior around the LSPhP frequency, and very large field enhancements around the gap antenna. Results from current ongoing work on processed CdO gap antennas on both sapphire and SiC will be presented.

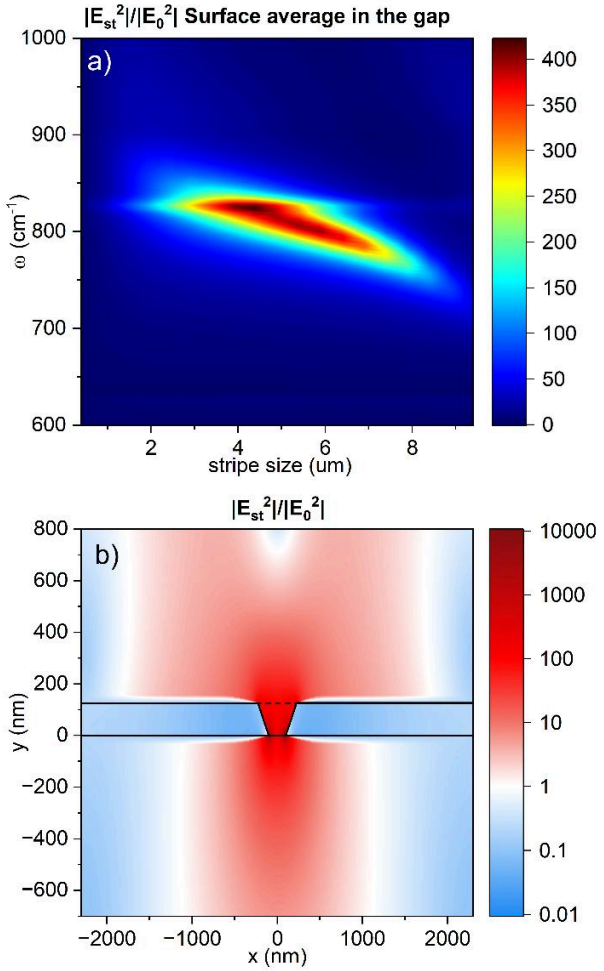

Figure 3: a) Gap near-field surface average for varying stripe widths and equal gap size ω =830 cm^{-1} b) Near-field simulation for the grid with gap size = 200 nm and stripe size = 4400 nm.

IV. Conclusion

We have demonstrated the presence of two surface plasmon polariton resonances in the CdZnO/SiC structures, correspondent to the symmetric and antisymmetric modes. We have shown the combination of the CdZnO antisymmetric mode with the LO phonon in SiC results in a hybrid surface plasmon-phonon polariton also found in sapphire. In this way we have shown the viability of SiC as a substrate for CdZnO thin films while maintaining plasma frequencies and optical losses comparable to those found in sapphire.

We have calculated the optimum grid geometry for maximum near-field amplification in a CdO/sapphire gap antenna, yielding an enhancement of the integrated near-field in the gap of $\times 422$ Furthermore, the enhancement extends hundreds of nm outside the gap nanoantenna too, facilitating its use in applications such as surface enhanced infrared absorption (SEIRA). The experimental results from the processed design will be presented.

***Abstract*— We establish n-type conducting polymer poly(benzodifurandione) (PBFDO) as a switchable organic plasmonic system. In doped state, PBFDO becomes optically metallic above 700 nm and supports plasmonic resonances when nanostructured, which can be reversibly turned on/off electrically/chemically. This stretches the horizon and functionalities of plasmonics for dynamic metasurfaces and adaptive optical devices.**

***Keywords*— conducting polymers, n-type nanoantennas, organic plasmonics, electro-tunable.**

SUMMARY

We have recently introduced p-type conducting polymers as a new class of materials for dynamically tunable plasmonics[1], [2]. In contrast to traditional metals, conducting polymers can reversibly switch between metallic behavior (negative permittivity) and dielectric behavior (positive permittivity) through changes in their redox state. Nanoantennas fabricated from these polymers can therefore exhibit plasmonic resonances that can be turned on or off on demand.

In our recent work [3], we showed for the first time that nanostructures made from an n-type conducting polymer named poly(benzodifurandione) (PBFDO)[4] support plasmon-like resonances [3] similar to p-type conducting polymers. We fabricated PBFDO thin film onto a substrate by spincoating and measured permittivity by ellipsometry. We observed negative permittivity in the near infrared for doped-conductive state, but positive permittivity for dedoped-dielectric state (See Fig. 1a) which shows promise for switchable plasmonic system. To realize PBFDO nanoantennas, we later patterned the film into nanodisk arrays using colloidal lithography. Spectroscopic measurements on the nanodisks showed size-dependent extinction peak-shift (see Fig. 1b) as expected for plasmonic resonance. This resonance was modulated through electrical or chemical control of the polymer's doping state (see Fig. 1c) governed by its charge carrier density. This work extends redox-tunable plasmonics beyond previously studied p-type systems. Integrating metasurfaces made of both p type and n type conducting polymers in tandem devices can enable new functionalities, including tunable p–n junction concepts for dynamic metaoptics.

***Abstract*— Optical vortices with different total angular momentum excite LPRs in gold nanodisks, studied by DDA. In circular disks, resonance wavelengths depend strongly on diameter and show an optimal excitation band. In polygonal disks, rotational symmetry controls excitable modes, and spectra switch with even/odd angular-momentum parity.**

***Keywords*— plasmonics, optical vortex, angular momentum, mode selectivity, plasmonic filter.**

I. Introduction

Structured light provides additional degrees of freedom to control localized plasmon resonances (LPRs) beyond conventional scalar illumination. Optical vortex beams have orbital angular momentum (OAM) according to the topological charge ℓ and spin angular momentum (SAM) according to the circular polarization helicity σ. It is possible to selectively excite a given multipole mode in an LPR through tailoring the total angular momentum (TAM) [1,2] of the incident beam. Figure 1 shows a conceptual diagram. We term this TAMSE: total-angular-momentum-selective excitation of LPRs under vortex illumination. More recently, cylindrical vector beams were shown to selectively excite bright and dark plasmon modes in triangular gold nanodisks by matching the spatial symmetry of the incident field to the mode character [3]. Despite these advances, a systematic comparison of continuous versus discrete rotational symmetry under vortex excitation, and its impact on TAM-dependent spectral shifts, mode order selection, and excitation efficiency, remains incomplete. Here we address this gap and further highlight a passive TAM-to-intensity mapping concept for plasmonic filters.

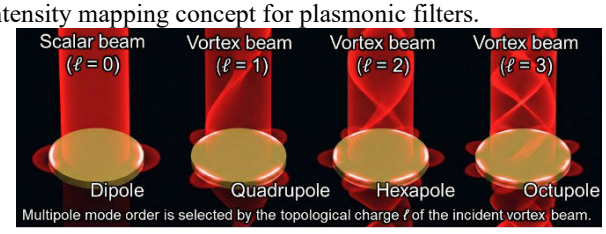

Fig. 1 Conceptual illustration of TAMSE. Under LCP vortex illumination, the dominant multipolar response can change with ℓ+σ, as identified by azimuthal lobe patterns in near-field distributions.

II. Methods

We performed electromagnetic simulations using the discrete dipole approximation based on DDSCAT [4] with custom optical vortex illumination. The target structures are 30-nm-thick metallic nanodisks: circular nanodisks with diameters from 200 to 600 nm and an equilateral triangular disk with a side length of 300 nm. The incident beam is a left-circularly polarized (LCP; σ=+1) optical vortex with topological charge ℓ. We compute extinction spectra and identify resonance mode order from distributions of electric field intensity at peak wavelengths using azimuthal lobe patterns.

III. Results and Discussion

Figure 2 shows the extinction spectra of circular gold nanodisks with diameters of 300, 400, and 600 nm under incident optical vortices with topological charges ℓ=+1 to +4, where the phase singularity of the vortex beam is aligned with the disk center. As ℓ increases, the resonance peak shifts systematically to shorter wavelengths. For a fixed ℓ, increasing the disk diameter causes a redshift of the resonance together with spectral broadening. The peak extinction is largest when the resonance wavelength lies in the 600−700 nm range, indicating a wavelength region where the excitation efficiency is maximized for these structures.

Size-dependent spectral shifts are common in confined optical systems. In molecules there is no universal rule linking molecular dimensions to absorption wavelength, although within analogous series a general trend toward longer wavelengths with increasing size is often observed. Simple models such as the quantum particle-in-a-box capture this qualitative behavior by predicting smaller energy level spacings for larger systems, though they are only crude approximations for real molecules. A closer analogy arises in semiconductor quantum dots, where Brus theory explicitly predicts size-dependent transition energies due to quantum confinement. The TAMSE response of nanodisks is similarly governed by confinement of the electromagnetic field at the surface; the disk effectively acts as a two-dimensional resonant cavity, so

increasing its physical dimensions lowers the resonance frequency and produces the observed redshift.

Figure 3 presents the near-field intensity maps at each peak wavelength for a 200-nm-diameter gold nanodisk. The results show that the resonant mode order increases from dipole to decapole mode with increasing TAM. The observed dependence of the resonance mode order on the TAM is independent of variations in disk diameter. Overall, these findings indicate that by tuning the disk size, plasmon resonances can be excited with the desired mode order while maximizing the excitation efficiency.

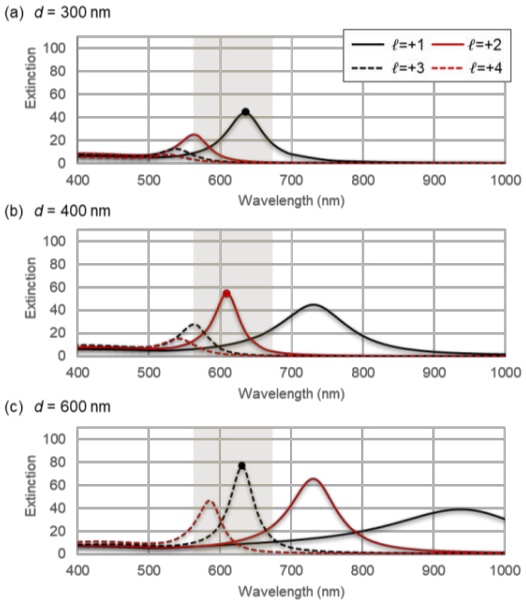

Fig.2 DDA-calculated extinction spectra of 30 nm thick circular nanodisks with different diameters under LCP vortex illumination (ℓ=+1 to +4). The filled circles indicate peak wavelengths. The shaded region indicates the wavelength band where the excitation efficiency (peak extinction) is maximized.

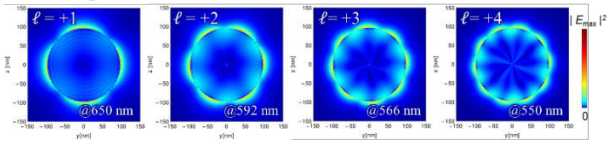

Fig. 3 Simulated field distribution maps at peak wavelengths for a single circular nanodisk with a diameter of 200 nm.

Fig. 4 shows the TAMSE of a single triangular nanoplate. Fig. 4(a) shows the schematic of the simulation conditions, and Fig. 4(b) shows the simulated extinction spectra at each ℓ. The extinction spectra have two peaks at around 550-700 nm and 910 nm. Examining the shorter wavelength side, the spectral shape varies depending on whether ℓ is even or odd, indicating that the excitable modes differ depending on the total angular momentum. At longer wavelengths, the peak value of the extinction spectra decreases linearly as ℓ increases, and the resonance wavelength remains unchanged regardless of ℓ. The order of resonance modes also remains in all cases (shown in Fig. 4(c)). We found that this typical characteristic was observed only for the triangular configuration. Comparing the electric-field maps and extinction spectra for the triangular and circular nanodisks indicates that the mode order plays a key role in determining the resonance wavelength. In the plane perpendicular to the incident beam, a circular disk exhibits continuous rotational symmetry about the beam axis. In contrast, a triangular disk has only threefold rotational symmetry together with a limited set of mirror symmetries. This reduction in symmetry lifts degeneracies present in the circular case and modifies the allowed modal structure, which likely accounts for the differences observed in the resonance states.

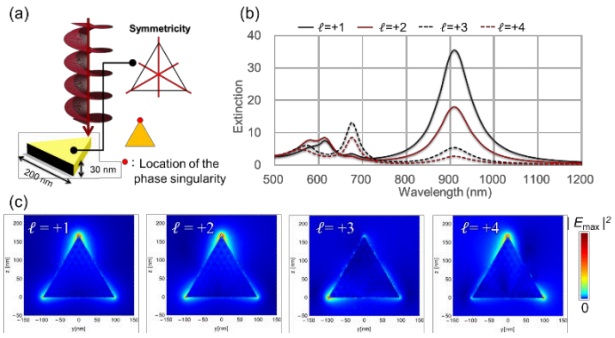

Fig.4 TAMSE of a single triangular gold nanodisk. (a) Schematic of on-axis optical-vortex illumination (vortex axis aligned to the disk edge) for a 30-nm-thick nanodisk. (b) Corresponding extinction spectra under vortex beams with ℓ=+1, +2, +3, +4, showing symmetry-dependent mode selectivity and distinct resonance features. (c) Near-field intensity maps at the long side peak wavelengths (910 nm) for each ℓ, where the azimuthal lobe patterns reveal the excited multipolar order. The color scale denotes the normalized field magnitude.

IV. Conclusion

We simulated the optical response of single circular and triangular gold nanodisks under optical vortex illumination to investigate TAMSE. The results show that the optical characteristics associated with TAMSE depend strongly on both the symmetry and size of the nanostructure. In particular, for triangular nanodisks, the extinction peak intensity varies linearly with the vortex topological charge ℓ under appropriate excitation conditions. This behavior suggests that such structures could function as passive transmission-type nano-filters that convert TAM states into measurable intensity contrasts for mode discrimination. Preliminary simulations further indicate that the same TAM-based selection principle may extend to other geometries, including to square and regular pentagonal nanodisks as well as multi-ring nanostructures, pointing to broader applicability of the approach.

***Abstract*— In this study, we demonstrated the application of quantum nanophotonics, specifically single-photon emission (SPE), in a strongly coupled Au plasmonic metasurface and a monolayer of WSe_2 at room temperature. The demonstrated SPE has high purity with an equal-time second-order correlation function $g^{(2)}(\tau = 0) = 0.00035$ at $\Omega_c = 0.5$ meV, via photon blockade.**

***Keywords*— metasurfaces, strong coupling, photon blockade, single-photon purity.**

I. Introduction

Quantum nanophotonics offers a versatile platform for confining and coherently controlling individual quanta of light and matter at deeply subwavelength scales. This enables on-chip quantum functionality and deterministic single-photon generation. In quantum communication and photonic quantum computing, single photons serve as a universal resource for qubit encoding. To develop scalable, integrable SP emitters that operate at room temperature, they should exhibit high emission efficiency and purity.[14] The purity of these photons can be measured via the second–order correlation function at zero delay, g(2)(0), with an ideal value of $g^{(2)}(\tau = 0) = 0$, corresponding to unity purity defined as $P = 1 - g^{(2)}(\tau = 0) = 1$.

A promising approach for single-photon generation with high brightness and purity involves cavity quantum electrodynamics (cQED). Despite advancements, achieving room-temperature SPSs with high purity remains a significant challenge, prompting new strategies in materials and device design. Here, we theoretically demonstrate that a strongly coupled hybrid platform composed of a compact Au plasmonic metasurface and a monolayer of WSe_2 enables scalable single-photon emission (SPE) at room temperature. After confirming strong coupling, both conventional photon blockades (CPB) at low drive strength and unconventional photon blockade (UnPB) using a two-tone coherent drive that causes destructive interference between two-photon excitation pathways were implemented in QuTiP.

As a result, the calculated equal-time second-order correlation function $g^{(2)}(\tau = 0)$ is resulted 0.0267 via CPB at lower drive. Moreover, due to the destructive quantum interference, the UPB induced higher purity with $g^{(2)}(\tau = 0) = 0.00035$ at $\Omega_c = 0.5$ meV.

II. Methods

Our methodology combines Lumerical simulation and modeling. The optical response of the WSe2 monolayer (thickness 0.7 nm) was modeled using a Lorentz oscillator formalism to describe its in-plane excitonic permittivity.[1]

The uncoupled Au metasurface was analyzed through multipole decomposition across various geometric parameters, revealing that the dominant plasmonic resonance is controlled by an electric quadrupole (EQ) mode. Then, the optical properties of the individual components and their hybrid configuration were simulated using the finite-difference time-domain (FDTD) method in Lumerical (Ansys). We used periodic boundary conditions in the x- and y-directions and a perfectly matched layer in the z-direction. A plane wave, incident along the z-axis and polarized along the y-axis, was employed in the simulations. Finally, numerical modeling was carried out using a Python-based quantum toolbox (QuTiP).

III. Results and Discussion

Strong coupling in the Au–WSe_2 heterostructure (Fig. 1(a-b)) was confirmed by extracting the polariton dispersion through thickness-dependent tuning of the Au nanostructure and fitting the resulting anticrossing behaviour using a coupled-oscillator model. [1,2]

$$\begin{pmatrix} E_P + i\gamma_P & g \\ g & E_X + i\gamma_X \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = E \begin{pmatrix} \alpha \\ \beta \end{pmatrix} \quad (1)$$

where $\hbar = 1$, E_P, and E_X are the resonance energies of the plasmon and exciton modes, g is the coupling strength, and Γ_P and Γ_X are the half-widths at half-maximum (HWHM) of the plasmon and exciton modes, respectively. The calculated Rabi splitting of Au-WSe_2 heterostructures strongly depends on the

catenary-like field enhancement induced by the Au cavity, resulting in a room-temperature coupling strength of $g = 36.26$ meV. It was confirmed that the calculated Rabi splitting of the system is nonvanishing and can be experimentally measured.

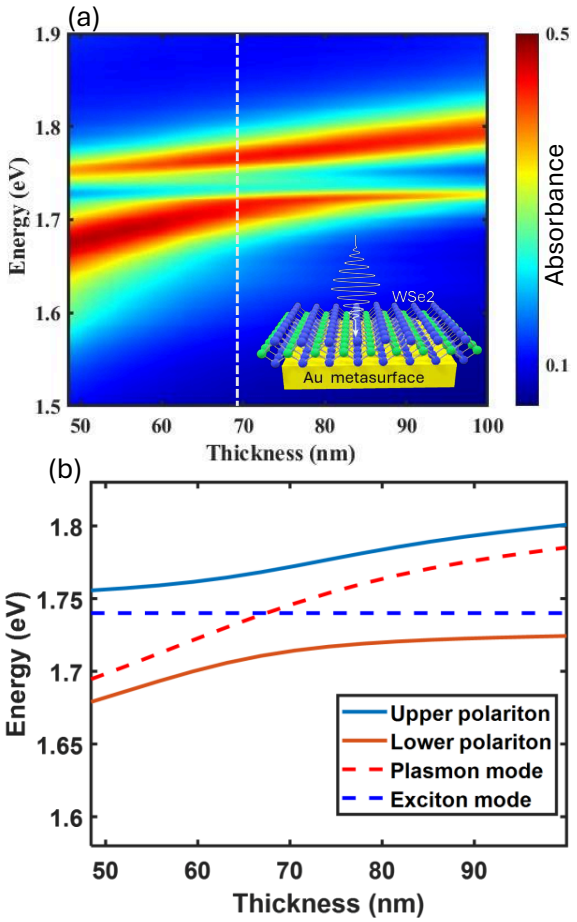

Fig. 1: Single-photon emission from a strongly coupled Au-WSe2 monolayer. (a) Absorbance map of the Au-WSe2 monolayer as a function of Au metasurface thickness. (b) The corresponding polariton dispersion curve [1]. The vertical dashed line in panel (a) indicates detuning.

After confirming the strong coupling in the EQ-mode of Au metasurfaces-WSe_2 monolayer, we simulated the quantum master equation for the second-order correlation function, $g^{(2)}(\tau)$ using QuTiP. The demonstrated strong coupling in the Au cavity–WSe_2 monolayer shown in Fig. 1 reveals that the system is highly anharmonic. Therefore, we first applied conventional photon blockades (CPB) at low drive strength and unconventional photon blockade (UnPB) using a two-tone coherent drive that induces destructive interference between two-photon excitation pathways (see Fig. 2). As a result, at a drive strength of $\Omega_c = 0020$ meV of the CPB, the calculated equal-time second-order correlation function $g^{(2)}(\tau = 0)$ is resulted 0.0267. Moreover, due to the destructive quantum interference, the UPB induced $g^{(2)}(\tau = 0) = 0.00035$ at $\Omega_c = 0.5$ meV. The results demonstrated are much larger than those of a single-photon purity, a strongly coupled few-layer hBN film, and a high-Q bound-state-in-the-continuum (BIC) cavity.[3] These findings demonstrate that Au-metasurface–WSe_2 monolayers are a scalable route to high-purity, room-temperature single-photon sources for integrated quantum photonics and quantum communication.

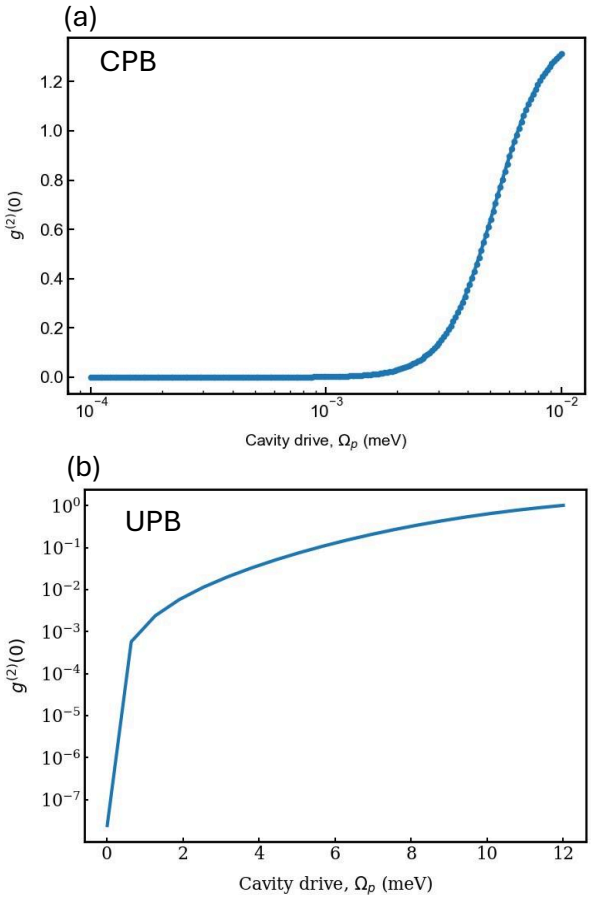

Fig. 2: Effect of drive strength on $g^{(2)}(\tau = 0)$ at the same coupling strength via (a) CPB and (b) UPB.

IV. Conclusion

We have demonstrated that compact, scalable single-photon emission can be achieved in a strongly coupled plasmonic metasurface with an EQ mode and a WSe2 monolayer. By fabricating the metasurface in a clean room using electron-beam lithography (EBL) and transferring the monolayer, the proposed design and modeling could provide a viable pathway toward integrated quantum light sources for quantum key distribution and low-power photonic quantum interconnects.

***Abstract*—We demonstrate enhanced transverse magneto-optical Kerr effect (TMOKE) in magnetoplasmonic multilayers via hybrid Fabry–Perot-plasmonic modes. Coupling evanescent plasmonic fields with propagating cavity resonances enables co-localized field enhancement within the magneto-active layer. Tuned multilayer heterostructures exhibit stronger TMOKE than single-mode designs, confirmed by modeling, simulations, and experiments.**

***Keywords*— TMOKE, magnetoplasmonics, Fabry-Perot resonances, plasmonic modes, multilayer structures, mode hybridization.**

I. Introduction

Plasmonic, a branch of photonics, investigates the interaction between electromagnetic radiation and conduction electrons at metal-dielectric interfaces. Such interactions give rise to collective surface electron oscillations known as surface plasmons (SPs)[1], coupled with incident photons. Due to their ability to confine light to scales below the diffraction limit and their high sensitivity to dielectric variations, SPs have enabled the development of diverse optoelectronic devices[2]. As we will show, Fabry-Perot (FP) microcavities together with plasmonic architectures allow the enhancement of internal electromagnetic fields through constructive interference between cavity and plasmonic modes.. This results in the enhancement of transverse magneto-optical Kerr effect (TMOKE).

Multilayered metal-dielectric-metal systems have proven to be versatile structures, in which both propagating and localized plasmon modes can coexist and couple with cavity modes, for example, FP-type resonances. This coupling enhances field confinement and enables spectral tunability and hybridization of optical modes in magneto-plasmonic multilayers. Nevertheless, previous studies have largely focused on symmetric and antisymmetric plasmonic modes in metal-insulator-metal (MIM) microcavities and on alternative routes to TMOKE enhancement[3], leaving the transverse magneto-optical Kerr Effect in the presence of FP resonances largely unexplored.

Here, we address these effects by investigating one of the architectures proposed in [4] of a multilayer magneto-plasmonic heterostructure in which propagating SP modes are phase-matched to FP cavity modes. This is achieved using two metallic layers that act as mirrors to generate FP modes together with the excitation of SPs modes. By tuning layer thicknesses and refractive-index contrast, we co-localize cavity antinodes and plasmonic near fields to achieve resonance overlap and constructive interference. To realize and test this concept, we employ a Prism/Metal/Dielectric/Metal/Ferromagnet/Dielectric (P/M/D/M/F/D) system and assess the impact of FP modes and propagating SP modes on TMOKE.

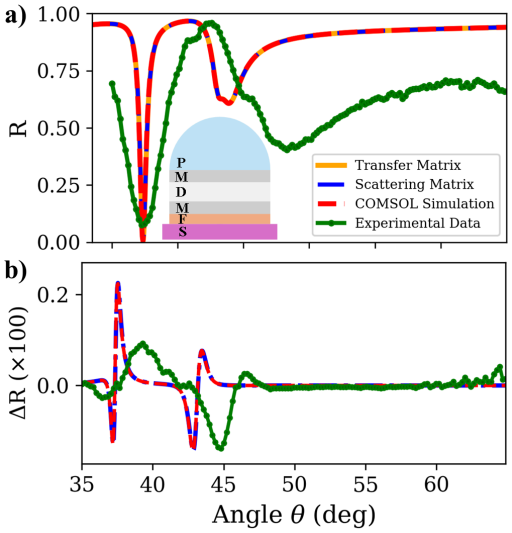

Fig. 1. **a)** Reflectance (R) and **b)** Reflectivity difference, $\Delta R = R(+M) - R(-M)$, as a function of the angle of incidence (θ) for the heterostructure. The experimental data (green line) is compared with theoretical models using the Transfer Matrix Method (TMM, blue solid line) and the Scattering Matrix Method (SMM, orange dashed line), as well as with numerical simulations (COMSOL, red dashed line).

II. Methods

We study a multilayer heterostructure in a Prism/Metal/Dielectric/Metal/Ferromagnet/Dielectric (P/M/D/M/F/D) configuration through a combined theoretical, numerical, and experimental approach (see figure 1):

1) **Analytical Modeling (TMM & SMM):**
   - The Transfer Matrix Method (TMM) models the system's isotropic optical response.

- Under an external magnetic field, the Scattering Matrix Method (SMM) calculates the TMOKE signal and reflectivity, accounting for the magneto-optical anisotropy.

2) **Numerical Simulation (FEM – COMSOL Multiphysics):**
   - Finite Element Method (FEM) simulations map the electric field profiles to physically characterize the modes.
   - This distinguishes between evanescent plasmonic modes (symmetric/antisymmetric) and propagating Fabry-Perot cavity modes.
3) **Validation:**
   - SMM/TMM results are cross-verified with FEM simulations.
   - Final model accuracy is confirmed by comparing numerical spectra with experimental laboratory data.

***Abstract*—We derive a 2D wave equation for surface plasmon polaritons on curved metal surfaces via a perturbative Maxwell expansion. Two linear curvature potentials emerge, distinguishing convex from concave surfaces. Applying our results to excited emitters on spheroids, we demonstrate curvature driven frequency shifts and superradiance.**

***Keywords*— Surface Plasmon Polaritons, Extrinsic Curvature, Geometric Potentials, Superradiance.**

I. Introduction

Surface plasmon polaritons (SPPs) at metal-dielectric interfaces enable rich photonic phenomena ranging from nanofocusing and enhanced biosensing to topological plasmonic lattices [1], [2], [3]. Advances in nanofabrication allow the realization of smooth metallic interfaces with prescribed curvature profiles [4], [5], motivating a systematic theoretical understanding of how curvature shapes SPP dynamics.

The defining feature of the SPP field is that the mode decays much more rapidly into the metal than into the dielectric. In contrast, light confined to a thin dielectric layer decays symmetrically, so that bending convexly or concavely yields identical physics, producing geometric potentials only at second order in curvature [6], [7], [8]. For SPPs, this symmetry is not present, and geometry-induced corrections can appear already at first order in the curvature [9], [10]. Prior work addressed this in specific geometries using paraxial or ray-based methods [9], [11], [12], [13], but a general two-dimensional wave equation valid for any smooth and weak surface modulation has been lacking.

II. Surface Helmholtz Equation on Curved Interfaces

We derive such an equation by expanding Maxwell's equations in the Lorenz gauge in coordinates adapted to the curved interface, parametrized by two tangential surface coordinates q_a ($a = 1, 2$) and a normal coordinate q_3. Working in a gauge where the tangential vector potential components vanish on a flat interface, and using the rescaled field $\mathcal{A}^i = \sqrt{\Omega}\, A^i$ with $\Omega = 1 - 2Hq_3$, the 3D metric near the interface expands as $g_{ab} = \gamma_{ab} - 2q_3 h_{ab}$, with γ_{ab} being the intrinsic surface metric and h_{ab} the second fundamental form [7].

The perturbative expansion parameter is H/k_{spp}, the ratio of the surface extrinsic curvature H to the flat-surface SPP wavenumber

$$k_{\mathrm{spp}} = k_0 \sqrt{\frac{\epsilon_m \epsilon_d}{\epsilon_m + \epsilon_d}}. \tag{1}$$

The SPP field samples the normal direction on a scale $|q_3| \sim \kappa_{d,m}^{-1} \sim k_{\mathrm{spp}}^{-1}$, so the curvature correction experienced by the mode is of order H/k_{spp}. Crucially, we retain a finite normal coordinate q_3, in contrast to the thin-layer limit $q_3 \to 0$ used in many dielectric waveguide studies [6], [7]. It is this q_3-dependent coupling to curvature, captured by the operator $2q_3\, h^{ab}\nabla_a\nabla_b$, that generates the linear-in-curvature potentials.

After a perturbative order-by-order expansion of the wave equations and curvature-modified boundary conditions, we obtain the effective two-dimensional wave equation for the transverse magnetic SPP mode ψ on the interface as

$$\left[\Delta_\gamma + k_{\mathrm{spp}}^2 + V_H + V_\sigma\right]\psi = 0, \tag{2}$$

with the two geometry-induced potential (operators)

$$V_H = \underbrace{\frac{k_0(\epsilon_d^2 + \epsilon_d\epsilon_m + \epsilon_m^2)}{(\epsilon_d + \epsilon_m)\sqrt{-(\epsilon_d + \epsilon_m)}}}_{C_H} H, \tag{3}$$

$$V_\sigma = -\underbrace{\frac{\epsilon_d^2 + 3\epsilon_d\epsilon_m + \epsilon_m^2}{k_0\epsilon_d\epsilon_m\sqrt{-(\epsilon_d + \epsilon_m)}}}_{C_\sigma} \sigma^{ab}\nabla_a\nabla_b. \tag{4}$$

Here, Δ_γ is the Laplace-Beltrami operator, $H = \frac{1}{2}\gamma^{ab}h_{ab}$ the mean curvature, and $\sigma^{ab} = h^{ab} - H\gamma^{ab}$ the traceless part of the second fundamental form.

The prefactor $C_H < 0$ for any material combination supporting SPPs. Consequently, a convex metal surface ($H < 0$) blue-shifts the SPP dispersion, while a concave surface ($H > 0$) red-shifts it [11], [12]. The anisotropic potential V_σ vanishes on isotropic surfaces (spheres and flat interfaces) and acts as a curvature-induced birefringence on surfaces with unequal principal curvatures.

The prefactor C_σ, in contrast to C_H can have different sign depending on the permittivities.

We verify that Eq. (2) reproduces established results for the sphere and cylinder as special cases, recovering the curvature-corrected wavenumbers of Refs. [13], [11] for the sphere and the paraxial Schrödinger equation of Ref. [9] for the cylinder.

III. SPP-Mediated Collective Radiance on a Curved Spheroid

As an application of Eq. (2), we study cooperative emission from an ensemble of quantum emitters interacting via SPPs on a macroscopically curved metal surface, a regime not previously analyzed. SPP-mediated superradiance and subradiance are well understood for planar interfaces [14], [15] and nanowire geometries [16], [17], but the effect of macroscopic curvature on the collective spectrum has not been addressed.

We consider N identical two-level emitters with normally oriented dipole moments placed in a ring near the pole of a silver–air spheroidal interface. For the special case of a spherical surface, the collective spectrum of $N = 9$ emitters is asymmetric with respect to $H = 0$, which means that convex and concave geometries redistribute the N collective eigenmodes differently between superradiant and subradiant channels, and the cooperative frequency shifts change sign depending on the curvature sign. This asymmetry is a direct consequence of the linear-in-curvature potential V_H.

For a spheroidal surface with fixed equatorial radius and varying polar radius, deviations from the spherical shape activate the anisotropic potential V_σ. As the aspect ratio moves away from unity (oblate or prolate deformation), the collective eigenvalues evolve asymmetrically around the spherical case. Decay rates are more sensitive to the deformation than frequency shifts and a selected mode can be driven from near-dark (subradiant) to bright (superradiant) by varying the eccentricity.

IV. Conclusions

We have derived a covariant surface Helmholtz equation for SPPs on weakly curved metal-dielectric interfaces, containing two geometric potential terms linear in the extrinsic curvature. The scalar potential V_H distinguishes convex from concave bending and shifts the effective SPP momentum uniformly, while the anisotropic potential V_σ introduces direction-dependent momentum and acts as a curvature-induced birefringence. Both effects have no analogue in symmetric waveguide systems and vanish in the thin-layer limit. Applied to emitters on a metallic spheroid, the equation predicts that macroscopic surface curvature can redistribute superradiant and subradiant decay channels and produce sign-dependent cooperative frequency shifts, offering a geometric knob for engineering plasmon-mediated light-matter interactions.

***Abstract*—We study the lateral Casimir force experienced by a particle rotating above a planar surface in uniform motion. Working with fluctuational electrodynamics, we investigated the conditions under which the total lateral Casimir force vanishes under different regimes and analysed to what extent it mimics a classical wheel rolling.**

***Keywords*— Casimir lateral force, quantum fluctuations, moving interfaces.**

I. Introduction

Fluctuation-induced forces, generally referred to as Casimir forces, emerge from vacuum and thermal fluctuations of virtual electromagnetic interactions. They are usually attractive and acts along the normal of the interacting surfaces. However, if two surfaces parallel to each other are set in relative motion, a new force component appears parallel to the surface [1], [2], commonly referred to as lateral Casimir force. Furthermore, a polarizable particle moving above a surface also experiences a lateral Casimir force [2], [3], [4], which depends linearly with respect to speed for non-zero temperatures and to the third power for zero temperature [5]. Moreover, other approaches have shown that linear motion is not the only possibility to create Casimir Lateral forces. Indeed, a rotating polarizable particle will interact with the vacuum and thermal electromagnetic fields differently based on the handedness of the field, creating an imbalance in the circularly polarized components which results in asymmetric fluctuations inducing a lateral Casimir force [6]. In the case of metallic materials, this "rotation" force was shown to be proportional to the particle's rotation frequency for non-zero temperature, and to its cube for zero temperature. This rotation frequency dependence behavior with respect to temperature is reminiscent of the speed dependence for a moving particle mentioned above. This raises a question, how would the lateral Casimir forces originating from rotation and linear motion interact, and under which conditions would they cancel out? In this work we consider both types of lateral Casimir forces simultaneously, studying them in different regimes and different assumptions for the particle polarizability. Finally, we analyse to which extent it mimics the behavior of a classical wheel rolling on a surface. This analogy was raised in Ref. [6] since their force and torque were satisfying the relation expected from a wheel in classical mechanics.

II. Analytical Model

In this work, we consider a spherical nanoparticle particle of temperature T_1 and radius R placed at a centre-to-surface distance d above a planar surface of temperature T_0 (see Fig. 1). Assuming the particle is small enough we can adequately describe it within the dipolar limit through a frequency-dependent polarizability $\alpha(\omega)$. We allow the particle to rotate along the y-axis at a frequency Ω which induces a lateral Casimir force along the x-axis [6], we refer to it as the rotation force. Furthermore, we assume the surface to be in uniform motion with velocity $\mathbf{v} = v\hat{\mathbf{x}}$, and calculate its reflection coefficients according to Ref. [7]. As shown in [7], in the case of a metallic surface, the surface's motion introduces an asymmetry in its surface modes dispersion relation, creating a momentum imbalance along the direction of motion, which induces a Casimir friction force along the x-axis, which we refer to as the friction force.

It is clear that the friction force induced by the moving surface is directed along the surface motion, we could imagine the surface trying to drag the particle with it. Therefore, by choosing wisely, we are able to counteract the force induced by rotation, and eventually cancel it.

Fig. 1. Schematic of the system under study. A spherical particle rotates at angular frequency Ω at a centre-to-surface distance d above the surface. The surface itself moves with a uniform velocity $\mathbf{v}$. Both, particle rotation and surface motion, induce a Casimir lateral force on the particle.

As an example, let's consider the particle and the surface to be made of the same metallic material, whose response at low frequencies, well below interband transitions, can be described in terms of the static conductivity σ_0. Using a Drude dielectric function $\varepsilon_r(\omega) = 1 + i\frac{\sigma_0}{\varepsilon_0\omega}$. When the relevant frequencies Ω, $k_x v$ and $k_b T/\hbar$ are much smaller than σ_0, we can approximate the polarizability, $\mathrm{Im}\{\alpha(\omega)\} \approx 12\pi R\varepsilon_0^2\omega/\sigma_0$, and the reflection coefficient $\mathrm{Im}\{r_p(\omega - k_x v)\} \approx 2\varepsilon_0(\omega - k_x v)/\sigma_0$. Using these, and considering the surface and particle to be at the same non-zero temperature ($T_1 = T_0 = T > 0$), it is possible to calculate the total force on the particle along the x-axis as follow,

$$F_{x,\mathrm{tot}} = \frac{3\pi\varepsilon_0^2 R^3 k_b^2 T^2}{2\hbar\sigma_0^2 d^4}\left(\Omega + \frac{1}{A}\frac{v}{d}\right) \tag{1}$$

where A is a constant coefficient which changes depending on the regime considered and polarizability model used. Considering the zero temperature limit, the force would behave as

$$F_{x,\mathrm{tot}} \propto \left[\Omega^3 + \frac{1}{B}\left(\frac{v}{d}\right)^3\right] \tag{2}$$

where B is also a regime dependant constant. Overall, we see that the lateral Casimir force experienced by the particle cancels out when,

$$v = -\eta\,\Omega d \tag{3}$$

with η is a positive constant replacing A and B. In analogy, a classical wheel rolling on a surface without sliding would satisfy $\eta = 1$. It is interesting to note that the equilibrium speed at which the force cancels does not depend on the radius of the particle, but rather on the centre-to-surface distance. This could be imagined as a ghost wheel with radius ηd rolling, strengthening the analogy with classical mechanics and rolling wheels.

III. Discussion

Our aim is to study various sceneries and determine how closes they mimic a classical wheel. The two main path corresponding to the thermal regime ($T > 0$) and vacuum regime ($T = 0$). In the thermal regime we can safely approximate the total force as a sum of a rotation force experienced by a rotating particle above a static surface, and a friction force experienced by a static particle above a moving surface, with no cross terms. However, in the zero-temperature limit (vacuum regime) the interplay becomes unavoidable, and both, friction and rotation force, have to be treated together. Furthermore, at higher temperature, we expect the total force to slightly deviate from the analytical model, as was observed for the rotation force in Ref. [6].

Aside from the temperature dependence, Casimir forces are know to be very model-dependent [2], [4]. For instance Ref. [4] considered a polarizable particle moving above a static surface, and included radiative damping in the particle's polarizability, in contrast with a static conductivity. Under this assumption, the speed and distance dependences change by a factor of $(v/d)^2$ with respect to a static conductivity. Therefore, it is mandatory for us to explore various assumptions. It is also interesting to explore different materials that are not described by a simple Drude model and study how it impacts the lateral forces.

Another possible path of study is the distance dependence. In Ref. [6] it was shown that for large nanoparticle of silicon carbide (with radius of 500nm) the force would oscillate as a function of distance. We may expect a similar behavior with the friction force decaying faster than the rotation force with respect to distance.

We are currently working on the subject and will explore all the available tracks in the future.

IV. Conclusion

We extend the previous research on Casimir lateral force by mixing two sources, a rotating particle and a moving surface. Mixing these we arrive at a condition to completely cancel the forces experienced by the particle, leading to a close analogy with a rolling wheel in classical mechanics. We explore all the different regimes and assumptions which can impact the lateral forces, in order to get a more complete understanding of the phenomenon.

***Abstract*—Plasmon-induced photochemistry exploits metallic nanostructures to concentrate light into localized electromagnetic energy, enabling otherwise inaccessible photochemical pathways. Hot-carrier generation is inherent to plasmonic nanoparticles and enhanced by morphology, composition, and interparticle coupling; this work targets the latter in nanoclusters via an efficient semi-analytical framework connecting plasmon modes to energy-resolved yields for photocatalytic design.**

***Keywords*— plasmonics, hot carriers, photocatalysis, hot spots.**

I. Introduction

Metallic nanostructures concentrate light below the diffraction limit through localized surface plasmon resonances (LSPR), whose spectral and spatial characteristics are governed by particle geometry and interparticle coupling [1], [2], [3], [4]. The non-radiative decay of these resonances produces non-equilibrium electron–hole pairs—so-called hot carriers—capable of driving photocatalytic reactions [5], [6], [7]. In nanoparticle clusters, plasmon hybridization gives rise to collective eigenmodes with modified field distributions and, consequently, altered carrier generation profiles [8], [9], [10]. As cluster complexity grows, efficient frameworks that link the electromagnetic response to energy-resolved hot-carrier production become essential [11], [12], [13].

II. Methods

We combine a semi-analytical treatment of cluster electrodynamics with Fermi's golden rule, linking plasmonic field enhancement directly to hot-carrier generation rates.

A. Boundary-Charge Method for Plasmon Hybridization

We obtain the plasmon-induced potential through the boundary-charge method (BCM). Given a cluster of N metallic spheres, the induced surface charge $\rho_i(\boldsymbol{r}_i)$ on each surface S_i that interact with every sphere j is determined by:

$$\frac{1}{2}\frac{\varepsilon_i+\varepsilon_h}{\varepsilon_i-\varepsilon_h}\rho_i(\boldsymbol{r}_i) - \sum_j^N \int_{S_j} \frac{\hat{\boldsymbol{n}}_i\cdot(\boldsymbol{r}_i-\boldsymbol{r}'_j)}{4\pi\|\boldsymbol{r}_i-\boldsymbol{r}'_j\|^3} \times \rho_j(\boldsymbol{r}'_j)\,dS'_j = \varepsilon_0\hat{\boldsymbol{n}}_i\cdot\hat{\boldsymbol{E}}_{\text{ext}}(\boldsymbol{r}_i). \quad (1)$$

Expanding ρ_i in spherical harmonics $Y_{\ell m}$ reduces this integral equation to a linear system, yielding semi-analytical expressions for the scalar potential $\phi(\boldsymbol{r},\omega)$ inside every particle for arbitrary cluster structures and illumination polarizations [14], [15], [16].

B. Hot-Carrier Generation via Fermi's Golden Rule

The resulting potential drives interband electronic transitions. The energy-resolved electron generation rate at final-state energy ε_f under monochromatic illumination at frequency ω reads:

$$\Gamma_e(\varepsilon_f,\omega) = \sum_i \mathcal{F}(\varepsilon_i)[1-\mathcal{F}(\varepsilon_f)]\frac{4}{\tau} \times\left[\frac{|M_{fi}(\omega)|^2}{(\hbar\omega-\varepsilon_f+\varepsilon_i)^2+\hbar^2/\tau^2} + \frac{|M_{if}(\omega)|^2}{(\hbar\omega-\varepsilon_i+\varepsilon_f)^2+\hbar^2/\tau^2}\right], \quad (2)$$

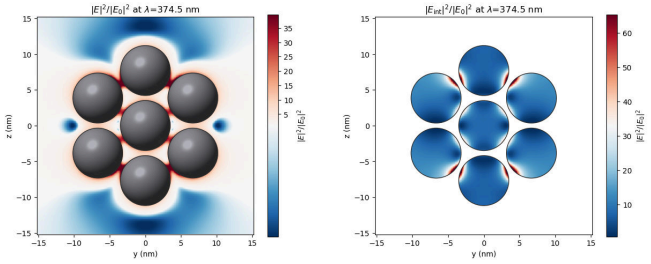
where $M_{fi} = \langle\psi_f|\phi|\psi_i\rangle$ are matrix elements of the BCM potential between electronic states, $\mathcal{F}$ is the Fermi–Dirac distribution, and τ is a phenomenological lifetime that broadens the energy-conserving delta functions [17], [6]. An analogous expression yields the hole generation spectrum. Together, these rates provide the energy-resolved hot-carrier distributions needed to evaluate photocatalytic figures of merit.

III. Results and Discussion

We illustrate the framework on a silver nanosphere heptamer illuminated at $\lambda = 374.5$ nm. This compact cluster supports a rich set of hybridized plasmon eigenmodes arising from the strong coupling between the central and peripheral spheres. Figures 1a and 1b show the external and internal normalized electric-field intensities obtained from the BCM expansion at the selected wavelength.

The external field (Fig. 1a) reveals pronounced hot spots in the six gaps between the central and peripheral particles as well as between adjacent satellites, with enhancements reaching $|E|^2/|E_0|^2 \approx 35$, characteristic of the bright dipolar mode of the heptamer. Inside the particles (Fig. 1b), the field is strongly redistributed toward the gap-facing hemispheres of the peripheral spheres, where enhancements exceed $|E_{\text{int}}|^2/|E_0|^2 \approx 60$. This asymmetric internal redistribution directly shapes the spatial profile of interband transitions and, consequently, the hot-carrier generation landscape.

Figure 2 presents the spectral hot-carrier generation rate Γ_e for a $D = 7$ nm silver nanoparticle, together with the



(a) (b)

Fig. 1: Normalized electric-field intensity at $\lambda = 376.9$ nm for a silver nanosphere dimer computed via the BCM. (a) External field $|E|^2/|E_0|^2$ showing hot spots at the gap and outer poles. (b) Internal field $|E_{\text{int}}|^2/|E_0|^2$ showing redistribution toward the gap-facing region.

absorption cross-section Q_{abs} and the thresholded rate for electrons above 1.2 eV. Two dominant resonances appear near 3.2 eV and 3.65 eV; the total generation rate closely tracks the absorption peaks, confirming that resonant modes govern carrier production. Importantly, only a fraction of the generated carriers exceed the energy threshold at each resonance, highlighting the need for mode-selective engineering to maximize useful hot-carrier yields.

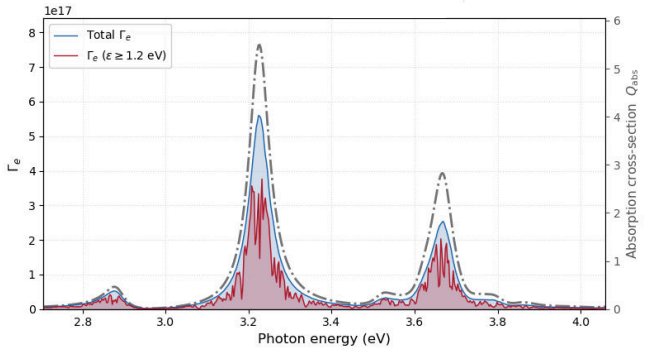


Fig. 2: Spectral hot-electron generation rate Γ_e (blue) and thresholded rate for $\varepsilon \geq 1.2$ eV (red) for a $D = 7$ nm silver nanoparticle with $\tau = 500$ fs. The absorption efficiency Q_{abs} (right axis) confirms that carrier generation peaks track plasmonic resonances.

These results demonstrate that the framework efficiently links near-field distributions to energy-resolved carrier metrics even for multi-particle clusters with dense mode spectra, providing a practical tool for scanning cluster geometries and identifying configurations that optimize photocatalytic performance.

IV. Conclusion

We have presented an efficient semi-analytical framework that connects plasmon hybridization in metallic nanoclusters to energy-resolved hot-carrier generation. By combining the boundary-charge method with Fermi's golden rule, the approach maps the plasmon-induced internal fields of arbitrary cluster geometries directly onto spectral carrier distributions. Applied to a silver nanosphere heptamer ($D = 7$ nm, gap ~ 0.5 nm), the framework captures the strongly enhanced internal fields arising from multi-particle hybridization and resolves two distinct plasmonic resonances that govern hot-carrier production. The computational efficiency of the method enables systematic scanning of cluster configurations, interparticle separations, and illumination conditions, providing a practical design tool for optimizing hot-carrier yields in photocatalytic and energy-harvesting applications.

Abstract — We demonstrate room-temperature lasing in a quasi-2D perovskite integrated with a high-Q plasmonic metasurfaces supporting a Γ-point quasi-bound state in the continuum mode. To clarify the nature of the lasing mode, we analyze the emission characteristics using polarization-resolved k-space spectroscopy and compare them with the calculated photonic band structure.

***Keywords* — High-Q plasminic metasurfaces, quasi-2D perovskite, room-temperature lasing, plasmonic quasi-BIC**

I. Introduction

Plasmonic surface lattice resonances (SLRs), supported by periodic arrays of metallic nanoparticles, have emerged as a representative high-Q plasmonic metasurface platform, providing robust optical cavities that can sustain high-quality-factor resonances at room temperature[1]. It has been widely utilized in applications ranging from refractive index sensing[2] to strong light-matter coupling[3] and nanoscale lasing[4]. The hybridization between localized surface plasmons (LSPRs) and diffracted orders in these periodic structures yields complex photonic band structures[5], hosting rich physical phenomena such as Bose-Einstein condensation[6] and nontrivial topological characteristics[7]. However, inherent ohmic losses in metallic components remain a fundamental limitation. When the electromagnetic field is tightly confined to the metal surface, substantial energy is dissipated as heat. To mitigate this, dark modes within the SLR cavity—often associated with optical bound states in the continuum (BICs)—have attracted considerable attention[8,9]. While quasi-BIC (q-BIC) SLR lasing has been demonstrated across various lattice geometries, the majority of these implementations rely on liquid-phase dye solutions as the gain medium, which limits their integration into on-chip photonic devices.

Building upon our previous demonstration of room-temperature SLR lasing using a quasi-2D perovskite (PVSK) film [9], this work we further presents an engineered square lattice design where a symmetry-protected BIC is spectrally aligned with the gain profile of the quasi-2D PVSK. We experimentally realize solid-state q-BIC lasing with a threshold of 56 μJ/cm^2 and utilize momentum-resolved (k-space) spectroscopy to reveal the photonic band structure. Furthermore, by employing polarization-resolved k-space spectroscopy, we analyze the far-field polarization states to investigate the modal characteristics associated with the BIC point.

II. Methods

- Sample fabrication

The High Q plasmonic metasurfaces were fabricated using a standard electron-beam lithography (EBL) and lift-off process. The square lattice patterns were defined on a positive ZEP-520 resist using an EBL system (Elionix ELS-BODEN 100). Subsequently, an aluminum (Al) film was deposited *via* evaporation on quartz substrate, followed by a lift-off procedure to form the Al nanoparticle arrays (aka SLR cavity). The quasi-2D PVSK film was spin-coated onto the designed structure, and the entire process was carried out in a glove box.

III. Results and Discussion

The SLR laser consists of a 70-nm-thick Ruddlesden-Popper phase quasi-2D PVSK layer ($PEA_2Cs_{n-1}Pb_nBr_{3n+1}$, with n=5)[10], and aluminum nanoparticles (54 nm in diameter and 60 nm in height) arranged in a periodic array with a pitch of 330 nm as shown in the Fig. 1A. Fig. 1B shows the calculated photonic band structure obtained by FDTD simulations, with the incident angle varied from 0° to 20°, where the angle is defined with respect to the surface normal. The calculated transmission spectra at θ = 0° and 1° in Fig. 1C are extracted from the photonic band structure reveals the resonant modes. More importantly, we calculated the mode distribution and define the dipole mode (560 nm) and the quadrupole mode (526 nm), as shown in Fig. 1D. Fig. 1E shows the measured k-space spectrum of the fabricated sample under 405 nm continuous-wave (CW) laser excitation. Details of the fabrication process can be found in the Methods section. The photoluminescence from the quasi-2D perovskite couples into the SLR modes, and the angle-resolved photon emission reveals the photonic band

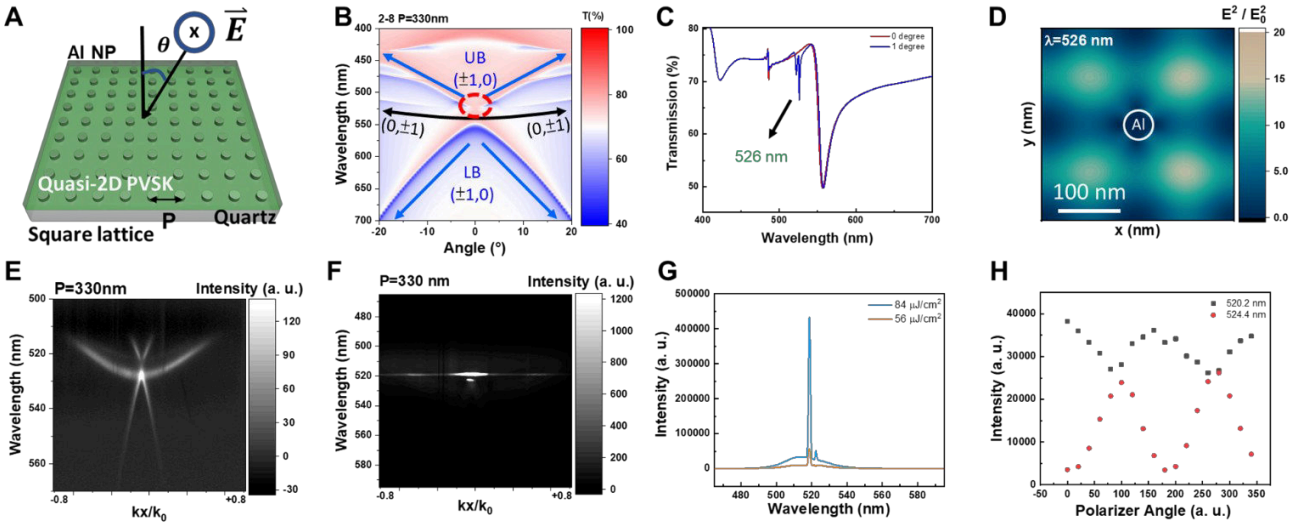

Fig. 1 Room-temperature lasing in quasi-2D PVSK coupled with high Q plasmonic metasurfaces. (A) Schematic of the designed SLR structure. A quasi-2D PVSK film (green layer) was spin-coated on top of the Al nanoparticle array fabricated on a quartz substrate. The angle θ in the inset indicates the electric field polarization used in the simulation. P stand for the period of the nanoparticle array. (B) FDTD-simulated angle-dependent transmission spectra of the designed device. The blue arrows and the black curves indicate the (±1, 0) and (0, ±1) modes of the SLR cavity, respectively. A Γ-point BIC can be observed inside the red dashed circle. **(C)** Simulated transmission spectra extracted from (A) at incident angles of 0° and 1°. **(D)** Calculated electric field distribution of the q-BIC at 526 nm (quadrupole mode). **(E)** Measured k-space spectrum under 405 nm continuous-wave (CW) laser excitation. **(F)** Measured k-space spectrum under lasing conditions with pulsed laser excitation. **(G)** Lasing signals of the q-BIC and dipole modes at an excitation fluence of 56 and 84 μJ/cm² respectively. **(H)**

structure of the fabricated device. The experimental data align perfectly with the simulation results (Fig. 1B). Not only the bandgap separating the upper branch (UB) and lower branch (LB) evident is in both the experiment and simulation, but the BIC at the Γ point of the UB is also clearly observed. To summarize, the fundamental difference between the UB and LB lies in their electric field distributions. The UB operates as a quadrupolar dark mode, whereas the LB acts as a dipolar bright mode.

When the sample is excited by a 400 nm ultrafast pulsed laser (1 kHz, 100 fs), a sharp q-BIC SLR lasing peak emerges at 520.4 nm with a full-width at half-maximum (FWHM) of ~1 nm under an excitation power of 56 μJ/cm², as shown in Fig. 1F and 1G. Additionally, a second sharp peak is observed at 524.4 nm, also exhibiting an FWHM of ~1 nm. The shorter-wavelength peak appears at the Γ point of the upper branch (UB), but its emission is not fully concentrated at 0° in the k-space spectrum. This offset is a characteristic trait of q-BIC lasing, as the mode cannot radiate exactly at normal incidence.

Due to the high quality factor of the q-BIC mode, the lasing threshold for the 520.2 nm peak is lower than that of the 524.4 nm peak (~84 μJ/cm²), which corresponds to classical SLR bright-mode lasing. Finally, in the light-in-light-out (L-L) curve from the power-dependent photoluminescence (PL) experiment, a superlinear transition in PL intensity, accompanied by linewidth narrowing, occurs at a pump fluence of 56 μJ/cm². These characteristics confirm that the sharp peak originating from the upper branch is indeed a q-BIC lasing signal.

Furthermore, we measured the polarization-dependent k-space spectra of these two lasing peaks, as shown in Fig. 1H. While the 520.2 nm peak exhibited a minimum intensity at a polarizer angle of approximately 90°, the 524.4 nm peak showed a maximum intensity. The polarization ratio defined by the eq. (1) are 76% and 17 % respectively. These polarization results indicate that the origins of these peaks are distinct, as their lasing polarizations are mutually orthogonal. Ultimately, these lasing characteristics reflect the difference in the electric field distributions between the quadrupole (dark) mode and the dipole (bright) mode.

$$P = \frac{(I_{max} - I_{min})}{(I_{max} + I_{min})} \quad (1)$$

IV. Conclusion

In summary, we successfully demonstrated plasmonic q-BIC lasing by integrating an aluminum SLR cavity with a novel quasi-2D PVSK. Our investigation demonstrates that the q-BIC originates from a quadrupolar dark mode at normal incidence, which transforms into a radiating bright state through in-plane symmetry breaking. The measured k-space spectra and the extracted photonic band structure exhibit excellent agreement with our FDTD simulation predictions. Under pulsed laser excitation, lasing action with difference polarization was definitively confirmed by a superlinear transition in the light-in-light-out (L-L) curve, accompanied by distinct linewidth narrowing. Furthermore, the lasing threshold for the 520.2 nm q-BIC mode was determined to be approximately 56 μJ/cm².

Benefiting from the high Q factor of the q-BIC, this threshold is lower than that of the classical dipolar SLR bright mode lasing at 524.4 nm (~84 μJ/cm²). Moreover, polarization-dependent measurements confirmed that these two lasing modes possess mutually orthogonal polarizations. This directly verifies their distinct physical origins, reflecting the fundamental difference in the electric field distributions between the quadrupolar and dipolar modes. These findings provide a concrete experimental and theoretical framework for manipulating bound states in the continuum within plasmonic architectures, offering a reliable platform for studying light-matter interactions.

***Abstract*—The fourth- and fifth-harmonic generation of mid-infrared pulses (3500 nm), accompanied by a broad luminescence from the gap-mode plasmon excitation in an STM nanojunction, was observed through the tip-enhanced process. This demonstrates that mid-IR field enhancement and visible plasmon resonance work together efficiently in tip-enhanced high-harmonic generation at the nanoscale.**

***Keywords*—tip-enhanced spectroscopy, high harmonic generation, plasmonic nanogap, strong-field phenomena.**

I. Introduction

Electric-field enhancement in plasmonic nanostructures has proven effective for amplifying nonlinear optical phenomena and inducing strong-field effects [1]. In particular, high-harmonic generation (HHG) has been demonstrated in periodic metallic nanostructures [2, 3]. However, such periodic structures inevitably lead to signal averaging over the focal spot on a micrometer scale. In contrast, plasmonic nanogaps formed between a metallic tip and a substrate confine optical fields to a single nanoscale hot spot beyond the diffraction limit, thereby enabling nanoscale chemical analysis, as exemplified by tip-enhanced Raman spectroscopy [4].

Although most tip-enhanced spectroscopy (TES) studies employ continuous-wave lasers, we have combined TES with ultrashort pulsed lasers and demonstrated tip-enhanced second-harmonic generation (TE-SHG) with near-infrared (IR) pulses [5, 9] and tip-enhanced sum-frequency generation (TE-SFG) [6–9] with both near-IR and mid-IR pulses. Through these studies, we have elucidated two enhancement mechanisms underlying TES: (i) incident field enhancement as the incident field is collected by the tapered shaft of the tip and guided to the apex (antenna effect); (ii) radiation efficiency enhancement arising from the gap-mode plasmon within the nanogap (plasmon resonance). Numerical simulations have revealed that the antenna effect becomes more pronounced at longer wavelengths, indicating that the mid-IR region provides significant enhancement of the incident field, whereas plasmon resonance enhances the radiation efficiency in the visible region [5, 6] (Fig. 1). This result suggests that tip-enhanced HHG (TE-HHG), driven by a mid-IR pulsed laser and generated in the visible region, provides a promising platform for probing strong-field phenomena at the nanoscale.

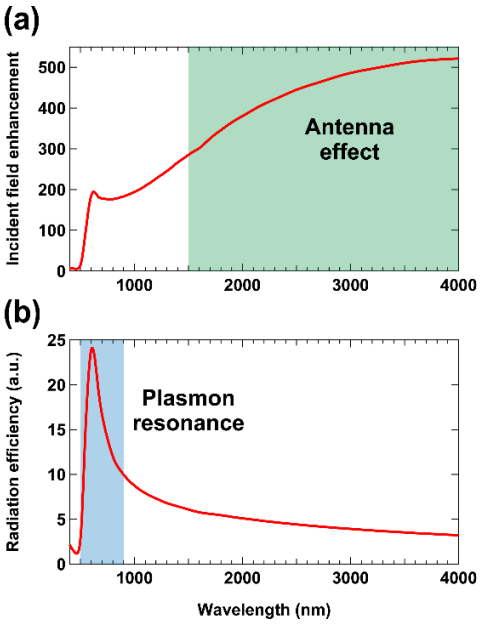

Fig. 1 (a) Enhancement of the incident field at the nanogap between a gold tip and a gold substrate, calculated using electromagnetic field simulations. (b) Radiation efficiency from the dipole in the nanogap, monitored at a position corresponding to the far-field. Details are described in Refs. [5, 6].

II. Methods

The experimental setup of the TE-HHG system is schematically illustrated in Fig. 2. In this system, the output from a mode-locked Yb:KGW laser (1029 nm, 108 fs, 140 nJ, 50 MHz) was used to pump an optical parametric oscillator (OPO), which generated two output beams: a signal (1.3–2 μm) and an idler (2.1–5 μm). The idler beam passed through a telescope to expand the beam diameter and compensate for its divergence, and subsequently through a pair of polarizers to adjust the beam intensity. The idler pulses (3500 nm, 0.8 nJ, 50 MHz) were then focused onto the nanojunction between a gold

tip and a gold substrate in a scanning tunneling microscope (STM) system at an incident angle of 55°. The beam was linearly polarized along the tip axis (*p*-polarization) to effectively excite the gap-mode plasmon. Two identical CaF_2 aspherical lenses were employed to focus the incident beam and collect the emitted signals. A dichroic mirror (reflective over 730–920 nm and transmissive over 2.5–8 μm) was placed in the incident beam path to collect the backward-scattered signal. Both the forward- and backward-scattered signals were focused by an achromatic doublet, passed through a short-pass filter (transmissive over the 500–900 nm range), and coupled into separate branches of a bifurcated optical fiber bundle, thereby enabling their simultaneous detection. The fiber-coupled signals were spectrally dispersed by a spectrometer and detected using an electronically cooled CCD camera.

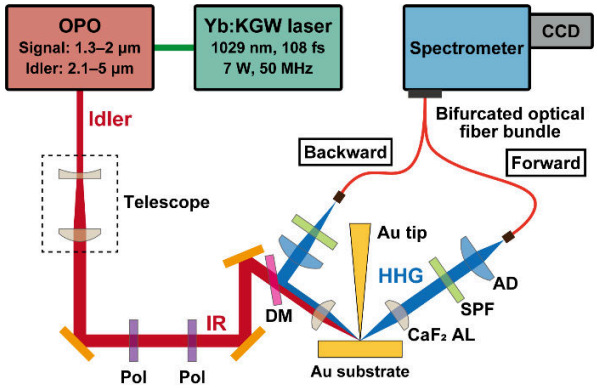

Fig. 2 Experimental setup of the TE-HHG system. Pol: polarizer, CaF_2 AL: CaF_2 aspherical lens, SPF: short-pass filter, AD: achromatic doublet. A dichroic mirror (DM) and a bifurcated optical fiber bundle were employed to simultaneously collect both forward- and backward-scattered signals.

III. Results and Discussion

The spectra of the (a) forward- and (b) backward-scattered signals are shown in Fig. 3. The black curves correspond to spectra obtained with the Au substrate retracted by 50 nm from the Au tip, which show almost no signal or spectral features. In contrast, the red curves correspond to spectra obtained with the Au substrate positioned within ~1 nm of the Au tip, which show two distinct peaks superimposed on a broadband luminescence. These two peaks correspond to the fourth- and fifth-harmonic generation (4HG/5HG) of the incident mid-IR pulses (3500 nm). The broadband luminescence is attributed to gap-mode plasmon excitation in the STM nanojunction. The luminescence induced by tunneling electrons in STM nanojunctions is known as STM luminescence, whereas in the present case, the luminescence is induced by irradiation with mid-IR pulses. A similar phenomenon has been reported under THz irradiation in the form of THz-field-driven STM luminescence [10]. The backward-scattering signal was approximately three times stronger than the forward-scattering signal; however, the intensity distribution varied significantly depending on the specific tips used. This variation originates from the nanoscale morphology of the tip apex, which critically influences near-field generation in the nanogap and thereby affects both the signal radiation efficiency and the emission direction, as previously reported for STM luminescence [11]. The simultaneous observation of 4HG/5HG and broadband luminescence, together with the different intensity distributions between the forward- and backward-scattered signals, suggests an enhancement of the radiation efficiency of HHG signals due to the plasmon resonance. This result demonstrates that the hybrid enhancement mechanism (i.e., the incident mid-IR field enhancement by the antenna effect and the radiation efficiency enhancement by the plasmon resonance) operates efficiently in the TE-HHG process.

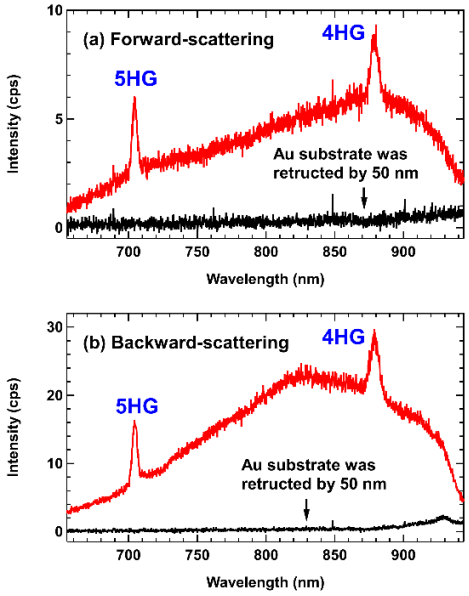

Fig. 3 Spectra of the (a) forward- and (b) backward-scattered signals. The black curves correspond to spectra obtained with the Au substrate retracted by 50 nm from the Au tip, whereas the red curves correspond to spectra obtained with the Au substrate positioned within ~1 nm of the Au tip, which show two distinct peaks corresponding to the 4HG and 5HG of the incident mid-IR pulses (3500 nm), superimposed on a broadband luminescence attributed to gap-mode plasmon excitation in the STM nanojunction. Intensities are normalized to counts per second (cps).

IV. Conclusion

We have demonstrated TE-HHG in an STM nanojunction between a Au tip and a Au substrate. Two distinct peaks were observed at the 4th and 5th harmonics of the incident mid-IR pulses, accompanied by a broad luminescence arising from gap-mode plasmon excitation in the STM nanojunction. This result indicates that the hybrid enhancement mechanism (the incident mid-IR field enhancement by the antenna effect and the radiation efficiency enhancement by the plasmon resonance) operates efficiently in the TE-HHG process at the nanoscale.

***Abstract*— Comparative studies of nanoplasmonic cavities formed in the interspace between gold microdisks and either a gold-coated AFM tip or a gold nanoparticle are presented based on enhanced Raman scattering of molecular self-assembled monolayers. These measurements deepen our understanding of plasmonic interactions and contribute to new sensing and photonic devices.**

***Keywords*— TERS, SERS, Raman spectroscopy, plasmonics, NPoM.**

I. Introduction

Nanoparticle-on-mirror (NPoM) platforms are stable, robust, and reproducible systems where light is squeezed into sub-nanometer volumes. They are made up of a metal nanoparticle (NP) over a metallic substrate. This system forms a plasmonic cavity, where the interaction between the localized surface plasmons of the NPs and the underlying substrate creates a highly confined electromagnetic field. The field not only enhances significantly the Raman signal from the molecules underneath, enabling detailed spectroscopic analysis at the nanoscale, but can also trigger photocatalytic reactions acting as nanoreactors. Despite the increasing amounts of promising applications [1,2], active surface sites of NPoMs remain hard to control, adding imprecision to these nanostructures.

Here we propose an alternative architecture where the metal NP is substituted by a metalized atomic force microscopy (AFM) tip. Such tip-on-mirror (ToM) cavities can be spatially scanned and combines the spatial resolution of AFM with the chemical specificity of tip-enhanced Raman spectroscopy (TERS). We have used a ToM to scan a NPoM platform and in this way compare the performance of both systems regarding their enhancement factors, spectral features, and stabilities.

II. Methods

Raman spectroscopy maps of a NPoM sample were measured using a ToM set-up to obtain both TERS and surface-enhanced Raman scattering (SERS) spectra. The sample consisted of a 24×24 array of gold disks, each with a height of 120 nm and a diameter of 12 µm. The surface of these disks was functionalized with a self-assembled monolayer (SAM) of biphenyl-4-thiol (BPT). A single 150 nm gold NP was placed on the surface of each disk following a procedure reported by Redolat *et al.* [1].

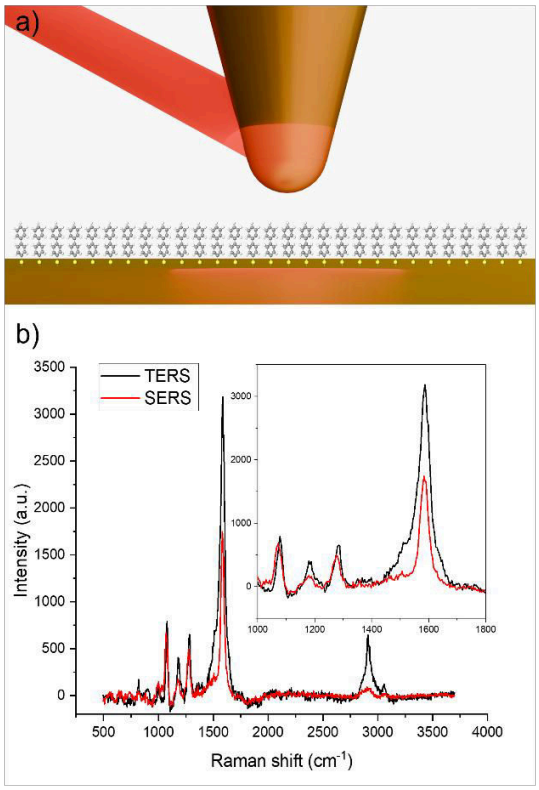

Fig. 1 a) Diagram showing the AFM tip over the BPT SAM. The laser is focused on the tip apex, and it excites the plasmon of the tip-surface system. The confined light, in turn, excites the vibrational modes of the molecules before being scattered. b) Comparison between TERS and SERS spectra. TERS measurements were taken at 200 µW laser power, and SERS at 500 µW.

TERS is a spectroscopic technique that integrates scanning

probe microscopy (SPM) with Raman spectroscopy to achieve nanoscale spatial resolution, surpassing the limitations imposed by the optical diffraction limit. This enhancement is accomplished by focusing a laser onto the apex of a metallic-coated scanning probe tip, exciting localized surface plasmons that generate a highly confined electromagnetic field. This field, in turn, amplifies the vibrational modes of molecules located beneath the tip, enabling precise molecular characterization at the nanoscale. This configuration is represented in the diagram in Fig. 1a.

SERS is another spectroscopic technique that makes use of the same underlying mechanism to enhance the measured signal. In this case, light is focused on a golden NP, exciting its surfaced plasmon and confining it in the nanocavity formed in the tight gap between the NP and the substrate. It does not improve the spatial resolution of regular Raman spectroscopy, but it can be done using the same microscope setup.

III. Results and Discussion

Experimental results show that the intensity enhancement in both SERS and TERS (Fig. 1b) are comparable, although TERS' enhancement factor is about 2 to 5 times higher than in SERS. We have also observed that TERS peaks are narrower than SERS peaks and appear shifted towards higher frequencies (Table 1).

BPT Mode	Mag (cm^{-1})	TERS	SERS
1080 cm^{-1}	Center	1078 ± 1	1071 ± 2
	FWHM	10 ± 2	20 ± 3
1280 cm^{-1}	Center	1282 ± 1	1276 ± 4
	FWHM	13 ± 3	28 ± 4
1580 cm^{-1}	Center	1588 ± 1	1583 ± 4
	FWHM	26 ± 3	33 ± 4

Table 1 Average magnitudes derived from the statistical analysis of the TERS and SERS maps' fitted peaks. The TERS data has been measured on zones of the golden disk with no NPs. TERS peaks appear narrower than SERS peaks. They are also slightly shifted towards higher frequencies.

TERS and SERS spectra are different due to their different plasmonic nanocavity geometries. The laser incidence direction and its polarization are different, and so are the shape of the excited plasmons. This changes the Raman selection rules and influences the measured spectra. TERS measurements have about 50 times better spatial resolution and can be done anywhere on the golden microdisks, while SERS measurements are confined to the area around the NPs.

TERS spectra around the NPs are significantly changed (Fig. 2). They are also affected by a change in the cavity geometry, as there are three bodies in this system: the tip, the substrate and the golden NP; and the interaction between their plasmons makes an effect on the dispersed light. It has also been reported that the citrate capping agent used to stop the growth of the NPs can degrade into graphitic or amorphous carbon after being heated up by the intense EM fields SERS measurements produce in a NPoM platform [3].

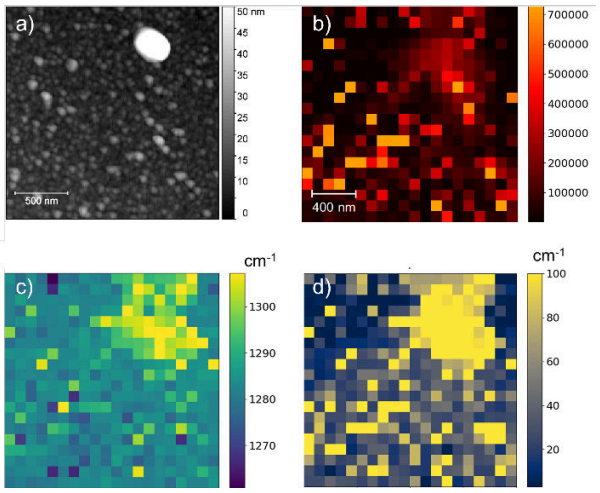

Fig. 2 TERS mapping over a gold NP. a) AFM topography image. b) TERS total spectral intensity. c) 1280 cm^{-1} mode peak center map. d) 1280 cm^{-1} mode peak FWHM map. The peak is broader and shifts towards higher frequencies around the NP.

IV. Conclusion

ToM platforms can be used to study and compare NPoM systems. We have been able to measure the Raman spectra of a BPT SAM using both TERS and SERS. TERS has shown better spatial resolution and enhancement factor, and a slight change in the spectra that can be explained by the different geometry of the plasmonic nanocavities. The change in spectra around the NPs hints toward the catalysis of chemical reactions in the NPoM system induced by the strong EM fields involved. These results open the door to the precise and detailed characterization of advanced sensing devices and deepen our understanding of the physical and chemical processes underlying the manipulation of light at the nanoscale, paving the way for the design and implementation of advanced sensing devices and photonic integrated circuits.

***Abstract*— We report surface lattice resonances in the 460 to 580 nm range in aluminum bowtie nanoantennas fabricated by electron beam lithography. Without post-annealing or symmetric refractive index material coating, fabricated arrays exhibit ultra-narrow 3.4 nm linewidth. These metasurfaces can support strong coupling for photocatalysis and quantum emitters.**

***Keywords*— metasurface, bowtie, surface lattice resonance, plasmonic gap.**

I. Introduction

Plasmonic nanoparticles can locally amplify optical fields within nanoscale volumes, making them functional for enhancing light-matter interactions in fields of photocatalysis, sensing and nanoscale light sources.[1,2,3] However, localized surface plasmon resonances (LSPRs) in metal nanoparticles typically exhibit low quality factor resonances arising from optical losses and plasmon damping.[4] Surface lattice resonances (SLRs) can be generated by arranging plasmonic nanoparticles in periodic arrays and can support higher quality factor resonances than LSPRs by suppressing radiative damping. The narrow linewidths, and consequently the higher quality factors of the SLRs, make them practical for surface-enhanced Raman spectroscopy, lasing, and strong coupling to molecular resonances and quantum emitters.[5] In particular, SLRs in arrays of aluminum (Al) nanoparticles are of interest, because they provide a route to access resonances in the blue and UV regions of the spectrum, which may not be achievable using typical lithography techniques on plasmonic metasurfaces based on noble metals.. Furthermore, the coupling of LSPRs and SLRs with guided mode resonances (GMRs), supported by a high-index buffer layer between the Al metasurface and the substrate, can generate hybrid modes with narrow linewidth features in the optical extinction spectra, which can be effectively utilized in the applications listed above.[6] Previously, surface plasmon resonances have been reported in the blue region of the spectrum using silver nanostructures, however, the plasmonic properties deteriorated with time due to oxidation and sulfidation of silver in air.[7,8] Here, we have experimentally demonstrated and numerically verified that periodic arrays of Al bowtie nanoantennas can support narrow-linewidth (FWHM 3.4-5 nm) SLRs in the green and blue regions of the spectrum.

II. Methods

The Al metasurface consists of bowtie nanoantennas made of equilateral triangles with side lengths of 85 nm, a bowtie gap of 15 nm, a thickness of 20 nm, and varying pitches ranging from 280 to 380 nm. The structures were simulated by finite element method using COMSOL Multiphysics. These bowtie nanoantennas were fabricated over 50 µm × 50 µm areas with high placement accuracy of a nanometer using electron beam lithography. The entire Al metasurface is fabricated on a 100-nm-thick ITO film on an SiO_2 substrate. The Al metal deposition was performed at low base vacuum of 5×10^{-8} Torr to reduce oxidation. A 0.07 N.A. lens was used for normal incidence excitation. All the absorption spectra were recorded in high resolution mode of Andor spectrometer (Kymera 328i) with 10 µm slit width and 500 l/mm grating that is blazed at 600 nm.

III. Results and Discussion

The high-index ITO film acts as a slab waveguide, supporting hybrid plasmonic-GMR resonances. A red shift in the SLR peak was observed from 460 to 580 nm with increasing bowtie period (figure 1a). SLR peak positions also found to match close to the simulated results which validates the high quality of fabricated structures. A quality factor of about 117 was measured for the SLR peak at 542 nm with a narrow spectral width of 4.6 nm. The linewidth of SLRs also depends on the bowtie counts and further reduced to 3.4 nm (for 461 nm SLR peak) with increasing counts as shown in figure 1b which is the among the best reported for Al nanoantenna arrays in this spectral region.[9] In addition to the observed narrow linewidth SLRs, we have also observed strong coupling between the LSPR of the bowtie nanoantennas and guided modes in the ITO film. The coupling of the LSPRs and guided modes in the ITO film result in hybrid modes separated by an energy equivalent

to a Rabi splitting of 259 meV, indicating a robust coupling regime.

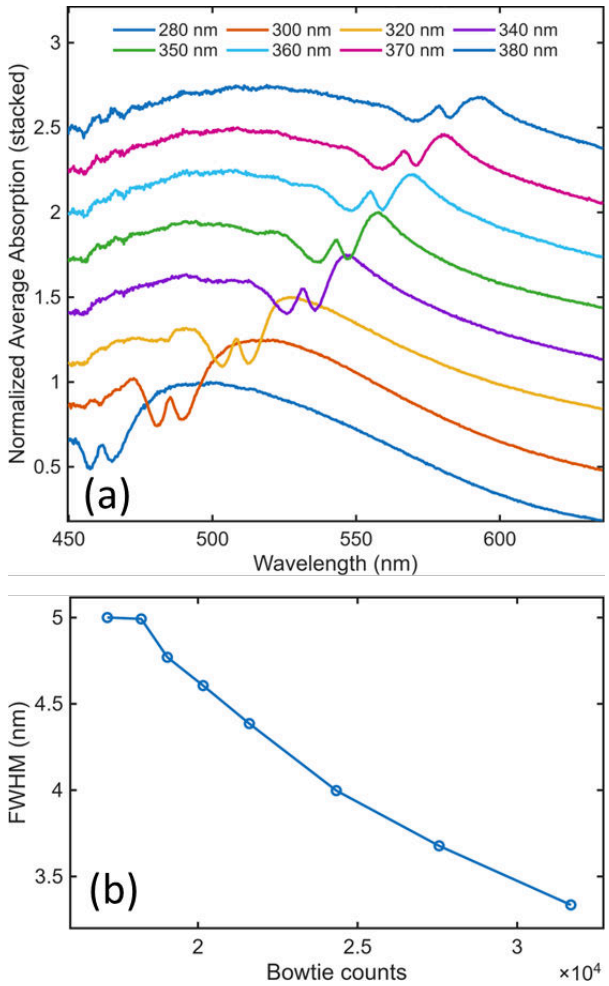

Figure 1 (a) Experimentally measured extinction spectra for arrays of Al nanoantennas with different pitches (b) the surface lattice resonance linewidth as a function of bowtie counts. The SLR peak at 461 nm has an observed FWHM of 3.4 nm.

IV. Conclusion

Overall, this report provides a route to obtain geometrically tunable SLRs in the blue/green region of the spectrum with narrow SLR modes within the broad LSPR modes. We believe that our findings in this study can contribute to the development of the field of strong light-matter interaction, particularly when photocatalysis or quantum emitters are strongly coupled to the Al metasurface.

***Abstract*—First-principles study of Mg-Al icosahedral clusters (0-100% Al) reveals starkly different photoabsorption spectra for clustered vs. random atomic arrangements. Random alloys exhibit a single, progressively broadening peak that evolves continuously from Mg to Al character. However, clustered configurations display multiple distinct peaks. Composition and atomic ordering enable controlled plasmonic properties.**

***Keywords*— metamaterials, Magnesium-aluminum alloys, icosahedral clusters, photoabsorption spectra, plasmonics, density functional theory, atomic configuration effects.**

I. Introduction

Bimetallic nanoparticles have emerged as versatile metamaterials for gearing optical, electronic, and catalytic properties by controlled manipulation of composition, size, and atomic arrangement [1]–[3]. Magnesium-aluminum (Mg-Al) alloys are particularly important among the several binary systems being studied because of their low density, high specific strength, and potential uses in lightweight structural materials, hydrogen storage, and plasmonics [4]–[6]. The optical behavior of Mg-Al nanoparticles, specifically the impact of atomic-scale chemical ordering on their photoabsorption spectra, is still largely unknown, despite the fact that the thermodynamic and mechanical properties of bulk Mg-Al alloys are well understood [7]. The plasmonic response of metallic nanoparticles is exceptionally sensitive to the local dielectric environment and electron density distribution [8]. Alloying introduces compositional and spatial degrees of freedom, which modulates the average electron density and the dielectric landscape whether randomly mixed or phase separated into distinct domains [9], [10]. Understanding how these factors interplay is crucial for designing nanoparticles with targeted optical responses. In this work, we present a comprehensive first-principles investigation of the structural relaxation and photoabsorption spectra of 147-atom icosahedral Mg-Al clusters across the complete compositional range (0-100% Al). We construct two distinct atomic configurations at each composition: clustered arrangements, where Al atoms aggregate into a contiguous domain mimicking early-stage phase separation, and random arrangements, representing homogeneous solid solutions. (Fig. 1)

II. Methods

All atomic structures and calculations were performed using the Atomic Simulation Environment (ASE) [11] in conjunction with the GPAW package [12], [13], using time-dependent density functional theory (TDDFT) utilizing the projector-augmented wave (PAW) method. The initial structure consisted of a 147-atom icosahedral magnesium cluster, constructed using ASE's cluster building tools. 81.63, 88.44, 95.24, and 100 at.% Al): (i) Random configurations, where Al atoms were substituted randomly at Mg sites, and (ii) Clustered configurations, where substitutions were biased to nearest-neighbor sites around an initial randomly chosen Al atom, creating a contiguous Al-rich domain. All structures were fully relaxed using the (Broyden Fletcher Goldfarb Shanno) BFGS optimizer in ASE. The Perdew–Burke–Ernzerhof (PBE) exchange–correlation functional [4] was employed, with a grid spacing of 0.2 and 0.3 $\AA$ for relaxation and groundstate calculations and the GPAW default setup for Mg and Al PAW datasets. Electronic temperatures were smeared using the Fermi–Dirac scheme with a width of 0.05 eV. Photoabsorption spectra were computed within the linear response regime using the dipole transition matrix elements between occupied and unoccupied Kohn–Sham states, with the imaginary part of the dielectric function broadened by a Lorentzian of width 0.1 eV to yield continuous spectra. To extract quantitative peak parameters—position (E_0), full width at half maximum (Γ), and oscillator strength (A)—all spectra were fitted with single or multiple Lorentzian functions as appropriate.

$$L(E) = \frac{A}{\pi} \frac{\Gamma/2}{(E - E_0)^2 + (\Gamma/2)^2} \tag{1}$$

where E_0 is the center of the peak, Γ is the full width at half maximum (FWHM) and A is the area under the peak (related to oscillator strength). For multiple overlapping peaks, a sum of Lorentzians is used:

$$\sigma(E) = \sum_j \frac{A_j}{\pi} \frac{\Gamma_j/2}{(E - E_{0,j})^2 + (\Gamma_j/2)^2}. \tag{2}$$

III. Results and Discussion

Computational results show:

- The photoabsorption spectra of the icosahedral Mg-Al clusters exhibit systematic evolution with aluminum concentration. To quantify the trends in the absorption spectrum, we fitted all spectra with Lorentzian functions (single or multiple peaks, as appropriate). (Fig. 2)

Fig. 1. Structures of Cluster (first row) and Random (second row) Mg-Al alloys. The green atoms are Mg and the grey atoms are Al

Fig. 2. Absorption spectrum of Cluster (first row) and Random Mg-Al (second row) Bimetallic system. In the top-left corner of each subplot we have Al percentage. The red line is lorentzian fit and the black line represent the absorption spectra of each system.

- We calculated the spectrum of pure Mg and pure Al particles; their respective sharp resonance peaks emerged at 4.80eV and 7.84eV, which are characteristics of collective plasmon excitation in these nanostructures. They have minimal damping in these homogeneous metallic systems.
- In random system the Mg and Al peaks hybridize and become broadened, this broadening reflects increased electron scattering due to disorder and the breakdown of translational symmetry.
- In cluster system we see multiple resonance peaks, with different intensities depending on majority atoms. The peaks tend to overlap at approximately 75% of the Al atoms and become broadened, indicating a strong electronic hybridization between the Mg and Al subsystems resulting in collective excitation that reaches the entire cluster.

IV. Conclusion

This comprehensive study of icosahedral Mg-Al clusters reveals that atomic-scale chemical ordering fundamentally dictates the photoabsorption response. Random solid-solution alloys exhibit a single, smoothly evolving plasmon peak that progressively broadens and shifts from Mg-like to Al-like character with increasing Al content—a homogeneous electronic response reflecting composition-averaged dielectric behavior. In contrast, clustered configurations produce multiple distinct absorption peaks throughout intermediate compositions (10-70% Al), arising from spatially separated Mg-rich and Al-rich domains that support independent plasmonic excitations. These multi-peak features persist until a critical concentration of approximately 75% Al, where the Al-rich domain percolates through the cluster, merging the separate resonances into a single hybrid peak. Our findings demonstrate that composition and atomic configuration provide dual, independent tuning knobs for engineering optical properties: random arrangements yield homogeneous single-resonance behavior adjustable by composition, while clustered arrangements enable heterogeneous multi-resonance response from identical compositions. The Mg-Al system thus offers a versatile platform for designing plasmonic materials with tailored spectral features for applications in sensing, broadband absorption, and nanophotonics.

Lithium Niobate Photonic Moiré Superlattice for Telecoms Wavelengths

Romae Grierson-Copeland[1], Christian Johnson-Richards[1], Noel Healy[1,*]

[1]School of Mathematics, Statistics and Physics, Newcastle University, Newcastle Upon Tyne, NE1 7RU, United Kingdom

***Abstract*—A 2D simulation studying photonic Moir´e superlattices made from triangular lattices of holes in lithium niobate is conducted. Field enhancement is observed due to flatbands in the photonic bandstructure. The lattice constant has a negative correlation with the flatband frequency, with 576nm enhancing the field at telecoms wavelengths in simulation.**

I. Introduction

Moiré patterns are the result of two or more periodic lattices of inclusions that are overlapped with each other by a twist angle, θ, creating long-range patterns. These structures have found applications in areas from condensed matter physics [1] to photonics, using twisted bilayer graphene and photonic crystals for quantum applications [2,3]. Our design takes inspiration from previous works [4][5], utilising 2 triangular lattices of holes to create a Moiré superlattice with hexagonal unit cells in a dielectric medium. This results in a field enhancement at the center of the superlattice unit cell, and this locality of the optical modes is essential to increase light-matter interaction at low operating powers. This has been shown to improve the interaction between excitons in single QDs [6], increase the yield of entangled photons from second order non-linear materials [7,8], and is a key step toward large-scale integrated quantum photonic circuits [9,10]. This light confinement is a result of a long wavelength periodic potential that can fold the electric band structure into a Moiré mini-Brillouin zone [11], capable of giving rise to the formation of flat bands in the photonic bandstructure. The implication of this leads to the emergence of linear photonic states which are completely localized in space [12]. When photons exist in these flat bands they do not propagate through the materials as they would in regular bands, behaving in a non-dispersive manner. Having a larger field enhancement contributing to the light matter interaction in an essentially 2 dimensional material also negates the requirement of phase matching for many quantum mechanical processes [13]. Lithium Niobate ($LiNbO_3$) is a versatile synthetic crystal widely used for its electro-optic, piezoelectric and nonlinear optical properties [14]. The interest in this material is also owed to the commercial availability of thin-film lithium niobate, as well as its second order non-linear susceptibility [15]. $LiNbO_3$ has been used in the extension of electric field poling techniques to two-dimensional lattices, enabling the demonstration of purely non-linear photonic crystals [16]. This, however, requires the material to be periodically poled to allow quasi-phase matching, a process that could be omitted through our design. In this work we investigate the possibility of designing a Moire superlattice using $LiNbO_3$. Taking advantage of the field enhancement in superlattice structures we propose a platform that drastically improves the efficiency in accessing the large second order non-linearity of $LiNbO_3$ for quantum and photonic applications. To do this we present an initial design in 2D and show changing the lattice constant of the triangular lattice can effect the position of the flatband in the band structure.

II. Methods

The simulation was designed using the eigensolver in the COMSOL Multiphysics RF module. The hexagonal superlattice was designed with periodic boundary conditions on all 6 sides. The solutions were retrieved for interpolated wavevectors encompassing the irreducible brillouin zone, tracing the unit cell's high symmetry points. In the initial study, we modelled the structure in 2D, which is expected to shift the bandstructure down in frequency and disregard losses. This allows us to rapidly prototype designs with less computational resources, to investigate trends in results. In the initial simulation, the model was designed with a lattice constant, a = 500 nm, a twist angle, θ = 6.01 degrees, the holes were sized with radius r = 0.24a. The period of the superlattice is therefore $a/2sin(\theta/2)$. The structure was configured as lithium niobate with a dispersive model [17] and air holes with refractive index n = 1. A parameter sweep was then conducted, in which the triangular lattice constant was varied to find out how this affects the frequency at which the flatband occurs to shift the flatband frequency, f_{flat}, to the desired operating range $\approx$ 190THz (1550nm).

III. Results and Discussion

The results of the 2D study are shown in Fig. 1, where the electric field distribution for the wavevector k is shown in Fig.1a and the band structure is shown in Fig.1b. The expected flatband in the bandstructure (highlighted by the red box) is present, showing that non-dispersive nature in the field distribution. The light confinement mechanism is in agreement with previous works [4], with the majority of the field distribution in the central 3 holes. The results for

Fig. 1. (a) Schematic of the superlatice including the magnetic field distribution for a solution in the flatband at K and with an f_{flat} around 222THz. (b) The complete band structure of the superlattice with a = 500nm and θ = 6.01 . The flatband is highlighted by a red box.

the lattice constant parameter sweep are presented in Fig. 2, here it is shown that there is a negative relationship between the lattice constant and flatband frequency that appears to be linear, with the red line in the figure presenting a linear fit. The dashed black line of the graph represents the telecoms band (λ = 1550nm), and using the linear fit a lattice constant for which the telecoms frequency of light will be confined can be estimated to be around a = 583nm, used to find the actual value a = 576nm. For the use of spontaneous parametric down conversion, the generated photons would need to be of telecoms wavelength as opposed to the input. Using the linear fit, a triangular lattice constant a = 273nm is extrapolated outside the range of tested results. A comprehensive study of the structure will be discussed including field enhancement at the center of the moire superlattice. A larger range of results will be shown for a more accurate fit and allow an improved estimate of the enhancement of nonlinear optical processes. The design will also be extended to demonstrate a suspended 3D slab.

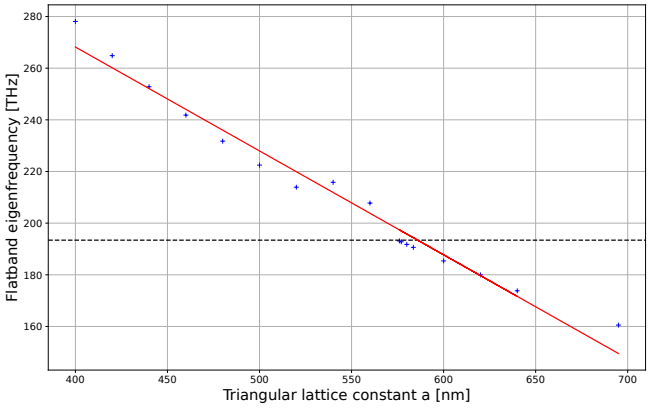

Fig. 2. The eigenfrequencies presenting the flatband of interest for different triangular lattice constants is represented by blue data points. The red linear fit has equation f_{flat} = -0.4023a + 429.0992. The black dashed line corresponds to a frequency in the telecoms band of λ = 1550nm.

IV. Conclusion

In this work we have demonstrated the design of a $LiNbO_3$ based Moiré superlattice and shown the dependence of the lattice constant on the flat-band frequency. As an example, the band structure and field distribution at the flatband of a superlattice designed with a = 500nm is shown. This work is the first step in designing a $LiNbO_3$ based platform for that may be exploited in producing entangled photons for use in quantum applications. an estimate of a design for spontaneous parametric down conversion that should output photon pairs of frequency in the telecoms band is found to have $a \approx$ 273nm.

Temporal Disorder in Two-Dimensional Phononic Time Crystals: A Numerical Study

Takamichi Terao[1]

[1]Department of Electrical, Electronic and Computer Engineering, Gifu University, Japan
*Corresponding author: terao.takamichi.x0@f.gifu-u.ac.jp

***Abstract*— Numerical simulations of a 2D mass–spring lattice with time-varying stiffness reveal parametric amplification of vibrational waves. The exponential growth depends on the modulation interval and temporal disorder. The Fourier analysis shows selective amplification of specific wavenumbers governed by momentum bandgaps that can be tuned or suppressed by temporal disorder.**

***Keywords*— time-varying metamaterials, momentum bandgaps, temporal disorder, phononic crystals.**

I. Introduction

In recent years, research on wave propagation characteristics at temporal boundaries in time-varying materials has attracted significant attention [1-4]. The importance of the physical problems posed by temporal boundaries was first proposed by Morgenthaler [5]. Subsequently, these phenomena were studied as the temporal analogy of spatial boundaries. With respect to this field, research on photonic time crystals (PTCs) has been actively pursued. Whereas photonic crystals are systems in which the permittivity varies periodically in space, in PTCs, the permittivity of the system varies periodically in time. Furthermore, attention is being focused on the wave characteristics in systems in which the material properties undergo nonperiodic temporal variations.

In reference [6], a one-dimensional (1D) phononic lattice was realized using repulsively coupled ring magnets that provided nonlinear intersite interactions. A time-varying medium was implemented by placing current-driven coils near the lattice sites. This electromechanical stiffness modulation enabled parametric wave phenomena such as amplification and modulation-induced bandgap formation. Analogous concepts can be applied to elastic waves rather than electromagnetic waves, namely phononic time crystals (PNTCs) [7,8].

Prior theoretical studies on time-varying media predominantly focused on 1D systems. In this study, numerical simulations were performed to elucidate the amplification characteristics of vibrational waves in higher-dimensional time-varying media.

II. Methods

This study analyzes systems in which the elastic modulus can be modulated by external fields, as introduced in the Introduction section, using a lattice model. Our calculations investigate lattice vibrations in a mass-spring model on a two-dimensional (2D) square lattice. This study adopts a scalar elasticity model [9] and incorporates uniform weak damping at each site.

In a scalar model, the equation of motion for (i,j) mass with displacement $u_{i,j}(t)$ can be written as follows:

$$m\frac{d^2}{dt^2}u_{i,j}(t) = k(t)\left(u_{i+1,j}(t) + u_{i-1,j}(t) + u_{i,j+1}(t) + u_{i,j-1}(t) - 4u_{i,j}(t)\right) - c\frac{d}{dt}u_{i,j}(t) \quad (1)$$

where c is a damping constant, and spring constant $k(t)$ in this model is time-dependent, unlike in conventional scalar elastic models. In this study, this is defined as follows:

$$k(t) = \begin{cases} K & (t_{2p} \le t < t_{2p+1}) \\ K + \Delta K & (t_{2p+1} \le t < t_{2(p+1)}) \end{cases} \quad (2)$$

where p is an integer, and $t_n = (n + \alpha\gamma_n)$ (T denotes a time interval, and $\{\gamma_n\}$ denotes a uniformly distributed real random number between 0.0 and 1.0). Furthermore, α is a parameter representing the magnitude of the temporal disorder, satisfying the condition, $0 \le \alpha < 1$. For the initial conditions, displacements $u_{i,j}(t=0)$ were set to be uniformly random between -0.5 and 0.5, whereas velocities $v_{i,j}(t=0)$ were set to zero. Periodic boundary conditions were applied in both the x and y directions.

III. Results and Discussion

In the following calculations, the system size was set to $L = 1024$. $K = 1.0$ and $\Delta K = 0.5$ were set for the spring constant, and the damping coefficient was set to $c = 2.0 \times 10^{-3}$. The time step was set to $\Delta t = 1.0 \times 10^{-4}$, and the time evolution of the system was numerically investigated.

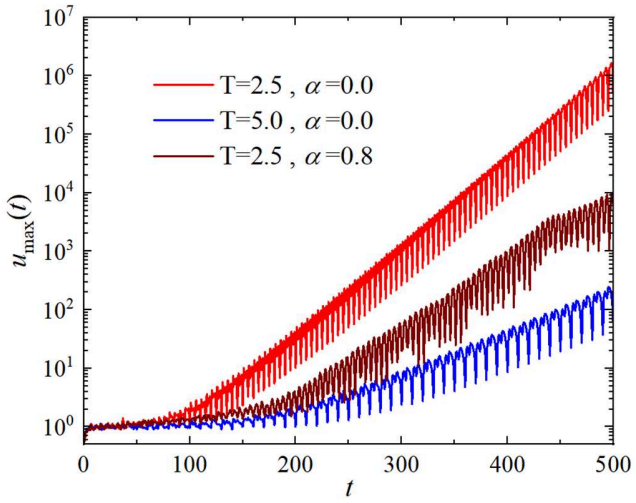

Fig. 1 Time development of maximum displacement $u_{\max}(t)$

Figure 1 shows the calculated time evolution of maximum displacement $u_{\max}(t)$. The red, blue, and brown lines represent the results for (T, α) = (2.5, 0.0), (5.0, 0.0), and (2.5, 0.8), respectively. In all the cases, the displacement exhibited exponential growth after a sufficient amount of time had elapsed. Furthermore, exponent λ, that represents the degree of amplification, depended on both interval T and temporal randomness α.

To further elucidate the amplification properties of the oscillating waves, a spatial Fourier transform of displacement $u_{i,j}(t)$ was performed to identify the amplified wavenumber components. Subsequently, $\{u_{ij}\}$ was analyzed based on the numerical results of the time evolution of the system described by Eq. (2) up to $t = 500.0$. Figures 2(a), and 2(b) show calculated Fourier components $F(k_x, k_y)$ for $(T, \alpha) = (2.5, 0.0)$ and $(2.5, 0.4)$, respectively. The values of $F(k_x, k_y)$ were normalized such that the maximum value was 1.0. The horizontal and vertical axes represent wavenumbers k_x and k_y, respectively. The yellow regions in the figures correspond to the wavenumber components where wave amplification occurs.

The results, as shown in Fig. 2(a), indicated that two distinct wave curves with different wavenumbers were amplified; these components propagated isotropically in all directions rather than in specific orientations. The deviation from circularity in the outer curve (where the wavenumber magnitude was approximately 2.0) was attributed to the anisotropy of the underlying square lattice that became more pronounced at shorter wavelengths. Figure 2(b) presents the results for the system when temporal randomness is introduced ($\alpha > 0$). By comparing this with Fig. 2(a), evidently, the outer curve—corresponding to the higher wavenumber—had vanished. Figure 2(c) shows the calculation results of $F(k_x, k_y)$ for a system with a larger interval T without temporal randomness. These results demonstrated that wave amplification occurred at lower wavenumbers in this regime.

The series of calculation results revealed that the wavenumber components undergoing amplification could be controlled by modulating the temporal variations of the spring constants. This wave amplification was attributed to the presence of a momentum bandgap. The disappearance of wave amplification at higher wavenumbers, as shown in Fig. 2(b), suggested that the momentum bandgap corresponding to these wavenumbers collapsed owing to the introduction of temporal disorder.

In this regard, the widths of the wavenumber regions where wave amplification occurred were examined. Figure 3 shows the k_x-dependence of $F(k_x, 0)$. Figures 3 corresponds to the wavenumber ranges associated with the inner and outer amplification regions, respectively, as observed in Fig. 2(a). Vertical axis represents the value of $F(k_x, 0)$. These results indicated that the wavenumber range of the amplification narrowed, as shown in Fig. 3(a), owing to the introduction of the temporal disorder, whereas the amplification region itself completely disappeared, as shown in Fig. 3(b). This result was qualitatively consistent with the numerical results, as presented in Fig. 2(b).

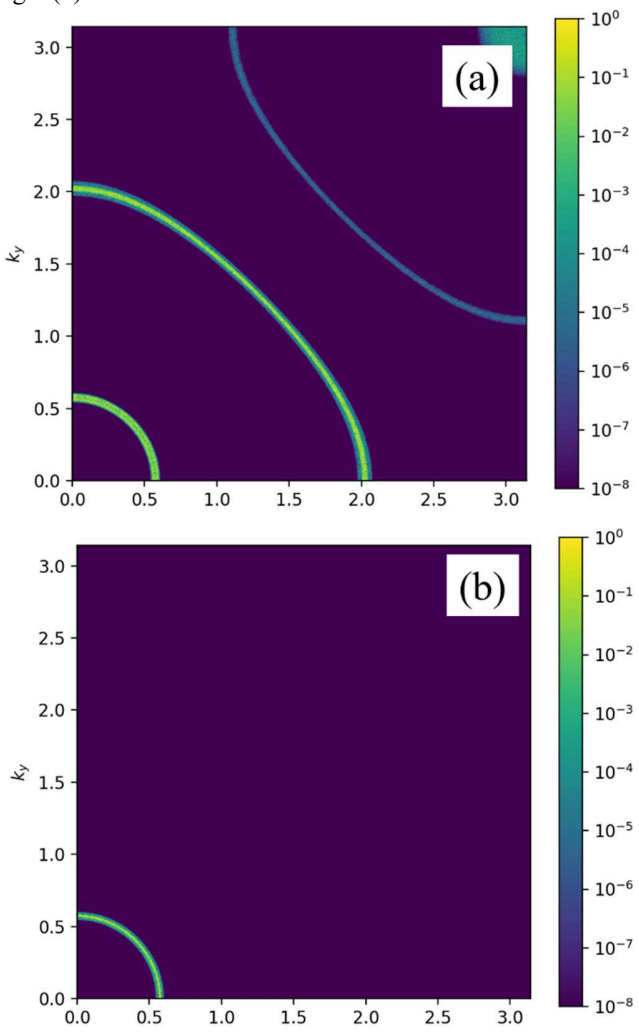

Fig. 2 Fourier transform of displacement $u_{i,j}(t)$ (a) $T = 2.5, \alpha = 0.0$ (b) $T = 2.5, \alpha = 0.4$

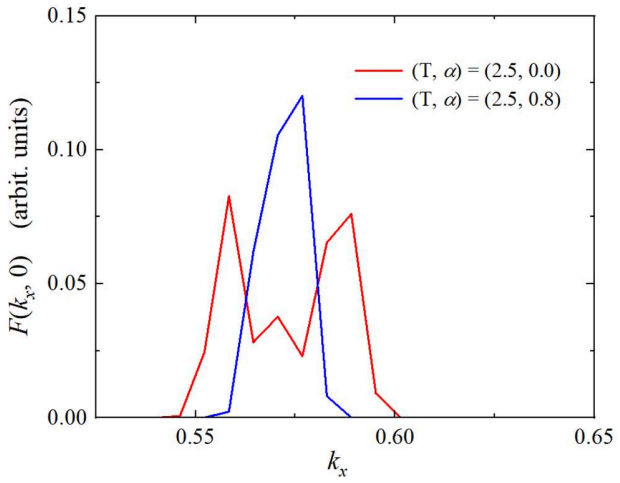

Fig. 3 Dependence of $F(k_x, 0)$ on temporal disorder α

Finally, this paper discusses time-varying media in uniform three-dimensional (3D) systems. This study focused on the analytical results of 2D time-varying phononic metamaterials. However, the author also conducted similar investigations on 3D phononic metamaterials and reported that the conclusions obtained were qualitatively consistent with those for the 2D systems presented here.

IV. Conclusion

In this study, the effects of the temporal disorder on phononic time crystals were clarified using numerical simulations. Whereas prior theoretical research on time-varying metamaterials—involving both electromagnetic and elastic waves—was largely limited to 1D spatial systems, this study elucidated their behavior in higher-dimensional systems. Given that the wave amplification characteristics can be controlled by modulating the functional form of the temporal variations in the medium, further advancements in this field are highly anticipated.

***Abstract*—We develop a novel hydrogel-based flexible acoustic metamaterial for underwater carpet cloaking. To elucidate the underlying mechanism of the proposed microstructure, the effects of anisotropic stiffness and anisotropic density are investigated. It suppresses shear waves and utilizes a longitudinal wave-dominant coupling mode, enabling excellent cloaking performance confirmed by simulations and experiments.**

***Keywords*—Hydrogel, Flexible Acoustic Metamaterial, Underwater Carpet Cloak, Wave Manipulation.**

I. Introduction

Hydrogels, with their high water content and matched acoustic impedance to water, show significant potential for underwater acoustic applications [1-4]. While traditional acoustic cloaks face challenges in eliminating acoustic-solid coupling and balancing performance with structural integrity, hydrogels offer a promising solution. Their unique properties, such as flexibility and load-bearing capacity, enable the design of advanced metamaterials. This study develops a flexible acoustic metamaterial based on hydrogels, and systematically validates its outstanding performance in underwater acoustic wave manipulation through a combination of theoretical analysis, numerical simulations, and experimental investigations.

II. Methods

This study designs a novel hydrogel-based flexible unit cell and proposes a rigid unit cell for comparative analysis. Both unit cell microstructures are designed based on a composite material paradigm, featuring a coupling of flexible hydrogel and rigid solid materials. As shown in the rigid cell in Fig. 1(a), which are connected to each other by solid materials. As shown in the flexible cell in Fig. 1(b), which are connected to each other by hydrogels.

For example, apply the designed unit cell to the underwater acoustic carpet cloak. Following the acoustic transformation theory under linear mapping, rigid (Fig. 2(a)) and flexible (Fig. 2(b)) underwater acoustic carpet cloaks were respectively designed based on these two unit cells, with steel employed as the solid material.

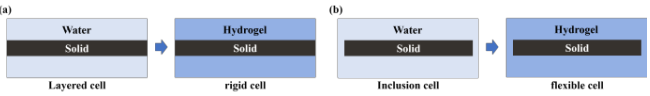

Fig. 1 (a)-(b) Design strategy of hydrogel-based unit cell microstructure.

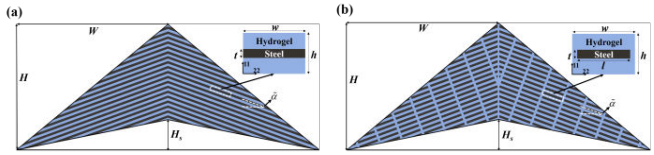

Fig. 2 (a) Rigid hydrogel-based unit cell and its assembled acoustic carpet cloak; (b) Flexible hydrogel-based unit cell and its constructed acoustic carpet cloak.

III. Results and Discussion

Firstly, we elucidate the transverse wave attenuation mechanism in the proposed acoustic metamaterial through the analysis of anisotropic stiffness and anisotropic density. It reveals that flexible hydrogel-steel unit achieves comparable effective mass density and modulus to rigid counterpart, while anisotropic stiffness analysis demonstrates a reduction in shear modulus and suppressed shear wave modes. Besides, anisotropic density analysis further identifies a single acoustic-solid coupled longitudinal wave mode in flexible unit cell, contrasting with multiple modes in rigid structures that cause parasitic scattering. .

Secondly, we investigated the scattering control performance of the designed hydrogel-based flexible underwater acoustic carpet cloak for plane waves incident at different angles using finite element simulations. As shown in Fig. 3, the scattered acoustic fields are presented for plane-wave incidence at 20 kHz across angles ranging from 0° to 90° in steps of 15°, comparing three types of underwater acoustic carpet cloaks.

The results indicate that the designed flexible acoustic carpet cloak achieves scattering control comparable to that of an ideal homogeneous carpet across the full angular range.

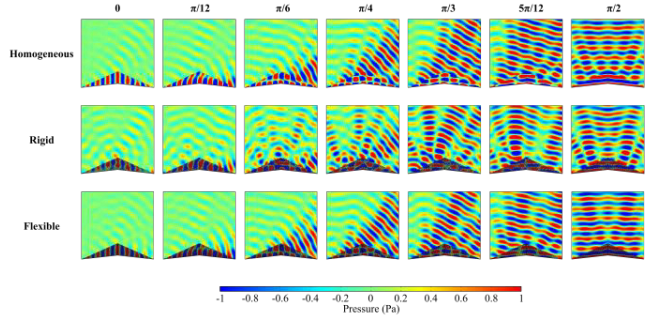

Fig .3. Acoustic wave fields demonstrating scattering control for 20 kHz plane waves under 7 incident angles.

Finally, the experimental results demonstrate the practical cloaking performance of the flexible underwater acoustic carpet cloak (Fig. 4(a)). As illustrated in Fig. 4(b), the experimental setup consists of a cylindrical transducer emitting Gaussian wave packet signals and six hydrophones receiving both incident waves and structural backscattering. Three scenarios were tested: (i) reference field (a flat empty surface without any test objects), (ii) uncloaked field (a stainless steel triangular prism scatterer placed on the flat surface), and (iii) cloaked field (the same scatterer covered with the fabricated flexible underwater acoustic carpet cloak). The incident signal was a 10 kHz–18 kHz Gaussian wave packet containing two cycles. To quantitatively evaluate the robustness of the theoretical cloaking performance of the designed flexible underwater acoustic carpet cloak, we adopted the RCS metric defined in Eq. (1) [5] was adopted to quantitatively evaluate the cloaking performance:

$$\zeta_{\mathrm{RCS}} = \oint_{\Omega} \left(\frac{\left| P_{\mathrm{Cloaked}} - P_{\mathrm{Reference}} \right|^2}{\left| P_{\mathrm{Uncloaked}} - P_{\mathrm{Reference}} \right|^2} \right) d\Omega \qquad (1)$$

Here, $P_{\mathrm{Reference}}$, P_{Cloaked}, and $P_{\mathrm{Uncloaked}}$ denote the instantaneous acoustic pressure values in the reference, cloaked, and uncloaked scenarios, respectively, while Ω represents the measured region.

Figure 4(c) shows the average RCS calculated over the echo time window from 0.4 ms to 0.9 ms, which remains below 0.25 across the 10 kHz–18 kHz frequency range, confirming that the flexible underwater acoustic carpet cloak effectively suppresses strong scattering induced by the object and achieves notable acoustic stealth performance.

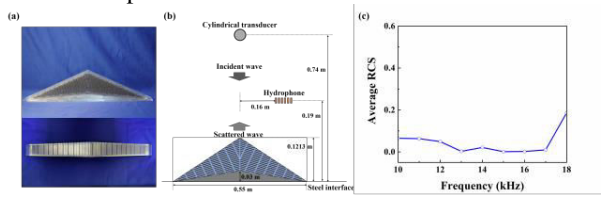

Fig. 4(a) Physical specimen of the flexible underwater acoustic carpet cloak: The specimen is composed of hundreds of stainless steel sheets wrapped with hydrogel material and the scattering body is made of stainless steel material; (b) Schematic diagram of the underwater acoustic experiment scene; (c) The average RCS experimental test values of the acoustic stealth carpet cloak in the range of 10 kHz to 18 kHz.

IV. Conclusion

Leveraging the unique properties of hydrogels, such as their near-perfect impedance matching with water, inherent load-bearing capability, and structural flexibility, we designed a novel flexible acoustic metamaterial based on hydrogels for underwater carpet cloaking, which possesses sufficient autonomous load-bearing capacity. Experimentally validated prototype demonstrates superior acoustic cloaking performance (RCS < 0.25) by minimizing shear wave interference within the microstructure. Subsequent discussions further confirmed the broadband and wide-angle cloaking capability of the designed flexible underwater acoustic carpet cloak. This approach enables advanced underwater wave manipulation and expands the scope for hydrogel applications in complex acoustic regulation structures.

***Abstract*—Designing complex multispectral metamirrors for cavities requires precise control of phase and reflectivity across subwavelength metaatoms. Diffusion-based generative models enable inverse design for such structures but are limited by dataset quality, especially when crucial regions are underpopulated. We present a pipeline that generates validated candidate geometries, yielding an enriched dataset.**

***Keywords*— metamirrors, multispectral cavities, diffusion, dataset enrichment, high reflectivity, inverse design.**

I. Introduction

Ultrastable optical cavities, fundamental to a wide range of precision measurement applications, are limited by Brownian thermal noise in conventional dielectric mirror coatings, affecting their performance [1]. A promising alternative to overcome this limitation is metamirrors-based cavity (Fig.1), which offers a route toward reducing coating-induced noise [2]. A metamirror consists of an array of subwavelength metaatoms designed to provide both high reflectivity and a prescribed spatial phase profile, allowing a curved optical wavefront to be realized on a planar surface and enabling compact cavity architectures. Additionally, it also allows for complex functionalities such as multispectral operation [3]. The need for multispectral cavities is observed in applications such as gravitational-wave detectors [4] or quantum photonic systems [5]. Designing the desired metamirrors poses a highly constrained inverse problem, as each metaatom geometry must simultaneously satisfy reflectivity and phase requirements at one or more target wavelengths. Recently, deep generative models, in particular diffusion-based architectures, have emerged as powerful tools for inverse nanophotonic design by learning to generate metaatom geometries conditioned on desired optical responses [6]. The effectiveness of these models, however, is critically dependent on the quality and structure of the training dataset [7].

A dataset constructed through random sampling of the geometric parameter space does not provide uniform coverage of phase and reflectivity, since high-reflectivity designs occupy only a small and highly structured region of the design space. To increase the number of useful samples, optimization-based filtering or targeted sampling toward high reflectivity is commonly employed. This strategy, however, introduces a new limitation: most optimization procedures converge toward a small number of similar geometries, leading to datasets that are biased not only toward high performance but also toward a narrow set of structural configurations, thereby severely reducing geometric diversity [8]. Such collapse of diversity in the high-reflectivity region restricts the ability of generative inverse design models to produce multiple distinct solutions for a given optical target.

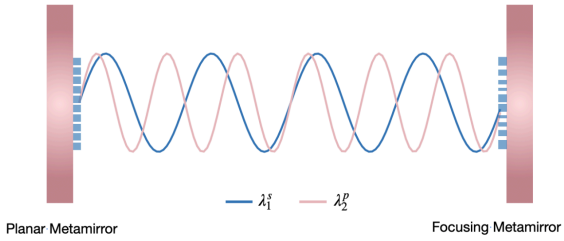

Fig. 1. Schematic representation of a non-conventional metamirrors-based cavity designed for different wavelengths and polarization states.

While surrogate-assisted sampling [8] and active learning [9] have been applied to inverse design problems and dataset acquisition for nanophotonics, existing methods do not focus on targeting and enriching rare high-performance regions with explicit response-space coverage goals. In this work, we investigate the construction of metaatom datasets, with a particular focus on balancing performance bias and geometric diversity. We introduce a dataset generation approach aimed at selectively enriching the high-reflectivity region of the design space, thus enabling the formation of an enriched dataset containing both a sufficient concentration of high-reflectivity samples and a broad range of distinct metaatom geometries.

II. Methods

Here we present our pipeline (Fig.2) which combines surrogate-guided sampling with phase/reflectivity binning to systematically populate the high-reflectivity region with

diverse optical responses, addressing a gap in current dataset construction strategies. This is the proposed pipeline:

- An initial dataset is generated by sampling the geometry and the corresponding optical responses (phase and reflectivity), for two wavelengths using rigorous coupled-wave analysis (RCWA) [10].
- The dataset is used to train a surrogate forward model that approximates the mapping from metaatom geometry to electromagnetic response.
- The predicted and simulated responses are analyzed to characterize the distribution of samples in phase–reflectivity–wavelength space and to identify regions of dense and sparse coverage.
- The dataset is filtered to high-performance samples by applying a reflectivity threshold ($R \geq 97\%$). These samples are discretized into bins according to phase and wavelength to quantify coverage of the high-reflectivity response space. Underpopulated or empty bins are designated as target response regions for further sampling.
- Additional candidate geometries are generated by random sampling through RCWA and evaluated using the surrogate model, and only those falling within the target response regions are retained.
- The selected candidates are simulated with RCWA for validation. Redundant geometries are removed using a similarity criterion to avoid near-duplicate samples.
- The newly validated samples are incorporated into the existing dataset.
- The surrogate model is retrained on this new dataset, and the procedure is iterated until the high-reflectivity region of the response space exhibits sufficient coverage and diversity.
- Finally, a diffusion model is trained on both the original dataset and the new enriched dataset to test its feasibility.

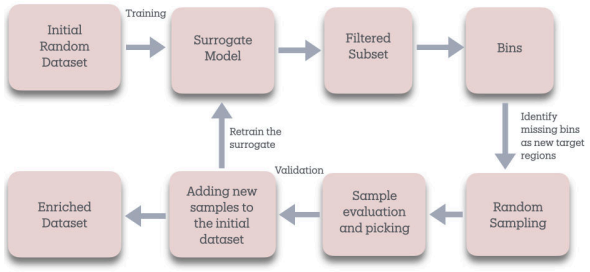

Fig. 2. Overview of the pipeline for dataset enrichment

III. Results and Discussion

We report on the behavior of the proposed dataset construction pipeline in terms of its ability to populate and uniformly cover the high-reflectivity region of the response space. In addition, we assess the practical feasibility of the method and analyze its computational efficiency when applied to large-scale dataset generation for inverse nanophotonic design.

Chiral Meta-atoms for Geometric-phase Manipulation in Metasurfaces Operating in the Visible Range

M. Giloan

MG Data, Cluj-Napoca, Romania
Corresponding author: mircea_giloan@yahoo.com

***Abstract*— The geometric phase method enables phase manipulation of circularly polarized incident light. We investigate the ability of chiral meta□atoms with specific geometries to convert incident circularly polarized light into its orthogonal handedness in transmission. Such meta□atoms can be used to design efficient, polarization□insensitive metasurfaces.**

***Keywords*— metasurfaces, chiral meta-atoms, geometric phase.**

I. Introduction

Optical devices require a specific phase distribution on a plane surface. The geometric phase method enables phase manipulation of circularly polarized incident light when the cross-polarized component is transmitted [1]. Chiral meta-atoms have been used to efficiently convert circularly polarized light into its cross-polarized component in transmission, enabeling the design of metasurfaces operating in the infra redrange [2].

In this theoretical study, chiral meta-atom with different geometries are investigated to identify the most suitable design for efficiently converting incident circularly polarized light into its cross-polarized transmitted component in the visible range.

II. Methods

The studied meta-atoms consist of TiO_2 structures on a SiO_2 substrate. Three-dimensional finite-difference time-domain simulations were performed [3]. The propagation of circularly polarized light normally incident on the metasurface was simulated. Figure 1 depicts the xy-plane cross-section of a meta-atom within a square unit cell of length 400 nm. The incident light propagates along z-axis. Periodic boundary conditions were applied along the x and y directions, while absorbing layers were used along the z direction. All depicted lengths are expressed in micrometers. The meta-atom geometry is chiral, since its mirror image cannot be superimposed onto itself. The height of meta-atom and the thickness of the substrate were set to 600 nm and 100 nm, respectively. The refractive index of the dielectric materials used in simulations, TiO_2 and SiO_2, were set to 2.41 and 1.45, respectively.

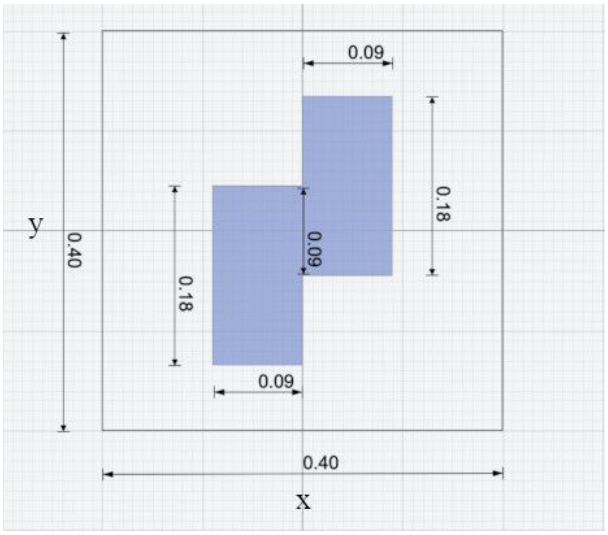

Fig. 1 Geometry of the studied chiral meta-atom, depicted in an xy-plane cross-section.

III. Results and Discussion

Figure 2 shows the real part of the electric-field component along z-axis for left-circularly polarized incident light at a wavelength of 568 nm. The distribution was computed in an xy-plane cross-section passing through the midpoint of the meta-atom height.

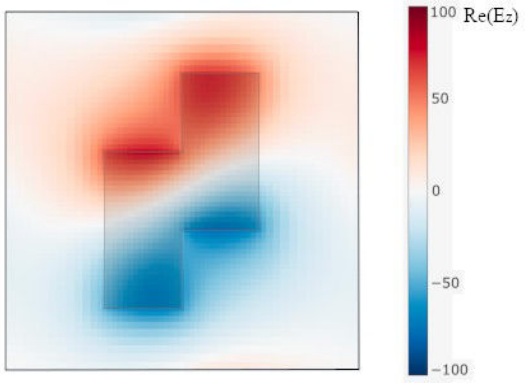

Fig. 2 Real part of the electric-field component along the z-axis for LCP incident light, shown in an xy-plane cross-section.

Figure 3 shows the real part of the electric-field component along z-axis for right-circularly polarized incident light at a wavelength of 568 nm. The distribution was computed in an xy-plane cross-section passing through the midpoint of the meta-atom height.

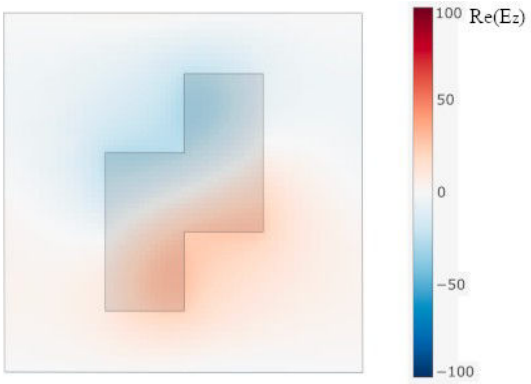

Fig. 3 Real part of the electric-field component along the z-axis for RCP incident light, shown in an xy-plane cross-section.

The difference in intensity observed in Figures 2 and 3 reflects the asymmetric transmission of left- and right-circularly polarized light produced by the studied meta-atom design.

IV. Conclusion

In this study, we analyzed the optical response of chiral dielectric meta-atoms designed for operation in the visible range using three-dimensional FDTD simulations. The investigated geometries exhibit asymmetric transmission for left- and right-circularly polarized incident light, enabling efficient conversion into cross-polarized component. The simulated field distributions and transmission spectra demonstrate that the meta-atom geometry strongly influences the achievable polarization-conversion efficiency. These findings confirm that properly engineered chiral dielectric meta-atoms are promising building blocks for metasurfaces based on the geometric-phase method, offering a viable route toward high-performance phase-manipulation devices in the visible spectrum.

***Abstract*—We present anisotropic metamaterials based on SiGe layers with alternating doping. They were grown by chemical vapour deposition and characterized using Fourier-transform infrared spectroscopy. Measured reflectance spectra show excellent agreement with full-wave simulations, indicating the presence of a hyperbolic metamaterial near the plasma edge.**

***Keywords*— hyperbolic metamaterial, germanium, fourier-transform infrared spectroscopy.**

I. Introduction

When the components of the dielectric permittivity tensor of a metamaterial along different axes have opposite signs, the isofrequency surfaces in its dispersion relation become hyperboloids instead of the typical ellipsoids (or spheres in the isotropic case)[1]. Such hyperbolic metamaterials enable propagation of waves with very large in-plane k-vectors that would normally be evanescent. This leads to a virtually-infinite local density of optical states.

Among other approaches, hyperbolic metamaterials can be realized as planar periodic multilayer structures featuring sufficiently thin metals and dielectrics. Effective medium theory predicts anisotropic materials in this case, with hyperbolic behaviour near the plasma frequency of the metallic component.

The mid infrared (MIR) spectral range is important for a number of practical applications, including spectroscopy, imaging, thermal detection, and optical communication. As metals in MIR feature excessive negative permittivities, they can not be leveraged for hyperbolic metamaterials. Instead one can rely on heavily doped semiconductors. MIR hyperbolic metamaterials have been demonstrated using GaAs/AlInAs heterostructures[2]. Striving to bring MIR hyperbolic metamaterials in line with more established silicon photonic technologies for improved applicability[3], here we propose and investigate hyperbolic metamaterials based on Si_5Ge_{95} stacks with alternating intrinsic and highly doped layers.

II. Methods

We model the permittivity of doped and undoped Si_5Ge_{95} layers using a Drude model

$$\epsilon(\omega) = \epsilon_{\infty,Si5Ge95}(1 - \frac{\omega_p^2}{\omega^2 + i\omega\gamma}). \quad (1)$$

Here, $\epsilon_{\infty,Si5Ge95} = 16.36$ and $\omega_p^2 = \frac{N_D e^2}{\epsilon_0 m_{eff}}$ is the squared plasma frequency. m_{eff} is the effective mass of electrons, e is the elemental charge, ϵ_0 is the vacuum permittivity and N_D is the concentration of active dopants.

Based on effective medium theory, the effective in-plane and out-of-plane permittivity of the layer stack of intrinsic ϵ_d and doped ϵ_m material can be modeled as

$$\epsilon_{||} = (1-f)\epsilon_d + f\epsilon_m \quad (2)$$
$$\epsilon_{\perp} = \epsilon_m\epsilon_d/(f\epsilon_d + (1-f)\epsilon_m), \quad (3)$$

where the filling factor f stands for the relative thickness of the doped region with respect to the multilayer period. To simulate light propagation in the full layer stack, we use the rigorous coupled wave analysis[4], considering only the 0^{th} Fourier order and assuming non-dispersive substrate materials, $\epsilon_{Si} = 11.7$ and ϵ_{Ge}=16.6.

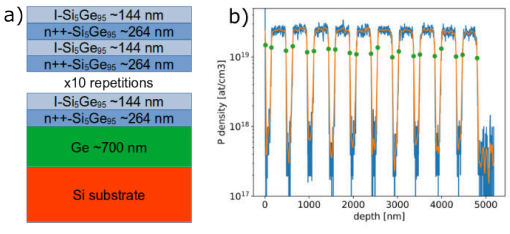

Fig. 1. (a) Sketch of the nominal structure of the sample. (b) SIMS measurements of the p dopant concentration in the grown sample.

We grew 10 repetitions of nominally 264 nm highly doped ($2.5 \cdot 10^{19}\mathrm{cm}^{-3}$) and 144 nm intrinsic Si_5Ge_{95} layers on a 700 nm Ge virtual substrate on Si by ultrahigh-vacuum chemical

vapour deposition, using SiH_4, GeH_4 and PH_3 as precursors (Fig. 1a)). Typically, one can expect about two thirds of the dopant atoms to be active. Secondary-ion mass spectroscopy (Fig. 1b)) confirms successful creation of steep doping profiles. Both doped and undoped layers are 20% thicker than their nominal values at 330±3 nm and 150±4 nm, respectively.

Fourier-transform infrared (FTIR) spectroscopy was performed in vacuum with a BRUKER VERTEX 70V spectrometer equipped with an angle-resolved reflectance setup, a wideband silicon beam splitter, a globar source and a pyroelectric detector with integrated preamplifier.

III. RESULTS AND DISCUSSION

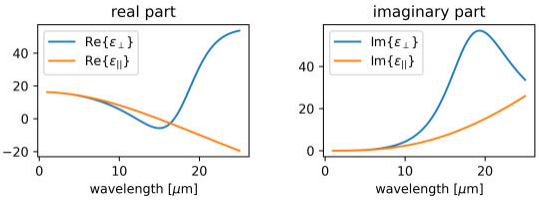

Fig. 2. Calculated real and imaginary parts of the in-plane and out-of-plane components of the relative permittivity of the metamaterial.

The calculated in-plane and out-of-plane permittivity for a metamaterial with $f = 0.68$ and $N_D = 1.8 \cdot 10^{19}\text{cm}^{-3}$ is shown in Fig. 2. The real parts of the out-of-plane and in-plane permittivity cross zero at $\lambda = 12\mu\text{m}$ and $\lambda = 15\mu\text{m}$, respectively. Between these, only the out-of-plane permittivity is negative, and we expect a hyperbolic metamaterial.

Fig. 3. Heatmaps of a) measured and b) simulated ratios of TE and TM reflectance as a function of wavenumber and angle of incidence. The red lines represent the wavenumber-dependent pseudo-Brewster angle (solid) and the numerical minimum of the dichroic ratio as shown in the heatmap (dashed) as a function of frequency. Black vertical lines mark the zero crossings of real parts of the in-plane and out-of-plane permittivity at 12 and 15 μm.

Experimental and full-wave simulated ratios of TM and TE reflectance as a function of angle of incidence θ and angular frequency ω are shown in Fig. 3. Agreement between them is best for lower angles of incidence. For the dielectric regime ($\lambda < 12\ \mu\text{m}$), we observe Fabry-Perot thickness oscillations, related to the thickness of the metamaterial layer. The singular Bragg peak at $\lambda = 3.6\ \mu\text{m}$ is caused by the periodic stack of doped and intrinsic layers.

We computed the pseudo-Brewster angle, which is the angle of minimized TM reflectance of a hypothetical infinite-thickness metamaterial slab in effective-medium approximation, thus disregarding Fabry-Perot and Bragg effects, shown in Fig.2a-b) as a red solid line. In hyperbolic metamaterials, one expects a discontinuity at the pseudo-Brewster angle at the onset of hyperbolic regime[2], at $\lambda = 12\ \mu\text{m}$ in our case. The fact that we only observe a dip in pseudo-Brewster angle, followed by an increase at the plasma edge, and no discontinuity, is due to considerable losses induced by the very high doping concentration(Fig.2b). A discontinuity can be observed when artificially increasing the electron mobility by a factor of 10 in simulation.

In addition to magnitudes, we also measured relative phase between TE and TM reflectance in a configuration similar to periodic ellipsometry, with a polarizer before the sample at 45° with respect to the plane of incidence and an analyzer after the sample rotated in increments of 5°. With this additional information we were able to fit our simulation model to the experimental data, with N_D and layer thicknesses as free parameters. From the fit, we obtain in $N_D = 1.62 \cdot 10^{19}\text{cm}^{-3}$, which is lower than expected but still high enough for a hyperbolic metamaterial according to our analytical model.

IV. CONCLUSION

We have grown anisotropic metamaterials as epitaxial silicon-germanium multilayer stacks with modulated doping. Experimental measurements strongly agree with simulations and fits on experimental data yield parameters close to nominal values, indicating hyperbolic optical properties in the mid-infrared regime. Typical optical features are obscured by losses in reflectance, and we intend a stronger demonstration of hyperbolic properties in transmission[5] or in layer stacks featuring less doping tailored to lower frequencies.

***Abstract*—Needle-beam metalens photoacoustic microscopy has emerged as a promising approach due to its extended depth of focus, which enables volumetric imaging with minimal axial resolution degradation. Despite this advantage, conventional PAM is constrained by limited axial resolution, hindering quantitative three-dimensional analysis at the cellular scale. To address, expansion microscopy was adopted with a needle-beam metalens PAM platform to enhance effective spatial resolution while preserving large-volume imaging capability. A modified phase design was further introduced to improve optical efficiency, yielding approximately two-fold higher brightness than conventional needle-beam configurations. A 2 mm metalens was fabricated on a 1 μm-thick silicon nitride substrate, and imaging was conducted using a custom-built transmission-mode photoacoustic system. Selective pigment-based labeling enabled neuron-specific photoacoustic contrast following tissue expansion. The proposed approach was evaluated using carbon nanoparticle phantoms and neuronal tissue samples. he results demonstrated an effective resolution improvement of 4–20× and enabled quantitative assessment of neuronal density changes after amyloid-beta treatment. Overall, this study highlights the potential of metalens-enabled PAM for high-resolution three-dimensional cellular imaging.**

***Keywords*— Needle beam metalens, photoacoustic microscopy, deep tissue imaging**

I. Introduction

Needle-beam metalens-based photoacoustic imaging has recently gained attention owing to its extended depth of focus, which enables volumetric imaging over large depths with minimal degradation in axial resolution. In addition, photoacoustic imaging offers rapid signal acquisition along the acoustic axis, making it well suited for high-speed three-dimensional imaging. However, conventional approaches are constrained by limited spatial resolution, particularly along the axial direction, which restricts quantitative analysis of fine structures in three dimensions. To address this limitation, expansion microscopy was incorporated into a needle-beam metalens-based photoacoustic imaging system to enhance effective spatial resolution while preserving large-volume imaging capability. Furthermore, a modified needle-beam metalens was introduced to improve optical efficiency, achieving approximately two-fold higher brightness compared with conventional designs. In neuroscience applications, resolving fine neuronal structures distributed in three-dimensional space is essential for understanding cellular function and organization. To validate the proposed imaging strategy, neuronal imaging experiments were conducted to assess its capability for high-resolution structural visualization.

II. Methods

In this study, a 2 mm diameter needle-beam metalens was fabricated on a 1 μm-thick silicon nitride substrate using electron-beam lithography followed by development and etching. Conventional needle-beam metalenses are implemented by randomly multiplexing phase maps corresponding to single-focus metalenses with different focal lengths. However, this approach suffers from reduced optical efficiency, as the intensity decreases proportionally to the square of the number of multiplexed phase components. Here, a newly developed phase design was introduced to overcome this limitation, enabling approximately two-fold enhancement in optical efficiency. The proposed 2 mm needle-beam metalens was validated through both numerical simulations and

experimental characterization.

Imaging experiments were conducted using a custom-built transmission-mode photoacoustic microscopy system. A 532 nm pulsed laser operating at 20 kHz and a 19 MHz ultrasound transducer were employed, achieving an axial resolution of approximately 100 μm and a lateral resolution of ~2 μm with a single-shot imaging depth of up to 1 mm. To address the intrinsic resolution limitation of photoacoustic microscopy, expansion microscopy was incorporated to physically enlarge the sample and enable high-resolution imaging. While conventional expansion microscopy relies on fluorescence labeling, it is not directly compatible with photoacoustic contrast generation. To overcome this limitation, antigen–antibody reactions combined with pigment-based staining were utilized to selectively deposit absorbing labels on neuronal structures. The proposed approach was evaluated using carbon nanoparticle phantoms and three-dimensional neuronal tissue imaging. Resolution changes associated with the use of needle-beam excitation and tissue expansion were systematically analyzed to demonstrate the effectiveness of the method. Furthermore, quantitative analysis of three-dimensional neuronal distributions following amyloid-beta treatment confirmed the applicability of this technique for structural analysis at the cellular level.

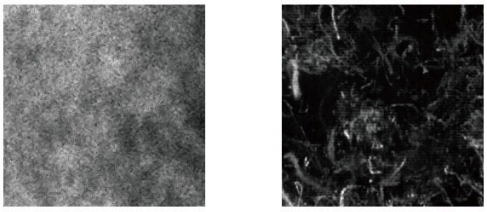

Fig. 1 Photoacoustic imaging of neurons. Conventional PAM (left) and proposed system (right)

III. Results and Discussion

Optical-resolution photoacoustic microscopy enables diffraction-limited imaging at the focal plane but suffers from defocus-induced blurring away from focus due to limited axial resolution and optical focusing constraints. By combining expansion microscopy with a needle-beam metalens, both effective resolution and depth of focus are enhanced, enabling high-resolution imaging over an extended axial range. In addition, the high sampling rate of ultrasound detection allows rapid axial data acquisition without mechanical scanning, supporting large-volume three-dimensional imaging. To validate this concept, imaging experiments were performed using carbon nanoparticle phantoms and neuronal tissues. With Gaussian-beam excitation, particles appeared increasingly blurred and enlarged with defocus, whereas needle-beam illumination provided uniform and sharp imaging over a depth of approximately 1 mm.

For biological validation, neuronal and glial structures were labeled and imaged to resolve fine three-dimensional architectures. A neurodegenerative condition was further mimicked via amyloid-beta treatment to assess whether structural alterations could be detected and quantified. Before expansion, limited resolution hindered clear discrimination of cellular morphology. After expansion combined with needle-beam imaging, fine structural details became clearly resolvable. The effective resolution improvement ranged from approximately 4× to 20×, enabling cellular-level imaging that is difficult to achieve with conventional photoacoustic approaches. In the disease model, three-dimensional imaging enabled quantitative analysis of neuronal density. An increase in neuronal density in the amyloid-beta-treated group was detected and quantified using the proposed method. These results demonstrate that needle-beam metalens-based photoacoustic imaging enables high-resolution three-dimensional visualization at the cellular scale. While expansion alone is limited by the short depth of focus of Gaussian beams, the needle-beam metalens provides uniform axial resolution, highlighting the potential of this approach for advanced optical imaging applications.

IV. Conclusion

We have demonstrated feasibility of modified needle beam metalens for thick tissue PAM imaging in expanded samples. Future work will extend the utilization of our system for high-resolution 3D PA imaging.

The model attains a mean absolute error of 0.0785 on 50,000 test samples at 511 designs per second.**

***Keywords*— metamaterials, thin-film optics, inverse design, Transformer, autoregressive generation.**

I. Introduction

Multilayer thin-film structures modulate reflectance through interference and are widely used in Distributed Bragg Reflector (DBR), dielectric mirror and anti-reflective coatings. However, inverse design of such structures remains challenging in practice due to the dimensional curse as the layer count increases. Early optimisation-based approaches are computationally expensive [1], scale poorly with increasing design complexity, and typically require physical prior and design experience to begin at a reasonable initial design to avoid low-quality local optima.

Data-driven deep learning models have been explored as alternatives for photonic inverse design. Nevertheless, the conventional single-step neural predictor is inherently limited when the structure contains a variable layer count, since the output dimensionality of the neural network is fixed. This constraint motivates reformulating multi-layer structure inverse design as a sequence-generation problem, where an autoregressive model predicts the structure token by token [2], [3].

Building on this idea, OptoGPT introduced an autoregressive framework for inverse design of multilayer structures using Transformer [4], demonstrating the ability to design structures with variable layer counts. Despite this progress, its tokenisation couples material and thickness into a single token, constraining thickness resolution to 10 nm or requiring a further thickness fine-tune.

To address the aforementioned issues, we propose an encoder–decoder Transformer architecture that supports flexible wavelength windows and employs a decoupled tokeniser, enabling material and thickness tokens to be predicted separately. This strategy increases thickness precision and reduces the vocabulary size. As the thickness is conditioned on material, this prediction order introduces more physical causality, improving both modelling efficiency and adaptability across design settings.

II. Results and Discussions

The schematic of the proposed model is illustrated in Fig. 1a. The encoder takes the wavelengths and spectral values, then outputs a contextual representation. The decoder autoregressively generates the structure conditioned on the encoder output via cross-attention.

We trained the model using the standard teacher-forcing method in the Large Language Model (LLM) [5]. The losses and accuracies are shown in Fig. 1b. The training loss dropped significantly within the first 1000 steps, and then gradually converged. The validation loss followed the training loss closely, indicating no overfitting occurred. The accuracy validated the loss trend, which indicated the performance improvement of the model during training.

A. Autoregressive Generation

The structure generation started from a special token BoS, and proceeded token by token. At each step, logits were temperature-scaled and masked to enforce the alternating material–thickness order. For example, at the turn of material prediction, the probabilities of thickness were set to zero, and vice versa. We used the nucleus (top-p) strategy with $p = 0.9$ to sample tokens and appended them to the generated sequences. The special token EoS served as the signal to stop the generation, which enabled variable layer counts.

In the test set with 50,000 samples, the trained model achieved an average MAE of 0.0785. Fig. 2a presents the MAE histogram, which is strongly right-skewed, indicating high design accuracy, with 95% of predictions achieving MAE < 0.164. We selected a representative design result (MAE $= 0.049998$) that demonstrated closely aligned spectral reconstruction, as shown in the Fig. 2b, validating the model's precision for multilayer inverse design. The structures of the ground truth and the predicted are listed in Table I. The first two layers showed high similarity, while the later layers had certain degrees of differences in thickness or material. An

III. CONCLUSION

We have presented an encoder–decoder Transformer for inverse design of optical multilayer thin-film structures. By decoupling material and thickness tokens, the proposed architecture achieves 1 nm thickness resolution, and the design order is more physically intuitive. The model attained a mean absolute error of 0.0785 at an inference throughput of 511 designs/s using a single GPU NVIDIA RTX 5090, enabling practical real-time design workflows. Future work will extend the framework to include real-time physical guidance into the model and use reinforcement learning to enhance the accuracy.

***Abstract*— Hyperbolic metamaterials (HMMs) offer ultrahigh photonic density of states for enhancing solid-state single-photon emitters. Using analytical and FDTD simulations, we evaluate Purcell factors and photon collection efficiencies for metal–dielectric HMM stacks coupled to two-dimensional emitters. We show that high Purcell enhancement often accompanies strong non-radiative losses, while surface gratings significantly improve far-field photon out-coupling.**

***Keywords*— Hyperbolic metamaterials, single photon emitters, photon extraction.**

I. Introduction

Solid-state single-photon emitters (SPEs) are essential building blocks for scalable photonic quantum information processing [1-2]. Despite deterministic single-photon generation, compatibility with nanophotonic architectures, currently available SPEs face several challenges like low emission rate, fast decoherence and less external control that hinder practical deployment [3]. A general strategy to address these challenges is to embed SPEs in nanostructured photonic environments with elevated photonic density of states (PDOS), thereby enhancing light-matter interactions [4]. The increased PDOS provides additional decay channels, enabling brighter single photon emission. Recent approaches using quantum dots in Bragg reflectors have demonstrated moderately bright and pure single photons, but face two drawbacks: (i) fabrication is complex due to selective emitter placement, and (ii) the enhancement of spontaneous emission remains modest. Hyperbolic metamaterials (HMMs), composed of alternating metal–dielectric layers, offer much higher PDOS compared to Bragg reflectors [5]. Light-matter coupling is strong at the HMM surface, making surface-integration of atomically thin 2D emitters ideal for achieving high Purcell enhancement. Defect-bound excitonic states in monolayer transition-metal dichalcogenides, such as WSe_2, provide reliable single-photon emission with sub-nanometer confinement [2], and are ideal candidates to be integrated on the HMM surface with minimal separation.

A plethora of experimental and theoretical studies have highlighted Purcell factor, given by $\frac{P_r + P_{nr}}{P_0}$ (P_r: radiative power dissipation, P_{nr}: non-radiative power dissipation, P_{tot}: total power dissipation in vacuum) as indicators of photon emission enhancement. However, as the definition suggests, Purcell enhancement includes radiative as well as non-radiative pathways. Often the latter is strong enough to have poor photon out-coupling. Therefore, depiction of PF alone is not enough for judging enhancements in emitter properties. In this study, we simulate PF as well as photon collection probabilities of hyperbolic metamaterials in order to account for non-radiative losses in the system that most studies overlook. We explore properties of photon emitters coupled to HMMs through analytical and Finite Difference Time Domain (FDTD) electromagnetic simulations. We consider HMM stacks with various dielectric and metal pairs and investigate their suitability to enhance single-photon emitters based on two-dimensional materials like tungsten selenide (WSe_2) and hexagonal boron-nitride (hBN).

II. Methods

To estimate the PDOS of a dispersive medium, we rely on the depiction of isofrequency surface that is defined by a surface in the k-space where all points correspond to states with same frequency ω (i.e., ω(k) = constant). In an isotopic medium, the linear dispersion leads to propagating waves with a spherical isofrequency surface given by the following equation: $k_x^2 + k_y^2 + k_z^2 = \epsilon\frac{\omega^2}{c^2}$; where, the propagating wavevector is $\boldsymbol{k} = (k_x, k_y, k_z)$, ϵ is the dielectric permittivity of the medium and ω is the frequency of light (Fig. 1(a)). If we consider an anisotropy, the isofrequency surface for a TM polarized wave reads as $\frac{k_x^2+k_y^2}{\epsilon_{zz}} + \frac{k_z^2}{\epsilon_{xx}} = \frac{\omega^2}{c^2}$ with an assumed dielectric tensor $\epsilon = (\epsilon_{xx} = \epsilon_{||}, \epsilon_{xx} = \epsilon_{||}, \epsilon_{zz} = \epsilon_{\perp})$. In such a case, the isofrequency surface is an ellipsoid. Interestingly, if there is an anisotropic material where the parallel and perpendicular components have different signs, that is $\epsilon_{||}.\epsilon_{\perp} < 0$, the isofrequency surface becomes an open hyperboloid. Such materials can be fabricated artificially by incorporating hybrid designs of metals and dielectrics and are termed as hyperbolic metamaterials (HMMs)

[6-7]. Interestingly the high k-waves that become evanescent in isotropic materials and decay exponentially are allowed to propagate in HMMs. The presence of high-k modes enhances the overall photonic density of states. A single photon emitter directly coupled to the higher PDOS of the HMMs display higher spontaneous emission rates and hence, stronger emission.

First, we identify the proportion ratios of metal and dielectric needed for hyperbolicity from Effective Medium Theory and thereafter, use analytical solutions and finite difference time domain (FDTD) simulations to find field enhancements, Purcell factors and photon collection efficiencies corresponding to artificial, multi-layered HMM stacks.

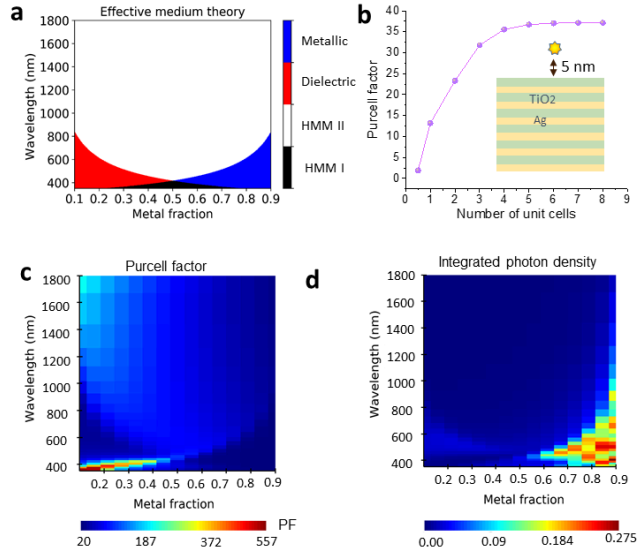

Fig. 1 (a) Estimation of metallic, dielectric, hyperbolic type-I and type-II regions as a function of metallic fraction and wavelength for TiO_2/Ag stack using effective medium theory. (b) Convergence test for Purcell factor of a horizontal dipole placed 5 nm above the stack as a function of number of unit cells consisting of a metal and a dielectric layer. Analytically calculated (c) Purcell factor and (d) integrated photon density as a function of metal fraction and wavelength.

III. Results and Discussion

We apply EMT to find the suitable wavelength regions of enhancement in a stack made of titanium oxide and silver. As seen from Fig. 1(a), this stack offers hyperbolic states in the visible spectrum for selected metal fractions around 0.5 and offers hyperbolicity in the near-infrared region throughout all metal fractions studied here. Prior to estimating the PF of the structure with various metal fractions and wavelengths, we perform a convergence test for the same and as depicted in Fig. 1(b), six unit cells comprising of a metal and dielectric material show optimized PF. We use this set-up for further calculations. To investigate the potential spontaneous emission enhancement through coupling with the HMM, we calculate the PF of TiO_2/Ag stack corresponding to varying metal fraction of Ag and spanning visible to the near infrared frequencies. To perform these simulations, we consider a horizontal dipole placed 5 nm above the metamaterial stack. As the analytical calculations reveal, the spectral and metal fraction regions corresponding to higher PF correlates strongly with the EMT map, as expected. Since the PF indicates the enhancement of spontaneous emission rate originating from both radiative and non-radiative channels, we also calculate the angle-integrated photon intensity and plot in Fig. 1(d). This allows distinction of the radiative contributions. Surprisingly enough, the higher photon collection probabilities are correlated with lower PFs, as clearly visible from Fig. 1(c) and (d). This stems from the non-radiative loss of the high-k modes taking place in the metal-dielectric interfaces of the stack. To overcome non-radiative losses, one must introduce a coupling element into the structure—such as a grating or a photonic crystal—so that high-k modes can be coupled out to the far field [8].

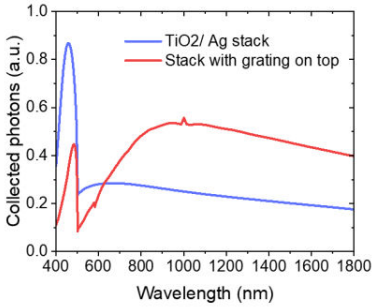

Fig. 2: Blue curve: Collected photon intensity at a far-field location above a HMM stack of TiO_2/Ag (20 nm/5 nm) with metallic fraction of 0.2, as a function of wavelength of dipole emission - estimated from FDTD. Red curve: same quantity with a 2D photonic crystal of etched on top TiO_2 surface (height: 20 nm). The etched PhC consists of square array of a period of 100 nm with radius of each pillar being 40 nm.

We perform FDTD electromagnetic simulations with a HMM stack with unit cells of 20 nm TiO_2 and 5 nm Ag and a horizontal dipole placed 5 nm above surface. We calculate the total photons collected at far-field as a function of emission wavelength which matches well with analytical result (metal fraction 0.2 in Fig. 1(d)). Next, we introduce a 2D photonic crystal array consisting of etched holes into the top TiO_2 surface layer and calculate the same quantity. As Fig. 2 depicts, we observe about a two-fold enhancement of the photon collection by introducing the etched grating structure. This result highlights the importance of a grating to out-couple the high-k modes that contribute to the high PDOS and strong light-matter interaction of the dipole emitter. Further, we study other combinations of materials and observe tunability in the photon out-coupling using two phase-change materials, namely-vanadium dioxide and antimony-sulfide.

IV. Conclusion

In this study, we explore the hyperbolic metamaterials from scratch and identify the important figures of merit for designing and fabricating a single photon emitter coupled to a hyperbolic metamaterial stack. We uncover that high PF is not a sufficient criterion for enhancing spontaneous emission rate of an emitter: the drawback being non-radiative losses in the metal-dielectric interfaces. Such bottleneck is overcome by enabling out-coupling of high-k modes of light through a photonic crystal on top of the metasurface stack. In addition, we investigate multiple materials and their suitability to enhance single photon emission from two-dimensional material based emitters.

***Abstract*—A mechanically reconfigurable, dual-band cavity-excited antenna is designed based on scattering constellations composed of metallic rods. The reconfigurability originates from modulating the sparse distribution of metallic rods inside the cavity, which offers vast design freedom. A hybrid BPSO-LS algorithm is employed to optimize the rod layout for target radiation patterns. By using only two distinct scattering constellations, the design enables dual-band beam switching between 0° and 30° at both 7 GHz and 12 GHz. Full-wave simulations validate the concept, demonstrating high-precision beam control.**

***Keywords*— dual band, beam switching, reconfigurable antenna, optimized algorithm, scattering constellation.**

I. Introduction

With the rapid evolution of wireless communication systems, reconfigurable antennas (RAs) have become a widely adopted approach for achieving functional agility. Traditional reconfiguration (p-i-n diodes [1], varactors [2], MEMS [3]) often introduces significant parasitic effects and ohmic losses, which can severely degrade the antenna's radiation performance. Moreover, complex biasing circuits make antenna design more expensive and complex [4]. Compared to electric reconfigurable techniques, mechanical solutions offer higher radiation efficiency and less interference. However, mechanical mechanisms often result in bulky, costly designs and offer limited structural freedom.

Among various mechanical reconfigurable architectures, the cavity-excited antenna based on scattering constellation emerged as a robust, all-metal structure [5]. Its design can offer immense degrees of freedom for reconfiguration and realize diverse radiation functionalities only by modulating the rods inside the cavity. The all-metal structure also simplifies fabrication.

In this work, we propose a dual-band beam switching scheme for a cavity-excited antenna based on the concept of scattering constellations. For illustration, the antenna is designed to operate at 7 GHz (C-band) and 12 GHz (Ku band). To achieve this design, an optimization algorithm is employed to determine the optimal sparse layout of the metallic rods, with the electric field characterized by a semi-analytical model. The proposed design is validated using two distinct scattering constellations: Constellation A generates a radiation beam at 0° for both 7 GHz and 12 GHz, while Constellation B directs the beam at 30° at the same frequencies. Simulation results confirm that dual-band beam switching between 0° and 30° is achieved by switching between the two constellations, with stable radiation performance at both frequencies. Moreover, the directivity of Constellation A matches well with that of an ideal uniform aperture of the same size, and the measured S11 values are below -10 dB at both frequencies, verifying excellent impedance matching for dual-band design.

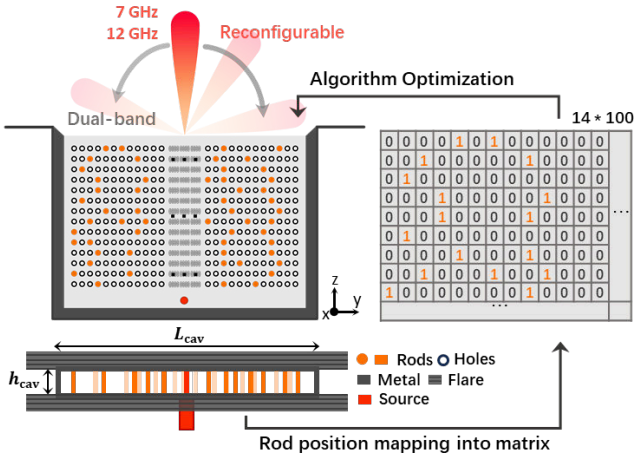

Fig. 1. Configuration of the cavity-excited antenna and the design procedure. Beam switching can be achieved simply by changing the rods distribution (constellations) inside the cavity.

II. Methods

The configuration of the cavity excited antenna is shown in Fig. 1. The antenna comprises a metallic cavity with a single radiation aperture, with the remaining five walls enclosed in metal. To minimize propagation discontinuities and ensure a smooth impedance transition, flare structures are integrated at the top and bottom edges of the aperture. Both the upper and lower metallic plates of the cavity are uniformly distributed with a 14×100 array of holes. These holes are precisely aligned between the two layers, such that the insertion of metallic rods establishes a reliable electrical connection between the top and bottom walls.

The cavity can be considered as a 2D configuration ($\partial/\partial x = 0$). The total field on the aperture can be considered as the sum

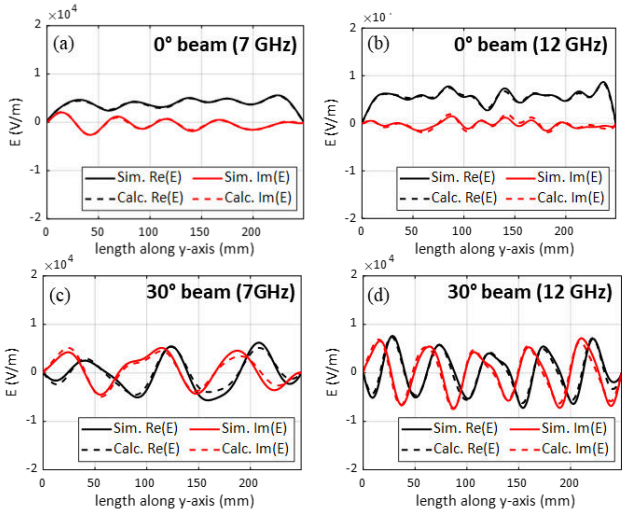

Fig. 2. Calculated E-field based on semi-analytical model and full-wave simulated E-field along the aperture at 7 GHz and 12 GHz.

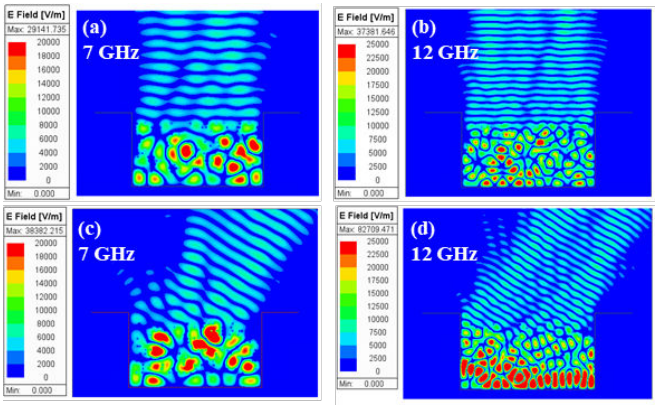

Fig. 3. The simulated field distributions for (a) 0° single-beam radiation and at 7 GHz, (b) 0° single-beam radiation at 12 GHz, (c) 30° single-beam radiation and at 7 GHz, and (d) 30° single-beam radiation at 12 GHz. The results in (a) and (b) are realized by the same antenna constellation, while those in (c) and (d) are achieved by another constellation.

of the E field from the source and the E field from the metallic rods:

$$E^{total}(y, z_{ap}) = E_x^{(s)}(y, z_{ap}) + \sum_{i=1}^{N_{rod}} E_x^{(i)}(y, z_{ap}) \quad (1)$$

Where $E_x^{(s)}$ represents E field from source, $E_x^{(i)}$ represents E field from rods. N_{rod} is the total number of rods inside the cavity, y is the location along the y-axis, and z_{ap} is the location of the aperture along the z-axis. So, different functions can be realized simply by changing the positions of the rods. We do not need to design the structure of every element.

The cavity's radiation state is dynamically reconfigured by inserting or removing metallic rods into these holes. This physical setup is represented by a binary matrix model, where each matrix element corresponds to a location: a 0 indicates an empty hole, and a 1 indicates a hole filled with a metallic rod. As a result, the algorithm's optimization goal is to find the best binary matrix (the ideal rod distribution) that achieves the desired dual-band radiation.

To optimize the sparse rod distribution within the vast 2^{1400} search space, a hybrid algorithm combining Binary Particle Swarm Optimization (BPSO) and Local Search (LS) is implemented. For the first 400 iterations, BPSO is utilized to navigate the high-dimensional landscape and prevent premature convergence to local optima. For the last 100 iterations with the total rod count fixed, the algorithm performs a localized search to fine-tune rod positions, ensuring convergence to the optimal configuration. The cost function is set as the sum of the differences between the calculated E-field using the semi-analytical equation and the ideal E-field.

III. Results and Discussion

To validate the method, two constellations are presented: Constellation A produces the single beam radiation at 0° at 7 GHz and 12 GHz, and Constellation B realizes a beam directed towards 30° at the same two frequencies. The distribution of the cavity-excited antenna rods (scattering constellations) is optimized using the method mentioned above. Antennas with optimized rod distributions are also simulated in HFSS. Results calculated from the semi-analytical model and simulated from HFSS are both obtained under a quasi-2D scenario. For the full-wave simulation setup, the metacavity is integrated within a parallel plate waveguide, and this configuration yields identical radiation performance to the 3D scenario with integrated flare structures.

The real and imaginary parts of the calculated results, compared with full-wave simulation results, along the cavity aperture are shown in Fig. 2, which exhibit high agreement. The level of correspondence between the two can be further enhanced by increasing the number of modes in the analytical model. The full-wave simulated electric field distributions for the two cases are presented in Figs. 3(a-d). Corresponding normalized radiation patterns are shown in Fig. 4. For cases (a) and (b), the main beam is directed at 0°, while for cases (c) and (d), it is steered to 30°. These results show excellent agreement with the design objectives. The full-wave simulations confirm that the optimized cavity design can precisely steer EM waves to the desired angles.

To characterize the performance of the proposed cavity-excited scattering constellation antenna, the directivity for Constellation A (0° beam) at 7 GHz and 12 GHz is compared in Fig. 5 against the theoretically calculated ideal uniform aperture of identical physical dimensions as the antenna's exit facet.

The maximum directivity of Constellation A reaches 9.73 dB and 14.55 dB at 7 GHz and 12 GHz, respectively, while the theoretical maximum directivity of the ideal uniform aperture is 10.09 dB and 14.78 dB. The main lobe profiles of the two are nearly identical, and this minimal directivity discrepancy verifies highly consistent directional radiation performance

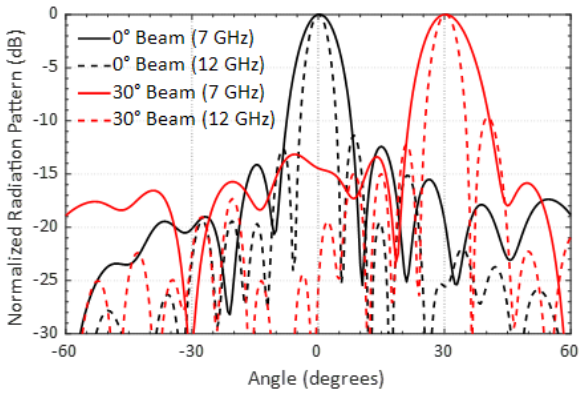

Fig. 4. Normalized radiation patterns for single-beam steering to 0° (black line) and 30° (red line) simultaneously achieved at both 7 GHz (solid line) and 12 GHz (dashed line).

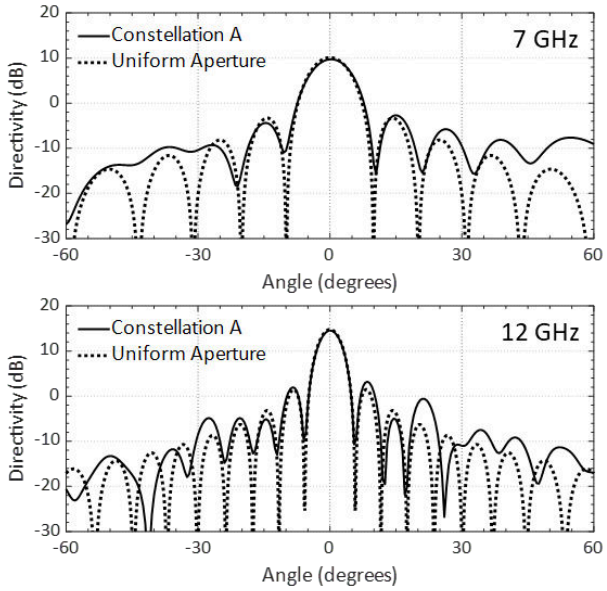

Fig. 5. Comparison of unnormalized directivity between constellation A (solid line) and an ideal uniform aperture (dashed line) at 7 GHz and 12 GHz.

between the proposed design and the ideal benchmark. Besides directivity, the S11 parameter of Constellation A was measured, with values of -12.40 dB at 7 GHz and -13.67 dB at 12 GHz.

IV. Conclusion

In conclusion, we have proposed and validated a dual-band beam-steering antenna based on a cavity-excited scattering constellation. A semi-analytical model enables efficient aperture field calculation, and a hybrid BPSO-LS algorithm successfully optimizes the binary rod distribution across the vast design space. The final design demonstrates the capability to independently steer a single main beam to 0° or 30° across two frequency bands with wide spectral separation, as confirmed by full-wave simulations. This work showcases a low-loss, mechanically reconfigurable approach to achieving multi-functionality in a single aperture. Future work may focus on expanding the functionality and implementing an automated mechanical control system for robust reconfiguration.

Retrieving colors hidden in a grey Fabry-Pérot cavity through coherent absorption

***Abstract*—A dielectric slab coated with thin metal films is the prototypical Fabry-Pérot cavity, featuring defined reflectance and transmittance spectral resonances. Here we challenge this common acquisition, showing that an appropriately chosen metal coating washes out the Fabry-Pérot resonances, that can be however fully retrieved by a coherent absorption measurement.**

***Keywords*— Fabry-Pérot, coherent absorption, cryptography.**

I. Introduction

Dielectric thin films are well known to exhibit structural colors, ultimately originating from the Fabry-Pérot spectral features. It is usually acknowledged that coating the two sides of the dielectric slab with metal thin films further enhances the resonant behavior, leading to high-finesse spectral peaks visible in transmittance and in reflectance. However, it was to date overlooked that a specially matched thin film, whose surface conductivity is purely real, plays exactly the opposite role, washing out any resonant behavior from the system, and resulting in spectrally flat reflectance and transmittance.

II. Methods and Results

The phenomenon relies upon a special case of the reflectance/transmittance formulas for a dielectric slab sandwiched between thin conducting interfaces. These formula read

$$r = -\frac{\alpha_{+-}\,\alpha_{--}\,e^{ikd} - \alpha_{-+}\,\alpha_{++}\,e^{-ikd}}{\alpha_{--}^2\,e^{ikd} - \alpha_{++}^2\,e^{-ikd}},$$

$$t = \frac{\alpha_{-+}\,\alpha_{--} - \alpha_{+-}\,\alpha_{++}}{\alpha_{--}^2\,e^{ikd} - \alpha_{++}^2\,e^{-ikd}},$$

where

$$\alpha_{++} = n + 1 + \sigma Z_0, \qquad \alpha_{+-} = n + 1 - \sigma Z_0,$$

$$\alpha_{-+} = n - 1 + \sigma Z_0, \qquad \alpha_{--} = n - 1 - \sigma Z_0.$$

Here, n is the refractive index of the slab, σ is the conducting interface sheet conductivity, Z_0 is the vacuum impedance, $k = 2\pi n/\lambda_0$ is the wavevector in the dielectric, and d is the dielectric thickness. If the ordinary, uncoated slab is considered, σ must be set to 0, leading to wavelength dependent reflectance and transmittance (Fig.1a). In general, a finite value of σ leads also to λ-dependent spectra, possibly with sharp features. However, if the special value

$$\sigma_M = \frac{n-1}{Z_0}$$

is employed, α_{--} becomes zero, and drastically simplified formulas emerge:

$$r = \frac{1-n}{n}, \qquad t = \frac{e^{ikd}}{n}.$$

Taking the moduli squared, the phase factor disappears, meaning wavelength- and thickness- independent reflectance and transmittance spectra (Fig. 1b). Nonetheless, a *kd*-dependent phase factor is still present in the *t* coefficient; intriguingly, this can be accessed through a coherent measurement performed by illuminating both sides of the cavity simultaneously with phase-locked beams (Fig. 1c).

If the double-beam absorptance is defined as $A_{db}=1-I_{out,I}-I_{out,II}$, being $I_{out,I(II)}$ the intensity recorded at detectors placed at either sides of the cavity, for the matched cavity one gets

$$A_{db} = A_{sb}\,(1 - \cos(kd)\cos(\phi))$$

having defined the single-beam absorptance $A_{sb}=1-|r|^2-|t|^2 = 2(n-1)/n^2$, and being ϕ the phase difference between the input

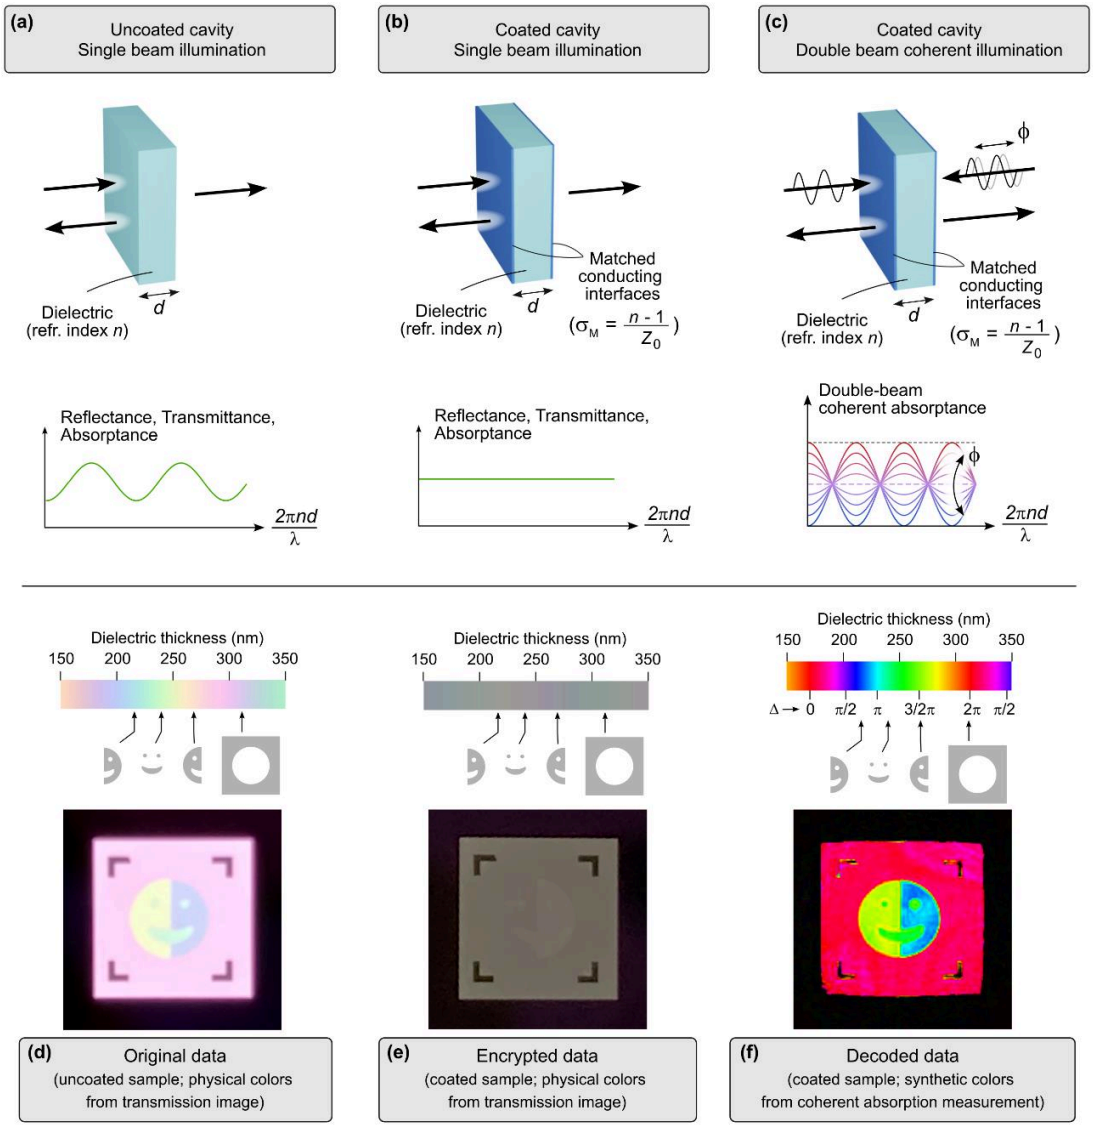

Figure 1. (a-c), concepts of spectrally flat, conductivity matched Fabry-Pérot cavity, and its interrogation through coherent absorption. (d-f), proposed application of the aforementioned phenomenon for cryptographic purposes.

beams. As illustrated in Fig. 1c, this implies the retrieval of spectral features originally present in the uncoated system; however, such features are now accessible only through a coherent-absorption scheme that grant access to A_{db}. Better yet, instead of relying upon measuring the total output intensity, one could consider that the individual intensities found at either sample sides follow the law

$$I_{\mathrm{out},I} = \frac{1}{2}\left(|r|^2 + |t|^2 + 2|rt|\cos(\phi + \frac{\Delta}{2})\right)$$

$$I_{\mathrm{out},II} = \frac{1}{2}\left(|r|^2 + |t|^2 + 2|rt|\cos(\phi - \frac{\Delta}{2})\right)$$

where $\Delta = 2kd$. By comparing the signals at the two detectors collected upon a sweep of input phase ϕ, one can strightforwardly and robustly determine the value of Δ and hence the dielectric thickness d.

This phenomenon, besides having a fundamental physics character, lends itself to applications in cryptographic schemes, where a piece of information is concealed to undesired recipients, while being still recoverable only by those agents who know a specific protocol. To demonstrate that, we fabricated a thin-film silicon nitride membrane, with lateral size 5x5 mm, featuring various areas with different thicknesses, such that the resulting spectral colors create a “smiley” image, see Fig. 1d. The chosen thicknesses fall within the 220-310 nm range, such that the spectra present a few oscillations in the visible spectral range, and ultimately resulting in well-defined spectral colors that can be observed by naked eye and captured by an ordinary smartphone camera (Fig. 1d).

After coating the sample with a thin Cr/Au film (4/6 nm thickness), which is the closest practical implementation to the

matching conductivity σ_M, the "smiley" feature is almost completely washed out, as visible in Fig. 1e. Here, all the sample is characterized by an extremely weakly saturated, low-brightness grey shade, consistently with the theroretical prediction that yields a spectrally flat transmittance amounting to $T = (1/n)^2 \approx 1/5$, having considered the typical value of silicon nitride refractive index.

However, we have been able to retrieve the data physically encoded in the sample, by performing coherent absorption imaging. Here, two He-Ne laser beams with variable phase delay are shone on either side of the sample, and the phase Δ is measured point-by-point. By mapping such phase on a properly chosen cyclic hue scale, the original appearance of the "smiley" can be recovered, although it was concealed from any single-beam measurement.

III. Conclusion

In summary, we have studied a simple yet powerful mechanism to conceal the spectral colors intrinsic to a thin dielectric film, by coating it on both sides with a conductivity-matched thin film. Notably, the hidden information can be retrieved with a specialized measurement scheme that amounts to illuminating the sample with phase-swept coherent beams. We believe that this results illustrates a fundamental photonic concept, and meanwhile a viable protocol for secure information transfer.

***Abstract*— We demonstrate local-to-nonlocal intersubband polaritonic metasurfaces that enable broadband two-dimensional control of second-harmonic generation. A local resonance enhances excitation at the fundamental frequency, while a nonlocal resonance governs dispersive emission at the second harmonic. Voltage and incident angle independently modulate the SH spectral response, enabling broadband two-dimensional control of SHG.**

***Keywords*— nonlinear metasurface, nonlocal metasurface, second harmonic generation, electrical tuning, angle tuning.**

I. Introduction

Electrically tunable nonlinear metasurfaces based on intersubband transitions in multiple quantum wells (MQWs) are a powerful platform for mid-infrared frequency conversion, providing strong out-of-plane nonlinearity and electrical tunability.[1] In many existing architectures, however, electrical bias primarily changes the generated SH intensity through modulation of the fundamental-field enhancement and the nonlinearity of MQW layer, while the SH spectral position is largely constrained by structure-oriented local resonance condition. In parallel, nonlocal resonances in periodic metasurfaces—such as guided-mode resonances, quasi-bound states in the continuum, and lattice resonances—offer narrowband spectral selectivity and strong angular dispersion, enabling wavelength tuning through incident-angle control.[2] Yet in nonlinear implementations, achieving both high conversion efficiency and additional tunability can be challenging because high-Q nonlocal resonances are sensitive to absorption loss of material.

In this work, we propose and demonstrate a hybrid SHG strategy that explicitly assigns two different modal roles within a single SHG process. A local resonance is used to induce excitation at the fundamental frequency (FF), maximizing nonlinear polarization inside MQWs under electrical control, while a nonlocal resonance is used at the second-harmonic frequency to obtain dispersive outcoupling and spectral positioning under angle tuning. This separation of functions enables two independent tuning knobs—voltage and angle—that map onto two distinct outputs: SH peak amplitude and SH peak wavelength.[3] The result is two-dimensional control of the SH spectrum, rather than a single-parameter tuning trajectory.

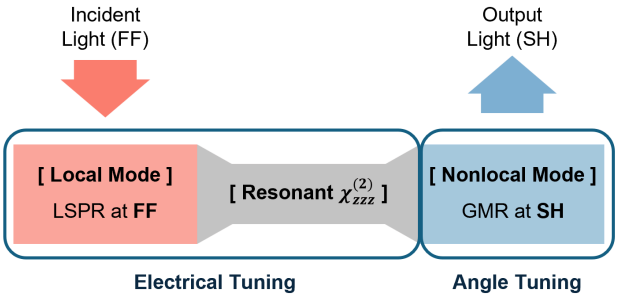

Fig. 1 A hybrid SHG scheme in intersubband polaritonic metasurfaces with local and nonlocal modes for dual tuning knobs.

II. Metasurface Design and Tunability

The metasurface is designed so that the unit cell supports a plasmonic local resonance at the FF (localized surface plasmon resonance) and an angle-dispersive nonlocal resonance at the SH frequency (TM guided mode resonance). Figure 2 shows the meta-atom geometry and the field distributions at both frequencies. A key design objective is to secure a nonzero overlap factor between the driven nonlinear polarization distribution inside the MQW layer and the radiative SH mode supported by the nonlocal resonance. Because nonlocal modes can exhibit highly symmetric field profiles that may lead to far field cancellation, the field distribution of the local resonance at the FF is asymmetrically shaped through the line connection of the upper side of the meta atoms and then it results to non-centrosymmetric field product. This design strategy ensures nonzero modal overlap factor as shown in Figure 2d which can be calculated by the equation (1),

$$\chi_{yxx}^{(2)\mathrm{eff}}(V,\theta) \approx \chi_{zzz}^{(2)\mathrm{MQW}}(V) \cdot \left[\int_{v_{\mathrm{MQW}}} \frac{E_z^{2\omega}(\theta)}{E_{y,inc}^{2\omega}} \frac{E_z^{\omega}(V)}{E_{x,inc}^{\omega}} \frac{E_z^{\omega}(V)}{E_{x,inc}^{\omega}} dv\right] / v_{\mathrm{unit}} \quad (1)$$

where the effective second order nonlinear susceptibility is the product of MQW nonlinearity and modal overlap factor. The integral term indicates modal overlap factor in equation (1).

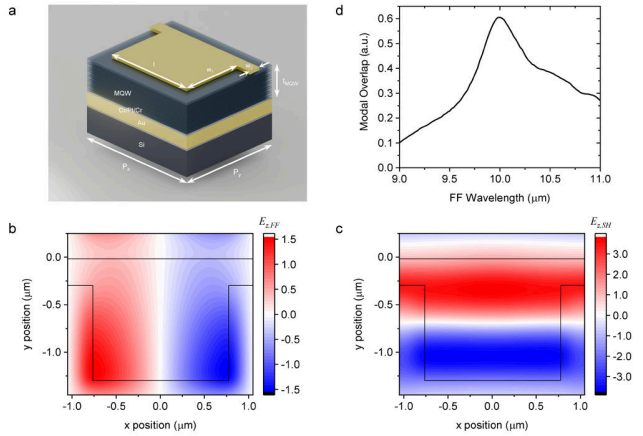

Fig. 2 a) Unit-cell geometry of the metasurface designed to support both local and nonlocal modes. b,c) Simulated E_z field distribution for b) the local mode under x-polarized FF excitation and c) the nonlocal mode under y-polarized SH excitation. d) Calculated modal overlap factor spectrum plotted versus the fundamental wavelength.

Figure 3a shows the electrical tuning which tunes the intersubband transition energies by quantum confined Stark effect (QCSE) that modulates the reflection spectrum at the FF due to strong coupling between local resonance and intersubband transition. Figure 3b shows the angle tuning which controls in-plane momentum and shifts the nonlocal resonance at the SH frequency through its angular dispersion. The detector position in the Fourier plane is directly translated into in plane momentum, which indicates the incident angle θ. And as a result, modal overlap factor and corresponding effective nonlinear susceptibility become a function of two independent variables, V and θ, which can be expressed as the equation (1).

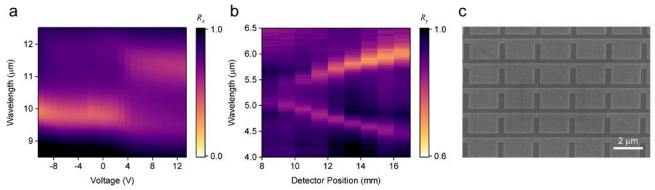

Fig. 3 a) Measured x-polarization reflection spectra of the fabricated sample as a function of applied voltage. b) Measured y-polarization reflection spectra of the fabricated sample as a function of detector position in the Fourier plane. c) SEM image of the fabricated sample.

III. Results and Discussion

Figure 4 summarizes the key outcome by comparing the effect of each tuning knob and their combination. Voltage tuning alone moves the SH response mainly along an amplitude axis at nearly fixed peak wavelength, while angle tuning alone moves it along a wavelength axis following the dispersive nonlocal resonance. Each tuning knob therefore traces an essentially one-dimensional trajectory in the space of 'SH peak wavelength versus amplitude'. When both angle and bias are used together, the accessible operating points expand into a two-dimensional region, enabling selection of target combinations of SH peak wavelength and amplitude rather than being restricted to a single tuning path. We experimentally achieved peak wavelength control from 10.04 μm to 9.66 μm, and 36% of peak amplitude modulation depth of SH response.

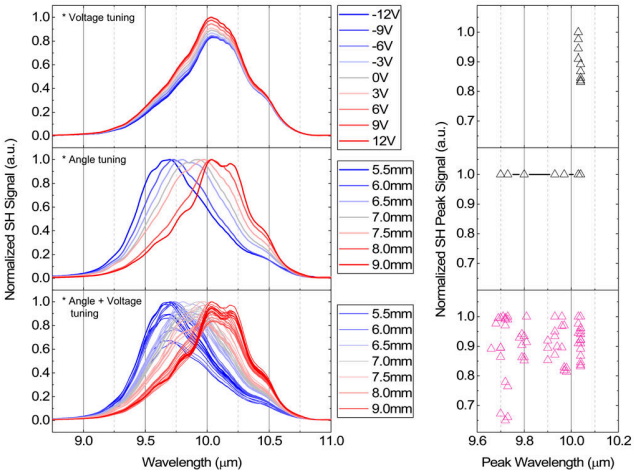

Fig. 4 Comparison of the impact of dual tunability enabled by the hybrid SHG process for 2D control of the SH spectrum. The panels on the left side represent normalized SH spectra, and the panels on the right side represent accessible peak positions of normalized SH spectra. top) Voltage tuning of SH spectra (single tunability). middle) Angle tuning of SH spectra (single tunability). bottom) Angle, voltage tuning of SH spectra (dual tunability). The legends of angle tuning indicate the pump laser position that represent corresponding incident angle tuning through the high NA lens.

IV. Conclusion

In conclusion, we demonstrate a hybrid SHG strategy in intersubband polaritonic metasurfaces where a local resonance is used to enhance excitation at the fundamental frequency while a nonlocal resonance governs dispersive emission at the second harmonic. This separation of roles provides two independent external controls: electrical bias predominantly modulates the SH amplitude by tuning the excitation strength in the MQW, whereas incident angle shifts the SH peak wavelength through the angular dispersion of the nonlocal emission channel. By combining these two knobs, we achieve two-dimensional control of the SH spectrum, enabling programmable selection of SH peak wavelength and amplitude beyond the one-dimensional tuning trajectories available in

conventional nonlinear metasurfaces with local or nonlocal modes. This approach establishes a general design principle for multifunctional nonlinear metasurfaces that require both strong frequency conversion and flexible spectral programmability.

***Abstract*—This work establishes rigorous conditions for designing achromatic metasurfaces, defining two regimes: achromatic (unitary Strehl ratio) and pseudo-achromatic (near-achromatic behavior via aberration compensation). It derives size limits and performance metrics, validated using FDTD simulations, to guide the design of broadband metasurfaces for applications like augmented reality and imaging.**

***Keywords*— metamaterials, metasurfaces, achromaticity**

I. Introduction

Metasurfaces start to be widely spread and are reaching the industrial levels. Conventionally, metasurfaces are designed at a single frequency, meaning that outside of this operating frequency the optical performances quickly drops. For several applications, such as for augmented reality or in imagery system, it is preferable to have large bandwidth operations, i.e. the optical function should remain the same at all frequencies with equal optical performances. Designing such componenents is challenging as it supposes to engineer and control the phase dispersion of each meta-elements constituting the metasurface.

In light of these challenges, several works have been realized to estimate limits in terms of size or optical performances of such achromatic metasurfaces in function of its constitutive parameters [1], [2], [3], [4].

In this work, we establish rigorous conditions to be satisfied by the phase dispersion of the meta-atoms in order to realize an achromatic metasurface. Based on those conditions, we define different regimes of operation of achromatic metasurfaces, (i) an achromatic regime garanteeing unitary Strehl ratio, (ii) pseudo-achromatic regime, where appropriate choice of meta-atoms leads to the compensation of the different chromatic aberrations and so to a near-achromatic behavior. We clarify how the previous limits compare with each others as well as to our approach.

II. Methods

In our theoretical framework, we consider metasurface introducing an optical-path difference $g(\boldsymbol{r})$ associated with phase function $\varphi(\boldsymbol{r},\omega) = \frac{\omega}{c} g(\boldsymbol{r})$. We show that in order to realize an achromatic metasurface with wavefront $g(\boldsymbol{r})$, the phase dispersion $\tilde{\varphi}_p$ of the meta-atoms should satisfy the *achromatic conditions*, for any meta-atoms (p, q),

$$\begin{cases} \tilde{\varphi}_p(\omega) - \tilde{\varphi}_q(\omega) = \dfrac{\omega}{c}[g(\boldsymbol{r}_p) - g(\boldsymbol{r}_q)], & \text{(1a)} \\ \dfrac{d\tilde{\varphi}_p}{d\omega}(\omega) - \dfrac{d\tilde{\varphi}_q}{d\omega}(\omega) = \dfrac{1}{c}[g(\boldsymbol{r}_p) - g(\boldsymbol{r}_q)], & \text{(1b)} \\ \dfrac{d^n\tilde{\varphi}_p}{d\omega^n}(\omega) - \dfrac{d^n\tilde{\varphi}_q}{d\omega^n}(\omega) = 0 \quad \text{for} \quad n \geq 2. & \text{(1c)} \end{cases}$$

Assuming those conditions we can derive the maximal size of an achromatic metasurface with unitary Strehl ratio from a certain dataset,

$$\frac{\Delta g}{h} + \Delta n_0 = \Delta n, \tag{2}$$

where Δn_0 is the dispersion, over the bandwidth, of a reference meta-atom placed at the center of the metasurface, and Δn the maximal variation of effective refractive index in this subset of meta-atoms, as illustrated in Fig. 1.

To validate our theory, we generated a dataset composed of more than 10000 elements of $1\mu m$-thick GaN pillars on Sapphire simulated with a FDTD software (Lumerical). We show the phase dispersion $\tilde{\varphi}_p$ of the p-th meta-atoms can be approximated over the whole visible range by a Taylor expansion at the second order with relatively small error. Consequently, each meta-atom can be represented by the triplet its phase, phase delay and phase delay dispersion at the central frequency, $\left(\tilde{\varphi}_p(\omega_c),\ \frac{d\tilde{\varphi}_p}{d\omega}\Big|_{\omega_c},\ \frac{d^2\tilde{\varphi}_p}{d\omega^2}\Big|_{\omega_c}\right)$ as in Fig. 1 (b-c).

To quantify how the optical perfomances are affected by the chromatic aberrations, we derived an expansion of the Strehl ratio in terms of chromatic wavefront aberrations δ_p, cf Fig. 1 (d),

$$S(\omega) \approx 1 - V_{0,0} - 2(\omega-\omega_c)V_{0,1} - (\omega-\omega_c)^2(V_{1,1}+V_{0,2}) - (\omega-\omega_c)^3 V_{1,2} - \frac{(\omega-\omega_c)^4}{4}V_{2,2},$$

with $V_{m,n}$ the covariance between the chromatic aberration of the wavefront of order m and n,

$$V_{m,n} = \langle \delta_m \delta_n \rangle - \langle \delta_m \rangle \langle \delta_n \rangle . \tag{3}$$

Fig. 1. **a.** Schematic representation of an achromatic metalens. **b.** Meta-atoms dataset representation in terms of phase $\Delta\beta_{p,0} = \tilde{\varphi}_p(\omega_c) - \tilde{\varphi}_0(\omega_c)$ and group delay $\Delta\beta_{p,1} = \frac{d\tilde{\varphi}_p}{d\omega}(\omega_c) - \frac{d\tilde{\varphi}_0}{d\omega}(\omega_c)$, relative to the reference meta-atoms. **c.** Meta-atoms dataset representation in terms of group delay $\Delta\beta_{p,1}$ and group delay dispersion $\Delta\beta_{p,2} = \frac{d^2\tilde{\varphi}_p}{d\omega^2}(\omega_c) - \frac{d^2\tilde{\varphi}_0}{d\omega^2}(\omega_c)$, relative to the reference meta-atoms. In **b.** and **c.** the red points are the targeted value and the blue points are the selected meta-atoms. **d.** Strehl ratio in function of the wavelength (top panels) as well as expansion coefficients (bottom panels).

III. Results and Discussion

Based on our framework, we identified at least two regimes of operation to realize an achromatic metasurface:

1) The first regime corresponds to the *achromatic regime*, where we are able to find meta-atoms of the dataset meeting the achromaticity conditions (1a)-(1c). In this regime, the Strehl ratio of the metasurface is unitary since the phase profile of metasurface matches exactly the targeted phase profile. Therefore we can rigorously calculate a maximum size for the achromatic metasurface and this size is independent from the bandwidth under consideration.
2) The second regime corresponds to the *pseudo-achromaticity regime*, where the achromaticity conditions are not strictly met but thanks to the correlations between the different aberrations, the overall performances of the metasurface remains good over the bandwidth. In this regime, determining the maximal size in function of the optical performances remains challenging as it depends on how the meta-atoms are chosen.

IV. Conclusion

We have derived rigorous conditions that must be satisfied by the meta-atoms in order to realize an achromatic metasurface. Based on those conditions, we identified several regime of operation. Our work aims at clarifying the physics of achromatic metasurfaces and help identify design guidelines.

***Abstract*—An underwater acoustic metasurface for wide-angle and efficient focusing in transmission mode is designed. Numerical results show that the metasurface can focus oblique-incident waves up to 45° at the same power level as the normal-incident case. The metasurface also exhibits good achromatic capability with a large spatial incident angle view.**

***Keywords*—metasurfaces, local resonance, underwater sound, transmission, focusing.**

I. Introduction

Metasurfaces, the two-dimensional counterpart of volumetric metamaterials, have attracted enormous attentions owing to its excellent abilities to arbitrarily reshape the wavefront of the incident waves. Relying on the abrupt shift of field amplitude and phase within subwavelength scale, metasurfaces have been created for various interesting devices, such as metalens, meta-coupler, holograms, beam splitters, and many others. Among various fascinating applications of metasurfaces, metasurfaces to act as a flat lens which can transform incident plane wave to a predesigned circular one are particularly of interest because of its ultra-compact design compared to the conventional bulky lenses which rely on the spatial variation of refractive index. Metasurfaces hold promise in many practical applications, such as controlling ambient sound fields. Depending on the specific design of the meta-atoms, metasurfaces can operate in reflective or transmissive mode. The design of transmissive metasurfaces is more challenging. Despite the great success of metasurfaces in the past years for efficiently focusing airborne sound, few attention and efforts have been made to apply them to spatial focusing of waterborne sound. Furthermore, metasurfaces are mostly designed at specific normal incidence with an incident angle θ_i=0° according to the generalized Snell's laws. However, for some practical applications, metasurfaces operating with a wide oblique incident angle range are highly desirable and can also greatly enhance the performance of conventional metalens.

This paper presents a highly efficient wide-angle acoustic metasurface for underwater sound. The proposed meta-atom is based on a locally resonant unit, and a large phase shift can be achieved by varying its geometric dimensions, with an average transmittance exceeding 90%. The final metasurface consists of three unit layers (total thickness approximately 0.26λ, where λ is the operating wavelength) and can efficiently focus obliquely incident plan waves continuously to one side, with an incident angle of up to 45°. Numerical results show that this metasurface exhibits good achromatic properties and a large spatial incident angle.

II. Methods

Compared to reflective metasurfaces, the main challenge in designing transmissive ones lies in simultaneously considering high transmission rate and full-range phase shift. The proposed unit cell is a perforated metal plate with a mechanical resonator (a composite of metal mass and rubber spring) attached to its sidewall. The transmission performance and phase shift depend on structural parameters, including the plate thickness, channel width, metal mass width and thickness, rubber spring width and thickness, and lattice period. Here, the element is proposed for high-efficient focusing and the working frequency is designed at 5 kHz.

To design a metasurface capable of converting incident plane waves into transmitted circular waves, the phase compensation by the designed acoustic metasurface should follow a parabolic distribution dependent on its spatial position. Commonly used phase formulas only apply to the case of normal incidence along the axis with an incident angle $\theta_i = 0°$. Based on the generalized Snell's law, here we use the universal phase distribution of the metasurface for both normal and oblique incidence along the x-axis, namely:

$$\phi(x) = k_0\left(\sqrt{(x-x_0)^2 + L^2} - L - (x-x_0)\sin\theta_i\right) + \phi_0 \qquad (1)$$

where L is the focal length, and ϕ_0 is the phase at the midpoint. The general phase distribution for wide-angle focusing includes incident angle θ_i which is dependent on the off-axis distance as indicated by x_0. For normal incidence, the general expression (1) can be degraded to the widely-used form with $\theta_i = 0$ and $x_0 = 0$ for on-axis focusing.

III. Results and Discussion

Firstly, to achieve full-range phase shift on metasurfaces for

efficient focusing, a meta-atomic structure consisting of stacked three-layer unit cells was constructed in the simulation setup. For the target frequency, the meta-atom thickness is 26 mm, the channel width is 10 mm, and the period is 20 mm. The widths of the rubber and the mass of the resonator (with a fixed ratio of 0.5) were used to adjust the phase shift. Figure 1 shows the simulated results using finite element method, demonstrating that a high transmission rate of over 0.9 and a full 2π phase shift are achieved within the parameter range.

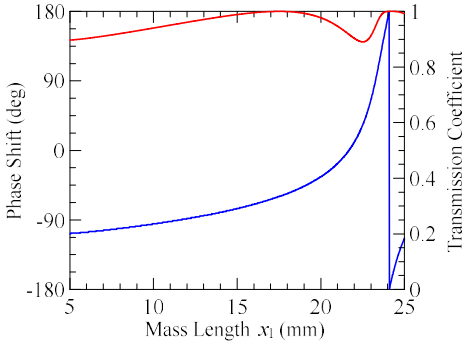

Fig. 1. Simulated results of transmission coefficient and phase shift of the meta-atom with three-layer unit cell as a function of mass length of the resonators.

Based on formula (1), the phase distribution along the x-axis for the normally incident pressure wave was designed under the conditions of wavelength $\lambda = 0.3$ m and focal length $L = 4\lambda$. As shown in Fig. 2, the focusing performance of normal incidence by the metasurface is given, and then its focusing performance under oblique incidence is further examined.

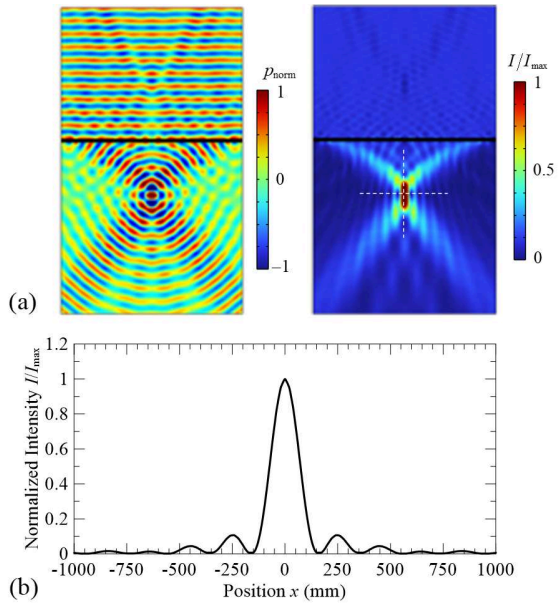

Fig. 2. Focused acoustic pressure field for the normally incident wave achieved by the designed phase-gradient metasurface.

Figure 2(a) shows the simulated focused acoustic pressure field for the normally incident wave in the $+y$ direction. The metasurface, composed of three layers of stacked unit cells, has a thickness of only 0.26λ (= 78 mm). It can be observed that a significant focusing effect is achieved at the predetermined distance $L = 4\lambda$. Furthermore, the acoustic pressure intensity at the focused spot is more than four times that of the incident pressure intensity, demonstrating the highly efficient sound focusing performance of the proposed metasurface. Figure 2(b) plots the normalized focusing pressure distribution along the x-direction (shown by the horizontal white dashed line) through the focused spot. Its full width at half maximum (FWHM) is approximately 0.46λ, indicating diffraction-limited focusing characteristics.

Figures 3(a–c) show the focused pressure fields at incident angles $\theta_i = 15°$, 30°, and 45°, respectively. It can be seen that, compared to the case of normal incidence, the metasurface can also focus obliquely incident waves well, maintaining good focusing performance even at incident angles as large as 45°. Comparing the focused pressure field distributions shows that their FWHM values remain almost unchanged even at oblique incident angles up to 45°, indicating that the proposed acoustic metasurface exhibits good achromatic properties at large spatial incident angles.

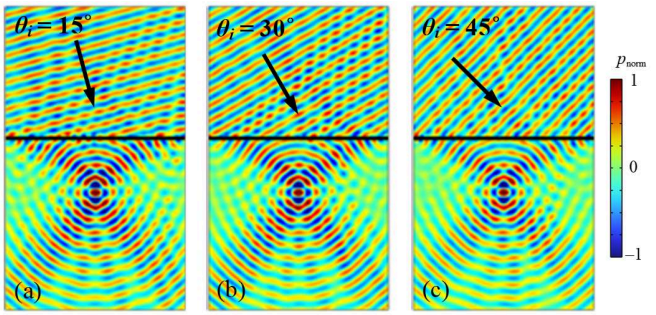

Fig. 3. Focused pressure fields by the designed metasurface at incident angles $\theta_i = 15°$, 30°, and 45°, showing that the metasurface can well focus obliquely incident waves with a wide incident angle.

IV. Conclusion

This paper presents an ultrathin metasurface lens with wide-angle and high-efficiency focusing capability. This wide-angle metasurface lens is based on the abrupt phase change of meta-atoms along the normal incident direction at the subwavelength scale, which conforms to the generalized Snell's law. It exhibits high-efficiency focusing performance, achromatic properties, and a wide incident angle.

***Abstract* — Training data is scarce when developing neural networks to model geometry-dependent scattering parameters of metamaterials. By applying transfer learning, we reduced the training data required for a neural surrogate model of a tunable composite metasurface more than twentyfold and demonstrate the approach's generalizability across different composite and fundamental structures.**

***Keywords* — metamaterials, transfer learning, inverse design, machine learning, tunable metasurface**

I. INTRODUCTION

Neural networks have the potential to accelerate the design process of artificial electromagnetic materials (AEM) by several orders of magnitude [1]. Yet, training an accurate neural network requires a substantial amount of training data to be obtained beforehand. This training data is typically specific to a particular set of geometrical and material parameters of the described AEM. However, transfer learning allows us to generalize training data from one AEM problem to another [1, 2, 3].

We use transfer learning to design a metasurface unit cell intended to enhance 5G/6G wireless links. In this setting, metasurfaces can boost a mobile user's signal-to-noise ratio by steering and concentrating the electromagnetic field onto the user [4]. Reducing side-lobe levels requires the phase of the reflected wave to be tunable over the full 0°–360° range while maintaining nearly constant reflectivity. This can be realized with composite unit cells consisting of two varactor-tuned dipoles [5]. Several dipole configurations can be considered for such a composite unit cell. Three example layouts are shown in Fig. 1(b-d).

II. RESULTS

All of these composite unit cells are based on the same fundamental structure, a single varactor-tuned dipole on top of an FR-4 substrate with a completely closed ground plane on the bottom layer of the substrate (see Fig. 1(a)). During the early design stage, we ignored the bias network for the varactors to accelerate training data generation, although the network is indicated as dashed lines in Fig. 1(a). The single dipole structure has four degrees of freedom (C, D, L, H), where C is the bias-voltage-dependent capacitance of the varactor diode (MACOM MAVR-011020-1411).

The composite unit cells are comprised of two of these varactor-tuned dipoles of different length. Fig. 1(b) shows a collinear configuration of the two dipoles. Their distance d is tunable, resulting in seven degrees of freedom for this structure (C_1, C_2, D, L_1, L_2, H, d). Figure 1(c) shows a parallel configuration of the dipoles. Finally, Fig. 1(d) displays another collinear dipole configuration, where we replaced the varactor diode with one of lower ohmic resistance (MACOM MGV 125-08).

We started our study with the collinear configuration from Fig. 1(b). The goal was to investigate whether transfer learning could reduce the number of simulations of this dual-dipole structure as inherently needed to train a direct model of the structure. This was examined by comparing the required simulations for training a direct model (multi layer perceptron, MLP) to those needed when first training a model on the single dipole (see Fig. 1(a)) and then applying a transfer model to learn the coupling between two dipoles, ultimately describing the same composite structure.

The objective of the transfer learning process was to train a model to accurately characterize the S_{11}-parameters of a single dipole, before feeding them into a transfer model designed to learn the coupling effects between two dipoles to describe the S_{11}-parameters of the composite structures. For this purpose, we first simulated and extracted the S_{11}-parameters of a single dipole dependent on the four parameters (C_i, D, L_i, H). Based on this data, we trained an MLP to output the S_{11}-parameters of a single dipole in a frequency range between 18 GHz and 34 GHz. The MLP had 4 input neurons, 4 hidden layers with 200 neurons each and 706 output neurons that represented the concatenation of $\mathrm{Re}(S_{11})$ and $\mathrm{Im}(S_{11})$ at 353 discrete frequency samples. In order to train the transfer model regarding the coupling between two dipoles, we used the S_{11}-parameters of the single dipole model as input for a second MLP of the same size that learned the dipole-dipole coupling dependent on the distance d between the two dipoles. The second MLP was trained on simulation data obtained from numerically simulating the S_{11}-parameters of the composite unit cell in Fig. 1(b).

In order to evaluate the benefit of this transfer learning scheme, we calculated the mean squared error (MSE) of the transfer-learned MLP over a test dataset for different sizes of training datasets. The result is illustrated by the solid blue line in Fig. 2. We see that the MSE reaches 0.05 with only 64 training simulations. In comparison, the dashed blue line in Fig. 2 represents a reference MLP of the direct model of the structure in Fig. 1(b). This reference network requires 1,280

simulations to yield an MSE of 0.05. As a result, the transfer-learning scheme requires 20 times fewer training samples of the composite unit cell than the directly trained reference model.

Although transfer learning requires additional simulations to train the single dipole, these simulations are typically faster due to the smaller and less complex geometry. Furthermore, the simulations of the single dipole can be recycled for composite unit cells with different coupling geometries between the dipoles.

We illustrate this fact with the parallel and the low-resistance collinear dipole configurations shown in Figs. 1(c) and (d). From the comparison of the training-data dependence of the test MSE in Fig. 2 - red and yellow lines - we find that transfer learning can decrease the training set size of the composite unit cells by up to a factor of 25. Hence, the method provides similarly substantial benefits as for the collinear unit cell.

In further investigations involving different fundamental structures, such as split-ring resonators and infinitely long wires, we likewise confirmed the advantages of the transfer learning approach, thereby establishing a data-efficient pathway toward automated, modular metasurface unit cell design.

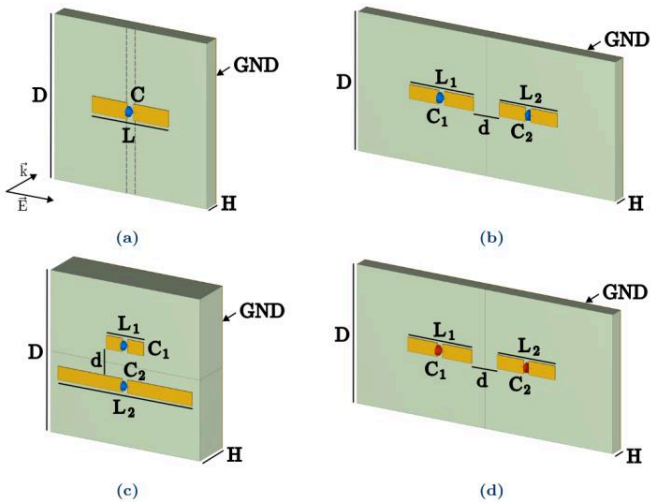

Figure 1: Singe-dipole and composite unit cell designs. (a) shows the single-dipole unit cell and the features (C, D, L, H) that were altered during the training data generation. Drafted in blue is the varactor diode. $\vec{E}$ and $\vec{k}$ indicate the polarization and the propagation direction of the incident plane wave. The dashed gray lines display the position of the bias lines, although they were omitted in the simulations. (b) shows the collinear dipole unit cell. (c) displays the parallel dipole unit cell. (d) illustrates the low resistance collinear dipole unit cell. It is identical to the collinear dipole unit cell but for the chosen varactor diodes (red) modeled with a resistance of 2.65 Ω to simulate the characteristics of the varactor diode MGV125-08 by MACOM. All three composite unit cells have the feature set (C_1, C_2, D, L_1, L_2, H, d) [3].

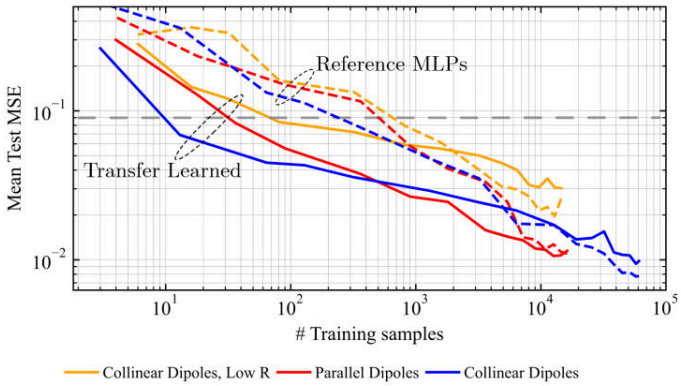

Figure 2: Log-log plot of the test MSE (prediction error) of different forward models versus the applied training set size. Solid lines depict the results of the transfer-learned models, whereas dashed lines illustrate the corresponding results of the reference directly learned models. The colors indicate the type of composite unit cell. Blue: collinear dipole unit cell; red: parallel dipole unit cell; orange: low resistance collinear dipole unit cell. The transfer-learned forward model requires up to 25 times fewer training data to achieve a test MSE of 0.09 (see gray dashed line). [3].

III. Conclusion

We demonstrated a transfer-learning framework for data-efficient forward modeling of composite metasurface unit cells. By leveraging pre-trained neural networks of simpler single-dipole structures, our method significantly reduces the amount of training data required to model more complex dual-dipole configurations. We showed that the proposed architecture can reduce training data demands by up to a factor of 25 while maintaining sufficient accuracy for practical applications, with mean squared errors below 0.09. Additionally, we extended the transfer learning approach to other fundamental unit cell structures, such as split-ring resonators and infinitely long wires, and obtained similarly promising results.

***Abstract*— In this work, we investigate the relationship between chiral dependent forces on chiral particles and the spatial distribution of electric fields that generate optical chiral field. Through analysis on planar plasmonic structures, we identify specific electric field distributions that significantly enhance the contrast between chiral dependent and independent forces.**

***Keywords*— metamaterials, plasmonic, chiral discrimination.**

I. Introduction

Optical chiral fields have long been studied in systems involving surface-localized plasmonic enhancements [1-3] or evanscent waves [4], due to their inherent phase-delay properties. The spatial overlap between electric fields and magnetic fields gives rise to optical chiral fields, which can be further enhanced or concentrated through nanophotonic structures. Since the optical chirality is a conserved quantity, strong localization of optical chiral fields can lead to enhanced chiral related gradient forces. However, strongly localized electric fields not only generate highly chiral fields, but also induce strong achiral gradient forces through the electric-field gradient. The achiral component of the optical forces therefore becomes an obstacle to chiral discrimination of molecular enantiomers.

To improve and optimize the design of plasmonic meta-material for chiral molecular discrimination, we identify spatial phase distributions as a critical factor. In particular, properly engineered phase gradients enhance chiral optical forces while suppressing achiral force contributions.

II. Methods

In this work, two kinds of nanostructures are discussed, including dimers and dislocated double-slit pairs. The generalized multipole Mie-solution (GMM) [5] is applied to the dimer structures, while for the dislocated double slit is simulated using finite-difference time-domain method (FDTD) in Lumerical. The generalized multipole Mie-solutions are Fortran-based codes developed from Professor Xu, Yu-lin's work, which have been wildly used for multipole and multi-particle solutions.

The simulation of structures considered in this work are shown in Fig. 1. The Mie scattering coefficients (a_n, b_n) not only provide results such as scattering cross sections and scattered fields, but also provide information on the scattering field of different orders that appear in the total scattering fields, as shown in the equation below, where $\vec{N}$ and $\vec{M}$ are vector spherical wave functions derived in Mie theory.

$$\vec{E}_s = \sum_{n=1}^{\infty} E_n(ia_n\vec{N}_{e1n}^{(3)} - b_n\vec{M}_{o1n}^{(3)}) \quad (1)$$

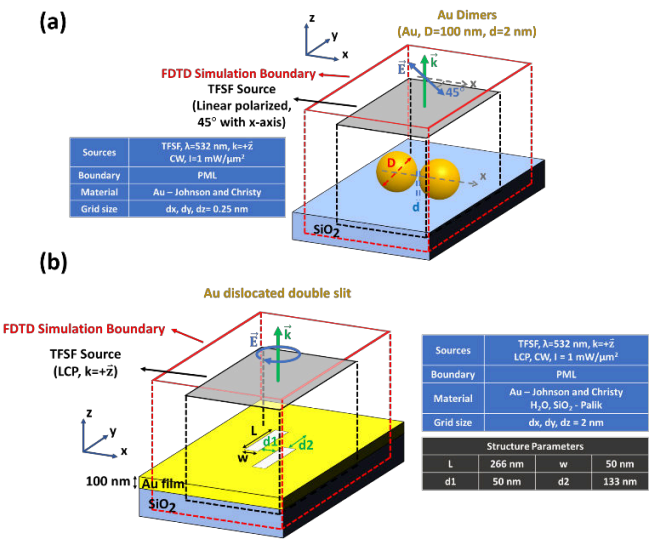

Fig. 1. Simulation setups and parameters

III. Results and Discussion

Fig. 2 (b) shows the simulation results of the total optical forces calculated by FDTD at λ=532 nm. The total optical forces include achiral reactive and dissipative forces, as well as chiral reactive and dissipative forces [6]. The reactive forces are the dominated terms, as shown below. Here, α, β, χ are the electric, magnetic and chiral polarizabilities of the chiral molecule, respectively, and ω is the angular frequency of light. C denotes the optical chirality, while $W_E = \|E\|^2(\varepsilon_m/4)$ represents the electric energy density and $W_H = \|H\|^2(\mu_d/4)$ represents the magnetic energy density.

$$F_{\alpha,\beta}^{reac} = \mathrm{Re}[\alpha]\nabla W_E + \mathrm{Re}[\beta]\nabla W_H \quad (2)$$

$$F_{\chi}^{reac} = \mathrm{Re}[\chi] \cdot \frac{c}{\omega} \nabla C \quad (3)$$

$$C = \frac{\omega}{2c^2} \mathrm{Im}[\vec{E} \cdot \vec{H^*}] \quad (4)$$

We found that under monochromatic illumination at λ=532 nm, the difference between the total optical forces of right/left-handed molecules is the largest. In our case, the right-handed molecules are attracted to the center, whereas left-handed molecules are not. This observation raises our interest. As shown in Fig. 2(a), λ=532 nm does not correspond to dimer's electric dipole mode or monomer's dipole mode. Instead, it corresponds to monomer's quadrupole (a_2, b_2) peak in the GMM analysis [7]. The spatial distributions of both monomers' quadrupole modes in the center region of the dimer also form quadrupole-like distributions.

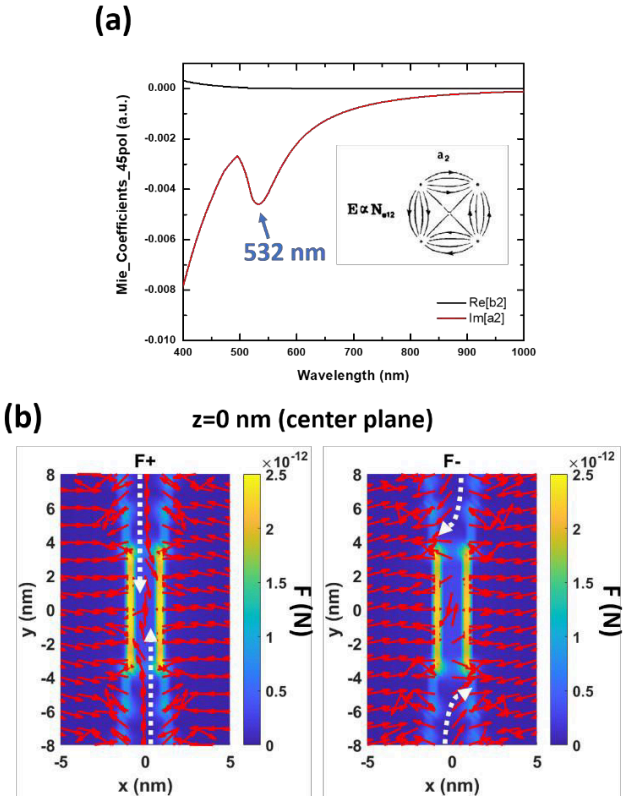

Fig. 2. Dimer simulation results (a) Mie scattering coefficient a_2 intensity and it's corresponding field distribution [ref] (b) Total optical forces (λ=532 nm) for chiral enantiomers of right-handed (F+) and left-handed (F-)

As we found the spatial phase distributions' effect on the difference in chiral optical forces, we attempted to generate a spatial electric quadrupole-like distribution. Coincidently, we found a previous work [8] that uses a dislocated double-slit to generate an overlap of electric field and magnetic field in the center region, thereby generating a high optical chiral field. However, we found that this configuration can generate not only a high optical chiral field, but also strong chiral optical forces, since the spatial phase in the central region forms an electric quadrupole-like distribution.

Notably, the largest difference between the chiral forces (F+/F-) in our simulations appears precisely at the phase-delay wavelength (λ = 2L), whereas the enhancement of the optical chirality field reported in previous works occurs at different wavelengths. This indicates that the chiral force difference observed here is governed by spatial phase distributions rather than by the maximization of optical chirality alone.

In Fig. 3(a), the maximum difference in optical forces occurs at 532 nm, which corresponds to the wavelength where the spatial phase delay induces an electric quadrupole-like distribution. As a result, within the separation region surrounded by the electric quadrupole-like distribution, vertically propulsion forces act on right-handed molecules, while vertically attraction forces act on left-handed molecules.

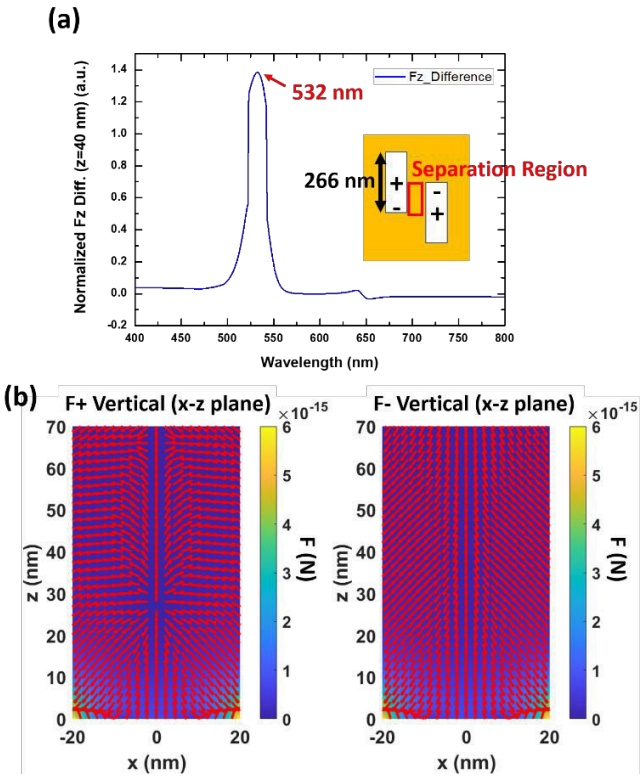

Fig. 3. Dislocated double slit simulation results (a) F+ / F-difference along z-axis at z=40 nm above (b) Total optical forces (λ=532 nm) for chiral enantiomers of right-handed (F+) and left-handed (F-) at center of separation region (y=0, x-z plane)

Fig. 3(b) shows the vertically total optical force difference on the center plane at λ=532 nm. Similar vertical force differences are observed throughout the entire separation region.

IV. Conclusion

From the results above, we identify the importance of the electric quadrupole effect on chiral optical forces. To form a single chirality trap in spatial domain, a single peak or valley of chirality is required. As mentioned previously, we focus on optimizing the spatial phase distribution to achieve a single chirality peak, motivated by the conservation property of optical chirality. From our perspective, the spatial phase distribution induced by the electric quadrupole is more directly related to the physical meaning of helicity, as it corresponds to the phase difference between right- and left-circularly polarized

(RCP and LCP) components. Under monochromatic excitation conditions, optical chirality and helicity are proportional to each other, further supporting this interpretation.

Interestingly, we find that the quadrupole plays a role not only in coupling the molecular quadrupole moment to the gradient of the optical chirality, as reported in previous studies [9, 10], but also in generating suitable chirality distributions that enhance chiral discrimination

I. Introduction

Cavity Resonator Integrated Guided-Mode Resonance Filters (CRIGFs) are a novel class of sub-wavelength-grating-based optical filters [1].

They are based on a guided mode confined in between two DBR mirrors, coupled to a propagating focused beam via a grating coupler (GC), thus giving rise to a Fano resonance. This type of structure is represented by a schematic figure 1.

Fig. 1. Schematic of a CRIGF structure.

Their responses are driven by the excitation of localized Fabry-Pérot modes, resulting in fixed-wavelength narrow band optical filters, with Q-factors that can exceed several thousand [2]. Combined with their angular tolerance [3], they are highly attractive for many applications.

Unlike other grating techniques (diffractive Volume Bragg Gratings (VBG) or Guided Mode Reflecting Filter (GMRF)), CRIGFs are spectrally insensitive to angular tuning. Achieving wavelength tunability thus requires either modifying the microcavity's geometric parameters or altering its waveguide's effective refractive index.

Electrically tunable CRIGF filters have been demonstrated on Thin Film Lithium Niobate, relying on its electro-optic sensitivity. However, the bias voltage required for optical tuning was in the hundreds volts range [4].

As pointed out by [5] in their metasurface studies, using Quantum Confined Stark Effect (QCSE), can lead to strong optical index modulation with low voltage. In this work, we investigate the possibility of combining CRIGF structures with QCSE using GaAs/AlGaAs materials.

II. Optical index modulation by QCSE in n-i-n structures

As compared to a previously demonstrated approach [5], based on a p-i-n doped heterostructure, we choose to use a n-i-n doped scheme. This configuration provides a flat band alignment at a zero voltage bias. It turns out that this configuration maximises the index modulation. The main drawback of such an approach is that n-i-n unipolar structures are known to be leaky at room temperature. In order to test this approach, a first structure was designed. It is presented in table I. A thick stack of 29 quantum wells (QWs) will provide the QCSE index modulation. It is embedded in between two $Al_{.4}Ga_{.6}As$ layers that act as electrical barriers to minimize the current leakage. Their thickness was optimized to maximise the stack reflectivity variation upon index modulation of the QW.

TABLE I
Stack used to measure the optical index modulation. The Quantum Wells are 10nm layers of GaAs spaced by 10nm $Al_{.15}Ga_{.85}As$ barriers. Both contacts layers are N-doped. All others layers are non intentionally doped (NID).

Layer role	Layer material	Thickness [nm]	Doping scheme
Top contact	GaAs	499	N_{++}
Barrier	$Al_{.4}Ga_{.6}As$	173	NID
QWs	$\overset{\text{barrier}\times 30}{\underset{\text{QWs}\times 29}{}}$	592	NID
Barrier	$Al_{.4}Ga_{.6}As$	200	NID
Bot. contact	GaAs		N_{++}

Reflectivity measurements under electrical modulation were conducted and are presented in figure 2. A comparison between these measurements and an optical model (that will be presented) allowed us to estimate an optical index modulation of 0.02 at 5V, in good agreement with theoretical predictions.

This rather large index modulation is interesting for applications such as actively tunable metamaterials. However the highly doped layers required for the electrical contacts may lead to absorption losses wich are not compatible with design of resonant meta-atomes used in metamaterials.

Fig. 2. Measured optical reflectance variation depending of the voltage applied to the stack described in table I

III. CRIGF WITH N-I-N INDEX MODULATION STRUCTURES

To evaluate the losses induced by the contact layers, we designed a Cavity Resonator Integrated Filter (CRIGF) [1] based on a similar structure. Those filters are know to be highly sensitive to absorption losses of the material [2].

A waveguide was designed to accommodate those requirements and the QCSE modulation scheme. Its vertical structure is depicted on table II. The waveguide is made of an active part, which is a stack of 31 QWs, embedded in between 90 nm $Al_{.4}Ga_{.6}As$ barriers, and top and bottom contact layers. It is optically isolated from the substrate by a thick low index $Al_{.95}Ga_{.05}As$ cladding layer.

TABLE II
STACK USED FOR THE DESIGN AND THE FABRICATION OF THE CRIGF. IT WAS EPITAXIED ON A GAAS N+ SUBSTRATE. THE QUANTUM WELLS ARE 10 NM LAYERS OF GAAS SEPARATED BY 10 NM $AL_{.15}GA_{.85}AS$ BARRIERS. ONLY THE CONTACT LAYERS ARE INTENTIONALLY N+ DOPED.

Layer role	Layer material	Thickness [nm]	Doping scheme
Top contact	GaAs	200	N_{++}
Barrier	$Al_{.4}Ga_{.6}As$	90	NID
QWs	$\begin{matrix}\text{barrier} \times 31\\ \text{QWs} \times 30\end{matrix}$	630	NID
Barrier	$Al_{.4}Ga_{.6}As$	90	NID
Bot. contact	GaAs	200	N_{++}
Cladding	$Al_{.95}Ga_{.05}As$	2500	NID
Substrate	GaAs		N_{++}

From numerical modeling, we decided to use a DBR and GC with a corrugation depth of 250 nm. The GC is 61 periods long, each period measuring 272 nm. The DBRs are 300 periods long with a period of 136 nm. The phase shift between GC and DBR is set at 102 nm.

The sample was fabricated in a clean room using standard III–V technological processes. First, a hard mask of SiO_2 was deposit by ICPECVD. A spin-coated layer of PMMA was then exposed by a Raith150 electron-beam lithography machine. After development in MIBK-IPA mixture, this mask was transferred to the SiO_2 using fluorinated ICP-RIE. GaAs etching was then made with chlorine ICP-RIE. Images figure 3 were made just before the removal of the SiO_2 mask with hydrofluoric acid. The Focused Ion Beam (FIB) etched view reveals an Aspect Ratio Dependent Etching (ARDE) as the GC is etched for 250 nm but the DBR is only etched for 205 nm.

Fig. 3. Images of the fabricated CRIGF. On the left, a FIB transverse view shows the profile of the etching. The red strip represents 300 nm, the view is tilted at 52°. On the right part is an optical microscopic view of the final CRIGF, the black strip represents 20 µm.

After fabrication, the CRIGF was characterised by reflectometry using a focused tunable Broadsweeper Laser in sweeping mode.

IV. FANO RESONANCE OPTICAL MEASUREMENT

The reflectivity of the structure is presented in figure 4. It showcases a sharp Fano resonance at 896.5 nm. The amplitude of the resonance is measured to be 45%. The full width at half maximum is of 0.70 nm.

Fig. 4. Reflectivity spectra of the fabricated CRIGF

We simulated the expected reflectivity using the RCWA simulation free software Nannos [6] on a standard workstation.

The optical indices considered for the $Al_xGa_{1-x}As$ are those published by K. Papatryfonos et al. in 2021 [7]. This simulation was run with different values of the imaginary part of the refractive index of the GaAs. It is presented figure 5. The amplitude of the resonance strongly varies with the absorption. It is at 45% for an imaginary part of the optical index of 4×10^{-4}.

Fig. 5. Simulated reflectivity of the crigf depending on the imaginary part of the optical index k for he contact layers.

Neither the etching profile geometry nor the ARDE were taken into account in our simulations to lower the computation cost. Would they be simulated, they could account for additional optical losses.

The influence of doping concentration on absorption in GaAs has been studied for some times [8]. As the doping goes up, the gap is shifted towards higher energies. Thus near the gap, in the transparency region, at a given wavelength, doping decreases the absorption.

This effect could relax the constrains on the realization of a unipolar based QCSE modulated CRIGF.

V. Conclusion

In this work, we demonstrated a QCSE based refractive index modulation on a n-i-n structure. Furthermore, a highly resonant CRIGF structure was fabricated and caracterized. Its resonance allowed us to evaluate the imaginary part of the optical index of the contact layers.

In our presentation, we will show electrically tuned resonance of CRIGF. This demonstration should open the door towards n-i-n structures QCSE modulated metasurfaces.

Inducing anisotropy in time via spacetime interfaces

Andrew M. Naylor[1] and Victor Pacheco-Peña[1*]

***Abstract*— Four-dimensional media have become an interesting paradigm for the manipulation of wave propagation in multiple dimensions. Here, we present a mechanism to induce isotropic-to-anisotropic time interfaces from entirely isotropic spacetime modulations.**

***Keywords*—spacetime metamaterials, photonic time interfaces.**

I. Introduction

The ability to manipulate electromagnetic (EM) waves in space has been at the core of multiple fields [1-3], with many applications benefiting from the advancements in this area. To that end, metamaterials [4-6] have been of particular interest, to further control EM propagation [7- 28]. Recent efforts by the scientific community have also demonstrated interesting features of time-varying materials. By considering a material that has optical properties [permittivity (ε) and permeability (μ)] that change in time [$\varepsilon(t)$ and $\mu(t)$], wave propagation can be controlled not only in space (x,y,z) but also in both space and time (x,y,z,t) [29-31].

An example of time modulated media is the case of time interfaces, which [32] consider a rapid variation in time of $\varepsilon(t)$ and/or $\mu(t)$. When doing so, a set of forward (FW) and backward (BW) waves are generated, which are now considered as the temporal analogue of the transmitted and reflected waves produced at a spatial interface between two materials of different impedances [3]. Time interfaces have recently been studied by different groups demonstrating exotic physical phenomena [33-44]. Importantly, experimental demonstrations have begun to emerge [45-48]. Among the different types of time interfaces, it has been recently shown that when they involve isotropic-to-anisotropic modulations (a change from ε_{r1}, to a tensor, $\overline{\overline{\varepsilon_{r2}}}$ [49-53]), the direction of the Poynting Vector, $\boldsymbol{S}$, is modified, while the wavenumber, $\boldsymbol{k}$, is invariant (as expected) [52,53].

Motivated by the interesting effects and applications of time interfaces and, in particular, photonic isotropic-to-anisotropic time interfaces, here, we present our recent efforts in emulating them using solely isotropic spacetime modulations[54]. To do this, multiple isotropic-to-isotropic time interfaces are applied at the same time in such a way that a spatially subwavelength multilayer structure is formed. As it will be shown, this performance can then be described by an effective permittivity tensor of the form $\overline{\overline{\varepsilon_{r2}}} = \{\varepsilon_{reff,z}, \varepsilon_{reff,x}\}$.

II. Methods

A schematic representation of the proposed scenario is shown in Fig. 1 with the case of an isotropic-to-anisotropic time interface presented in Fig. 1a. This scenario was discussed in [24] but we present it here to put our system into context. For times $t < t_0$, a monochromatic signal is propagating within an unbounded isotropic (ε_{r1}) medium with an angle θ_1 (i.e., the wavenumber $\boldsymbol{k}$ and Poynting vector $\boldsymbol{S}$ are parallel). Then, at

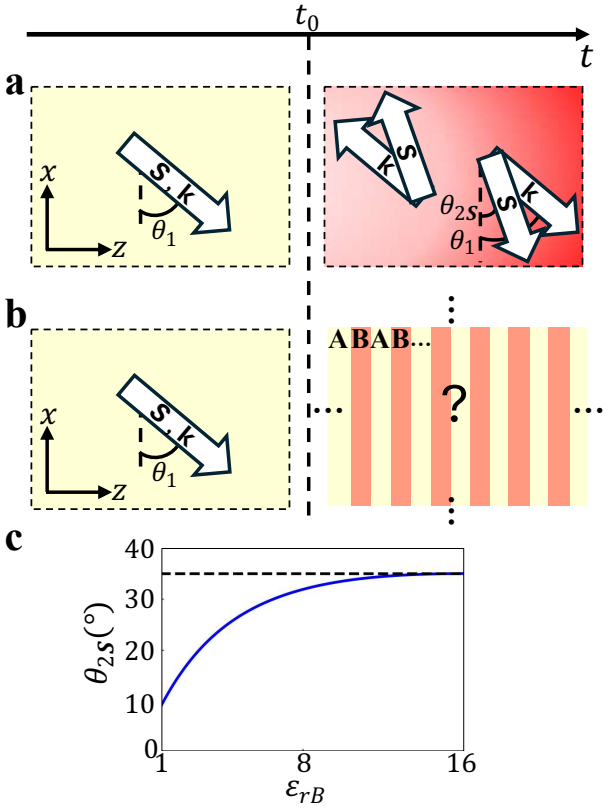

Fig. 1 Schematic of **a.** (left) a wave propagating in an unbounded, isotropic (ε_{r1}) medium with an incident angle θ_1 for $t < t_0$. (right) An anisotropic time interface is then induced at $t = t_0$. **b.** (left) same as panel **a** but in this case multiple isotropic-to-isotropic time interfaces are created in different spatial regions (right). **c.** Poynting vector for the case from panel **b.** when $\theta_1 = 35°$, $\varepsilon_{r1} = \varepsilon_{rA} = 16$ and $\widetilde{\Delta x_1} = 0.5$.

$t = t_0$, an isotropic-to-anisotropic interface is induced, meaning that for times $t > t_0$ we have, $\overline{\overline{\varepsilon_{r2}}}$ and $\theta_1 = \theta_{2k} \neq \theta_{2S}$, as explained in [24].

To emulate this response, we propose the scenario from Fig. 1b where isotropic spacetime modulations are used instead. For times $t < t_0$, the same incident signal, as in Fig. 1a, is propagating in the isotropic medium. Then, at $t = t_0$, multiple isotropic-to-isotropic time interfaces are created, forming spatially subwavelength multilayers. As will be shown in the conference, and presented schematically in Fig. 1b, one of the considered cases is when the spatial layers 'A' have the same permittivity as the initial medium for $t < t_0$ while layers 'B' vary (i.e. $\varepsilon_{r1} = \varepsilon_{rA} \neq \varepsilon_{rB}$). This structure can produce effective permittivity values such that $\varepsilon_{reff,z} \neq \varepsilon_{reff,x}$ [42]. This means that the proposed structure can be used to mimic isotropic-to-anisotropic time interfaces and its related effects (such as the change of direction of energy propagation in real time).

To illustrate an example, we provide in Fig. 1c the theoretical calculations of the direction of the Poynting vector, for the scenario shown in Fig. 1b at times $t > t_0$, as a function of the permittivity of layers B when layers A are time-independent ($\varepsilon_{r1} = \varepsilon_{rA} = 16$). In these calculations a filling fraction of $\widetilde{\Delta x_1}$=0.5 is used with $\widetilde{\Delta x_1} = \Delta x_1/(\Delta x_1 + \Delta x_2)$, $\Delta x_1, \Delta x_2$ as the absolute thicknesses of layer A and B, respectively. The incident angle is $\theta_1 = 35°$ for times $t < t_0$. As it can be observed in this figure, the Poynting vector varies depending on ε_{rB} (i.e., using isotropic spacetime modulations). Moreover, when $\varepsilon_{rB} = \varepsilon_{rA}$, the direction of the Poynting vector is not changed, as expected, as this will account for an isotropic-to-isotropic time interface instead. As shown in Fig.1b,c, here we consider the creation of vertical multilayers in time. The case where horizontal multilayers are induced in time will also be presented during the conference, as well as detailed discussion of the effect of the filling fraction on the overall performance of the proposed spacetime structure.

III. Conclusion

In summary, we have proposed a mechanism to emulate isotropic-to-anisotropic interfaces using isotropic spacetime modulations. The method involves multiple isotropic-to-isotropic time interfaces produced at the same time but in different spatial regions. This results in a spatially subwavelength multilayer structure that can be described by an effective permittivity tensor.

Fundamental Study on Lamb Wave Control Using Resonator-Based Acoustic Metasurfaces

Kent Hora[1], Toshihiko Sugiura[1,*]

[1]Keio University, Japan

*Corresponding author: sugiura@mech.keio.ac.jp

***Abstract*— Previous studies numerically demonstrated that lamb-wave propagation can be suppressed by controlling boundary conditions using resonator-based acoustic metasurfaces. This study aims to experimentally verify this effect and explore its application to a pseudo band-pass filter, demonstrating attenuation characteristics and the feasibility of such filtering using resonator-based metasurfaces.**

***Keywords*— acoustic metasurfaces, lamb wave, resonator.**

I. Introduction

Acoustic metamaterials are artificial structures that exhibit properties not found in nature, and they are known to suppress the propagation of specific acoustic waves due to these properties. Such structures that especially focus on surface configurations are referred to as acoustic metasurfaces. Technologies for controlling acoustic waves are expected to find applications in noise reduction and nondestructive testing. Unlike conventional soundproofing and vibration-damping materials, these approaches offer advantages such as compact device size and ease of installation and modification. Previous studies have focused on mode conversion induced by resonators under specific boundary conditions for lamb waves propagating along boundaries, and numerical simulations have demonstrated that the propagation of particular modes can be suppressed by realizing certain boundary conditions using resonators [1]. This study demonstrates these effects experimentally and also investigates their applicability to a structural pseudo band-pass filter for lamb waves by combining resonators of different heights.

II. Theory

For lamb waves, the phase velocity dispersion curves shown in Fig. 1 as blue lines are obtained under stress-free boundary conditions on both surfaces of the thin plate. In this study, attention is focused on the fundamental modes S0 and A0 that occur in the low-frequency region.

As in Ref. [1], this study applies the following Mindlin boundary condition to the upper surface of the thin plate, as shown in Fig. 2:

$$w = \sigma_{31} = 0 \quad (z = h) \tag{1}$$

The dispersion characteristics of the wave mode propagating under this condition, hereafter referred to as the X mode, are shown by the red lines in Fig. 1. Furthermore, it has been reported that when the Mindlin boundary condition is applied only to a portion of the surface, the S0 mode is converted into the X0 mode with a similar phase velocity and propagates, whereas the A0 mode does not propagate because no corresponding mode with a similar phase velocity exists [1]. Although the Mindlin boundary condition can be readily expressed mathematically, resonators are attached to the surface in order to realize this condition in practice.

III. Numerical Analysis and Experiment

The Mindlin boundary condition can be reproduced by utilizing the anti-resonance of a resonator [1]. The resonator in this study is made of aluminum and has dimensions of 5 × 5 × 33.7 mm³.

In the simulations, models for free vibration and forced vibration were prepared, as shown in Fig. 2, and finite element analysis was performed using COMSOL. In the free-vibration model, the natural frequencies of the resonator were analyzed, while in the forced-vibration model, the displacement of the bottom surface was obtained as a frequency response function when excitation at frequency f was applied in the direction normal to the bottom surface, assuming the A0 mode. As a result, consistent with Ref. [1], the free-vibration model was found to exhibit a natural frequency at 38 kHz, corresponding to the anti-resonance frequency of the resonator. This indicates that the Mindlin boundary condition can be realized by the resonator at 38 kHz.

The model used for the transient analysis is shown in Fig. 3. To verify the filtering effect, the second resonator was introduced, and comparative investigations were conducted for models with one and two resonators. The second resonator indicated by the dashed line in Fig. 3 has a height of 10.6 mm so that its anti-resonance frequency is 120 kHz. In addition, a flat plate model of the same size without resonators was also prepared to evaluate the attenuation of the A0 mode induced by the resonators. Excitation was applied in the z direction from both sides of the plate with the same phase using a continuous sinusoidal wave, so that only the A0 mode propagated within the plate. The amplitude ratio of the metasurface to the flat plate was calculated. The results are shown in Figs. 4 and 5.

Experiments were performed using a similar model to verify whether attenuation of the A0 mode occurs in practice. A normal-incidence transducer was used for transmission to apply out-of-plane excitation, and the same transducer was employed for reception. The transmitted signal was a five-cycle sinusoidal burst with a Hanning window. The amplitude obtained from the measurements was used to perform the same calculations as in Figs. 4 and 5, and the results are shown in Figs. 6 and 7.

IV. Discussion

The trends observed in Figs. 4 and 6 for the single-resonator case are similar. In both cases, suppression of A0-mode propagation is confirmed in frequency bands different from the anti-resonance frequency of 38 kHz. This is considered to be due to differences in the applied stress conditions. In the frequency response function analysis, a uniform stress normal to the bottom surface is applied, whereas in the transient analysis, a propagating wave results in a nonuniform stress distribution. In contrast, for the two-resonator case shown in Figs. 5 and 7, suppression of A0-mode propagation is observed near the anti-resonance frequencies of 38 and 120 kHz. This is presumed to be because the resonator on the transmitting side reduces the nonuniformity of the applied stress. In addition, attenuation is reduced at frequencies between the anti-resonance points, specifically around 70 and 80 kHz.

V. Conclusion

For the single-resonator model, suppression of A0-mode propagation was confirmed in frequency bands different from the anti-resonance frequency through both numerical analysis and experiments. In contrast, for the two-resonator model, propagation suppression was observed at the anti-resonance frequencies, while attenuation was reduced in the frequency band between the anti-resonance points, demonstrating the functionality of a pseudo band-pass filter.

***Abstract*— Drone utilization for different areas such as delivery, monitoring etc. suffers the rapid growth that causes air traffic and thus requires proper navigation and control. The most challenging are targets with the comparable to clutter or critically low radar cross-section (RCS) value. Therefore, we introduce a concept of evolutionarily designed metamaterial structure in the form of multilayer stacks array of strongly coupled electric and magnetic resonators that provide a broadband end-fire backscattering RCS approaching 1 m² (a human comparable) at 10 GHz and, despite their compact footprint, achieve over 10% fractional bandwidth, meeting essential radar requirements for high-range resolution. We have demonstrated 1.5-5 times range detectability enhancement based on DJI Mini 2 drone tagged with genetically designed volumetric metastructures.**

***Keywords*— metamaterials, machine learning, range extension, scattering maximization.**

I. Introduction

Electromagnetic wave interactions with matter remain a key research area, evolving with applications in telecommunications, medical imaging, and radar [1-2]. Metamaterials enable wave manipulation, with negative index materials used for radar cloaking [3-4]. Early designs relied on homogenization approaches, but modern computational power and machine learning allow direct optimization of complex structures [5].

This work focuses on volumetric structures maximizing electromagnetic scattering for emerging wireless applications. These structures, composed of electric and magnetic resonators, are referred to as evolutionarily designed metamaterials [6]. A major application is UAV detection in urban radar environments. Small drones are difficult to detect, and while active transponders are mandated, passive labels improve monitoring without power demands. The design must balance radar cross-section (RCS) enhancement with aerodynamic and size constraints.

Traditional retroreflectors (e.g., corner reflectors, Luneburg lenses, and Van-Atta arrays) provide high RCS but are often too large. For X-band radar, a UAV's RCS (~10 cm²) is significantly lower than the ~1 m² target, necessitating compact solutions. Superscatterers, highly resonant subwavelength structures, offer enhanced scattering via resonance cascading, overcoming conventional bandwidth and size trade-offs. However, their near-field energy accumulation makes them sensitive to material losses and fabrication tolerances.

Optimization, particularly via genetic algorithms, is essential for designing superscatterers, allowing exploration of novel geometries [7]. This study investigates 3D architectures using near-field coupled resonators, demonstrating the impact of volumetric design on scattering performance.

II. Design and Experimental Validation

In this work, we propose a radar range enhancement strategy based on superscatterer-enabled drones, where engineered electromagnetic structures are used to deliberately amplify the backscattered radar signature. We introduce evolutionarily optimized volumetric metamaterials implemented as compact multilayer stacks of strongly coupled electric and magnetic resonators. The optimization search space includes discrete choices and three continuous parameters per pixel (position and rotation), resulting in a 135-dimensional space for a 2×2×2 and 3×3×3 structures (Fig. 1). The objective function maximizes radar cross-section (RCS) over a 10% bandwidth in the X-band (8-12 GHz), commonly used for radar monitoring. We employ the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) algorithm, optimizing RCS over selected frequency points to ensure broadband performance.

The structures were fabricated with a conventional printed circuit board (PCB) methodology following chemical etching of copper elements on a very thin dielectric substrate Rogers 3003 ($\varepsilon_r = 3$, $tan(\delta) = 0.001$) with a thickness of 0.127 mm. Each fabricated layer was separated by foam breaks, material of which is transparent for EM wave propagation at the investigation frequency range. The fabricated structure – 2x2x2

is then used for experiment (Fig. 2), while the 3x3x3-dimentional structure and results of its measurements will be demonstrated during the presentation.

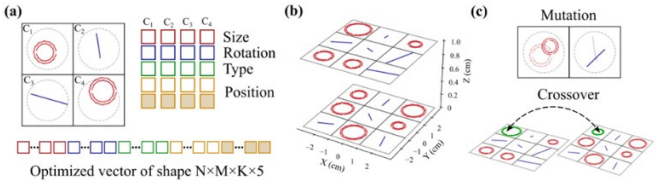

Fig. 1 Genetical algorithm principle for 3D-scatterer design and optimization based on electric (straight wires) and magnetic dipoles (split-ring resonators) (a). The algorithm considers layered structures 2x2x2 and 3x3x3-dimentional structures spaced by 1 cm along Z-axis (b) and perform mutation and crossover for searching for the best backscattering performance (c).

Experimental validation using a DJI Mini 2 drone equipped with genetically designed volumetric metastructures (Fig. 2) was outdoor with a custom-made continuous wave (CW) radar, based on Keysight P9374A Network Analyzer 300 kHz - 20 GHz (Fig. 2(b)). The 2-ports PNA, operated by Matlab, was connected to Tx and Rx broadband horn antennas (NATO IDPH-2018, 2-18 GHz). Horizontal polarization related to the terrain was maintained. The output power (at Tx) was 20 dBm. A low-noise amplifier (LNA, MWA-020180-1-4019, 2-18 GHz) was applied at the Rx. To avoid a feedback loop between transmit and receive channels, the antenna isolation was maintained at more than a 30 dB level, which was checked by monitoring the S_{21} spectrum before introducing the drone. This is the reason why Tx and Rx were taken apart, compared to the laboratory experiments. The bandpass filter (VHF-6010+, 6.3-15 GHz) was used to suppress noise at frequencies irrelevant to the experiment. Photographs of untagged and tagged drones appear in Fig. 2(c and d).

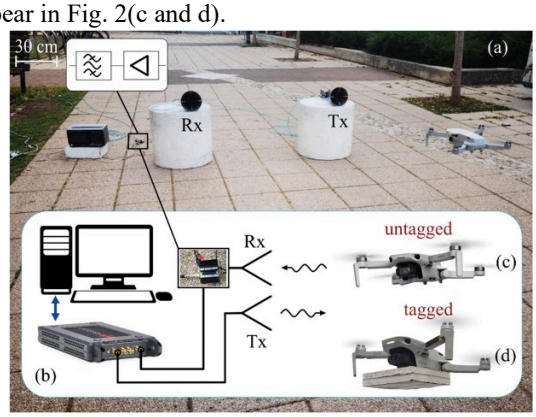

Fig. 2 Experimental setup for outdoor measurements that depict the photo (b) schematic of the CW radar as well as untagged (c) and tagged (d) drone with 2x2x2 designed scatterer.

Finally, to explore additional capabilities of tagging and relate it to real distances, the following analysis has been done. First, the measured drone velocity (e.g., from Doppler maps in Fig. 3) was translated to the distance in meters considering the nonuniform accelerated motion. This mapping with the CW radar is made possible since the target flies toward the radar and co-locates with it at a known time. The Doppler filter was adjusted to fit the 7–9m/sec drone's velocity. Results demonstrate a 1.5-fold increase in radar detection range for the equipped by the 2x2x2 scatterer UAV, considering the take-off payload ability of the used UAV. In the case of 3x3x3 scatterer, the 5-fold increase in radar detection range, in direct agreement with radar equation predictions. The presented results establish a practical and scalable approach to extending radar coverage for small drone detection in next-generation airspace monitoring systems.

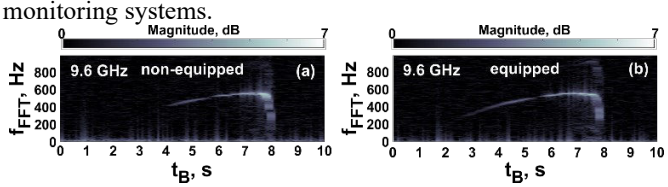

Fig. 3 Short-Time Frequency Transform for the untagged (a) and (b) tagged drone flights at different carrier frequencies of the used CW at 9.6 GHz – maximum of the tag's scattering.

III. Conclusion

We proposed an evolutionarily optimized metamaterial design for enhancing radar scattering in end-fire incidence scenarios. The structure consists of multi-layered arrays of near-field coupled electric and magnetic resonators. A multi-objective genetic optimization algorithm was employed to maximize radar cross-section (RCS) while maintaining a high fractional bandwidth. The resulting design achieves broadband scattering of ~1 m^2 at 10 GHz with over 10% fractional bandwidth. Despite its compact broadside dimensions, the metamaterial scatterer maintains a sub-wavelength end-fire cross-section.

For practical validation, UAV monitoring in urban environments was selected as a demonstration case. We showed that the inherent ~10 cm^2 RCS of a small drone can be enhanced by three orders of magnitude using the metamaterial scatterer. Outdoor experiments confirmed a two-fold increase in detection range with a minimal-sized scatterer attached to the drone.

***Abstract*—A self-assembled plasmonic metamaterial composed of aggregated gold nanoparticles promotes nonlinear mixing between mid-infrared and visible light. By enhancing and co-localizing the fields in nanometer gaps containing $\chi^{(2)}$-active molecules, sum-frequency generation is observable even from low-power CW illumination. This offers an avenue for broadband, room-temperature mid-infrared detection.**

***Keywords*—metamaterials, mid-infrared, plasmonics, sum-frequency generation.**

I. Introduction

The mid-infrared region of the electromagnetic spectrum contains a wealth of information about molecular composition, structure, interactions, and dynamics. However, these insights are obscured by the limitations of existing mid-infrared (MIR) detectors, which (in contrast with their optical domain counterparts) are typically slow, cumbersome to use, cryogenically cooled, and suffer from high noise levels. One way around this problem is to upconvert MIR photons to the visible regime (where excellent single-photon detectors exist) via nonlinear optical processes such as sum- or difference-frequency generation (SFG and DFG) [1], [2]. If the MIR frequency is tuned to a simultaneously Raman- and infrared-active molecular vibration, optomechanical coupling improves the efficiency of the conversion process (illustrated in the Fig. 1 top inset). Nevertheless, only a tiny percentage of MIR photons will undergo upconversion under typical circumstances.

Plasmonic systems — with their characteristic small mode volumes and large electric field enhancements — can enormously improve the efficiencies of these nonlinear processes. In this paper, we present results on a plasmonic metamaterial composed of self-assembled multilayer aggregates (MLaggs) of close-packed gold nanoparticles, separated by ∼1nm gaps scaffolded with 4-nitrothiophenol (4NTP), as illustrated in Fig. 1. Although composed of ∼65% gold, MLaggs can be modeled as a high-refractive-index, surprisingly-low-loss dielectric at MIR wavelengths. These aggregates exhibit dual resonances in the visible and MIR regimes, simultaneously enhancing and co-localizing both electric fields onto the scaffolding molecule within the gaps, which possesses a strongly Raman- and MIR-active vibrational mode that provides a large nonlinear coupling. We demonstrate MIR-to-visible upconversion in this system under CW illumination with microwatts of power. The MLaggs, consequently, act as broadband, room-temperature detectors for MIR light.

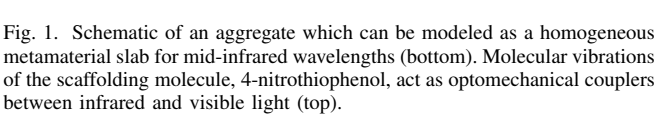

Fig. 1. Schematic of an aggregate which can be modeled as a homogeneous metamaterial slab for mid-infrared wavelengths (bottom). Molecular vibrations of the scaffolding molecule, 4-nitrothiophenol, act as optomechanical couplers between infrared and visible light (top).

II. Methods

Multilayer aggregates are formed using a self-assembly process similar to that reported in e.g. [3]. First, 500µL of colloidal gold nanoparticles (250nm diameter, citrate capped, BBI Solutions) are added to 500µL of chloroform in an Eppendorf tube. The two immiscible solutions remain distinct and form a liquid-liquid interface. Next, we add 400µL of 1mM 4NTP (Sigma Aldrich) solution and shake for one minute. The 4NTP glues the nanoparticles into a 3D aggregate which then settles at the chloroform interface. Excess solutes can be washed by repeated dilution with deionised water. Most of the remaining water is then extracted, leaving a droplet with a 2D nanoparticle aggregate on the surface. Drop-casting this droplet and drying on the surface of a MIR-transparent

CaF_2 substrate (Crystran) leaves 1–2 layers of random-close-packed gold nanoparticles separated by ∼1nm gaps scaffolded by 4NTP. The aggregate is then immersed for ∼16 hours in 10mM 4NTP to ensure saturation of the plasmonic nanogaps. Excess 4NTP is washed away with ethanol and the sample is dried using an N_2 gun.

Mid-infrared spectroscopy and characterization of the MLaggs was performed in an FTIR microscope (Shimadzu AIM-9000 FTIR microscope, liquid nitrogen cooled MCT detector, Cassegrain 15X objective 0.7N.A., 20µm spot size, Happ-Genzel apodization). Modeling of the resulting MIR reflectance spectra used a custom transfer-matrix method code, treating the MLagg as a homogeneous slab whose dielectric constant is the fit parameter.

Upconversion experiments used a tuneable QCL MIR pump laser (LaserTune, Block Ltd.) operating at a 5% duty cycle. This was focused onto the sample from below through a 0.5NA, 40x reflective objective (Thorlabs). A 785nm diode laser (MatchBox, Integrated Optics Ltd.) was passed through an AOM operating at a 15% duty cycle synchronised to the QCL to temporally overlap the MIR and visible/near-infrared beams, before being focused onto the sample from above through a 0.9NA 100x dark field objective in a customised commercial microscope (BX51, Olympus). Light was collected in reflectance from above and sent through notch filters (785–20 NNF, Iridian) to remove Rayleigh scattered light. The remaining light was passed through a monochromator (i303, Shamrock) and dispersed by a 150 lines/mm grating onto an EMCCD (Newton, Andor).

III. Results and Discussion

Fourier-transform infrared spectroscopy of 4NTP-aggregated MLaggs reveals strong surface-enhanced infrared absorption (SEIRA) signals from the molecule. From this we can confirm its presence within the plasmonically active gaps between nanoparticles. The metamaterial possesses a Fabry-Perot resonance whose spectral positions comes in discrete steps based on the number of layers present in the sample. By modeling the aggregate as an effective dielectric arranged as a homogeneous slab, allowing the refractive index

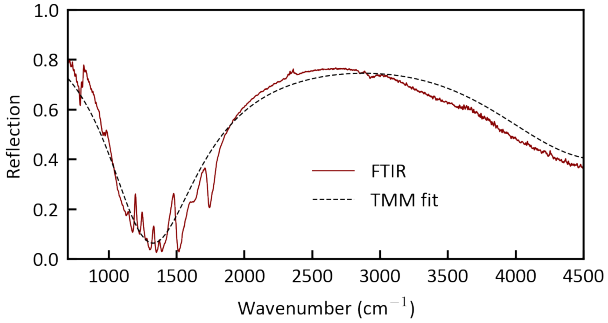

Fig. 2. FTIR spectrum of a nanoparticle aggregate with a transfer-matrix method fit using $n \approx 4.7 + 0.1i$.

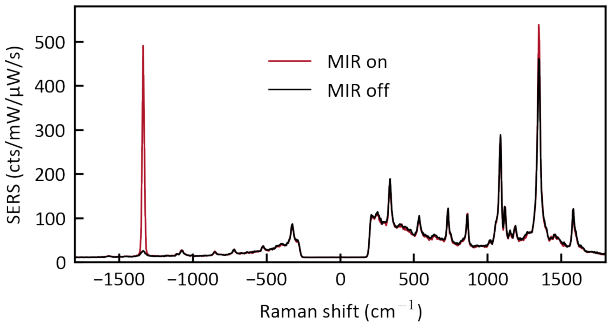

Fig. 3. Spectra of a 4NTP MLagg with (red curve) and without (black curve) a MIR beam tuned to the 1338cm^{-1} molecular vibrational resonance.

to vary but setting the aggregate thickness to that expected from a close-packed stack, we can use the transfer-matrix method to fit our FTIR spectra and calculate an experimental value for the dielectric constant. An example is shown in Fig. 2 with a refractive index of $n \approx 4.7 + 0.1i$, but much larger values should be achievable [4].

To perform nonlinear mixing on these samples, we illuminated them with CW light: 23µW of 785nm near-infrared (NIR) from above, and 220µW of 1338cm^{-1} MIR from below (tuned to the vibrational energy of the 4NTP NO_2 functional group). In Fig. 3, we compare spectra taken with MIR off (black curve) and on (red curve). The signal is unchanged except for a large increase at the sum-frequency, which is a signature of coherent SFG.

Next, we varied the MIR wavenumber to evaluate the relative importance of resonant and non-resonant contributions to the SFG (i.e. that from the vibration and that from the background $\chi^{(2)}$). The bright diagonal in Fig. 4a where the anti-Stokes Raman shift equals the MIR pump wavenumber demonstrates completely broadband SFG. A line-cut across that diagonal (as well as the equivalent diagonal on the Stokes side) is shown in Fig. 4b, where it is easier to see the Fano lineshape of the SFG near vibrational resonances. This is due to interference between the aforementioned resonant and non-

Fig. 4. (a) Metamaterial difference spectra (MIR on minus MIR off) as the MIR wavenumber is scanned from 960cm^{-1} to 1630cm^{-1}. (b) Line-cuts of the Raman shift equals MIR wavenumber diagonals on the Stokes (DFG, red curve) and anti-Stokes (SFG, blue curve) sides from the scan in (a), plotted on the same scale but vertically offset for clarity.

resonant contributions, whose relative phase shifts by π as the MIR wavenumber crosses a particular vibration. Further to this, we can see that the DFG signal (red curve), although similar in magnitude, is significantly noisier than the SFG signal.

IV. Conclusion

We have showcased a self-assembled plasmonic metamaterial with the capacity for extraordinary nonlinear mixing between MIR and visible/NIR light. Close-packed layers of gold nanoparticles separated by 4NTP molecules act as an effective dielectric in the MIR with a large refractive index and low loss. The Fabry-Perot resonances from such structures can be observed in FTIR spectroscopy and modeled using the transfer-matrix method to extract experimental values for the measured refractive indices, which sit near $n \approx 4.7 + 0.1i$. The plasmonic enhancement of MIR and NIR light within the metamaterial enables remarkably strong nonlinear mixing between the two fields, generating easily detectable SFG signals even under CW illumination at 20μW of 785nm and 220μW of 1338cm^{-1}. These signals are detectable broadband, making it a feasible avenue for future room-temperature MIR detectors.

Efficient bio-sensor based on terahertz metasurface

Pradeep Tiwari, Deepak Kala, Maciej Sakowicz
CENTERA Laboratories, Institute of High Pressure Physics PAS, 01-142 Warsaw, Poland
e-mail address: pradeep.tiwari@unipress.waw.pl

***Abstract*-Terahertz metasurfaces enable safe, label-free biosensing with sensitivity to water and weak molecular interactions. Micrometer gaps concentrate fields, overcoming wavelength–biomatter mismatch. Simulations show that low-index PMP substrates maximize response. An H-split metasurface achieves 800 GHz/RIU, experimentally validated with BSA, delivering 31.25 µg/mL LOD and 343 GHz/(ng/mm²) sensitivity via reduced mode volume and increased light–matter interaction**.

Keywords — metasurfaces; terahertz; biosensing; COMSOL

I. INTRODUCTION

Sensors based on terahertz metasurfaces (THz MSs) are starting to get big attention in sensors community [1]. The main focus is in bio-sensing because of properties of the THz radiation. It is non-ionizing (safe for biological samples and operator [2]), sensitive to water content and week molecules interactions (resonances of hydrogen and van der Waals bonds lay in the THz spectral region as well) [3,4]. Also rotational and vibrational modes of molecules all lay in this spectral region.

A THz metasurface usually has a dielectric substrate with a repeating metallic pattern on top of it. This kind of structure helps with one of the biggest problems with THz biosensing: the difference in size between biological objects like cells, bacteria, viruses, proteins, and DNA (which are smaller than a micrometer) and the THz wavelength (which is hundreds of micrometers) [5]. Subwavelength gaps in the metallic pattern that are usually a few micrometers wide govern the electromagnetic response [6]. These narrow gaps strongly confine electromagnetic fields and enhances light-matter interaction with bio-molecules.

The substrate critically influences sensor performance. Important parameters include substrate thickness, refractive index, and dielectric loss. Since most of THz sensors operate in transmission mode, researchers widely use low-loss substrates like high-resistivity silicon and polymers such as polyethylene (PE), polytetrafluoroethylene (PTFE), and polymethyl pentene (PMP). Thinner substrates make things more sensitive, while thicker, higher-index materials add capacitance that can hide spectral changes caused by analytes. To get the most sensitive detection, low-refractive-index substrates are the best choice [7]. The current work is focused on how low and high refractive index substrates influence the sensitivity of metamaterial.

Bovine serum albumin (BSA) is a common model protein used to study how biomolecules interact with surfaces. When BSA sticks to a THz metasurface, it changes the dielectric environment around it and moves the resonance frequency. It makes it possible to detect biomolecules very easily.

II. METHOD

The numerical response of the THz MS is modelled using COMSOL Multiphysics with RF module, using the finite element method. In the simulation, x-polarized light travels along the z-axis and is incident normal to the metasurface. To ensure accurate simulations, periodic boundary conditions are enforced in the x- and y-directions, while perfectly matched layers are employed to truncate the infinite space along the z-direction. The dielectric constant of metal (gold) is described by the Drude-Lorentz model $\boldsymbol{\varepsilon = 1 - \frac{\omega_p^2}{(\omega^2 + i\gamma\omega)}}$ in which we take the plasma frequency $\frac{\omega_p}{2\pi}$ = 2175 THz and the collision frequency $\frac{\gamma}{2\pi}$ = 9 THz [8]. A thickness of 110 nm was used for the metal and we took 500 µm as a thickness of both the substrates in the simulations. To study the sensitivity of our metasurfaces in the simulations we put onto the metasurface a layer of dielectric (10 µm thick) with various dielectric constants (from 1 to 2). This will simulate covering the metasurface with bio-matter. For our investigations we used two designs of THz MSs (Fig. 1). Among other we used previously studied metasurface to have additional verification of our simulations.

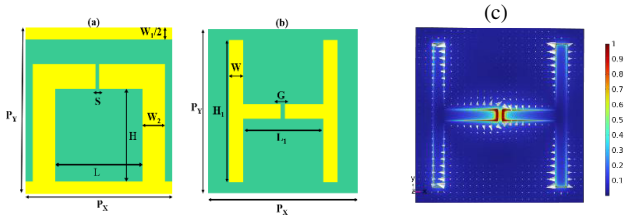

Fig. 1. (a) Schematic of unit cell of the metallic Fano resonance structure. (b) H-split structure. The Fano structure (a) are characterized by specific dimensions: both PX and PY measure 40 µm, W1 is 8 µm, W2 is 6 µm, L is 24 µm, H is 22 µm, and the gap width is denoted as S=1.5µm. (b) H-split structure has the dimension PX= PY=55 µm, G=2µm L1=36 µm, W=4 µm and H1=45 µm. (c) electric field intensity of on the PMP substrate in the XY plane (scolor scale) and current distribution at the resonance (arrows)

As we can observe in Fig. 2, there is a redshift in the frequency of the resonance as we vary refractive index (n) from 1 to 2. It can be seen that sensitivity defined as the frequency shift per refractive index unit (RIU) decreases as we move from PMP to the silicon. This behavior is due to the following factors: (i) the increase in non-radiative losses associated with substrates of higher permittivity, (ii) the enhancement of electromagnetic field confinement within the substrate, rather than extending into the surrounding medium

where the analyte is present. In the case of silicon, high refractive index pulls the field much deeper into the substrate. This confinement reduces the overlap between the evanescent fields of the metasurface and the analyte layer, decreasing the interaction volume and, consequently, the sensor's sensitivity[9]. From linear fit to simulation data of resonance shift we obtained sensitivity of 800 GHz/RIU.

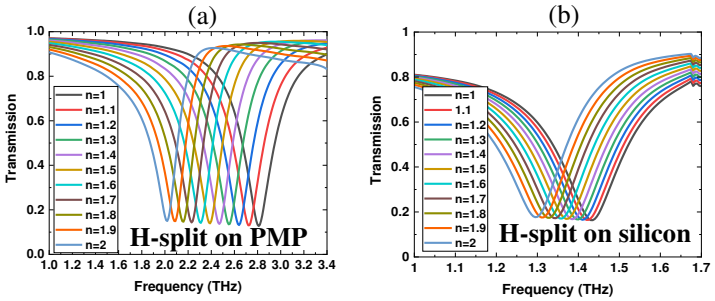

Fig. 2. The H-split structure: (a) simulation result of transmission magnitude on the PMP substrate; (b) simulation result of transmission magnitude on the silicon substrate.

III. Result and Discussion

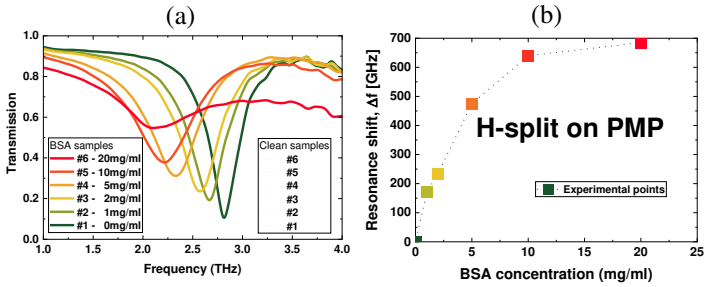

Fig. 3. (a) Transmission spectra for six samples of H-split structure on PMP with varying BSA concentrations (thick solid lines). (b) Resonance shift as a function of BSA concentration, derived from data in the panel (a).

The validate our method and the results of simulations we conducted BSA detection experiments. One of four experimental results is presented in Fig. 3, where we show resonance shift (Fig. 3b) as a function of BSA protein concentration, derived from the transmission spectra of H-split structure on PMP (Fig. 3a). This simulates covering the metasurface with a material of increasing refractive index, as in the simulations. The observed shift (Δf) saturates at 685 GHz for the highest BSA concentration of 20 mg/ml. This shift corresponds to the simulation result for a refractive index of 1.86 (Δn = 0.86). Notably, this value matches the value reported for BSA (n = 1.8) in the literature [24,25]. So to obtain the experimental sensitivity in GHz/RIU, one should divide experimental Δf (in GHz) by 0.8 RIU. This gives experimental sensitivity of 856 GHz/RIU.

VI. Conclusion

In conclusion, we experimentally demonstrated an ultrasensitive H-split design-based meta-biosensor, achieving an exceptional sensitivity of 800 GHz/RIU.

The increased sensitivity comes from the low-refractive-index substrate, which supports tighter electromagnetic confinement and lower mode volume, resulting in stronger light-matter interaction and higher sensing capabilities. The simulations were experimentally validated and compared with previous experimental studies on Fano resonance structures [10]. Our results represent a crucial step toward the development of next-generation high-sensitivity sensing platforms. The proposed H-split metasurface presents an approach for developing ultrasensitive biological sensors, nonlinear photonic devices, and platforms for enhanced light-matter interaction.

***Abstract*—We use an extended geometrical optics theory to derive an evolution equation for polarization in complex media. Considering moving media, we show that motion affects polarization via new spin-orbit mechanisms. Because they arise from properties bestowed to the medium by motion, these effects should also manifest in static complex media.**

***Keywords*—spin-orbit interaction, light polarization, geometrical optics, moving medium**

I. Introduction

Propagation of electromagnetic waves in a medium is modified when the medium is moving. Historically Fizeau [1] showed that medium motion can affect the phase velocity of light. Later Player [2] and Jones [3] demonstrated that both the group velocity, hence the trajectory of light rays, and the polarization of light were also affected by motion. Although as demonstrated by original studies [3], [4] these effects are small in dielectrics under normal conditions, more recent experiments showed large rotations of a light beam image propagating in a rotating medium under slow-light conditions [5], or in a rotating plasma [6].

The emergence of such manifestations of light in moving media can be explained by the fact that a moving medium appears, for an observer in the lab frame, as a complex medium manifesting for example (bi)anisotropy [7], magneto-electric coupling and spatial dispersion [8]. Because of this complexity, most of the studies, both theoretical [2], [9], [10], [11], [12] and experimental [3], [4], [5], [6], were carried out in very specific and simple geometrical configurations. It thus remains to be seen how motion may, when considering a more generic problem, lead to new wave manifestations.

In the present communication, we make use of a very general eikonal theory to model the propagation of waves in moving media in more general configurations. A key building block of this model is the Extended Geometrical Optics (XGO) theory derived by Ruiz and Dodin [13], [14] to solve wave equations asymptotically assuming quasi-plane wave solutions in the limit of short wavelengths. Supporting mode conversion, this theory describes how the modes amplitudes evolve along light rays and then the dynamics of the wave envelope. Going further, we extend this work to derive a transport equation for the wave polarization, that is an equation capturing the dynamics of polarization along the ray. This important equation allows us to identify which physical effects contribute to variations of the wave polarization.

By applying this model to electromagnetic waves in moving media, we can capture light polarization dynamics in very general configurations. Doing so, we not only confirm known dynamical effects of motion and extend them to more general geometrical configurations [15], we also interestingly predict new effects of motion beyond those accessible in the specific configurations that had previously been considered [15], [16]. Precisely, we find that motion is responsible for a spin-orbit interaction (SOI) of light leading to polarization rotation. Importantly, we demonstrate that, if the medium is time dispersive at rest, a SOI can be induced even if the ray is straight [16], in contrast to the classically studied SOI of light for which a redirection of the ray trajectory is usually required [17].

Looking beyond moving media, it stands to reason that such effects should be at play in other complex media, even at rest, if they present similar properties such as anisotropy, magneto-electric coupling or spatial dispersion. This is particularly true of spacetime modulated metamaterials mimicking moving media [18], [19] or in other metamaterials exhibiting magneto-electric coupling. More generally, the versatility of XGO makes it interesting for studying wave propagation, especially polarization dynamics, in such media.

In this communication, we first introduce the XGO theory, starting with a brief introduction to usual Geometrical Optics (GO) to then expose how the first-order equations capture spin-orbit interactions and gradient corrections. Secondly, we show how a moving medium can be treated like any other medium at rest with complex properties, and from there review what XGO applied to this problem can tell on the effects of motion on polarization.

II. Extended geometrical optics theory

Extended Geometrical Optics (XGO) as presented here is based on the theory derived by Ruiz & Dodin [14], [20], [13] but finds its roots in short-wavelength asymptotic theories like eikonal theory, WKB approximation, semiclassical approximation, polarized geometrical optics or post-geometrical optics which share basically the same asymptotic structure and are already largely used in optics, quantum mechanics, acoustics and seismology.

A. Classical geometrical optics

Because XGO is an extension of the usual GO we recall here first the basic underlying principles. Both are based on the same assumption, that is that the wavelength λ is small compared to the characteristic lengths L of the medium variations [21] ($\epsilon \doteq \lambda/L \ll 1$). Locally the medium then appears homogeneous. In this limit one may look for local plane-wave solutions $\propto e^{i\epsilon^{-1}(\omega t - \boldsymbol{k}\cdot\boldsymbol{x})}$ with local frequency ω and wavevector $\boldsymbol{k}$. The corresponding algebraic equation, which importantly should not include gradients of the medium properties, gives the dispersion matrix [21]. The eigenvalues and the eigenvectors of this matrix are respectively the dispersion functions and the polarization states of the wave modes. Using the dispersion function as the Hamiltonian in Hamilton equations gives the ray tracing equations of GO. The solutions to these equations are rays describing the trajectory of the energy of the propagating waves. The group velocity $\boldsymbol{v}_g$ is then a vector tangent to the ray.

In this procedure the mode polarization states are defined up to a phase whose choice amounts to fixing a non-physical gauge [22]. Moreover, this zeroth-order approach (gradient of the medium properties have so far been neglected) does not give dynamical equation for the complex amplitudes of the modes. To have the full gauge-independent dynamics of the wave envelope, one has to perform a proper asymptotic expansion of the wave equation in ϵ and consider the next order, as done below.

B. Extended geometrical optics

To capture the wave envelope dynamics, XGO assumes solutions in the form of quasi-plane waves. This wave form is locally a plane wave but allows the envelope $\boldsymbol{\mathcal{E}}$ to vary slowly compared to the dynamical phase Φ. It is written

$$\boldsymbol{E}(\boldsymbol{x},t) = \boldsymbol{\mathcal{E}}(\boldsymbol{x},t)e^{i\epsilon^{-1}\Phi(t,\boldsymbol{x})} \tag{1}$$

with $\boldsymbol{\mathcal{E}} = \underline{\boldsymbol{\Xi}}\boldsymbol{a}$ the wave envelope composed of the vector $\boldsymbol{a}$ of the complex amplitudes of the resonant modes, i.e. modes that have the same dispersion relation to zeroth order, and the polarization matrix $\underline{\boldsymbol{\Xi}}$ gathering the eigenvectors of these modes [14]. While classical GO describes the dynamics of the dynamical phase Φ, XGO describes in addition the dynamics of $\boldsymbol{\mathcal{E}}$ including the dynamics of the wave polarization. For that, by considering the first-order terms in the ϵ-expansion, XGO provides a transport equation for $\boldsymbol{a}$ along the ray that governs the evolution of the complex amplitude of the modes. These may be coupled in the presence of mode conversion [14].

C. Polarization evolution equation

The unit polarization vector of the quasi-plane wave, describing the wave polarization state and direction, is defined as [23], [15]

$$\hat{\boldsymbol{e}} = \boldsymbol{E}e^{-i\Phi}/|\boldsymbol{E}|. \tag{2}$$

From the equation for $\boldsymbol{a}$ we derive a transport equation for $\hat{\boldsymbol{e}}$ that writes [15]

$$\frac{d\hat{\boldsymbol{e}}}{ds} = \text{parallel transport term} + \text{gradient corrections}. \tag{3}$$

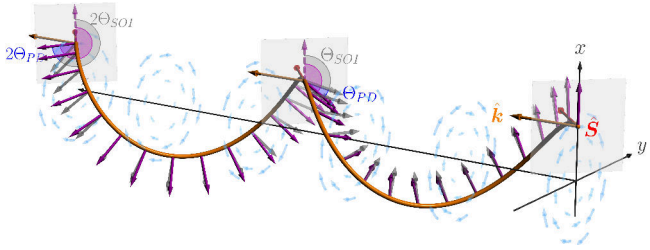

Fig. 1. In a rotating isotropic non-dispersive medium, the ray trajectory (orange) is dragged so that it can be a helix and hence have a non-zero torsion. Since the polarization plane (gray) is redirected, a spin-redirection Berry phase is accumulated and the polarization (purple) undergoes a Rytov rotation by an angle Θ_{SOI} after each cycle. In addition to this purely geometrical effect, a dynamical effect called polarization drag makes the polarization rotates in its plane of an angle Θ_{PD}. The total polarization rotation is then the combination of these two phenomena.

The first term describes the parallel transport of the polarization vector $\hat{\boldsymbol{e}}$ along the ray parameterized by s, and the second term captures changes of $\hat{\boldsymbol{e}}$ induced by non-uniformities (gradients) of the medium properties.

III. Predicted Effects of Motion on Polarization

We apply here the above XGO theory to moving media to understand how the dynamics of polarization is affected by motion. First, we show how the moving medium as seen from the lab frame can be seen as an equivalent effective medium at rest [24]. Equipped with this result, we then introduce the new polarization effects induced by motion.

A. Description of medium motion as a magneto-electric coupling

In order to describe the moving medium as an equivalent effective medium at rest, the flow velocity field $\boldsymbol{v}(\boldsymbol{x}) = \boldsymbol{\beta}(\boldsymbol{x})c$ is considered as a vector property of the medium, which introduces locally a preferred direction and hence anisotropy [7]. As a result, a medium that is isotropic at rest will appear from the lab frame to be anisotropic when in motion. Just like other medium properties, GO assumptions require that the velocity field varies slowly in space compared to the wavelength [25]. Consequently, the wave sees locally a uniform rectilinear motion and special relativity is then valid locally and instantaneously [25]. To have the medium response to the wave, it is then possible to perform local Lorentz transformations $\mathcal{L}$ in the rest frame constitutive relations according to Minkowski's theory [26]. For example for an isotropic medium this procedure gives

$$\begin{cases} \boldsymbol{D}' = \varepsilon'\boldsymbol{E}' \\ \boldsymbol{B}' = \mu'\boldsymbol{H}' \end{cases} \overset{\mathcal{L}}{\Longrightarrow} \begin{cases} \boldsymbol{D} = \varepsilon'\boldsymbol{E} + (\varepsilon'\mu'c^2 - 1)\boldsymbol{\beta}\times\boldsymbol{H}/c \\ \boldsymbol{B} = \mu'\boldsymbol{H} - (\varepsilon'\mu'c^2 - 1)\boldsymbol{\beta}\times\boldsymbol{E}/c \end{cases} \tag{4}$$

We see here that the obtained lab-frame constitutive relations exhibit anisotropy and a magneto-electric coupling. Propagation in a moving medium can accordingly be treated using XGO like propagation in any other medium at rest, with the difference that the medium considered is an equivalent

effective medium with additional properties compared to this same medium at rest [24].

B. Spin-orbit effects

When computing the polarization evolution equation (3) for the moving medium, we find a parallel transport term that is entirely due to motion, revealing a SOI induced by motion [15] which as usual is associated with the accumulation of a Berry phase [27]. Precisely, we identify this Berry phase caused by motion to be a spin-redirection phase, similarly to that observed for example in twisted optical fibers [28]. For moving media though, we find that this spin-redirection phase can have two distinct origins as explained now.

1) Ray-redirection Berry phase induced by motion: In a non-dispersive isotropic medium, through light-dragging effects [29], [30], a non-uniform motion is able to bend light rays [31], [32] and even to render them non-planar [15] as represented in Fig. 1. As a consequence, analogously to gradient-index media at rest [23], [33], the polarization plane, which is normal to the ray trajectory, is redirected and a spin-redirection Berry phase is then accumulated [15]. This phase originates from the parallel transport of the polarization in the parameter space since this latter has a curved geometry. Since this effect is caused by the redirection of the ray we call this phase *ray-redirection Berry phase* [16]. However, unlike in most of the existing studies on SOI of light that are focused on media at rest [23], [34], ray redirection is led by $\boldsymbol{w} = \boldsymbol{k} + (n'^2 - 1)\omega/c\boldsymbol{\beta}$ [15], instead of $\boldsymbol{k}$, due to light-dragging effects [24]. This novelty introduced by motion shows that a spin-redirection SOI is possible even if $\boldsymbol{k}$ is not redirected as it is the case in Fig. 1. Yet, the effect of this SOI on the polarization remains the well-known Rytov rotation [35], [20], [13], that is a rotation of the polarization in its plane due to parallel transport along a ray with non-zero torsion as depicted in Fig. 1.

2) Spin-deviation-redirection Berry phase induced by motion: Spin-redirection Berry phase is often believed to require non-planar rays, as discussed above. Yet, we find through the same formalism that motion combined with time dispersion can in fact induce a spin-redirection Berry phase with rays with zero torsion [16]. To see this, consider the particular case of a moving unmagnetized cold plasma, for which rays are singularly not affected by motion [36], [24], i.e. there is no transverse drag. In this case, as illustrated in Fig. 2, rays are straight lines just as in a homogeneous plasma, and hence there cannot be ray-redirection SOI. Yet, we find that there is still a spin-redirection SOI: this is because the polarization plane is redirected by motion, and as a result is no longer normal to the ray. This deviation of the polarization plane from the ray, shown in Fig. 2, constitutes an additional degree of freedom for its redirection. A non-uniform motion can then redirect the polarization plane independently from the ray. Reflecting its origin, that is a geometric phase due to the redirection of the polarization plane even if the ray is straight, we call this contribution *spin-deviation-redirection Berry phase* [16]. As a spin-redirection phase it also is classically associated with a Rytov rotation of the polarization.

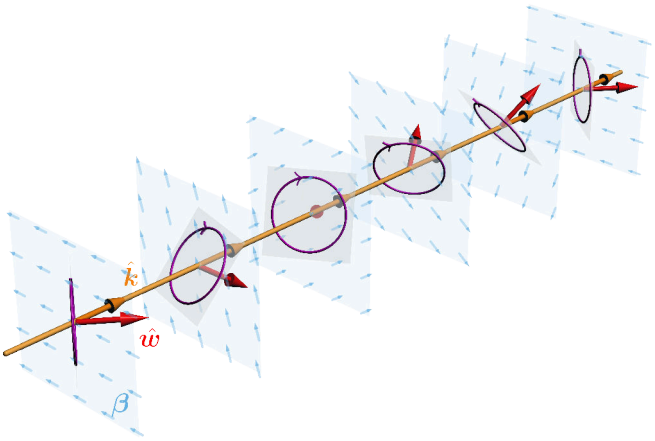

Fig. 2. In a moving unmagnetized cold plasma, the ray (orange) is not affected by motion (blue) and is therefore a straight line if the plasma is homogeneous. However, the motion makes the polarization plane normal (red) deviate from the ray tangent being $\boldsymbol{k}$ (orange). Its redirection by a non-uniform motion leads to a novel type of SOI – the *spin-deviation-redirection SOI* – and induces a Rytov-like rotation of the polarization.

C. Dynamical effects

The spin-orbit effects described above are purely geometrical effects. However, motion also induces a dynamical effect named polarization drag [37] that leads to an additional rotation of the polarization in its plane, which, as shown in Fig. 1, can compete with or add to Rytov rotation. This effect is well-known but was only studied for rigid-body rotation in the case where the wavevector is aligned with the rotation axis [4], [9], [38], [39], [40]. The gradient correction term in Eq. (3) now captures this effect for an arbitrary velocity field $\boldsymbol{\beta}(\boldsymbol{x})$ in a general configuration, i.e. for a wavevector $\boldsymbol{k}$ with an arbitrary direction [15]. We find that the intensity of this effect depends on the local vorticity of the flow and on the angle between the latter and the polarization plane normal. As expected this results reduces to the historical result for a non-dispersive isotropic medium [37], [4], [9] and to the result that has more recently been predicted for a rotating unmagnetized plasma [41].

IV. Conclusion

We exploited a very general asymptotic theory named *Extended Geometrical Optics* (XGO), rigourously developed using Wigner-Weyl formalism, to derive an evolution equation for the dynamics of wave polarization along the rays, obtained using classical geometrical optics. This equation is very general and can therefore be used to study the behavior of light polarization in media with complex properties including anisotropy, magneto-electric coupling and spatial dispersion. Because it captures mode conversion, this theory can also handle degenerate or resonant modes.

As a particular case and making use of its versatility, we apply this formalism to describe the dynamics of light polarization in moving media. We then find that the polarization is governed by two contributions. The first one, a geometrical effect, captures a parallel transport of the polarization in the parameter space. The second one, a dynamical effect named polarization drag, acts to rotate the polarization in its plane.

The first effect is a spin-orbit interaction of spin-redirection type. Yet, the mechanism at play in moving media differs from that in gradient-index media at rest where SOI of light have been classically studied. Specifically, for a moving non-dispersive isotropic medium, the spin-redirection Berry phase does not depend on the redirection of the wavevector $\boldsymbol{k}$, but rather on the redirection of the group velocity $\boldsymbol{v}_g$ [15]. Even more interestingly, when the medium is dispersive at rest, for instance in a plasma, the polarization plane normal can deviate from the ray. This additional degree of freedom then allows for SOI even if rays are straight, since the polarization plane can be redirected independently from the ray. We called this effect *spin-deviation-redirection SOI* [16] as it requires a deviation of the polarization plane normal from the ray, and a variation of this deviation along the ray.

This new flavor of spin-redirection SOI is particularly interesting in that it can be tuned independently from the ray trajectory, whereas up until now spin-redirection SOI essentially required engineering the ray trajectory. This added control in turn offers new possibilities for light manipulation. Importantly, it is expected that this added control may be enabled beyond moving media, in particular in static metamaterials, and notably in spacetime modulated metamaterials mimicking moving [18], [19].

***Abstract*—Understanding and controlling the scattering response of metasurfaces often relies on expressing their electromagnetic behavior in terms of multipolar contributions, but redundant higher-order moments can unnecessarily increase the complexity of the model. Here, we identify an optimal decomposition origin for both even and odd parity components to minimize excess multipoles contributions for each. This strategy enables accurate reproduction of the full scattering behavior with a reduced dipolar description.**

***Keywords*— metamaterials, Multipolar decomposition, GSTC, Optimal origin.**

I. Introduction

A multipolar approach offers a clear physical picture of the scattering mechanisms responsible for metasurface functionalities, including the Kerker effect, symmetry-protected or accidental bound states in the continuum, and beam steering. The practical use of multipolar expansions, therefore, demands careful control over the number of retained moments. This aspect is therefore fundamental to multipolar metasurface modeling and designing; otherwise, an excessive number of redundant multipole moments increases model complexity and computational cost.

Several factors govern how many multipolar moments are required to accurately capture the response of a metasurface, including the electrical size and geometry of the unit cell, lattice couplings, the symmetry origin (Wyckoff position), incident angle and the selected coordinate origin for the decomposition [1].

In this work, we identify an optimal coordinate origin for multipolar decomposition that minimizes higher order contributions and corresponds to an equilibrium position of the moments. To accommodate moments with different equilibrium positions, we further separate the response into even and odd parity components, allowing better flexibility in the choice of multiple origin [2]. This parity separation ensures that shifting the origin of one set of moments acts orthogonally to the other and leaves the total response unchanged. With effective electric and magnetic boundary conditions defined at these equilibrium positions, the metasurface scattering can be accurately reproduced using fewer multipolar contributions, ultimately reducing the description to a dipolar level.

II. Methods

We can model the electromagnetic properties of metasurfaces using generalized sheet transition conditions (GSTCs) through effective boundary conditions. For TE-polarized illumination, the GSTCs reduce to the following relations involving the y-component of $\Delta\mathbf{E}$ and the x-component of $\Delta\mathbf{H}$ [2]

$$\Delta\mathbf{E}_y^{\mathrm{TE}} = \tilde{M}_x + \tilde{Q}_{yz}^{(\mathrm{e})} + \tilde{Q}_{xx}^{(\mathrm{m})} + \tilde{Q}_{zz}^{(\mathrm{m})} + \tilde{O}_{yzx}^{(\mathrm{e})}, \tag{1a}$$

$$\Delta\mathbf{H}_x^{\mathrm{TE}} = \tilde{P}_y + \tilde{M}_z + \tilde{Q}_{xz}^{(\mathrm{e})} + \tilde{Q}_{yx}^{(\mathrm{e})}\tilde{O}_{yxx}^{(\mathrm{e})} + \tilde{O}_{yzz}^{(\mathrm{e})}. \tag{1b}$$

and corresponding scattering parameters as [2]

$$r^{\mathrm{TE}} = \frac{E_y^{\mathrm{r}}}{E_y^{\mathrm{i}}} = \frac{1}{2}\left(\Delta\mathbf{E}_y^{\mathrm{TE}} - Z_{yy}\Delta\mathbf{H}_x^{\mathrm{TE}}\right), \tag{2a}$$

$$t^{\mathrm{TE}} = \frac{E_y^{\mathrm{t}}}{E_y^{\mathrm{i}}} = 1 - \frac{1}{2}\left(\Delta\mathbf{E}_y^{\mathrm{TE}} + Z_{yy}\Delta\mathbf{H}_x^{\mathrm{TE}}\right). \tag{2b}$$

Here, $\tilde{P}$, $\tilde{M}$, $\tilde{Q}$, and $\tilde{O}$ denote normalized electric dipole, magnetic dipole, quadrupole, and octupole contributions, respectively; $\Delta\mathbf{E}$ and $\Delta\mathbf{H}$ are the tangential field discontinuities, Z_{yy} is the TE wave impedance, and r^{TE} and t^{TE} are the reflection and transmission coefficients.

It can be shown that shifting the coordinate origin leaves $\Delta\mathbf{E}_y$ and $\Delta\mathbf{H}_x$ invariant, affecting only their phase. This behavior is expected, since the boundary conditions already encode the full scattering information, and scattering is inherently independent of the choice of origin. Exploiting this property, different origins can be selected for each boundary condition, with each one associated with a specific multipolar parity. In earlier approaches, the choice of origin was restricted to a single global point, requiring a compromise that reduced redundant multipoles only for specific terms [1]. Here, by treating even and odd parity contributions separately, we lift this restriction and allow independent optimization of the origin for each parity, enabling a more efficient and physically transparent description.

III. Results and Discussion

We modeled a bianisotropic cone [Fig. 1 (a)] under normal incidence and applied multipolar decomposition using Eqs. (1a) and (1b). This formulation enables the extraction of effective boundary conditions for the structure within different parity channels. By independently shifting the decomposition origin for each boundary condition, we identify the minima of higher order contributions for the electric (odd-parity) and

Fig. 1: (a) Unit-cell geometry of the proposed metamaterial and (b,c,d) corresponding multipolar decomposition for different origins. (e) Optimum dipolar moments at each positions and (f) retrieved scattering parameters from optimal multipolar response compared with full wave simulations.

magnetic (even-parity) moments, respectively. The multipolar decomposition evaluated at the center of mass is shown in Fig. 1 (d), while the decompositions at the optimal electric and magnetic origins are presented in Fig. 1 (b) and Fig. 1 (c), respectively. As observed, the center of mass decomposition contains both electric and magnetic quadrupoles, as well as higher order contributions such as octupoles. In contrast, at the parity optimized electric and magnetic positions, the response is dominated by dipolar contributions. The gray diagrams correspond to multipoles that are not associated with the selected parity or boundary condition; although these modes formally exist at the chosen origin, only the moments consistent with the parity of the corresponding boundary condition are retained in the model. In Fig. 1 (e), we show that the response of the structure can be accurately captured using only dipolar moments. In Fig. 1 (f), an excellent agreement is observed between the scattering parameters retrieved from full-wave simulations and those obtained using the double-origin method described above.

IV. Conclusion

In conclusion, we demonstrated that separating the metasurface response into parity resolved channels enables independent optimization of the multipolar decomposition origin. This approach significantly suppresses redundant higher order contributions and allows the full scattering behavior to be accurately captured at the dipolar level. The resulting framework provides a physically transparent and computationally efficient route for modeling bianisotropic metasurfaces.

***Abstract*—We investigate the scattering behavior of a cylinder, with infinite length, whose permittivity is periodically modulated in time. By exploiting the interference among scattering coefficients associated with different temporal harmonics and multipolar orders, the radiation pattern can be engineered through appropriate adjustment of the modulation parameters.**

I. Introduction

Modulating a medium's material properties in time provides additional degrees of freedom for tailoring the wave–matter interactions [1]. Such modulation can be discontinuous, aperiodic, or periodic variations [2], [3]. When the modulation is periodic in time, the Floquet theory offers a suitable analytical framework. It has been demonstrated that a homogeneous medium subject to periodic temporal modulation of its electromagnetic properties exhibits the formation of momentum bandgaps [4], [5]. Moreover, scatterers of various geometries and time-varying material properties have been reported in the literatures [6], [7], [8].

In this work, we examine cylindrical scatterers with time-modulated relative permittivity. We discuss our analytical results for the parametric Mie resonances, and identify the required modulation conditions. Furthermore, we explore how the far-field radiation pattern can be engineered by tailoring the interference among different scattered harmonics.

II. Formalism

We consider a dielectric cylinder of infinite length, whose relative permittivity, ε_r, varies sinusoidally in time as follows:

$$\varepsilon(t) = \varepsilon_{r0} + \Delta\varepsilon\cos(\omega_{\mathrm{m}}t) = \sum_{n=-N}^{N} \varepsilon(n)\exp(in\omega_{\mathrm{m}}t) \quad (1)$$

Here, ε_{r0} denotes the reference permittivity of a time-invariant system, and $\Delta\varepsilon$ represents the modulation amplitude. The terms $\varepsilon(n)$ correspond to the Fourier coefficients, with the series truncated at a maximum harmonic order N. The modulation angular frequency is $\omega_{\mathrm{m}} = 2\pi/T_{\mathrm{m}}$, where T_{m} is the modulation period. The scattered field components contain harmonics at frequencies $f - nf_m$, where f is the incident frequency, n is the scattered harmonic order. Using the Floquet theory, the electric and magnetic fields can be expressed as Fourier series in time. By substituting these field expansions, together with the expanded form of ε_r, into Maxwell's equations, we obtain an eigenvalue problem that characterizes the periodically time-modulated homogeneous medium, given as follows:

$$\mu_c(2\pi\frac{f-nf_m}{c})^2 \sum_{\nu=-N}^{N} \varepsilon(n-\nu)\mathbf{E}^{(\nu)} = q^2\mathbf{E}^{(n)}. \quad (2)$$

Here μ_c denotes the permeability of the medium, assumed to be $\mu_c = 1$. q is the square root of the eigenvalues, and corresponds to the permitted wavenumbers in the time-modulated medium. The associated eigenvectors $\mathbf{v}_\nu$, each consisting of $2N+1$ elements representing the amplitudes of the scattered harmonics.

For a cylindrical scatterer with time-modulated permittivity, the total fields in both the host medium and inside the cylinder are represented using cylindrical wave expansions. To illustrate this, we present the expressions of the transverse electric (TE) polarization, in which the electric field is normal to the cylinder axis. The corresponding expressions for the electric field are given below.

$$\mathbf{E}_{\mathrm{h}}^{(n)}(\mathbf{r}) = i\sum_{l}\left[a_l^0\mathbf{m}_l(k_0,\mathbf{r})\delta_{n0} + a_{l+}^{(n)'}\,\mathbf{m}_l'(q_{\mathrm{h}n},\mathbf{r})\right] , \quad (3)$$

$$\mathbf{E}_{c}^{(n)}(\mathbf{r}) = i\sum_{\nu=-N}^{N} v_\nu(n)\sum_{l} a'_{l;\nu}\mathbf{m}_l(q_\nu,\mathbf{r}) \ . \quad (4)$$

Here $\mathbf{m}_l$ denotes the vector cylindrical harmonic of order l. The quantity $a_{l+}^{(n)'}$ represents the scattering coefficient of the n-th harmonic generated by the time modulation. When normalized to the incident coefficient a_l^0, it is expressed as $a_{l+}^{(n)} = a_{l+}^{(n)'}/a_l^0$. The wavenumber of the n-th harmonic in the host medium (assumed hereafter to be free space) is given by $q_{hn} = \frac{\omega - n\omega_m}{c}$, while k_0 denotes the wavenumber of the incident wave in the host medium. The magnetic field components are formulated in a similar way using vector cylindrical harmonics - also expressed in terms of Bessel functions—and are omitted here for brevity.

Under the boundary conditions ar $r = R$, which is the radius of the cylinder, based on the tangential components of $\mathbf{E}$ and $\mathbf{H}$, we arrive at,

$$\sum_{\nu=-N}^{N} a_{l;\nu}\, v_\nu(n)\frac{\partial J_l(q_\nu R)}{\partial(q_\nu R)} = \frac{\partial J_l(k_0R)}{\partial(k_0R)}\delta_{n0} + a_{l+}^{(n)}\frac{\partial H_l(q_{\mathrm{h}n}R)}{\partial(q_{\mathrm{h}n}R)} \ , \quad (5)$$

$$\sum_{\nu=-N}^{N} b_{l;\nu}\, v_\nu(n) J_l(q_\nu R) = J_l(k_0 R)\delta_{n0} + b_{l+}^{(n)} H_l(q_{\mathrm{h}n} R)\ , \tag{6}$$

where J_l, H_l are the Bessel and Hankel function (of order l), respectively. With the relationships $a_{l+}^{(n)} = \sqrt{\mu_h/\varepsilon_h}\, b_{l+}^{(n)}$, we have $2(2N+1)$ variables that can be solved numerically.

The total scattering efficiency is then defined as,

$$Q_{\mathrm{sc}} = \sum_{n=-N}^{N} Q^{(n)} = \sum_{n=-N}^{N} \frac{2}{|q_{\mathrm{h}n}|R} \sum_l \frac{2}{1+\delta_{l0}} |a_{l+}^{(n)}|^2\ . \tag{7}$$

We should note that if $N = 0$, the above formalism reduces to the classical problem of scattering from a time-invariant infinite cylinder [9].

III. Results and Discussion

Following the method outlined in Section II, and setting the modulation frequency to $f_m = 2f$, we find that, under the assumption of weak modulation, the dominant scattered harmonics at parametric resonances are $n = 0, 1$. These correspond to frequencies $f_{n=0,1} = \pm f$. In this case, the system of equations in Eq.,(5) simplifies to four coupled equations, supplemented by the eigen-condition in the absence of incident excitation. Nontrivial solutions for the scattering coefficients are obtained by solving this truncated eigenvalue problem, which yields the required modulation strength for each modulation frequency (with $f_m = 2f$ thoughout).

With parameters $\varepsilon_{r0} = 12$, $R = 5\,\mathrm{mm}$, the semi-analytical results are shown in Fig.,1. The upper and lower panels correspond to TE and TM polarizations, respectively, with colored solid curves indicating different multipolar orders l. These curves are referenced to the left vertical axis in each subplot. Also plotted is the scattering efficiency as a function of incident frequency, in black dashed lines for a static cylinder with $\varepsilon_{r0} = 12$, referenced to the right vertical axis. Distinct Mie resonances of various orders are clearly observed within the selected frequency range.

The threshold modulation strength, $\Delta\varepsilon_{th}$ (upper curves), for each multipolar order l reaches its minimum at the frequency f corresponding to the Mie resonance of the static reference cylinder ($\varepsilon_r = \varepsilon_{r0} = 12$). Notably, this minimum decreases with increasing l, which can be attributed to the lower losses associated with higher-order Mie resonances, as reflected by the increasingly sharp peaks of the dashed curves at higher frequencies.

For TE polarization, an alternative method was employed to determine the required modulation strength $\Delta\varepsilon_{th}$ for achieving parametric resonance. This approach is based on the coupled equations in Eqs.,(5) and (6) and incorporates higher-order scattered harmonics up to $N = 3$. The results for different multipolar orders l are shown as colored dots in Fig.,1, on top of the predictions from the truncated eigenvalue problem. Larger discrepancies appear at higher $\Delta\varepsilon_{th}$, as stronger modulation produces non-negligible higher-order scattered harmonics, reducing the accuracy of the truncated approximation. The overlapped dots of different colors indicate modulation conditions where different multipoles can be excited simultaneously. For instance, in the TE-polarized case around 12 GHz with $\Delta\varepsilon \approx 5.5$, both the electric dipole and quadrupole are simultaneously excited, producing backward radiation for specific modulation parameters, as illustrated by the field distribution in Fig.,2. The interplay between different modes, combined with the phase relationships among the harmonics generated by the time modulation, enables the engineering of diverse far-field radiation patterns.

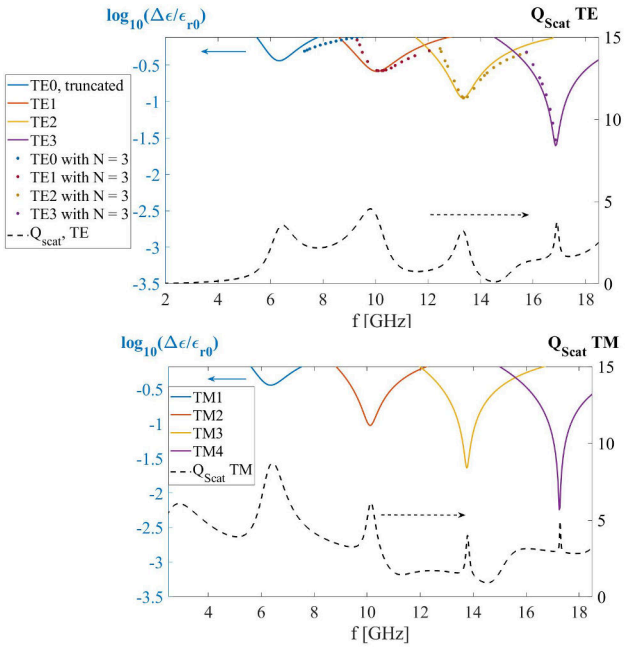

Fig. 1. Left axes (both panels): Logarithmic scale of the ratio between the threshold modulation strength $\Delta\varepsilon_{th}$ required for parametric resonance at $f_m = 2f$ and the reference relative permittivity $\varepsilon_{r0} = 12$ ($R = 5$mm) shown as colored solid curves versus the incident frequency f. Right axes: Scattering efficiency of a static system of $\varepsilon_{r0} = 12$ versus frequency on a linear scale, plotted as black dashed curves. Upper panel: TE polarization; colored dots show results from Eqs.,(5) and (6) including harmonics up to third order. Lower panel: TM polarization.

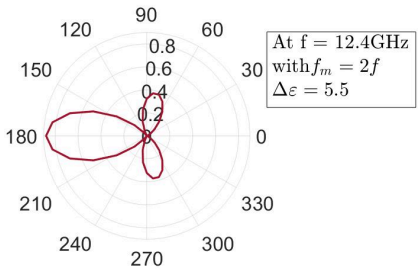

Fig. 2. Farfield distribution $|E|^2$, for a time-modulated cylinder of $\varepsilon_{r0} = 12$, $R = 5\,\mathrm{mm}$, $f = f_m/2 = 12.4\,\mathrm{GHz}$, $\Delta\varepsilon = 5.5$.

IV. Conclusion

We have studied an infinitely long cylindrical scatterer with periodically time-modulated relative permittivity. Semi-analytical calculations of the scattering properties, based on Floquet–Mie theory and the relevant spatial boundary conditions, show that the modulation parameters required to achieve parametric Mie resonances are closely linked to the resonant characteristics of the corresponding static scatterer. Multipolar modes of different orders can be simultaneously excited, enabling the design of a variety of far-field radiation patterns. Future work will extend this analysis to plasma cylinders with time-varying plasma properties, which could be implemented by controlling the plasma ignition or sustainment sources in practice. Such time-modulated scatterers could be arranged into dynamic metamaterial structures, with potential applications in wavefront shaping and related areas.

***Abstract*— The paper presents numerical simulation results of the ultrashort bright envelope solitons in a normally magnetized parallel-plate waveguide completely filled with a nonlinear ferromagnetic metamaterial. It is shown that in high-intensity magnetic biased fields, the soliton width of an "extraordinary" slow forward electromagnetic wave reaches several hundreds of picoseconds.**

***Keywords*— microwave metamaterials, solitons.**

I. Introduction

In 2005, Dewar suggested to embed a periodic lattice of the dielectrically insulated thin metal wires inside a dielectric ferromagnet (FM) host and described his model the so-called "left-handed" FM metamaterial (MM) [1] The model was based on the effective medium approximation and did not take into account the spatial dispersion of the periodic lattice. In 2023, Amel'chenko with coauthors, utilizing the MaxLLG software [2], carried out the numerical simulation of a parallel-plate waveguide (PPWG) completely filled with Dewar's FM MM thin plate placed in two (normal or longitudinal) magnetic biased field H_0 orientations [3]. The numerical simulations were conducted for slow-intensity magnetic biased fields (of about 0.1 T) and they confirmed the existence of a backward electromagnetic wave (BEMW) in such double negative (DNG) (ε_{eff}<0, μ_{eff} <0) medium for both types of H_0 orientation. In 2025, the same authors showed that the bandwidths of two slow EMWs (the BEMW existing at the frequencies corresponding to DNG-medium and a forward EMW (FEMW) existing at the frequencies of double positive (DPS) (ε_{eff} >0, μ_{eff}>0) medium) have opposite magnetic field dependencies [4]. So, the BEMW bandwidth is decreased and the FEMW bandwidth is increased with the increasing of the magnetic biased field strength.

In addition to its dispersive properties, a FM is also a nonlinear medium that possesses the formation of bright envelope solitons (BESs) [5]. These are formed on the magnetostatic spin waves and have durations of about several tens of nanoseconds. In the paper, it is demonstrated that the BESs can be formed on the slow FEMW existing in the FM MM and have the subnanosecond durations at high-intensity magnetic biased fields.

II. Methods

Fig. 1(a) represents the schematic diagram of a normally magnetized PPWG completely filled with FM MM plate containing the dielectrically insulated wire inclusions. The dispersion equation for the transversely magnetized FM MM has the following form [1]:

$$k - k_0^2 \varepsilon_{eff\perp} \mu_{eff\perp} = 0, \tag{1}$$

where k - is a wavenumber of EMW propagating in FM MM, $k_0 = \omega/c$ - is a wavenumber of EMW propagating in vacuum, $\mu_{eff\perp} = (\mu^2 - \mu_a^2)/\mu$, $\mu = (\omega_\perp^2 - \omega^2)/(\omega_{||}^2 - \omega^2)$, $\mu_a = \omega_M \omega/(\omega_{||}^2 - \omega^2)$, $\omega_\perp = \omega_{||}\omega_{ar}$ is a ferromagnetic resonance (FMR) frequency for transverse magnetization, $\omega_{ar} = \omega_{||} + \omega_M$ is a frequency of anti-FMR, $\omega_{||} = \gamma H_0$ is a FMR frequency for longitudinal magnetization, γ is a gyromagnetic ratio, $\omega_M = 4\pi\gamma M_0$, $4\pi M_0$ is saturation magnetization;

$$\varepsilon_{eff\perp} = \varepsilon_r\left[1 - \omega_{p\perp}^2/(\omega^2 + i\alpha_\perp)\right],$$
$$\omega_{p\perp}^2 \cong 2\pi/\langle \varepsilon_f T^2 \mu_0 \{ln(r_2/r_1) + \mu_{eff\perp}[\ln(T/r_2) - (3 + \ln 2 - \pi/2)/2]\}\rangle,$$

$\alpha_\perp = \varepsilon_f \omega \omega_{p\perp}^2/\sigma_{eff}$, $\varepsilon_f = \varepsilon_0\varepsilon_r$ – is the absolute permittivity, $\varepsilon_0 = 1/(\mu_0 c^2)$ is the vacuum constant, μ_0 is the vacuum permeability, $\sigma_{eff} = \pi r_1^2 \sigma/T^2$ is the effective conductivity of the wire array, σ is the conductivity of the wires, T is an array period, r_1 is a wire radius and r_2 is an outer radius of the cladding material.

For a nonlinear model it is assumed that the longitudinal component M_y of the magnetization vector depends on the square of the alternating magnetic field amplitude $|\varphi|^2$, and this dependence has the following view:

$$M_y \approx M_0(1 - a|\varphi|^2), \tag{2}$$

where $a = (1 + \omega_H^2/\omega^2)/2$.

The nonlinear Schrodinger equation (NSE) was obtained from the nonlinear dispersion equation. The NSE has the following form:

$$j\left(\frac{\partial}{\partial t} + V_g\frac{\partial}{\partial z}\right)\varphi + \beta\frac{\partial^2\varphi}{\partial z^2} - \chi|\varphi|^2\varphi = 0, \tag{6}$$

where $V_g=\partial\omega/\partial k$ is the slow FEMW group velocity, $\beta=\partial^2\omega/\partial k^2$ is the dispersion of the slow FEMW group velocity, $\chi=\partial\omega/\partial|\varphi|^2$ is the wave nonlinearity coefficient. To obtain the soliton solutions, the values of the dispersion β and nonlinearity χ coefficients of NSE must satisfy the Lighthill criterion ($\beta\chi$<0) and have the opposite signs.

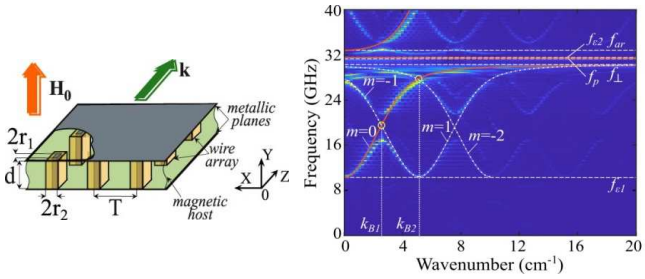

Fig. 1 (a) A scheme of normally magnetized PPWG completely filled with FM MM plate. (b) Dispersion responses of the EMWs existing in the FM MM thin plate at H_0=1 T. The solid red lines correspond to the Dewar's analytical theory. The calculations were performed for $4\pi M_0$=1750 G, ε_r=16, r_1=0.01 cm, r_2=0.03 cm, T=0.2 cm, d=0.05 cm, and $\sigma=10^8$ S/m.

III. Results and Discussion

The simulation results of the dispersion responses (DRs) of the EMWs in the normally magnetized PPWG completely filled with a FM MM thin plate are presented in Fig. 1 (b). They are obtained by the use of the MaxLLG software. It can be seen that the frequency band of the zero spatial harmonic of the slow FEMW increases to 20 GHz in the magnetic biased field with the strength of 1 T. On the contrary, the frequency band of the zero spatial harmonic of the BEMW decreases.

Fig. 2 demonstrates the bright envelope soliton train that is formed on the zero spatial harmonic of the slow FEMW, when the NSE was solved numerically with periodic boundary conditions. In simulation, the soliton generation frequency was outside the frequency band of the first Bragg resonance and the FEMW wavenumber was higher than the Bragg wavenumber. For such frequency, the Lighthill criterion was satisfied. The FEMW bright envelope solitons have the 250 ps-duration that is two oders of magnitude shorter than the duration of MSW bright envelope solitons.

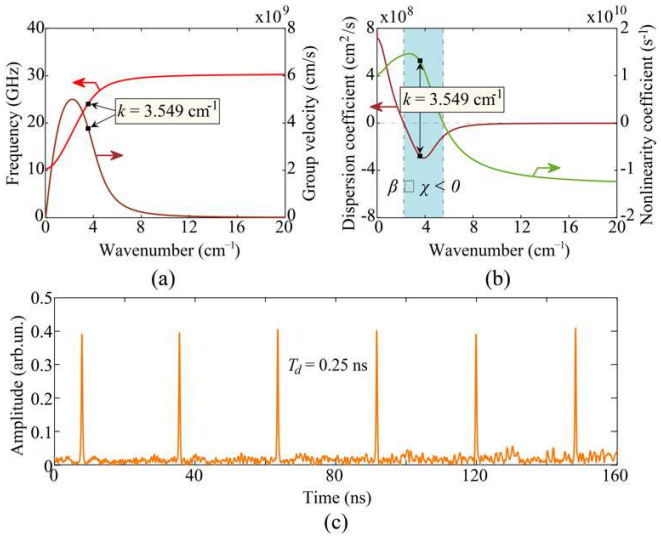

Fig. 2. (a) DR and group velocity of the slow FEMW; (b) the coefficients of dispersion β and nonlinearity χ as the functions of wavenumber k; (c) the envelope wave front evolution in the Dewar's FM MM. The calculations were made for:H_0=1 T, $4\pi M_0$=1750 G, ε_r=16, r_1=0.01 cm, r_2=0.03 cm, T=0.2 cm, and f=24 GHz.

IV. Conclusion

We have demonstrated that in the FM MM layer, which is a dielectric FM thin plate, containing a periodic lattice of the dielectrically insulated metal wires in high-intensity magnetic biased fields, a bandwidth of the "extraordinary" slow FEMW reaches several octaves in microwave range. The FEMW bright envelope solitons obtained by the use of nonlinear Schrodinger equation have duration of about two hundreds of picoseconds.

***Abstract*—A design-space exploration of a mechanically reconfigurable linear-to-circular polarization (LTC) metasurface is presented. Latin Hypercube Sampling with full-wave simulations is employed to map broadband LTC behavior beyond single-point optimization. Extended high-performance regions and a bandwidth–robustness trade-off are identified, enabling selection of tolerant and reliable metasurface designs.**

***Keywords*— metasurface, circular polarization, linear-to-circular converter, broadband microwave, microwave polarization control, reconfigurable electromagnetic devices.**

I. Introduction

Linear-to-circular polarization (LTC) devices are key components in modern electromagnetic systems, as circular polarization improves robustness against misalignment and mitigates multipath effects [1]. Transmissive LTC metasurfaces are particularly attractive for multilayer and conformal architectures; however, achieving broadband conversion in transmission while maintaining low loss and structural simplicity remains challenging [2].

In previous work, a mechanically reconfigurable transmissive LTC metasurface based on dual-layer L-shaped resonators was demonstrated [3]. The structure enables handedness switching through a 90° mechanical rotation while providing approximately 26% relative bandwidth under the 3 dB axial-ratio criterion. Although the design was optimized using conventional parametric sweeps, the global structure of the design space and the robustness of high-performance solutions were not systematically analyzed.

In this work, a statistical design-space exploration based on Latin Hypercube Sampling (LHS) [4], [5] is employed to investigate the dominant geometrical parameters of the converter. In contrast to conventional parametric optimizations—where the geometry is tuned to maximize bandwidth around a single best-case design—the proposed approach maps the design space, identifies high-performance regions, and evaluates the robustness of the LTC response. Rather than pursuing an isolated optimum, the objective is to identify extended regions of the design space that preserve broadband LTC behavior under geometrical variations, thereby providing depper insight into the design methodology of mechanically reconfigurable polarization converters.

II. Methodology

The analyzed structure consists of a dual-layer arrangement of L-shaped metallic resonators located on opposite faces of a low-permittivity dielectric slab (foam). The resonators are made of low-carbon steel wire (AWG-25), with a total length of 20 mm and a 90° bend forming two equal arms. Electromagnetic coupling between the orthogonal current modes supported by the two resonators produces the quadrature phase shift required for circular polarization conversion. A 90° mechanical rotation interchanges the resonators' orientation with respect to the incident field, thereby reversing the handedness of the transmitted wave [3].

The global design space is explored by varying the lateral dimension of the unit cell, p, and the dielectric thickness, t, while keeping the size and shape of the resonators constant to target LTC operation around the X-band. The operating frequency band can be shifted by properly scaling the resonator geometry. The exploration begins with 100 configurations generated using an LHS distribution within predefined parameter ranges. An additional refinement sampling is subsequently performed to focus on the regions exhibiting the highest performance.

For each configuration, the polarization-conversion performance is evaluated using full-wave simulations (CST Studio Suite 2025, frequency solver). The relative bandwidth (RBW), defined as the continuous frequency interval over which the axial ratio (AR) remains below 3 dB, is used as the primary performance metric. Additional statistical descriptors of the AR response are computed to quantify robustness and stability of the LTC behavior.

All results reported in this work are obtained from full-wave numerical simulations. Experimental validation is not repeated here, since the same metasurface configuration was experimentally characterized in [3], where measurements confirmed both the preservation of the relative bandwidth and the robustness of the mechanical RHCP/LHCP switching mechanism.

III. Results and Discussion

Figure 1 shows the RBW distribution across the explored parameter space. A well-defined high-performance ridge is observed around $p \approx 17$ mm, extending over dielectric thickness values between approximately $t \approx 4$ and 8 mm.

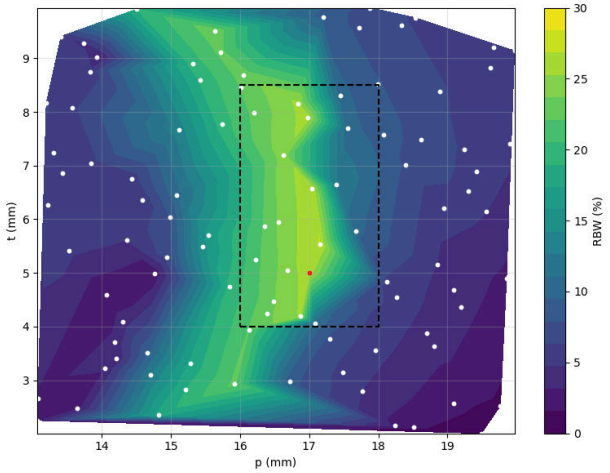

Fig. 1. Relative bandwidth (RBW) obtained from the Latin Hypercube Sampling (LHS) exploration over the design space defined by the unit-cell size p and dielectric thickness t. White markers indicate simulated configurations. A continuous high-performance ridge associated with broadband LTC conversion is observed. The previously reported configuration ($p = 17$ mm, $t = 5$ mm) [3] is highlighted with a red marker and lies within the primary ridge. The black dashed rectangle indicates the region selected for local refinement sampling.

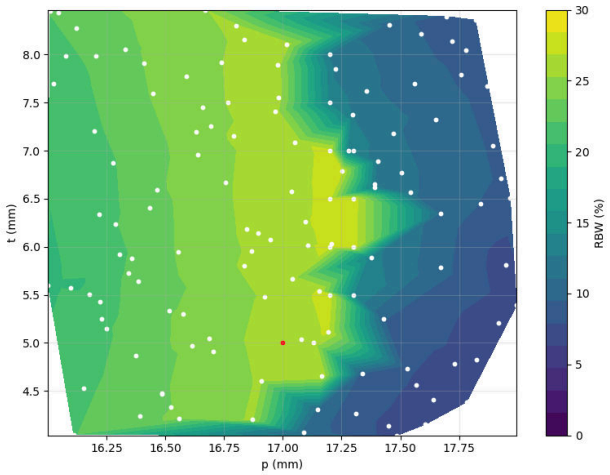

Fig. 2. Local refinement of the primary RBW ridge using an additional LHS sampling restricted to the region indicated in Fig. 1.

The configuration previously reported in [3] ($p = 17.0$ mm, $t = 5.0$ mm) lies within this ridge, confirming that the reference design is located near the the dominant high-performance domain.

To resolve the local structure of this region, a refinement sampling was carried out within the parameter window marked in Fig. 1. The zoomed map in Fig. 2 shows that the primary ridge forms a relatively broad plateau rather than a narrow peak. This behavior indicates that the wideband polarization conversion is preserved under moderate variations of p and t, suggesting inherent robustness and relaxed manufacturing tolerance within the identified parameter domain.

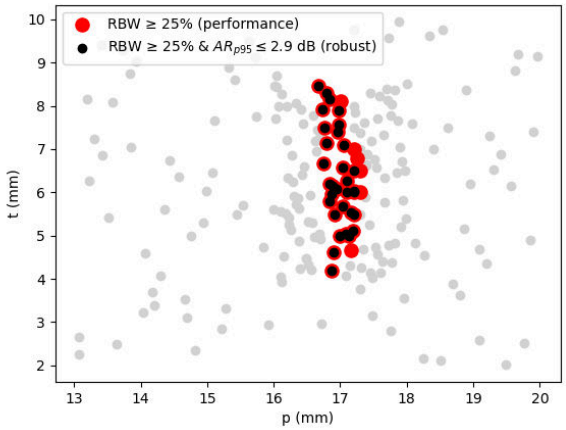

Fig. 3. Global distribution of LTC configurations obtained from the LHS exploration. Grey markers correspond to all simulated geometries. Red circles indicate configurations with RBW≥25%, and black markers denote the subset that additionally satisfies the stability requirement $AR_{p95} \leq 2.9$ dB.

To quantitatively assess performance and robustness among the LTC solutions, a sequential filtering strategy was applied. First, a performance criterion was imposed by selecting configurations with RBW≥25%, matching the bandwidth level of the reference design in [3]. This filter isolates a set of broadband configurations concentrated along the main ridge identified in the RBW maps.

Although RBW captures the extent of the LTC band, it does not quantify the statistical stability of the axial ratio inside that band. A second stage was therefore introduced by requiring the 95th percentile of the axial-ratio distribution to satisfy $AR_{p95} \leq 2.9$ dB. This constraint ensures that the vast majority of frequency samples within the LTC band remain comfortably below the 3 dB threshold, providing a margin against degradation due to fabrication tolerances and modeling uncertainties.

The global distribution of the configurations satisfying these criteria is shown in Fig. 3. Grey markers represent the full LHS dataset, red circles denote the subset meeting the RBW requirement, and black markers indicate the subset that additionally satisfies the robustness condition. The robustness filter removes only a limited fraction of high-bandwidth solutions, confirming that broadband LTC behavior is not confined to an isolated optimum but instead distributed along an extended region centered around $p \approx 17$ mm and $t \approx 6$ mm.

Notably, the robustness criterion tends to exclude some configurations exhibiting the absolute maximum RBW values (close to 28%). This observation suggests a bandwidth–robustness trade-off: solutions optimized to maximize RBW operate closer to the axial-ratio threshold and consequently exhibit larger AR excursions within the operating band. In contrast, slightly reduced RBW values are typically associated with smoother AR responses and improved statistical stability.

Overall, the combined analysis indicates that the proposed

TABLE I
REPRESENTATIVE LTC CONFIGURATIONS IDENTIFIED IN THE LHS EXPLORATION.

Case	p (mm)	t (mm)	f_0 (GHz)	RBW (%)	$\overline{AR}$ (dB)	σ_{AR} (dB)	AR_{p95} (dB)
Original	17.0	5.0	11.76	26.0	1.96	0.57	2.52
Max RBW	17.3	6.5	11.65	27.7	2.25	0.57	2.97
Most robust	17.0	5.7	11.70	26.0	1.88	0.44	2.40

metasurface supports broadband LTC conversion over a wide and tolerant region of the design space. This characteristic is advantageous for practical implementations, since it relaxes fabrication constraints while maintaining high polarization-conversion performance.

To facilitate a direct comparison of representative solutions, Table I summarizes three configurations: (i) the reference design reported in [3], (ii) the configuration achieving the maximum RBW within the explored set, and (iii) the most robust configuration, defined as the case with the minimum AR_{p95} among those satisfying RBW$\geq$25%. In addition to the geometrical parameters and RBW, the mean axial ratio $\overline{AR}$ and its standard deviation σ_{AR} are reported to characterize the stability of the polarization response.

All three configurations exhibit similar center frequencies, with $f_0 \approx 11.7 \pm 0.1$ GHz, indicating that variations of p and t within the dominant ridge primarily affect the quality and robustness of the LTC response while leaving the operating band essentially unchanged. The maximum-bandwidth case achieves the largest RBW (27.7%), but shows the poorest robustness metrics, with AR_{p95} approaching the 3 dB limit and increased $\overline{AR}$ and σ_{AR}. This confirms that the highest RBW values are obtained at the expense of operating closer to the LTC conversion threshold.

In contrast, the most robust configuration preserves the RBW of the reference design (26%) while improving the AR statistics, with lower $\overline{AR}$ and reduced variability. This result confirms that slightly reduced RBW values can yield a more stable circular-polarization response across the operating band. Overall, the LHS-based analysis shows that broadband LTC conversion is supported over an extended and tolerant region of the design space rather than around a single finely tuned optimum, highlighting the value of statistical design-space exploration beyond conventional parametric sweeps.

IV. CONCLUSIONS

A Latin Hypercube Sampling (LHS)–based design-space exploration has been applied to a mechanically reconfigurable linear-to-circular polarization (LTC) metasurface. The analysis reveals that broadband LTC conversion is not limited to a single optimal configuration but occurs over an extended region of the (p, t) parameter space.

Designs optimized exclusively for maximum bandwidth tend to exhibit reduced robustness, whereas alternative configurations achieve comparable relative bandwidth with improved polarization stability. These results demonstrate that statistical exploration provides a practical and effective approach to balancing bandwidth and robustness in mechanically reconfigurable polarization converters.

***Abstract*— Automotive radar detection depends on vehicle radar cross-section (RCS), yet modern vehicles lack dedicated reflectors. We propose an optically transparent metasurface integrated on the rear windshield, formed by conductive wires satisfying the first Bragg condition. A 10×10 cm² prototype achieves ~90% optical transparency and an RCS of 8 m².**

***Keywords*— metamaterials, RCS, radar.**

I. Introduction

Ensuring road safety relies on ADAS sensors, with radar being primary due to its robustness in adverse conditions. Automotive radars (77–81 GHz) assist in collision avoidance and object detection but face challenges like limited angular resolution and multipath effects. A key factor in detection reliability is the target's RCS, which for passenger vehicles typically ranges from 10 to 100 m^2 [1]-[3]. RCS enhancement, widely used in maritime applications, can significantly improve radar detection, increasing the effective range and signal-to-noise ratio [4].

Despite its advantages, integrating radar reflectors into vehicle design remains a challenge due to aesthetic and space constraints. The rear windshield, largely unused apart from defogging elements, presents a viable alternative for a functional backscatter reflector. A 1 m^2 windshield, modeled as a square plate, theoretically yields an RCS of 1000 m^2 at 80 GHz, highlighting the potential for enhanced detectability.

Maintaining optical transparency is crucial. Transparent antennas and reflectors find applications in automotive wireless communication, wearable electronics, and security [5]-[8]. Technologies like transparent conductive oxides, metal meshes, and pattern transfer printing (PTP) enable fabrication of optically transparent yet conductive surfaces. We employ PTP with silver pastes to print sub-millimeter conductive patterns onto glass, ensuring both transparency and high radar reflectivity.

II. Methods

The proposed structure for increasing the radar cross section (RCS) magnitude is based on a well-studied wire grid [9]. The fabricated metasurface with selected geometrical parameters provides a significant increase in vehicle visibility - Fig. 1(a). The insets in Fig. 1(a) schematically describe the scattering process and an example of the resulting radar map.

In order to achieve an in-phase response from an array of parallel wires, it is necessary that the path difference to neighbouring elements is a multiple of the wavelength [10]: $2d\sin(\theta) = \lambda$.. In this equation, d is the period of the reflector, θ is the angle of incidence of the plane wave and λ is the wavelength in the medium. For the considered frequency range and typical angle of inclination of a car window ($\theta = 45$ degrees), the period d=2.65 mm was selected. In order to demonstrate the performance of the proposed concept, a sample was simulated and fabricated on a glass of thickness 4 mm with a dielectric permittivity 6 with dimensions of 10*10 cm^2 and with thickness of conductive strips of 0.02 mm. All numerical simulations were performed in CST Microwave Studio, with a linearly polarized plane wave as the source.

Fig. 1(b) shows the 3D pattern of bistatic RCS at 80 GHz. The plane wave was incident on the sample surface at an angle of 45 degrees, while the electric vector E remained co-directional with the wires. Since the system is optimized for such parameters, four beams are expected: two reflected from the plane of the metasurface and two passed through it. The insets in Fig. 1(b) show the direction of incidence of the plane wave on the structure and the color scale of the RCS magnitude in m^2. The beam returning back to the radar is quite narrow - the RCS value attenuates by 6 dB over a range of 1.8 degrees from the original direction.

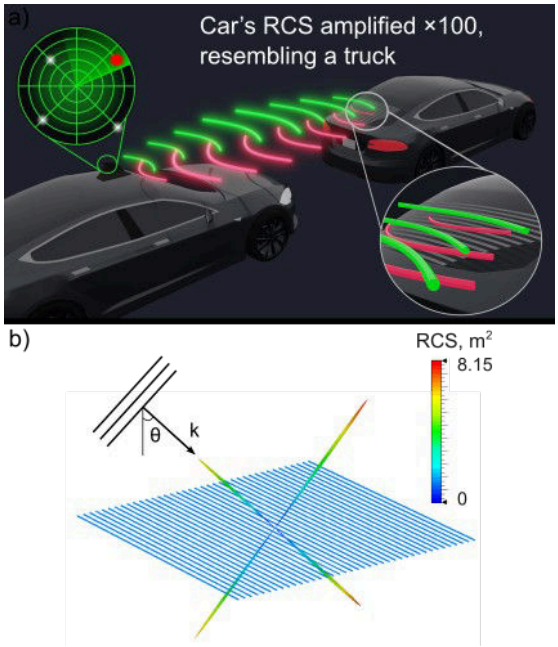

Fig. 1 Illustration of the proposed concept for increasing the RCS of a vehicle (a). The metasurface on the rear window of a vehicle significantly improves its visibility to radars. The 3D bistatic RCS pattern for angle of incidence θ = 45 degrees at 80 GHz carrier frequency (b).

III. Results and Discussion

The optical properties of the SUTs were investigated using a standard method to confirm the transparency of the glass samples. A collimated visible light beam illuminated the sample, and the transmitted light was collected into an optical fiber and analyzed using an Avantes spectrometer. The transmission spectrum (Fig. 2(a)), normalized to the lamp signal, showed that plain glass had approximately 90% transparency at lower wavelengths, while the deposition of a transparent polarizer reduced it by about 2%, indicating minimal optical loss.

The result of a numerical simulation of the scattering of a developed metasurface at different incident plane wave angles for different frequencies is shown in Fig. 2(b). The incident wave angle was varied from 0 to 60 degrees with a step of 1 degree, and the carrier frequency was varied from 75 to 110 GHz with a step of 0.1 GHz. The figure highlights a narrow maximum at normal incidence (θ = 0 degrees) and an additional line at the 30–45-degree section.

Considering the Bragg condition and the simulation results, the reflection measurements were conducted in an anechoic chamber (Fig. 2(c)). The setup includes a PNA controlled via MATLAB, with the SUT placed at the center of a rotating styrofoam table. The SUT consists of conductive wires on a glass substrate. Measurement was performed for azimuthal rotations of 0:1:60 degrees and fixed elevation angle 0 degrees (wires parallel to the vertically polarized antenna). Strong reflection was observed across 75–110 GHz for 0 degrees azimuth and 0 degrees elevation and additional reflections appeared between 30–45 degrees azimuth due to Bragg condition optimization (Fig. 2(d)).

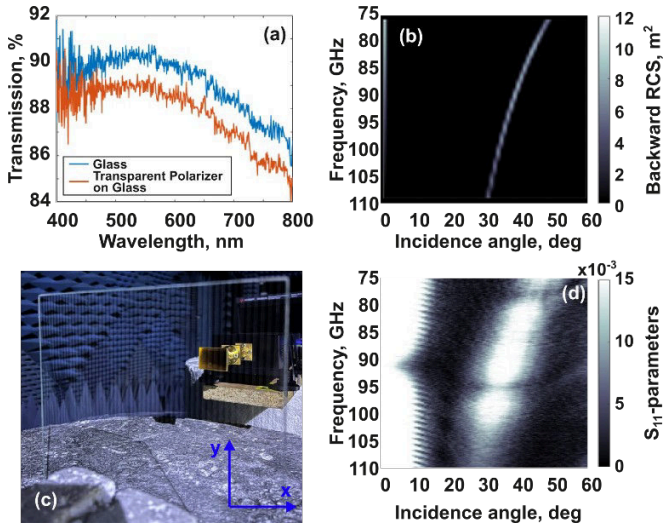

Fig. 2 Experimental result in the optical laboratory for glass SUT in the visible wavelength range (a). Simulation results - dependence of the backward RCS in linear scale on the frequency and angle of incidence of a plane wave (b). Experimental setup for measurement the S_{11}-parameters (c)-(d).

IV. Conclusion

We have demonstrated a 3D-printed optically transparent metasurface designed to enhance automotive radar visibility while maintaining high optical transparency. The metasurface, composed of conductive wire arrays, was optimized to satisfy the Bragg condition, ensuring strong radar reflections in the 77–81 GHz band. Both simulations and experimental measurements confirmed a significant increase in RCS, with a fabricated 10*10 cm^2 sample achieving an RCS of 8 m^2. Extrapolating this to a full rear windshield suggests an RCS of up to 1,000 m^2, improving vehicle detectability by nearly two orders of magnitude. The proposed approach offers a scalable solution for integrating electromagnetic functionality into automotive glass, with potential applications in radar sensing, wireless communication, and smart infrastructure.

***Abstract*—We present a framework for interfacing an ultra-stable laser resonator with photonic integrated circuits via low-noise resonator mirrors and show initial simulation and experimental results of large-area grating couplers with near-Gaussian beam diameters of 300 µm at λ = 1.55 µm on an SOI-platform.**

***Keywords*— ultra-stable lasers, grating couplers, photonic integrated circuits, optical resonators**

I. Introduction

Ultra-stable lasers (USLs) are a key enabling technology driving the quantum revolution. They provide the stable frequencies needed for precise interrogation of narrow atomic transitions in atoms or ions. Additionally, they are indispensable for precision measurements in fields such as gravitational wave detection [1] and tests of fundamental physics [2]. Current state-of-the-art USLs operated at 1.55 µm achieve a sub-10 mHz linewidth, limited by the fundamental thermal Brownian noise of the mirror coatings [3]. The bulky design of conventional USLs, requiring extensive thermal shielding, also necessitates large optical systems for operation [4]. While integrated lasers based on micro-ring resonators [5] and chip-coupled micro-resonators [6] offer compact solutions, they still lack the mid- and long-term stability often required. To overcome these limitations, our novel resonator approach leveraging multifunctional mirrors and integrated photonics aims to meet the stringent SWaP (size, weight, and power) requirements of the quantum revolution. While coupling and stabilizing on-chip laser light to mm-scale micro-resonators has been recently demonstrated [6], ultra-stable laser resonators (USLRs) exhibit lengths on the cm-scale. These cm-scale resonator lengths, however, demand large, Gaussian output beams emitted from the chip with mode field diameters in the range of several hundreds of micrometers.

In this work, we present the design approach and experimental data of fully-etched grating couplers on a 220 nm silicon-on-insulator platform emitting large mode field diameter Gaussian beams at 1.55 µm wavelength suitable to be directly coupled into cm-scale USLRs. Figure I displays the envisioned approach, where the resonator mirror (center) consists of multiple vertically stacked functional layers, with the photonic integrated circuit (PIC) at the very bottom. This

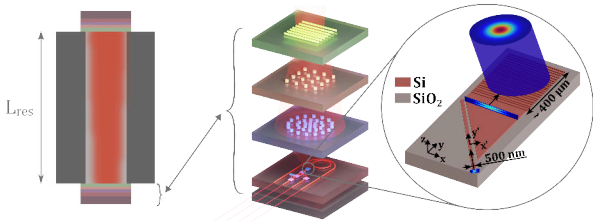

Fig. 1. A macroscopic, optical resonator (left) with L_{res} on the order of centimeters is interfaced to a photonic chip which is integrated into the lower mirror substrate. The proposed vertical structure of the chip and mirror (center) consists of the photonic integrated circuit (dark red), two layers for beam shaping (blue, brown) and finally the low-noise meta mirror (green).

PIC provides the light in- & out coupling, routing, and light modulation necessary for locking a laser to the resonator. The following description of the design and experimental realization of large-area grating couplers marks the first step towards multifunctional low-noise resonator mirrors, interfacing integrated photonics with free-space USLRs.

II. Methods

The geometry, i.e. the length of the resonator and the curvature of the second mirror, dictates the spatial distribution of its fundamental mode: for a fixed resonator length of $L_{res} = 4$ cm consisting of one flat mirror and one focusing mirror, the fundamental mode will depend on the radius of curvature of the focusing mirror. As a starting point, a radius of curvature of 100 mm was chosen, corresponding to a beam waist diameter of 300 µm at the plane mirror. Since the plane mirror defines a perpendicular propagation vector in respect to its surface, it is chosen as the incoupling mirror with the PIC attached to the back of it. The resulting emission diameter of the grating coupler located on the PIC thus needs to equal this beam waist diameter of 300 µm. The required local coupling strength κ of a grating, which emits a beam intensity profile $S(y) \propto |E(y)|^2$, can be expressed through

$$\kappa(y) = \frac{S(y)}{P(-\infty) - \int_{-\infty}^{y} S(t)dt}, \quad (1)$$

where $P(-\infty)$ is the initial power in the waveguide. For classical chip to SM-fiber (≈10 µm mode diameter) coupling

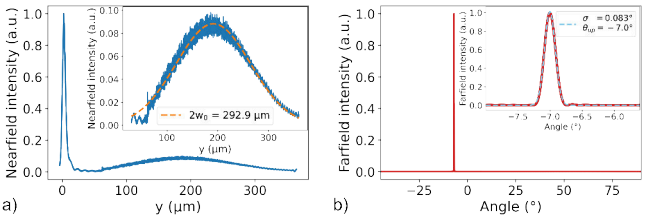

Fig. 2. (a) Nearfield and (b) farfield emission profiles of the cherry-picked sub-wavelength grating coupler extracted from a 2D-FDTD simulation. The simulated beam diameter is 292.9 µm with an emission angle of $-7°$.

applications, the coupling strengths need to be on the order of $10^{-2}...10^{0}$ µm^{-1}. However, for beam diameters of several hundreds of microns, small coupling strengths down to 10^{-4} µm^{-1} are required. To achieve such large output diameters, a sub-wavelength grating-based approach was chosen, as the coupling strength can be tuned to almost arbitrarily small values [7]. FDTD-simulation sweeps were performed over large design spaces and the coupling strength for each design was recorded. Designs of these sweeps were cherry-picked to best fit the required coupling strength-function according to Eq. 1, where $S(y)$ is the Gaussian intensity profile with a beam waist diameter of $2w = 300\,\mu\text{m}$. While a Gaussian beam is advantageous for a USLR, the present design concept enables the realization of arbitrarily shaped intensity profiles defined by $S(y)$.

In addition to the grating coupler, an evanescent mode converter (Figure I, right) was analytically designed to convert the waveguide mode to a slab mode with a width of 300 µm to obtain a circular Gaussian beam emission from the grating coupler, similar to the design process shown in [8]. The resulting gap function between the waveguide and the slab is then expressed by

$$g(y') = -\frac{1}{b}\ln\left(\frac{\lambda_0}{\sqrt{2}aw\pi^{3/2}}\frac{e^{-2\frac{(y'-L)^2}{w^2}}}{1-\text{erf}\left\{\sqrt{2}\frac{y'-L}{w}\right\}}\right) \quad (2)$$

where a, b are parameters derived from the effective mode index, w is the desired waist of the slab mode, L is the center of the slab mode and y' the spatial coordinate along the waveguide (see Figure I for reference).

III. Results and Discussion

Different cherry-picked gratings for a beam diameter of 300 µm at different emission angles have been designed and fabricated. The simulated 2D-FDTD response of a design for an emission angle of $-7°$ is shown in Figure 2. The emitted beam exhibits a broad Gaussian shape, spanning over several hundreds of microns with a fitted beam diameter of 292.2 µm in the nearfield 2 µm above the grating and an upwards transmission efficiency of 47 %. Due to the symmetric nature of the fully-etched gratings, the upper limit of the efficiency lies at 50 %. The distinct emission peak at the beginning of the grating is attributed to the abrupt change in the effective refractive index of the mode when it transitions from the slab waveguide to the grating. As the design emission angle approaches 0°, the grating enters the Bragg-reflection regime, where most of the light is reflected back into the input slab. Since the emission angle should ideally be 0° for efficient resonator-coupling, an angle-correcting meta surface similar to the one in [9] will be employed in future steps.

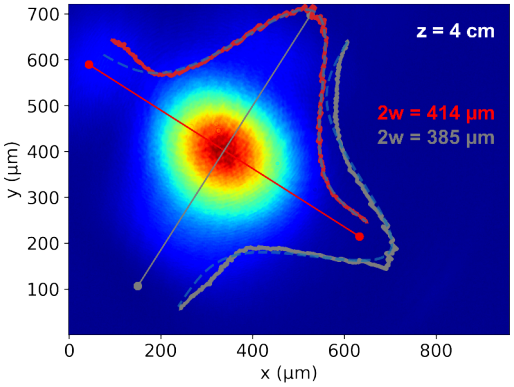

Fig. 3. (a) Experimentally measured beam profile at a height of z = 4 cm above the chip with two line profiles along the grating ridges (gray) and perpendicular to them (red). The ellipticity of the beam is due to the non-zero emission angle.

Figure 3 displays the experimentally acquired cross section profile of the emitted beam at a height of 4 cm above the grating coupler, corresponding to the location of the curved resonator mirror. The emission angle relative to the chip's surface normal was experimentally determined to be $-10.9°$. Due to additional refraction at the SiO_2/air-interface, the expected emission angle in air is $\theta_{\text{up}}^{\text{air}} = \arcsin(\frac{1.444}{1}\sin(-7°)) = -10.1°$, which closely matches the experimental value of $-10.9°$. This non-vertical emission accounts for the elliptical beam profile in cross-sections parallel to the chip's surface. Thus, the actual beam waist diameter $2w$ along the red axis in Figure 3 is 414 µm · cos(10.9°) = 407 µm, while the waist diameter of 385 µm along the gray axis does not need adjustment since this axis is oriented along the grating ridges. The resulting ellipticity of this design is therefore $e = 385\ \mu\text{m}\ /\ 407\ \mu\text{m} \approx 0.95$ at a height of $z = 4$ cm.

IV. Conclusion

In conclusion, we have shown a pathway and first steps towards designing compact ultra-stable laser resonators by employing a multi-functional resonator mirror approach. We experimentally demonstrated the feasibility of our cherry-picking design method for designing and fabricating fully-etched grating couplers on an SOI-platform that can emit collimated, large-scale Gaussian beams on the order of hundreds of micrometers.

***Abstract*— We show that periodic modulation of the refractive index of a nonlinear material on the wavelength scale can modify the angular dispersion of the interacting waves. This modification improves the phase-matching conditions and can significantly reduce beam walk-off. As a result, the efficiency of second-harmonic generation can be enhanced.**

***Keywords*— metamaterials, second harmonic generation, nonlinear optics, photonic crystals.**

I. Introduction

Efficient second-harmonic (SH) generation critically depends on the fulfillment of the Phase-Matching (PM) condition, which ensures that the interacting fundamental (FW) and harmonic waves propagate with matched phase velocities. In birefringent nonlinear media, exact phase matching is realized for a specific propagation direction (incidence angle) corresponding to a given fundamental frequency. In the present work, we restrict our analysis to the two-dimensional (2D) case; in a fully three-dimensional (3D) geometry, the phase-matching condition is satisfied along closed curves -typically circles or ellipses - in the azimuthal and polar angular domains.

In the vicinity of the PM point, the phase mismatch exhibits a linear dependence on the angular deviation from the phase-matching direction, as illustrated schematically in Fig. 1. In the angular (spatial Fourier) domain, this dependence defines the angular bandwidth of efficient SH generation. In the corresponding spatial domain, the linear phase mismatch manifests as a walk-off between the interacting fundamental and second-harmonic beams, arising from the anisotropic refractive index of the birefringent medium. This spatial walk-off leads to a progressive separation of the interacting beams and, consequently, to a reduction in the effective nonlinear interaction length. In the absence of walk-off, the SH intensity increases quadratically with the interaction distance, reflecting perfect phase matching over the interaction length. By contrast, when the walk-off is present, the overlap between the interacting beams diminishes with distance, and the SH conversion efficiency grows only linearly with the crystal length.

Here, we demonstrate that periodic modulation of the refractive index on a wavelength scale within a nonlinear crystal, implemented in both longitudinal and transverse directions, can substantially modify the fundamental phase-matching condition and profoundly alter the beam walk-off behavior. The underlying concept of this work is based on the well-established principle that periodic modulation of the refractive index on a scale comparable to the optical wavelength can significantly modify the spatial dispersion properties of propagating waves. This effect becomes particularly pronounced when both the longitudinal and transverse modulation periods approach specific resonant conditions, known as Talbot resonances. In the vicinity of such resonances, the periodic modulation induces strong coupling between spatial harmonics, leading to substantial modifications in the effective dispersion relations of the interacting waves.

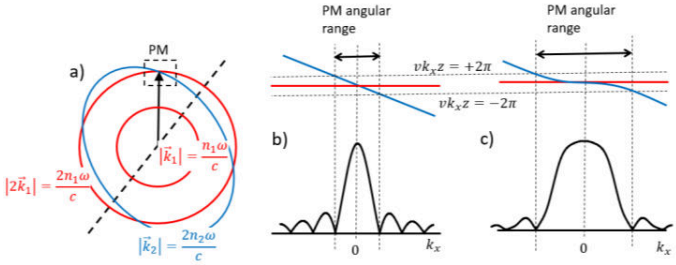

Fig. 1 a) The SH generation is at PM at a particular direction of the incident beam propagation (black arrow) at a PM angle with respect to the axis of birefringent media. b). In the vicinity of the PM point the dispersions of interacting waves can be approximated as linear ones with respect to k_x, crossing at a particular angle. This intersection angle results in a finite PM angular range of the second harmonics. c) The idea is to deform the dispersion curve in the vicinity of the PM point, in order to obtain a broader phase matching angular range.

II. METHODS

We employ the split-step beam propagating method to simulate the beam propagation, dispersion, and SH generation. The photonic crystal was estimated as being sinusoidally modulated along the transverse x and longitudinal z dimensions as a phase mask:

$$Mask = \Delta n \cdot \cos(\frac{x}{a_x}) \cdot \sin(\frac{z}{a_z}).$$

The complex beam envelope u was propagated along the photonic crystal by iterating:

$$u_{l+1} = \mathcal{F}^{-1}\left(e^{i \cdot Difr} \cdot \mathcal{F}(u_l \cdot e^{i \cdot Mask})\right),$$

where *Difr* is the normal, unmodulated dispersion that is either circular for the FW or a rotated ellipse for the SH.

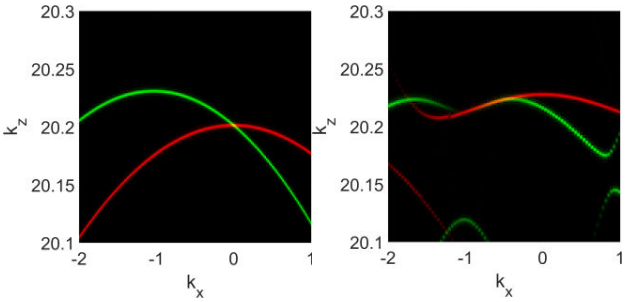

Fig. 2 Spatial dispersion curves of the FW (red) and the SH (green). The left image shows normal dispersion, whereas the right image shows engineered dispersion with a significantly greater overlap between the FW and SH.

Nonlinear coupling between the FW and SH is introduced as first-order finite-difference terms:

$$u_{l,\omega} = u_{l,\omega} + i \cdot k_\omega \cdot \frac{d_{eff}}{n_\omega} \cdot {u_{l,\omega}}^* \cdot u_{l,2\omega},$$

$$u_{l,2\omega} = u_{l,2\omega} + i \cdot k_{2\omega} \cdot \frac{d_{eff}}{n_{2\omega}} \cdot {u_{l,\omega}}^2,$$

where d_{eff} is the effective nonlinear coefficient.

III. RESULTS AND DISCUSSION

Broadening of the PM angle can be achieved for many configurations of the photonic crystal. One such example for β-BBO, corresponding to the dispersion curves shown in Fig. 2, is:

- $a_x = 2$ µm;
- $a_z = 26$ µm;
- $\lambda_{FW} = 1.03$ µm.

The equivalent angular conversion efficiency is shown in Fig. 3. The photonic crystal shifts the central PM angle by 2 degrees while broadening it from 0.12 degrees to 1.7 degrees. The peak SH generation efficiency in the photonic is approximately 43% of the unmodulated case.

It should be noted that this decrease in peak conversion efficiency is not exclusive to this particular example but rather a common factor for all configurations. This is because in a photonic crystal part of the radiation may project into dispersion bands other than the one exhibiting PM.

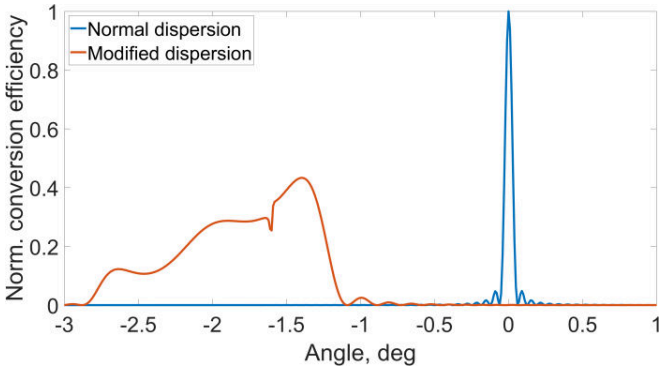

Fig. 3 Angular dependence of the normalized conversion efficiency for $a_x = 2$ µm; $a_z = 26$ µm, $\lambda_{FW} = 1.03$ µm. The crystal length is 5 mm.

While peak angular conversion efficiency is reduced, this may be less relevant for somewhat focused beams. In this case, rather than peak efficiency, the determining factor would instead be the integral of angular efficiency. Assuming the beam covered the entire PM area in each case, the modulated dispersion results in a 6.3 times higher total conversion efficiency.

IV. CONCLUSION

We have demonstrated control of spatial dispersion to enhance phase matching in second second-harmonic generation by the use of photonic crystals. The angular range of phase matching is increased by up to 14 times, while total conversion efficiency is increased by up to 6.3 times.

Abstract **— Zero angle of incidence polarizers in reflection/transmission based on Fano resonances in periodically nanostructured dielectric thin films are analyzed. Its main optical characteristics for 1064 nm wavelength are investigated in the context of laser applications, including laser damage evaluation with a discussion of resonance-related electric field distribution.**

Keywords**— polarization control, all dielectric structure, conformal deposition, optical damage, electric field distribution.**

I. Introduction

Linear polarizers are a kind of optical filter whose optical properties, as transmission/reflection, depend on the polarization state of incident radiation. The simplest example of polarization selectivity can be obtained with a plain glass substrate tilted at the Brewster angle, allowing partial reflection only for *S* polarization, but polarization contrast falls way below what a full-fledged polarizer must demonstrate. Up-to-date linear polarizers comprise a wide diversity, such as absorptive, birefringent or thin-films polarizers. These optical elements can provide an outstanding polarization extinction ratio of $>10^3$:1 [1]. However, most of them have exploitation inconveniences, coming from their inner structure: selective absorption-based polarizers have low laser-induced damage threshold (LIDT), excluding high-power applications; birefringent and thin-film polarizers are for non-normal incidence and are bulky solutions for space-limited optical systems. Considering these drawbacks, such already well-established polarizing elements can hardly be integrated into the resonators of constantly developing microlasers, such as microchip lasers or semiconductor VECSELs. Thus, there is an evident lack of compact radiation-resistant polarizers suitable for normal incidence.

Following this discussion, in this work, we explore and demonstrate ultra-compact, zero-angle polarizers, based on the waveguiding structure of dielectric nano-modulated thin films. The design of our polarizing structure consists of a high-index dielectric coating layer on a periodically patterned surface, as schematically shown in Fig. 1. Its main optical characteristics are investigated in the perception of the laser applications, including laser damage evaluation and its correlation with resonance-related electric field distribution within the structure.

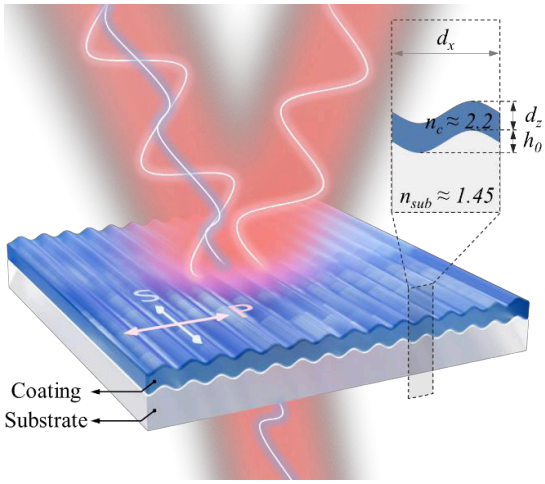

Fig. 1 Schematic representation of the geometry for the resonant coupling between normal incident waves and planar waveguiding modes [2].

II. Methods

Our methodology includes numerical simulations of the waveguiding structure's optical characteristics, optimization, followed by fabrication of the element and its experimental characterization. Target optical properties of the polarizing element were set for radiation of 1064 nm wavelength incident at 0° angle. Numerical simulations of the periodically structured polarizing element were calculated by a commercial solver of Maxwell-Bloch equations MC Grating [3]. Two distinct designs of single-layer and multilayer structures were created and experimentally realized via conformal deposition of dielectric layers on a pre-patterned substrate (with $d_x = 625$ nm, $h_0 = 200$ nm, variable layer thickness d_z) by ion beam sputtering technology.

Optical characterization included measuring transmission spectra for two orthogonal linear polarizations in the spectral range of 400 – 1400 nm for a normal angle of incidence. Optical resistance was evaluated with a laser-induced damage test for single-shot nanosecond pulses (1-on-1 test). After exposure, the surface was inspected with an optical microscope to verify the presence of damage and investigate its morphology.

Additionally, the contact profilometer was used to determine the damage profile.

III. Results and Discussion

A simple design of a thin single-layer coating of a high refractive index dielectric material, such as niobium oxide, was realized at subwavelength linear grating features a polarization-dependent Fano-like resonance. As a result, as shown in Fig. 2 (a, b), optimized thickness of the layer can form a high polarization contrast region around the target wavelength. Simulated transmittance values at 1064 nm are 0.0022 % and 98.12 %, while measured transmittance values are 96.22 % and 0.01 % for *P* and *S* polarizations, respectively. These experimental results correspond to an averaged polarization contrast of approximately 1:1000, with a more precise extinction ratio of 1:962. The discrepancy in transmittance for *P* polarization is attributed to back reflection of several per cent from the rear surface of the glass sample, which is not taken into account in the numerical evaluation.

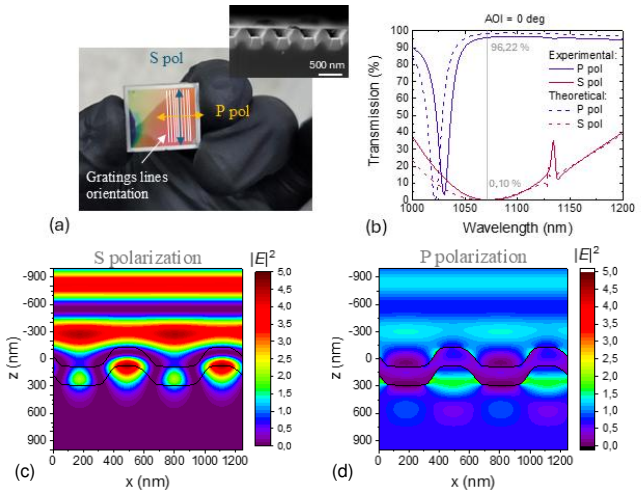

Fig. 2 Experimental realization of the polarizing waveguiding structure: (a) a photograph of the sample and an SEM cross-section of the fabricated structure; (b) Transmittance at 0° angle of incidence for *S* and *P* polarizations; (c, d) simulated electric field distribution within the single-layer structure for perpendicular polarizations for 1064 nm wavelength [2].

Considering laser applications, another important aspect to discuss is the laser damage, which is tightly connected to the distribution of the electric field within the structure. As it is known, strong field localization can lead to a significant intensity enhancement, which increases the probability of structural damage and thus lowers the laser-induced damage threshold (LIDT).

The LIDT measurement of the presented single-layer polarizing structure showed values of 0,7 J/cm² for *S* polarization and 3,1 J/cm² for *P* polarization. The correlation for both polarizations coincides with the respective field distributions within the structure, which are shown in Fig. (c, d). Since the architecture of the waveguiding structure is optimized for operation at *S* polarization resonant condition, its higher field enhancement (evident from the color scale) within the coating results in optical damage at lower laser fluence, compared with the off-resonance condition for *P* polarization at target wavelength. Nevertheless, these LIDT values are already higher than those reported for commercial 0° angle-of-incidence polarizers [4].

Since a single-layer thin film structure does not possess much optimization freedom in order to improve the optical resistance, the multilayer architecture was realized. Experimentally formed multilayer structure showed a slight improvement of LIDT and a more evident correlation of laser-induced damage and electric field distribution within the coating, which will be discussed during the presentation.

IV. Conclusion

The main conclusion is that an ultracompact thin-film polarizer has been proposed, designed, and experimentally demonstrated. The polarizer shows theoretically unlimited contrast for monochromatic plane waves at normal incidence and has experimentally achieved values as high as approximately 1:1000. Polarization-selective resonant phenomena occurring in subwavelength high refractive index structures cause increased electric field intensity, favouring lower laser-induced damage threshold values. As this investigation suggests, further work is ongoing to optimize the architecture of the polarizer and its electric field distribution in order to further enhance the polarization contrast ratio and LIDT.

I. Introduction

Optical metasurfaces as two-dimensional structures composed of subwavelength-sized nanoscatterers, commonly referred to as meta-atoms, can be used to tailor light-matter interaction for applications, e.g., in sensing or multispectral photodetection. [1] Metasurfaces offer remarkable control over the phase and propagation of light, their fabrication on 300 mm substrates has been successfully demonstrated. However, the front-end-of-line integration into device fabrication processes on the cost-effective complementary-metal-oxide-semiconductor (CMOS) platform remains challenging. [2] Possible advantages of integrating metasurfaces as functional layers directly into devices comprise realizing new device functionality such as wavelength- or polarization-selectivity while simultaneously harnessing electromagnetic field enhancement within the metasurface for absorptance enhancement compared to bulk photodiodes with the same thickness of the absorbing layer.

II. Methods

The fabrication of our CMOS compatible Ge metasurfaces (Fig. 1) was performed in a state-of-the-art 0.13 µm SiGe BiCMOS technology pilot line for 200 mm wafers [3], by structuring an oxide/nitride mask using deep ultraviolet photolithography and reactive ion etching. Subsequently, selective epitaxial growth of Ge was carried out by reduced pressure chemical vapor deposition (RPCVD) [4]. Ge metasurfaces with footprints of 3x3 mm^2 were obtained, with pitches ranging from 490 nm to 1165 nm and diameters of the individual Ge pillars ranging from 245 nm to 850 nm.

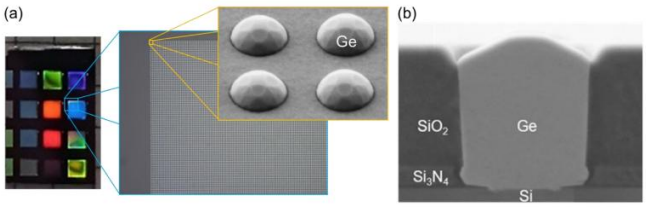

Fig. 1 (a) Images of metasurfaces as well as the constituent meta-atoms obtained from optical and scanning electron microscopy. (b) Cross-sectional scanning electron microscopy image of a single meta-atom of the metasurface fabricated using chemical vapor deposition of Ge into a nanostructured SiO_2/Si_3N_4 mask. Epitaxial growth of the Ge nanostructures on the Si wafer has been achieved.

Optical characterization was carried out using a Bruker Invenio Fourier-transform infrared (FTIR) spectrometer coupled to a Bruker Hyperion II FTIR microscope with an InGaAs detector. Absorptance spectra of the metasurfaces on substrate were derived from transmittance and reflectance measurements. Transmittance measurements of an adjacent unstructured substrate area enabled the separation of wafer absorption from metasurface absorption and Fabry-Pérot inferences of the SiO_2. The metasurface absorptance was obtained using a de-embedding approach [5]. Additionally, the absorptance of the metasurface was simulated using the rigorous coupled-wave analysis (RCWA) method [6].

Reflectance spectra at incidence angles of 10°, 15° and 20° with p-polarization were measured using a LAMBDA 1050+ UV/Vis/NIR spectrometer with a Si-detector for the 1000 nm - 1100 nm wavelength region and a n InGaAs detector for the 1100 nm - 2000 nm wavelength region.

III. Results and Discussion

Our metasurface is designed as the absorbing layer of a wavelength-selective photodetector in the near-infrared range. A full device integration requires in particular the realization of a top electrode. In this work, we focus on FTIR and wavelength-dependent reflectance spectroscopy measurements of the metasurface itself. The metasurface's optical behavior arises from the interplay between Mie resonances of the individual meta-atoms, collective lattice resonances due to their mutual coupling and diffraction grating effects. Here, the optical properties are investigated as a function of pitch (P) and diameter (D).

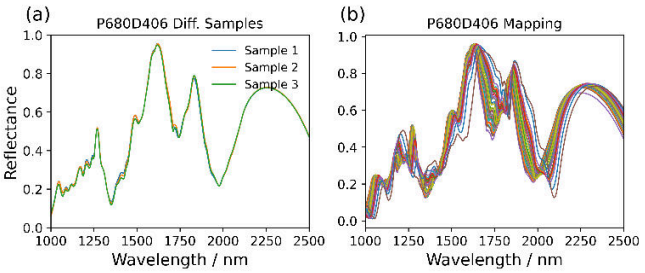

Fig. 2 (a) Reflectance spectra measured by Fourier-transform infrared (FTIR) spectroscopy on (a) the center of different metasurfaces with the same geometry from different positions on a 200 mm wafer and (b) at 30 different positions on the same 3 x 3 mm^2 metasurface (mapping).

Reflectance measurements demonstrate the homogeneity of optical properties when comparing different metasurfaces with the same geometry at different positions on the wafer (Fig. 2 (a)). Furthermore, 30 measurements taken on the same 3 x 3 mm^2 metasurface with an illumination spot size of 100 µm × 100 µm show good agreement (Fig. 2 (b)).

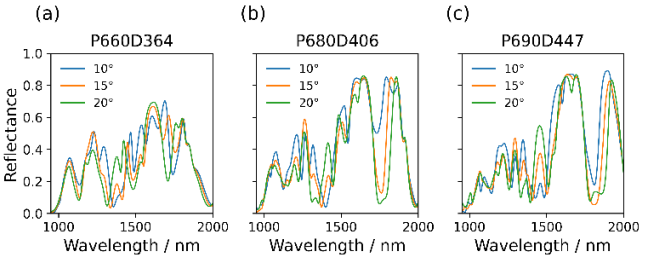

Fig. 3 Measured reflectance spectra at different angles of incidence for metasurfaces with different pitch (P) and diameter (D) (a) P = 660 nm and D = 364 nm, (b) P = 680 nm and D = 406 nm, and (c) P = 690 nm and D = 447 nm.

Reflectance measurements of the metasurfaces under varying angles of incidence show a large dependence of the reflectance on the angle of incidence (Fig. 3). This is also relevant for the measured absorptance spectra. The absorptance spectra of the metasurfaces are predicted by simulation to exhibit multiple absorption peaks governed by the optical resonances (Fig. 4 (a-c)). Increasing diameter and pitch shifts the absorptance peaks to higher wavelengths. In the measured absorptance spectra, the drop in absorption at wavelengths corresponding to the bandgap of Ge is well reproduced, however, no clearly defined peaks are visible. We attribute the difference between measurement and simulation mainly to a variation in the angle of incidence induced by the objective of our FTIR measurement setup. This aspect will be addressed in future metasurface designs.

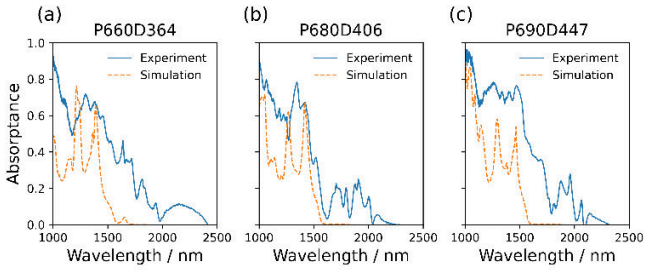

Fig. 4: Measured and simulated absorptance spectra for metasurfaces with different pitch (P) and diameter (D) (a) P = 660 nm and D = 364 nm, (b) P = 680 nm and D = 406 nm, and (c) P = 690 nm and D = 447 nm.

IV. Conclusion

We present first results of the optical characterization of CMOS compatible Ge-based metasurfaces with geometry-dependent absorption spectra in the near-infrared range. Our results are the starting point for the development of wavelength-dependent photodetectors for wavelengths up to 1600 nm on the Si photonics platform.

***Abstract*— We address a fundamental question – What is the ultimately minimal embodiment of optical objects that produce useful optical effects? We show that such an object does not require non-zero physical and optical-path-length volume. Two-dimensional polarizing sheets are the minimal optical objects and practically realizable using 2D materials or polarizing ceramics.**

***Keywords*— low-dimensional materials, photonic lattices, guided-mode resonances.**

I. Introduction

A common intuition in optics is that a structure becomes optically inactive when its optical path length and physical thickness simultaneously approach zero. In such an extreme sparsity limit, no phase delay can be accumulated within the material, and the elementary processes that give rise to reflection, diffraction, and scattering are therefore expected to disappear. From this perspective, a system with strictly vanishing optical path length would conventionally be regarded as incapable of producing any meaningful optical response.

Nevertheless, recent developments in atomically thin material systems challenge this conventional notion that finite optical path length is necessary for producing substantial optical effects. Experiments on atomic monolayer of transition-metal dichalcogenide and graphene sheets have demonstrated guided propagation of visible and infrared waves even as their characteristic optical path length effectively vanishes, indicating that optical functionality may persist in the limit of vanishing OPL.

In this study, we examine the limiting case of a susceptibility distribution whose optical path length is strictly zero. We show that zero-OPL δ(x) susceptibility is a conceptually minimal embodiment capable of supporting the fundamental processes of reflection, diffraction, and guided propagation, as well as their coherent combinations. Furthermore, when such zero-OPL sheets are arranged into resonant periodic arrays, their individual responses combine to yield pronounced and functionally useful optical effects that extend beyond previously reported single-sheet waveguiding phenomena. We briefly discuss the relevance of these findings to lower-frequency spectral regimes, where material platforms with exceptionally large polarizability are more readily available.

II. Results

We begin by considering a planar slab composed of a fictitious dielectric medium whose permittivity is defined to scale inversely with its physical thickness h such that

$$\varepsilon_s = 1 + L_\delta h^{-1}, \quad (1)$$

as schematically illustrated in Fig. 1A. When the slab thickness enters the deep-subwavelength regime $h \ll \lambda$, this construction approaches the behavior of a two-dimensional material whose optical path length becomes effectively vanishing. In the limit $h \to 0$, OPL thickness $h_{OPL}=\varepsilon_s^{1/2}h=(h^2+L_\delta h)^{1/2}$ of the slab tends to zero while the susceptibility integrated across the slab thickness, *i.e.*, $\int\chi\cdot dx = \int(\varepsilon_s-1)\cdot dx = L_\delta$, remains a non-zero constant at L_δ, as shown in Fig. 1B. Thus, even though h_{OPL} disappears in this limit, the persistence of this finite integrated susceptibility suggests that appreciable optical response may still arise from the slab. Surface dipole density S_P under unit applied electric field is determined by $S_p=\varepsilon_0\int\chi\cdot dx=\varepsilon_0 L_\delta$ which does not depend on h. Therefore, the vanishing-OPL thickness of this fictitious slab can be interpreted as a medium compression of 3D dielectric medium in to a 2D material while conserving the total electric dipoles of the medium which serves as the fundamental origin of optical effects.

More rigorous argument can be obtained directly from mathematical principles of the classical electrodynamics. By introducing an ideal zero-OPL δ-dielectric sheet into the Maxwell equations and imposing corresponding interface conditions, a noteworthy feature emerges: a discontinuity appears in the first-order spatial derivative of the tangential field normally across the sheet. This jump in the first-order derivative constitutes the electromagnetic signature of the zero-OPL δ-dielectric sheet and give rise to significant partial reflection even though the sheet has vanishing h_{OPL}. For plane-wave incidence on a zero-OPL δ-dielectric sheet, non-zero reflection coefficient $r_{s/p}$ are obtained for both transverse-electric (TE) and transverse-magnetic (TM) polarizations as

$$r_s = i\sin u_s \exp(iu_s) \text{ and } r_p = -i\sin u_p \exp(iu_p), \quad (2)$$

where the parameter $u_{s/p}$ is given by $u_s=\tan^{-1}(\sigma_\delta \sec\theta)$ and $u_s=\tan^{-1}(\sigma_\delta \cos\theta)$ with $\sigma_\delta=\pi\varepsilon_b^{-1/2}(L_\delta/\lambda)$.

Beyond reflection, zero-OPL δ-dielectric sheet also supports optical guiding for TE polarization. A fundamental TE guided-mode solution with effective index

$$n_f = n_b\sqrt{1+\sigma_\delta^2} \quad (3)$$

This guiding effect persists even in the weak-polarizability regime $\sigma_\delta << 1$ where $n_f \approx n_b(1+\sigma_\delta^2/2) > n_b$, ensuring that the guided mode remains robust.

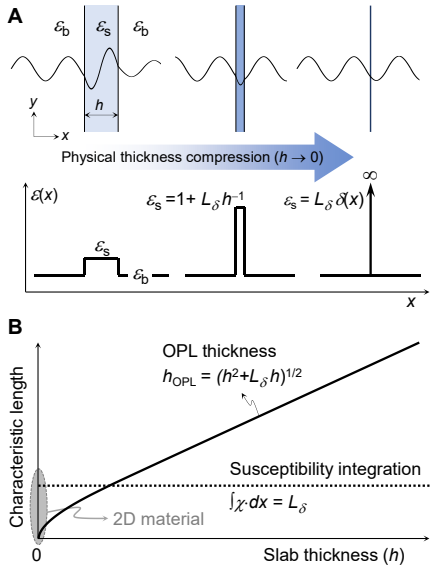

Figure 1 . Concept of a zero-OPL δ-dielectric sheet. A) Schematic representation of a fictitious dielectric slab which gradually morphs into a 2D dielectric material in its vanishing thickness limit ($h \to 0$). B) Essential h-dependence of the OPL thickness and susceptibility integration length of the fictitious dielectric slab.

We further investigate horizontal arrays of zero-OPL δ-dielectric sheets under TE-wave incidence. In this configuration, the elementary responses of individual sheets combine coherently across the array, giving rise to pronounced collective optical behavior.

We consider a subwavelength-periodic array structure schematically illustrated in Fig. 2A. Because each sheet produces partial reflection, as discussed earlier, the periodically arranged segments modulate the incoming wave and generate a set of discrete diffracted components propagating at well-defined angular orders. Under appropriate phase-matching conditions, one of these diffracted orders can couple to a guided mode supported by the zero-OPL sheet, producing a guided-mode resonance (GMR). This resonance manifests as a sharp spectral feature accompanied by strong variations in both the amplitude and phase of the reflected and transmitted fields. The phase-matching occurs when the in-plane wavevector of a diffraction order coincides with the effective propagation constant of the guided mode, leading to the pronounced resonant response characteristic of guided-mode resonance.

To validate the analytical prediction, we compare it with numerical simulations performed using rigorous coupled-wave analysis (RCWA). Since an ideal δ-function permittivity profile cannot be directly implemented within a conventional RCWA framework, we instead employ an approximate model in which each δ-sheet is replaced by an ultrathin high-index dielectric slab consistent with Eq. (1) in the deep-subwavelength OPL-thickness limit of $\varepsilon_s^{1/2}h << \lambda$. We confirm that, in a deep-subwavelength thickness limit of $h/\lambda < 10^{-2}$, this approximate-slab accurately yields propagation constants and mode profiles that closely match those of the ideal guided mode described by Eq. (3). This agreement confirms that the RCWA model faithfully captures the physics of the zero-OPL sheet in the vanishing-thickness limit

The predicted GMR clearly appears in our sufficiently converged RCWA model, as shown in Figure 2B for the angular spectrum map and Figure 2C for the spectral profile at angle of incidence θ = 20°. The simulated resonance exhibits characteristic GMR signatures, including an asymmetric Fano-like lineshape and the formation of a spectral gap near normal incidence. The detailed parameter values used in the simulation are summarized in the figure caption.

The RCWA spectra are in close agreement with the theoretical dispersion obtained from the phase-matching condition. In Fig. 2B, the calculated dispersion curves are overlaid and accurately trace the loci of the observed resonances. Furthermore, field distributions shown in Figs. 2D and 2E at λ/Λ=1.66 demonstrate that the resonant fields in the RCWA structure correspond closely to the guided mode supported by the ideal zero-OPL δ-dielectric sheet. This comparison confirms that the observed GMR originates from coupling to the underlying guided mode of the zero-OPL interface.

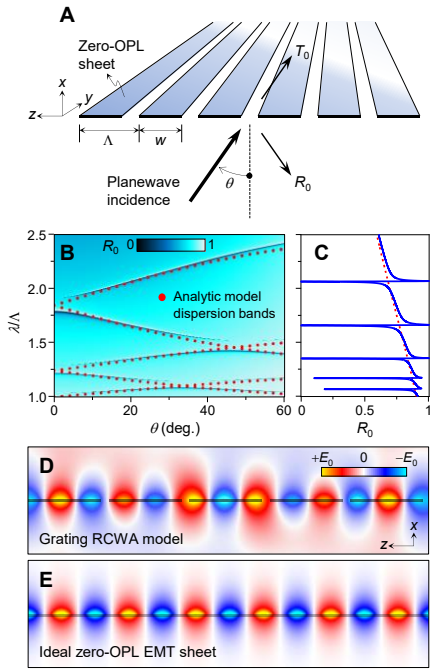

Figure 2. Horizontal guided-mode resonance. (a) Schematic

of a horizontal periodic array composed of zero-OPL δ-dielectric sheets. (b) Reflectance map calculated for an approximate-slab grating model (Λ = 1.5 μm, w = 1.35 μm, ε_s = 1+10^4, h = 0.15 nm) as a function of incidence angle θ and normalized wavelength λ/Λ. The overlaid red dots indicate analytic model dispersion bands for the fundamental guided mode supported in an ideal zero-OPL EMT sheet (L_δ = 1.35 μm). (c) Spectral reflectance profile (blue solid curve) extracted from (b) at θ = 20° compared with the non-resonant reflectance spectrum (red dotted curve) of an ideal zero-OPL EMT sheet predicted by Eq. (2). (d) Spatial distribution of electric field component Ey at the resonance center at λ/Λ = 1.66 and θ = 20° obtained from the RCWA model. (e) Corresponding guided-mode field profile Ey for the ideal zero-OPL EMT sheet at λ/Λ = 1.66.

III. Conclusion

We have identified a zero-OPL polarizing sheet as a conceptually minimal embodiment capable of producing fundamental optical responses. When such a sheet is appropriately structured to sustain resonant excitations, it can generate pronounced and practically useful optical functionality despite possessing vanishing optical-path-length thickness. An intuitive model and a corresponding theoretical framework have been developed to describe elementary processes such as partial reflection and guided propagation in this idealized zero-OPL limit.

Using rigorous numerical simulations, we confirm both the fundamental characteristics predicted by the idealized theory and the emergence of pronounced optical responses in horizontal arrays of zero-OPL sheets, arising from guided-mode excitations that operate in essentially the same manner as in their three-dimensional structural counterparts.

Intriguingly, our result suggest a conceptual framework for realizing optical or electromagnetic components that occupy minimal physical volume while remaining mechanically flexible and dynamically responsive. Such functionality may be implemented using 2D material platforms or other media exhibiting strong electric polarizability. In particular, dielectric constants on the order of 10^2 – 10^3 in the MHz–GHz frequency range are available in several ceramic systems, including $CaCu_3Ti_4O_{12}$, $Cu_2Ta_4O_{12}$, and $La_{15/8}Sr_{1/8}NiO_4$. Taking the approximation scheme in Eq. (1) into account, compact and lightweight optical components can be constructed while maintaining strong electromagnetic response.

I. Introduction

Metasurfaces are thin optical devices, that can influence the phase, amplitude, and polarization of light. As those properties can be tailored precisely along the surface, a metasurface can reflect light with a defined angle of incidence θ_i to an arbitrarily defined angle of reflection θ_r. The ability to reflect light in a direction that deviates from the conventional law of reflection is the defining feature of anomalous reflecting metasurfaces. Metasurfaces with this behavior are called anomalous reflecting metasurfaces or anomalous reflecting metamirrors.

Anomalous reflecting metamirrors can be divided into two categories: local and nonlocal. The behavior of local metasurfaces is dictated by individual meta-units [1]. This means that the optical response of each element depends exclusively on its own geometry and is not influenced by interactions with neighboring structures. As a result, the entire metasurface can be considered as an array of independent building blocks. Though this approach does impose limitations of reflectivity on the anomalous reflecting metasurface.[2].

To overcome these limitations, nonlocal metasurfaces can be utilized. Here each individual structure contributes to the formation of one collective mode across multiple adjacent meta-units. The physical principle underlying nonlocal metasurfaces is the interaction of energy with evanescent surface waves traveling along the surface. While the metasurface modifies the electromagnetic field, these surface waves act as energetic channels that transport energy along the metasurface. The interference of these surface waves with the incident and transmitted fields results in a targeted redistribution of power density at the surface. This directs the energy in the desired direction and reflects it back into the free space [3]. In this way, the energy can not only be redistributed locally but also actively directed back toward the desired direction, theoretically, without causing energy losses. These mechanisms of energy circulation along the surface are essential for passively and losslessly realizing sophisticated functions such as anomalous reflection or directional changes [3].

Therefore, the response of the surface to the incident light for nonlocal metasurfaces is tailored by the interacting meta-units [1]. One meta-unit can be a distinct metaatom or one section of a larger metaatom. This holistic approach allows for higher precision in the description of the forming mode at the surface. Hence, the reflectivity can be increased compared to local anomalously reflecting metasurfaces. However, to design a highly efficient anomalous reflecting metasurface the dimensions of all meta-units have to be very precise. Hence, to consider all meta-unit interactions and design the perfect mode at the surface, simulations with optimization approaches are most promising.

Highly efficient anomalous reflecting metasurfaces allow for increasing the optical beam length in space-limited setups. Herriott cells are one configuration where an increased beam length is achieved by a folded light path. To shape this light path, Herriott cells use concave mirrors. Since metasurfaces are planar and significantly thinner than concave mirrors, they are better suited for compact integration. Hence, metasurfaces are a promising alternative to decrease the thickness of the cells and simplify the ability to integrate these cells into on-chip devices.

Another field of application is rubidium and cesium isotope analysis. Here, a folded light path is able to increase the interaction length between the light and the alkali vapor, similar to the approach proposed in [4]. This increased interaction length enhances the sensitivity of the measuring system and thereby lowers the limit of detection. These systems exploit the high absorption cross-sections of the alkali atoms at their respective D1 and D2 transitions. Consequently, the anomalous reflecting metamirrors must be designed specifically for these target wavelengths: $794.98\ \mathrm{nm}$ (D1) and $780.24\ \mathrm{nm}$ (D2) for rubidium, and $894.59\ \mathrm{nm}$ (D1) and $852.35\ \mathrm{nm}$ (D2) for cesium. Given the narrow linewidths of these transitions, the operation frequency of the metamirrors has to fit these wavelengths for maintaining high reflectivity at the exact resonance frequencies.

An example of a configuration that increases the beam length is shown in Figure 1. The beam path starts at the incoupling point. Afterwards it hits the first anomalous reflecting metasurface normally. The reflection of the anomalous

metasurface is now under an angle. This directs the beam path into a zig-zag configuration formed by regular reflecting metasurfaces. At the end of this section is another anomalous reflecting metasurface, which reflects the incoming light. The incoming light is incident under an angle and gets reflected normal to the surface. Now the light can couple back out into free space or be reflected back into another zig-zag configuration in the same way described. Each transition between two zig-zag configurations can be used as a point to rotate the next zig-zag path to the previous one. Thereby, the square shape depicted in Figure 1 can be achieved.

As described earlier, the rubidium and cesium analysis operates at distinct wavelengths. The same accounts for gas sensing applications that utilize Herriott cells. They have to operate at wavelengths matched to the absorption of the gases detected. Each wavelength needs a specific metasurface with distinct dimensions and materials designed for the exact wavelength. In this work, we focus on a design wavelength of $1550\ \mathrm{nm}$. This choice is motivated by the high maturity of silicon-on-insulator (SOI) fabrication processes, which allows for sub-nanometer control over the Bezier-defined geometries. By utilizing this established platform, we can precisely characterize the physical limits and challenges of nonlocal mode excitation. The methodology and the resulting design rules are inherently scalable, providing a direct blueprint for the realization of metasurfaces at the specific resonance frequencies required for rubidium and cesium analysis.

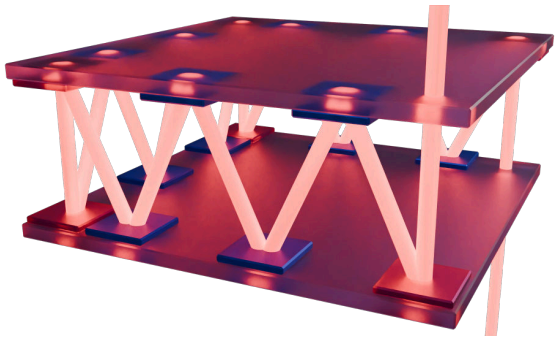

Fig. 1. Schematic configuration of the folded beam path utilizing anomalous reflecting metasurfaces. Inspired by the Herriott cell design, this setup increases the interaction length by folding the beam between two parallel substrates. The anomalous reflecting metasurface pairs in the corners (red) redirect the beam and rotate the propagation plane by $90°$, while regular reflecting metamirrors (blue) maintain the periodic zig-zag pattern.

II. Methods

The design of a nonlocal anomalous reflecting metasurface requires a holistic approach, as the individual contributions of each meta-unit and their mutual interactions must be fully accounted for. A high number of degrees of freedom is necessary to tailor both the meta-atoms and the gaps between them to excite the specific surface modes required. Since a single parameter change can influence the entire mode profile, even slight dimensional variations in one meta-unit may alter the overall functionality of the surface. This interdependency results in complex meta-atom geometries and necessitates a dedicated optimization approach, where the dimensions of each meta-unit serve as independent degrees of freedom.

The primary objective is to maximize the reflectivity of the metasurface at a specific anomalous angle, which serves as the figure of merit for the optimization. For this task, Rigorous Coupled-Wave Analysis (RCWA) offers several distinct advantages. Since the metasurface is treated as a periodic arrangement, RCWA leverages the Floquet-Bloch theorem to solve Maxwell's equations in Fourier space. This approach eliminates the need for full-volume meshing, thereby significantly reducing memory overhead and execution time compared to FDTD or FEM. Furthermore, RCWA inherently calculates the complex amplitudes of specific diffraction orders. For an anomalous reflector, this allows for the direct extraction of power flow into the target angle, bypassing the need for additional near-field to far-field transformations. Finally, as a frequency-domain method, RCWA provides high accuracy for monochromatic sources, such as the $1550\ \mathrm{nm}$ wavelength used in this work, while avoiding the dispersive errors or long stabilization times often encountered in time-domain simulations.

The optimization focuses on the shape and fill factor of each unit cell to define the diameter of each meta-unit. These parameters are defined by 20 control points, as illustrated in Figure 2. They are spaced equally along the y-direction with an optimizable lateral gap. To ensure symmetry along the x-axis, the points are mirrored across the y-axis. All points are connected using Bezier curves to prevent fabrication inaccuracies typically associated with sharp corners.

Fig. 2. Schematic visualization of the design approach for the Bezier-shaped metaatom. The unit cell is shown in gray and the metaatom in orange. Red markers indicate the control points used for optimization, while the purple line represents the resulting Bezier curve. For clarity, only 10 control points are displayed, whereas 20 points are utilized in the full optimization process. The incident wave propagates along the negative z-direction, and the reflected wave propagates along the positive z- and positive y-direction

III. Results and Discussion

To satisfy the design restraint of the anomalous reflecting metasurfaces described in Figure 1, the angle of incidence of the simulation is set to zero degrees. For this configuration the highest anomalous reflectivity the optimization was able to achieve so far is $R_{an} = 90.92\ \%$ for an angle of $38.5°$. It corresponds to the geometry shown in Figure 3. This figure also shows the angular reflectivity distribution. A fraction of the incident power is still redirected into parasitic diffraction orders, specifically the 0^{th} and the -1^{st} orders. Given that

the total reflectance of the metasurface is $R_{\mathrm{total}} = 93.51\ \%$, it follows that $2.59\ \%$ of the total intensity is shifted into these unwanted orders.

However, the optimization result is limited by several factors. The described power redistribution along the surface does not perfectly transfer to the desired reflection order if the geometry does not precisely match its condition. The constraints on the unit cell size and the height of the metaatom lower the degrees of freedom for the optimization and thereby limit the power redistribution. Additionally, the number of generations of the optimization was limited as well to save computational time. Future optimization runs with a higher number of generations are expected to further enhance the anomalous reflectivity.

Fig. 3. Visualization of the shape of the optimized metaatom (left) and corresponding Polar-Plot of the angle dependant reflectivity (right). The peak anomalous reflectivity for a wavelength of $1550\ \mathrm{nm}$ of $90.92\ \%$ is achieved at $38.5°$.

IV. Conclusion

In this work, we have developed an optimization-based design for a nonlocal anomalous reflecting metasurface at $1550\ \mathrm{nm}$. By utilizing a semicontinuous metaatom geometry defined by Bezier curves and a TPE optimization approach, we achieved an anomalous reflectivity of $R_{an} = 90.92\ \%$ for an angle of $38.5°$.

The ability to steer light at normal incidence with high efficiency is a crucial step toward the realization of compact, on-chip folded beam paths. Such setups, inspired by the Herriott cell, can significantly increase the interaction length for gas sensing or isotope analysis while maintaining a minimal footprint. The detection sensitivity can be increased by this increased interaction length.

Future work will focus on scaling the optimization to a higher number of generations to further suppress parasitic diffraction orders and approach the ideal lossless reflection regime. Additionally, the robustness of the optimized geometries against fabrication tolerances will be investigated. Following the experimental characterization of the fabricated metasurfaces, the measured performance data will be reintegrated into the optimization loop to further refine the designs and achieve even higher reflectivities.

***Abstract*— Underwater detection of airborne sound is challenging because acoustic waves significantly attenuate when propagating from air into water. We present a meta-acoustic sensor combining a piezoelectric element and a perforated 3D-printed cavity. Quarter-wave resonance selectively amplifies weak airborne acoustic signals at multiple target frequencies underwater while suppressing background noise.**

***Keywords*— metamaterials, multi-frequency, signal amplification, underwater, acoustic waves.**

I. Introduction

Detecting airborne acoustic sources from underwater environments is challenging because acoustic waves undergo strong reflection and severe attenuation when propagating from air into water [1,2]. Resonant acoustic structures offer a potential solution by selectively amplifying weak signals at target frequencies. In particular, quarter-wave resonance cavities can enhance acoustic pressure through standing-wave formation within confined structures. Here, we propose a metastructure-based underwater acoustic sensor that exploits quarter-wave resonance to selectively amplify weak acoustic signals at multiple target frequencies. The sensor integrates a piezoelectric element with a perforated cavity structure designed to support multiple resonant modes. Our results demonstrate significant signal enhancement, achieving a maximum 43-fold increase in voltage response compared with a conventional configuration.

II. Methods

The proposed sensor is composed of a 3D-printed structure containing an off-center slit, which promotes bending-dominated deformation of the structure. Because bending stiffness is substantially lower than compressive stiffness, this deformation mode effectively reduces the acoustic wave speed within the structure. The resulting slow-wave effect enables quarter-wavelength resonance within a subwavelength cavity. Depending on the resonance order, mechanical stress is either concentrated or suppressed at the location where the piezoelectric element is attached. Specifically, stress maxima occur at odd multiples of the quarter-wavelength resonance, while stress minima appear at even multiples, enabling simultaneous amplification and suppression of multiple frequency components. The resulting stress modulation is converted into electrical signals by the piezoelectric element, producing frequency-selective signal amplification and suppression.

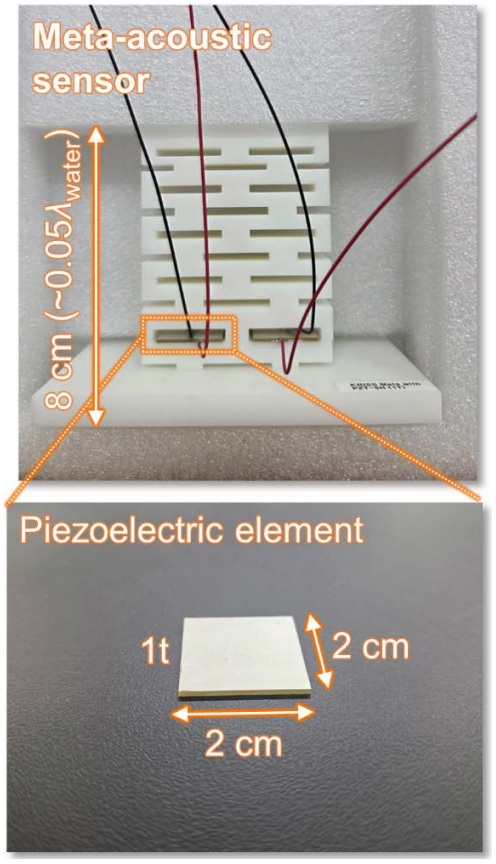

Fig. 1 Geometry of the meta-acoustic sensor composed of a metastructure integrated with a piezoelectric element.

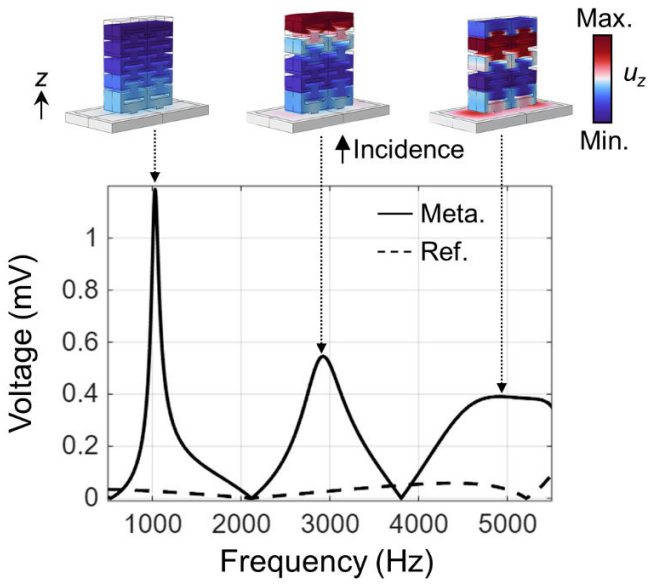

Fig. 2 Voltage response of meta-acoustic sensor. The pressure wave is incident along the z-direction, and the corresponding displacement distribution in the z-direction at the peak frequency is presented. "Meta." and "Ref." denote the metastructure-integrated sensor and the reference sensor without the metastructure, respectively.

III. Results and Discussion

- Selective amplification near 1, 3, and 5 kHz corresponding to odd multiples of the quarter-wave resonance, with suppression near 2 and 4 kHz.
- Up to a 43-fold increase in voltage response compared with the reference sensor without the metastructure.

IV. Conclusion

This study presented an underwater acoustic sensing strategy for enhancing weak airborne acoustic signals in underwater environments. The signal amplification mechanism of the metastructure-based acoustic sensor, arising from structural resonance, was systematically investigated. Our results confirmed that the proposed meta-acoustic sensor provides significantly improved sensitivity compared with a reference acoustic sensor. These results suggest that the proposed approach offers a promising pathway for high-sensitivity underwater detection and may be extended to advanced underwater sensing systems for airborne source monitoring.

Temporal Coupled Mode Theory for a Single Floquet-Sheet Resonator

Yao-Ting Wang* and Hsu-Hui Chou

Department of Photonics, National Sun Yat-sen University, Kaohsiung, 80424, Taiwan
*Corresponding author: ytwang@mail.nsysu.edu.tw

We develop a rigorous Temporal Coupled-Mode Theory (TCMT) specifically tailored for a single Floquet-sheet resonator governed by time-modulated conductivities. By invoking photon-number conservation during frequency conversion, we derive characteristic radiative decay rates and coupling coefficients that account for the frequency ratio between channels. We establish a systematic bridge to the Floquet Transfer Matrix Method (TMM), providing closed-form analytical expressions that map scattering parameters to the Drude-type physics of the sheet. Our model explicitly captures the resonant coupling between the 0th-order propagating channel and the -1st-order surface-mode channel. Validated by COMSOL numerical simulations, the theory remains robust even when intrinsic material loss is incorporated. This framework offers an intuitive pole-expansion representation for designing time-varying photonic interfaces.

***Keywords*— Temporal Coupled-Mode Theory, Transfer Matrix Method, Floquet-sheet resonator, time-varying media.**

I. Introduction

In the latest decade, the field of photonics has witnessed a major transition from spatially inhomogeneous structures to temporally modulated systems. Time-varying materials have opened up unprecedented avenues for controlling light-matter interactions, such as temporal aiming [1], multiple light conversion [2]. By modulating the constitutive parameters of a medium, on a timescale comparable to the optical cycle, researchers have demonstrated exotic phenomena including adiabatic frequency conversion [3], topological effects in photonic time crystals [4], and the electronic circuit for time-reversal wavefronts [5]. While conventional metamaterial/photonic crystals rely on spatial periodicity to control the wavevector, time-varying media utilize temporal modulations to redistribute energy across the frequency spectrum.

To provide a unified and analytically tractable description of these resonant systems, TCMT has emerged as a cornerstone in the photonic community. TCMT was firstly proposed by Fan and colleagues [6][7][8] to describe systems with energy conservation and time-reversal symmetry. In their a series of seminal articles, a resonator is characterized by its eigenfrequency, radiative decay rates, and coupling coefficients to external ports. For time-modulated systems, TCMT can be used as a powerful tool to separate different modal coupling. It allows for the description of frequency conversion as a resonant process, where energy is exchanged between different Floquet channels through a discrete set of coupling equations, ensuring that the complex physics of time-varying systems can be understood through a compact, intuitive pole-expansion representation.

Despite the success of TCMT in describing various time-varying photonic resonators, its application to Floquet-sheet resonators, specifically those governed by time-modulated conductivities/Drude weight, remains unexplored. While numerical approach like transfer matrix method (TMM) can simulate these systems, a rigorous analytical bridge that connects the macroscopic scattering parameters to the microscopic physics of the sheet is still missing. Particularly, the relationship between the surface modal excitation in the -1st Floquet channel and the resulting scattering in the 0th channel has not been fully formulated within a TCMT framework. This paper seeks to fill this gap by developing a TCMT model specifically tailored for a single Floquet sheet and establishing a systematic connection to the TMM. Furthermore, the underlying concepts and the mapping procedure established herein are generalizable to a wide range of other time-varying resonant systems.

II. Methods

Figure 1 illustrates a Floquet sheet whose surface current density obeys a lossless Drude-type dynamic equation $dJ/dt = \eta_0^{-1} W_p(t) E_x$, where η_0 is vacuum impedance and the Drude weight $W_p(t)$ is temporally modulated as

$$W_p(t) = W_{p0}\left(1 + 2\alpha\cos\Omega t\right). \quad (1)$$

If the surface modal excitation is described by a complex amplitude a, then the excitation dynamics induced by the Floquet sheet with modulation frequency Ω can be written in the coupled-mode form

$$\frac{da}{dt} = \left(-i\omega_s + \gamma_s\right)a + e^{i\Omega t}\boldsymbol{\kappa}^T \mathbf{s}_+ \quad (2)$$

where ω_s is the eigenfrequency of the surface mode, γ_s accounts for radiative leakage of the surface mode into the external scattering channels, and $\boldsymbol{\kappa}$ denotes the coupling coefficient between the incident waves and the surface excitation. The amplitude is normalized so that $|a|^2$ equals the energy stored in the surface mode. In the ideal lossless limit considered here, the intrinsic dissipation rate γ_i is set to be zero. In addition, the radiation from the Floquet sheet back into the propagating channels is described by

$$\mathbf{s}_- = C\mathbf{s}_+ + e^{-i\Omega t}\mathbf{d}a \quad (3)$$

where C is the direct S-matrix pertaining to the incoming and outgoing waves of the sheet, and **d** characterizes how the resonant surface excitation radiates into the external channels. The explicit time factors in Eq. (2) and (3) are introduced to satisfy the frequency matching condition to connect the input channel at ω_0 and the surface mode channel at $\omega_{-1} = \omega_0 - \Omega$.

When the incident wave $\mathbf{s}_+$ impinges on the Floquet sheet at a frequency ω_0, the time modulation enables frequency conversion between the propagating channels at ω_0 and the surface-mode channel centered around $\omega_{-1} = \omega_0 - \Omega$ so that the detuning entering the resonance denominator is $\omega_0 - \Omega - \omega_s$. Solving Eq. (2) and (3) in the frequency domain then yields the scattering relation

$$\mathbf{s}_- = S\mathbf{s}_+ = \left[C + \frac{\mathbf{d}\boldsymbol{\kappa}^T}{\gamma_s - i\left(\omega_0 - \Omega - \omega_s\right)}\right]\mathbf{s}_+ \quad (4)$$

To determine the radiative decay rate γ_s and the coupling vector **d** under our chosen normalization of the surface-mode amplitude, we invoke photon-number conservation for the frequency-conversion process. Although the sheet is temporally modulated and electromagnetic energy is not required to be conserved, a monochromatic conversion event still allows one to enforce conservation of the number of photons exchanged between the surface excitation at ω_s and the radiated waves at ω_0. With the normalization $|a|^2$ representing the energy stored in the surface mode, we define the surface-mode photon number as $N_s = |a|^2/\omega_s$. For the propagating channels, the photon flux is proportional to $N_0 = |\mathbf{s}|^2/\omega_0$. Hence, photon-number conservation requires

$$\frac{d}{dt}\left(\frac{|a|^2}{\omega_s}\right) = \frac{|\mathbf{s}_-|^2 - |\mathbf{s}_+|^2}{\omega_0} \quad (5)$$

The left-hand side represents the change of surface modal photon numbers in time, whereas the right-hand side is the photon numbers after the interaction with single Floquet-sheet resonator. Substituting Eq. (2) and its time-conjugate into the left-hand side of Eq. (5), it becomes

$$\frac{d}{dt}\left(\frac{|a|^2}{\omega_s}\right) = \frac{2\gamma_s|a|^2 + e^{i\Omega t}a^*\boldsymbol{\kappa}^T\mathbf{s}_+ + e^{-i\Omega t}a\boldsymbol{\kappa}^\dagger\mathbf{s}_+^*}{\omega_s} \quad (6)$$

Next, from Eq. (3), the intensity of the outgoing wave can be written as

$$|\mathbf{s}_-|^2 = |C|^2|\mathbf{s}_+|^2 + |\mathbf{d}|^2|a|^2 + e^{i\Omega t}a^*\mathbf{d}^\dagger C\mathbf{s}_+ + e^{-i\Omega t}a\mathbf{s}_+^\dagger C^\dagger\mathbf{d} \quad (7)$$

In the lossless background S-matrix, $|C| = 1$. By plugging Eq. (3) into the right-hand side of Eq. (5) yields

$$\frac{|\mathbf{s}_-|^2 - |\mathbf{s}_+|^2}{\omega_0} = \frac{|\mathbf{d}|^2|a|^2 + e^{i\Omega t}a^*\mathbf{d}^\dagger C\mathbf{s}_+ + e^{-i\Omega t}a\mathbf{s}_+^\dagger C^\dagger\mathbf{d}}{\omega_0} \quad (8)$$

Equating Eq. (6) and (8) for arbitrary $(a, \mathbf{s}_+)$ then fix the coefficients uniquely

$$2\gamma_s = \left(\omega_s/\omega_0\right)|\mathbf{d}|^2 \quad (9a)$$

$$\boldsymbol{\kappa}^T/\omega_s = \mathbf{d}^\dagger C/\omega_0 \quad (9b)$$

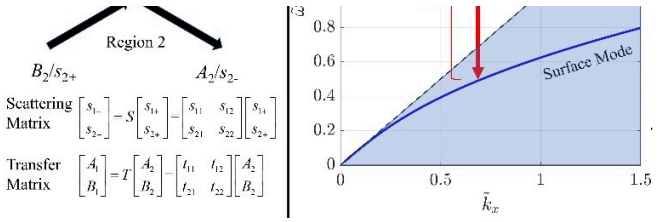

Fig. 1: (a) Schematic of the incident and outgoing wave components across the conducting sheet in region 1 and region 2. The corresponding scattering matrix *S* and transfer matrix *T* definitions are provided below. (b) Normalized dispersion diagram ($\tilde{\omega} = \omega/W_{p0}$ and $\tilde{k}_x = ck_x/W_{p0}$) illustrating the light line, the supported surface mode, and the frequency modulation process $\tilde{\Omega}$ coupling a propagating wave to the surface state.

III. Results and Discussion

It is noteworthy that we covers the functional form of the seminal temporal coupled-mode theory proposed by Fan et. al., [6]

$$S = \begin{bmatrix} r_0 & t_0 \\ t_0 & r_0 \end{bmatrix} - \frac{\gamma_s\left(r_0 + t_0\right)}{\gamma_s - i\left(\omega_{-1} - \omega_s'\right)}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \quad (10)$$

where

$$\gamma_s = \left(\frac{\omega_s}{\omega_0}\right)\frac{2\alpha^2\eta_1^{-1}W_{p0}/\cos\theta_i}{\left(2\eta_1^{-1}/\cos\theta_i\right)^2 + \left(W_{p0}/\omega_0\right)^2} \quad (11a)$$

$$\omega_s' = \omega_s\left[1 - \frac{\alpha^2\left(W_{p0}/\omega_0\right)^2}{\left(2\eta_1^{-1}/\cos\theta_i\right)^2 + \left(W_{p0}/\omega_0\right)^2}\right] \quad (11b)$$

This correspondence is underpinned by the 2π phase difference between the reflection coefficient r_0 and transmission coefficient t_0, i.e., $r_0 + t_0 = e^{i\phi}\left(|r_0| + i|t_0|\right)$, under

the condition of identical surrounding materials. This structural identity demonstrates how the surface modal resonance within the -1st Floquet channel facilitates resonant scattering into the 0th channel.

Eq. (11a) also quantitively links the square of the modulation strength α^2, Drude weight W_{p0}, and the incident angle θ_i with the radiative rate, thereby elucidating the physical origin of the resonance in temporally modulated conducting sheet. Additionally, Eq. (11b) reveals that the surface-mode frequency ω_s' undergoes a subtle shift due to the temporal modulation. To ensure a well-defined resonance with minimal frequency deviation, maintaining a small W_{p0}/ω_0 ratio is essential, which necessitates that the modulation frequency Ω remains sufficiently higher than the excitation.

In Fig. 2, it is evident that the numerical results from COMSOL and the analytical predictions from the TCMT model exhibit an excellent fit across the entire frequency range, which validates the TCMT model. As the modulation strength α increases, the resonance peak in reflectance and the corresponding dip in transmittance broaden, indicating that stronger temporal modulation enhances the radiation loss and strengthens the coupling between the surface mode and the incident free-space wave.

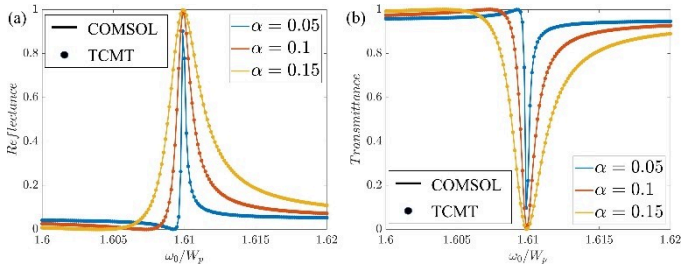

Fig. 2: (a) Reflectance and (b) transmittance as a function of the normalized frequency ω_0/W_p for various modulation strengths $\alpha =$ 0.05, 0.1, and 0.15. The solid lines represent the numerical results obtained from COMSOL Multiphysics, while the dot markers denote the analytical results derived from the TCMT.

IV. Conclusion

In conclusion, we have developed a comprehensive TCMT description for a single Floquet-sheet resonator and established a systematic connection to a Floquet transfer-matrix formulation. To determine the key parameters of the resonator, we introduce photon-number conservation for the frequency-conversion process, which necessitates a characteristic frequency ratio correction in the coupling coefficients to ensure physical consistency. This structural identity demonstrates how the surface modal resonance within the -1st Floquet channel facilitates resonant scattering into the 0th channel, effectively recovering the functional form of seminal TCMT while successfully incorporating the complexities of temporal modulation.

The analytical expressions derived via TMM provide a quantitative link between the modulation strength, Drude weight, and incident angle with the radiative decay rate, thereby elucidating the microscopic physical origin of the resonance in time-modulated-sheet systems. Our investigation into the effects of intrinsic material loss confirms that the simplified resonance form remains robust, with analytical predictions matching full-wave numerical results across a wide range of loss parameters. Furthermore, the symmetry of the coupling vectors confirms that the surface excitation maintains an even distribution due to the inherent mirror symmetry of the sub-wavelength sheet. The mapping procedure and underlying concepts established in this work are generalizable to a broad spectrum of time-varying resonant systems. These results provide a vital theoretical foundation for future explorations into multi-sheet configurations, non-reciprocal topological interfaces, and advanced periodic synthetic spaces in the frequency domain.

***Abstract*—We present a MEMS-based reconfigurable intelligent surface (RIS) with switchable microbridges for sub-THz beam control. Simulations demonstrate a phase tuning range of 300° at 100 GHz with a reflection magnitude over 0.9 and a usable bandwidth exceeding 4 GHz. A 10x10 unit cell prototype was fabricated, demonstrating the feasibility of our design.**

***Keywords*— beam steering, wireless communication, MEMS, RIS.**

I. Introduction

As wireless communication systems move toward increasingly higher operating frequencies, extending into the terahertz (THz) range to support higher data rates, they encounter new challenges. These include shorter propagation distances and frequent blockage of line-of-sight links caused by obstacles such as buildings and vegetation [1,2]. Reconfigurable intelligent surfaces (RIS) have emerged as a promising approach to mitigate these limitations by enabling signals to be redirected around obstacles and dynamically focused toward one or multiple users [1-6]. This functionality is realized through a large array of RIS unit cells, each with individually controllable electromagnetic properties. By independently adjusting the phase of the reflected signal at every unit cell, the overall wavefront can be engineered to perform operations such as beamforming, beam steering, and beam splitting.

Traditional RIS implementations typically employ varactor diodes [5,6], which provide continuous capacitance tuning through a DC bias voltage, or PIN diodes, which allow only two discrete phase states [3,4]. However, when operating in the sub-THz frequency range, designing diode-based unit cells capable of achieving a phase tuning range close to 180° over a sufficiently wide bandwidth becomes increasingly challenging. This difficulty is often accompanied by a noticeable reduction in reflection amplitude. Consequently, the beamforming performance of RIS operating at sub-THz and THz frequencies remains significantly limited.

To address these limitations, we propose a MEMS-based RIS consisting of an array of switchable microbridges. The microbridges are fabricated from SiO_2 and copper on a silicon substrate with a metallized backside, which enables the application of a DC voltage between the bridges and the ground plane. By varying this voltage, a quasi-continuous mechanical deflection of the microbridges is induced. This mechanical actuation allows continuous tuning of the electromagnetic response of each unit cell, providing functionality analogous to varactor diodes used at lower frequencies. Figure 1 shows a drawing of the unit cell design with and without a voltage applied between the bridges and substrate backside.

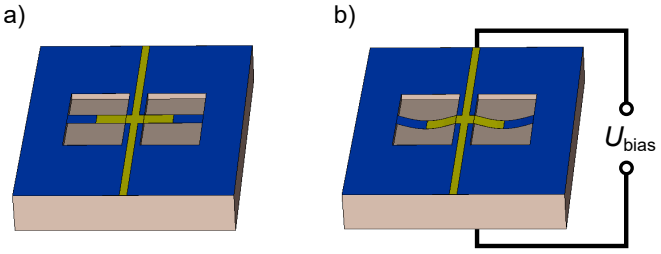

Fig. 1. Unit cell design based on two half-side metallized microbridges a) without applied voltage and b) with applied voltage.

II. Methods

First, we analyzed the S_{11}-parameters of the microbridge-based RIS unit cells in CST Microwave Studio to identify a geometry that enables a near-360° reflection phase shift at 100 GHz while maintaining a reflection magnitude $\geq$0.9.

After identifying a suitable geometry, we fabricated a prototype RIS consisting of 10×10 unit cells using standard lithography on 200 μm-thick, (100)-oriented silicon wafers. We dry-oxidized the wafers to form a 300 nm-thick SiO_2 layer. Fig. 2 shows a flowchart of the fabrication process.

First, we applied a positive photoresist (Microchemicals AZ1512HS) to the wafer and patterned it using a direct laser writer (Microtech LW405D). We then transferred the resulting pattern into the oxide layer via HF etching with buffered oxide etch (7:1), thereby defining the eventual lengths of the microbridges.

Next, we cleaned the wafer with acetone and isopropyl alcohol and applied a second layer of positive photoresist. We patterned this layer again with the direct laser writer and carefully aligned it to the holes in the oxide. Subsequently, we coated the wafer with 50 nm of titanium followed by 200 nm of copper using an electron beam evaporator (Pfeiffer Classic

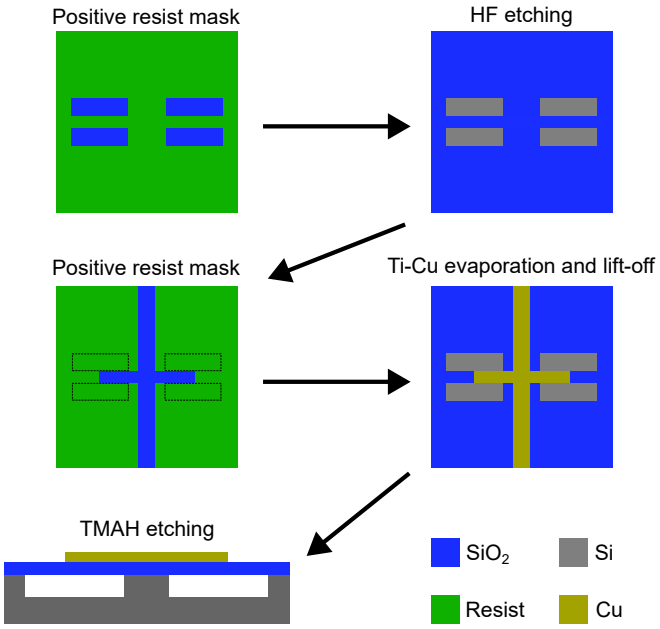

Fig. 2. Flowchart for the fabrication of a microbridge-based RIS. The upper and middle row show a top-view of the sample, the lower row a cross-section through the silicon wafer.

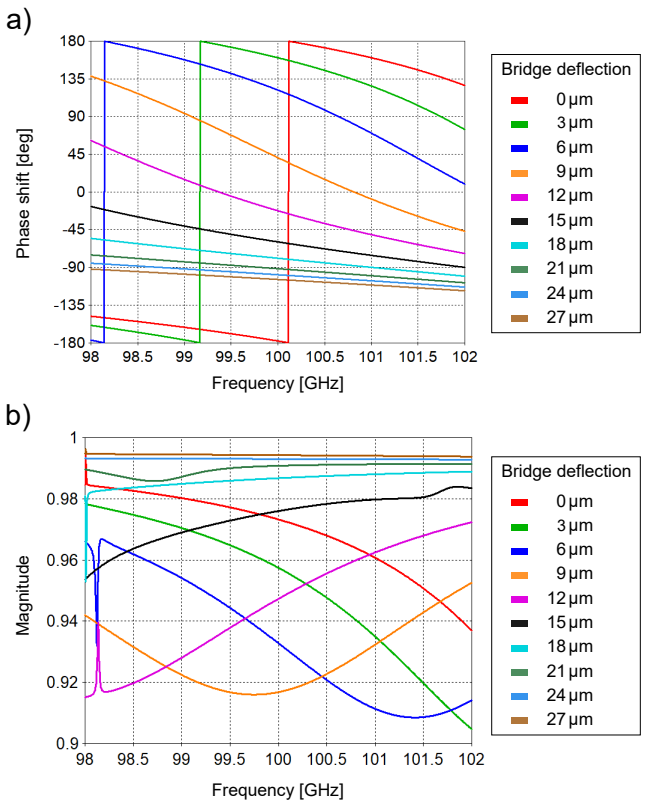

Fig. 3. Simulated S_{11}-parameters of the radiation reflected from a microbridge-based unit cell array shown in terms of a) phase shift and b) magnitude. Each curve corrresponds to a different maximum deflection of the bridges. The bridges are 750 μm long and 80 μm wide, with a 50 μm gap between them. The unit cells have a length and width of 1750 μm each. The silicon substrate is 200 μm thick.

500L). After performing a lift-off process, we obtained the transmission line and the half-side metallization of the bridges.

We then etched the exposed silicon in a 10% aqueous TMAH solution at 70°C for 75 minutes, which produced an etch depth of 30 μm. We rotated the unit cells by 45° with respect to the wafer flat, which allowed the TMAH solution to underetch the bridges. After etching, we first immersed the wafer in isopropyl alcohol and then dried it in air instead of using a nitrogen spray gun in order to protect the extremely thin bridges. Finally, we completed the fabrication of the RIS by flipping the wafer and coating the entire backside with 50 nm of titanium and 200 nm of copper using the electron beam evaporator.

III. Results and Discussion

From the unit cell simulations, we found that the deflection of the microbridges produces a phase shift in the reflected radiation, as expected. Figure 3a) illustrates the phase shift for microbridges with different maximum deflections as a function of the radiation frequency. In this configuration, the bridges have a length of 750 μm and a width of 80 μm, while the gap between adjacent bridges is 50 μm. The unit cell itself has dimensions of 1750 μm × 1750 μm. The thickness of the silicon substrate was fixed at 200 μm, corresponding to the thickness of the available wafers.

At an operating frequency of 100 GHz, the phase shift can be tuned over a range of approximately 300°, with the highest sensitivity observed at small deflections. Across the full simulated frequency range from 98 GHz to 102 GHz, the tuning range remains above 240°. In this range, the magnitude exceeds 0.9, indicating a usable bandwidth exceeding 4 GHz. Outside this range, the phase shift may still exceed 180°, which is sufficient for beam steering applications [7], but the reflection magnitude decreases to values below 0.9.

Since the geometry described above proved to be optimal in terms of both phase shift range and reflection magnitude, a first 10 × 10 unit cell RIS prototype was fabricated. Because the bridges required a width of 80 μm for best performance, while the desired etch depth was only 30 μm, complete underetching was geometrically not feasible. Therefore, holes with dimensions of 5 μm × 10 μm were etched into the oxide layer along the entire length of the bridges. This enabled the TMAH solution to underetch the microbridges independently of their size.

Figure 4 shows a microscope image of a single RIS unit cell before the final etching step in TMAH, as well as an SEM image of a bridge after TMAH etching and air drying. While the overall fabrication process was successful, the bridges exhibit a larger-than-expected initial bending toward the substrate. We suspect this to be caused by the surface tension of isopropyl alcohol pulling the bridges toward the silicon during drying.

Since the highest sensitivity of the bridges occurs at small deflections, and almost no phase shift is observed when the

bridge is bent more than 15 μm toward the substrate, this RIS prototype is not yet suitable for beam steering applications. To overcome this issue, we intend to repeat the fabrication process using a critical point dryer to evaporate the isopropyl alcohol, thereby significantly reducing the effects of surface tension.

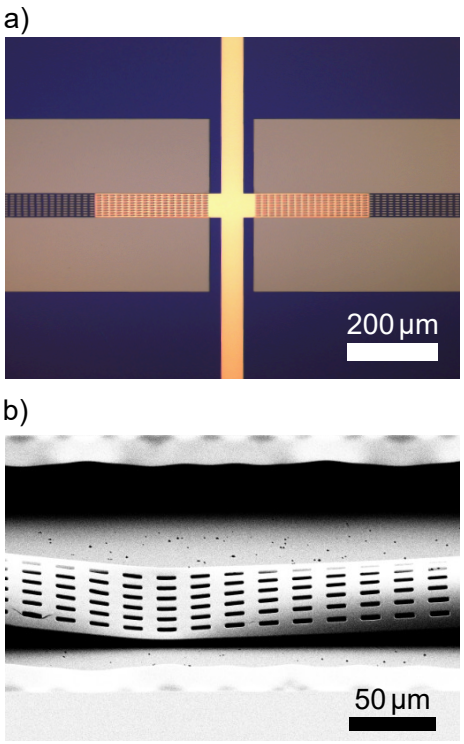

Fig. 4. a) Microscope image of a single unit cell before TMAH etching, b) SEM image of a bridge after TMAH etching and drying in air.

IV. Conclusion

We have presented the design, simulation, and initial fabrication of a MEMS-based RIS using switchable microbridges. Simulations demonstrated that the microbridge deflection enables a phase shift of up to 300° at 100 GHz and a usable bandwidth exceeding 4 GHz. A 10×10 unit cell prototype was successfully fabricated, validating the proposed fabrication approach. However, surface tension during air drying caused a large initial bending of the bridges, severely limiting the achievable phase tuning and rendering the current prototype unsuitable for beam steering applications. Future work will focus on optimizing the fabrication process using critical point drying to minimize surface tension effects, enabling fully functional RIS devices capable of dynamic beam control at sub-THz frequencies.

***Abstract*— This study evaluates crystalline and amorphous silicon metasurfaces as compact optics for ultrafast lasers. Using a 1030 nm, 270 fs laser, both platforms demonstrated over 90% spatial shaping efficiency. Although moderate temporal dispersion, increased pulse duration, and damage thresholds limit high-fluence use, this proves their relevance for low-power applications.**

***Keywords*— silicon metasurfaces, ultrafast optics, beam shaping, group delay dispersion, laser-induced damage threshold**

I. Introduction

Ultrafast lasers have become indispensable tools across various scientific and industrial domains, making a profound impact on laser processing of materials, spectroscopy, and imaging.[1–3] However, the traditional transmissive optical components required to manipulate these light fields present significant limitations; the complex optical setups required for these systems are often costly, bulky, and challenging to align.

Optical metasurfaces—dense 2D arrays of subwavelength metaatoms—offer a revolutionary alternative to traditional optics.[4–6] By engineering the phase, amplitude, and polarization response of these nanostructures, metaoptics allows for the combination of multiple functions in one essentially flat optical component.[7,8] Furthermore, this technology is highly compatible with standard semiconductor nanofabrication techniques, allowing for unprecedented precision.

Despite these transformative capabilities, most metasurface research until now has focused on continuous wave lasers, and applications for ultrafast lasers are still largely uncharted.[9,10] Deploying metasurfaces in the ultrafast regime requires overcoming specific spatiotemporal challenges, most notably the management of group delay dispersion (GDD) to prevent temporal pulse broadening and ensuring a sufficiently high laser-induced damage threshold (LIDT) to withstand intense peak powers.

To address this research gap, we present a comparative feasibility study of two distinct silicon-based metasurface platforms for ultrafast pulse applications: monolithic crystalline silicon (c-Si) and thin-film amorphous silicon (a-Si). While c-Si allows for the fabrication of high-aspect-ratio geometries, amorphous silicon offers a highly accessible, lower-profile alternative. By evaluating the LIDT and temporal dispersion characteristics of both platforms, we aim to demonstrate their viability as compact, passive elements for spatiotemporal beam shaping in integrated ultrafast systems.

II. Methods

To fabricate the metasurfaces, we employed standard electron beam lithography (EBL) followed by a lift-off process to define the etching mask. The silicon nanostructures were subsequently patterned using a continuous inductively coupled plasma reactive ion etching (ICP-RIE) process with a fluorine-based mixed gas chemistry of SF_6 and C_4F_8. This exact protocol was utilized for both the thin-film a-Si samples on fused silica substrates and the monolithic c-Si samples. For the latter, the absence of an etch-stop layer typically introduces aspect-ratio-dependent etching (ARDE) challenges. However, this effect was effectively mitigated by employing the Pancharatnam-Berry (PB) phase delay configuration; because the local pattern density remains uniform across the device in a PB design, we successfully achieved uniform final aspect ratios of approximately 10.

Experimental characterization of the metasurfaces was performed using a Yb:KGW ultrafast laser system (Pharos, Light Conversion) operating at a fundamental wavelength of 1030 nm with a pulse duration of 270 fs in a custom micro-spectroscopy setup. To precisely evaluate the temporal effects of the metasurfaces on the transmitted pulses, temporal pulse broadening were measured using a scanning autocorrelator (GECO, Light Conversion) and frequency-resolved optical gating (FROG). A single diffraction order was spatially filtered in a conjugate back-focal plane and fed into the autocorrelator, ensuring that the temporal measurements explicitly isolated the specific beam generated by the metasurface, eliminating background interference. Finally, the laser-induced damage threshold (LIDT) for both silicon platforms was evaluated using the standard S-on-1 testing protocol to determine their power-handling capabilities and overall feasibility for practical ultrafast applications.

III. Results and Discussion

The spatial wavefront shaping capabilities were validated by analyzing the back focal plane images of the transmitted 1030 nm beam. Using PB-phase metasurfaces, we encoded a variety of phase profiles, including spherical, cylindrical lenses, OAM generators, axicons, and computer-generated holograms. To evaluate the efficiency of these elements, we measured the amount of light deflected into a diffraction order by a simple linear phase gradient—a deflector. Both the monolithic c-Si and thin-film a-Si platforms achieved a relative efficiency of >95%. This excellent performance closely aligned with the theoretical efficiency predicted by numerical simulations when optimizing the metaatoms as half-waveplates.

S-on-1 testing was performed to determine the power-handling capabilities of both silicon platforms using the 1030 nm, 270 fs laser source. The monolithic c-Si metasurfaces exhibited a robust damage threshold of 32.8 mJ/cm^2 (99.0 mJ/cm^2 unstructured reference substrate). The thin-film a-Si metasurfaces demonstrated a slightly lower, yet highly practical, LIDT of 11.1 mJ/cm^2 (41.3 mJ/cm^2 unstructured reference substrate). Both values fall comfortably within the operational fluences of typical ultrafast oscillators and amplifiers used in micro-spectrometry, confirming the feasibility of both platforms without rapid structural and optical degradation.

To evaluate the temporal effects of the metasurfaces, one transmitted diffraction order of the PB-based deflector device was isolated using the micro-spectrometry setup. Autocorrelation and FROG measurements of the pulses passing through both the a-Si and c-Si metasurfaces revealed a deflection angle dependent temporal broadening. At low deflection angles (<10 deg) the added temporal FWHM is negligible and is comparable to reference Si slab (~270 fs). Beyond 10°, the FWHM increases non-linearly to approx. 320 fs at 20° deflection. This finding demonstrates that such passive flat optics sufficiently maintains temporal integrity of the ultrafast pulses.

When comparing the two platforms, a practical trade-off emerges. Monolithic c-Si avoids the constraints of an etch-stop layer and exhibits a moderately higher laser-induced damage threshold (LIDT). Conversely, thin-film a-Si offers a more accessible, cost-effective, and substrate-versatile fabrication route while matching the spatial and temporal optical performance of its crystalline counterpart.

However, a candid evaluation of the measured LIDT values dictates the immediate practical scope of these devices. While these thresholds are reasonable for nanoscale silicon structures, they fundamentally cannot compete with the damage resistance of macroscopic, low-index refractive optics or specialized dielectric mirror coatings used in high-energy laser amplifiers. Consequently, the deployment of these metasurfaces as direct replacements in high-peak-power beamlines is currently unfeasible.

Instead, the true potential of these silicon metasurfaces lies in low-power ultrafast pulse applications. Because they can combine multiple optical functions—such as simultaneous beam deflection, focusing, and polarization control—into a single, compact element, they are perfectly suited for integration into systems where fluences are low, space is tight, and alignment of multiple closely spaced components is cumbersome. Future work will focus on implementing these ultrafast-grade metasurfaces into integrated low-power devices, such as custom-built multiphoton microscopy assemblies, or compact ultrafast spectroscopy systems. By targeting these specific low-energy regimes, silicon metasurfaces can successfully reduce the footprint, cost, and alignment complexity of ultrafast optical setups without risking optical damage.

***Abstract*—Broadband low-frequency acoustic absorption is constrained by large wavelengths and high-dimensional design complexity. We propose a physics-guided inverse design framework using a Conditional Invertible Neural Network (cINN) for a 20-parameter multilayer acoustic metamaterial absorber. Trained on one million Latin Hypercube Sampling (LHS) samples and validated via Transfer Matriacx Method (TMM), it achieves $< 0.3\%$ error.**

***Keywords*— Acoustic metamaterials, low frequency absorption, machine learning, inverse design.**

I. Introduction

Recent advancements in machine learning have drastically changed the design paradigm of acoustic metamaterials by enabling data-driven exploration of complex design spaces. However, conventional design methodologies still largely rely on forward simulations and large-scale parametric sweeps to estimate desired responses, which are computationally expensive and often constrained by intuition-driven exploration [1]. While gradient- based and evolutionary optimization methods have enhanced automation, they still remain reliant on the use of iterative numerical computations and become inefficient in case of highly dimensional and multi-constrained design spaces. Additionally, the traditional absorber architecture based on canonical resonators restricts bandwidth, tunability, and structural diversity. To mitigate the effect of these limitations, a robust inverse model that can directly relate the target functionality to structural parameters is essential. Data-driven neural models offer a promising solution by learning complex nonlinear relationships between geometry and the acoustic response, while incorporating physics-driven loss functions to enforce governing physical constraints and ensure physically consistent predictions [2].

In this work, we propose a physics-guided inverse design framework based on a Conditional Invertible Neural Network (cINN) for a 20-parameter multilayer AMA. The model directly retrieves structural parameters from a target absorption spectrum while ensuring physical consistency. The presented method opens new avenues for automating the metasurface design process and enables a more generalized and broader scope of optimal designs beyond acoustic applications by incorporating physics-based loss functions to ensure physically consistent and realistic solutions.

II. Methods

The proposed approach aims to develop an inverse design framework to predict the structural parameters for a given spectrum of absorption coefficients in the frequency range of 1-1000 Hz. The following subsections provide a comprehensive elucidation for each stage of the adopted pipeline.

A. Metamaterial Parameterization And Acoustic Response

Each unit of the employed structure consists of 10 layers of rubber substrate with a few hollow layers and a rigid backing at the bottom [3], as illustrated in Fig. 1 (a). Each layer of the coating is perceived as a combination of multiple layers of rubber with distinct equivalent parameters [3] (Fig. 1 (b) and (c)).

The entire structure possesses 16 distinct geometric parameters and 4 material parameters, which were primarily utilized in computing the broadband absorption spectrum with careful examination and strict adherence to the analytical derivation of the complex absorption determination presented in [3]. Subsequently, an extensive dataset was constructed consisting of 1,000,000 rows of the aforementioned 20 sensitive parameters and the corresponding computed absorption coefficients. This dataset was generated randomly using the Latin Hypercube Sampling (LHS) method while ensuring compliance to their respective predefined structural limits and their corresponding absorption coefficient values.

B. Computational Model And Implementation

Following data generation, we trained the conditional Invertible Neural Network (cINN) to build the aforementioned inverse design framework. Fig. 1 (d) illustrates the workflow of the developed model. The proposed network includes a spectrum encoder that transforms the 1000-frequency absorption spectrum into a 128-dimensional embedding vector, forcing the network to learn essential spectral features instead of memorizing the noise. Subsequently, the 20-dimensional parameter sets and the embedded vector from the training subset were utilized to train 8 identical conditional affine coupling blocks for 250 epochs. Each block comprises a 3-layer Multi-Layer Perceptron (MLP) with LeakyReLU activations, responsible for transforming the input parameter sets. These blocks collectively function in two possible directions: the forward pass during training and the reverse pass during testing.

Fig. 1. Physics-guided inverse design framework for broadband underwater acoustic metamaterials. (a–c) Multilayer unit-cell configuration with 20 design parameters (16 geometric, 4 material). (d) Conditional Invertible Neural Network (cINN) architecture mapping 1000-point absorption spectra (1–1000 Hz) to structural parameters, generating 20 candidate designs per target. (e) Predicted absorption spectra demonstrating high-fidelity full-spectrum reconstruction.

For each training epoch, we employed the Negative Log-Likelihood (NLL) as the loss function, averaged across the entire training batch, which is given by (1).

$$\text{NLL} = \text{mean}\left(\frac{1}{2}\|\mathbf{z}\|^2 - \log|\det(\mathbf{J})|\right) \tag{1}$$

Here, $\frac{1}{2}\|\mathbf{z}\|^2$ represents the squared L_2 norm of the latent variable, and $-\log|\det(\mathbf{J})|$ is the log-determinant of the Jacobian matrix that accounts for volume distortion during the transformation. Cosine annealing was consequently applied after each epoch to control the learning rate and fine-tune the optimization process.

Each target spectrum, alongside 20 independent Gaussian vectors, undergoes reverse processing through the entire network, producing 20 different parameter sets, each conditioned for the same target, explicitly addressing the one-to-many mapping between geometry and acoustic absorption, and thereby exploring different regions of the solution space.

C. Theoretical Validation

With the intent to evaluate the performance of the model, we constructed a Transfer Matrix Method (TMM) physics engine, based on the analytical derivation of the absorption spectra proposed in [3], to compute the absorption spectra using the predicted candidate sets. Since the proposed framework yields 20 possible solutions to a target, the deterministic physics engine was implemented to select the best configuration among them. This engine computes the predefined acoustic equations and compares the Root Mean square error (RMSE) of each candidate, thereby identifying the parameter set with minimal spectral variance. The use of this evaluation measure was mainly to filter the final result, ensuring the candidate isolation which best represents the extreme resonance points and general topology of the target spectrum.

III. Results and Discussion

This section analyses the trained conditional Invertible Neural Network (cINN) model on unknown test samples. To strictly assess the effectiveness of the model, we inspected several different evaluation measures on the entire test data. The mean spectral relative error of the proposed model came out to be 0.2932%, with the minimum value of 0.0046% respectively. Moreover, the model achieved a full-spectrum average Root Mean Square Error (RMSE) of 0.00108624 and a Mean Absolute Error (MAE) of 0.00076246. Subsequently, Fig. 1 (e) compares the absorption spectra for the top three performing designs of two representative test samples, where each candidate successfully replicates the targeted spectrum with high precision, thereby demonstrating the fidelity and robustness of the proposed model.

IV. Conclusion

In this work, we proposed a cINN-based inverse design framework for broadband underwater acoustic metamaterials

across 1–1000 Hz. On 100,000 unseen samples, the model achieves a mean spectral RMSE of 0.00109, MAE of 0.00076, and a mean relative error of 0.29%. Unlike ref. [3], that employs MLP limited to a single averaged absorption metric, our framework solves the full-spectrum inverse problem and generates 20 diverse candidate designs per target, addressing the one-to-many nature of inverse design. Coupled with a TMM-based physics filter, the pipeline delivers validated absorber configurations in a single inference pass.

I. Introduction

The attenuation of low-frequency underwater noise remains challenging due to long acoustic wavelengths and impedance mismatch between water and conventional absorbers [1]. Multilayer acoustic coatings with internal cavities have shown strong absorption performance in the 1–1000 Hz range. A representative multilayer rubber coating proposed by Gao et al. [2] depends on twenty geometric and material parameters, making exploration of the design space computationally expensive despite accurate forward prediction using equivalent medium theory and the TMM.

Recent machine learning approaches have accelerated forward prediction and inverse design of acoustic metamaterials [3]. However, deterministic models such as feed-forward neural networks, tandem networks, and conditional variational autoencoders reduce the inherently one-to-many inverse problem to a single solution. This limitation becomes more significant when only the average absorption coefficient is used, as spectral information is lost and multiple distinct structures may produce identical responses. To address this challenge, this work proposes a physics-guided Conditional Diffusion Model for inverse design of underwater acoustic metamaterial coatings, capable of generating multiple physically consistent candidate designs for a target average absorption coefficient.

II. Methods

The proposed inverse design framework is illustrated in Fig. 1(a). The material architecture follows a 10-layer configuration with rigid backing and hollow sub-layers, represented by 20 sensitive variables (16 geometric and 4 mechanical parameters). We adopt the analytical TMM formulation of [2] to compute the average absorption coefficient and build a large-scale dataset using LHS.

A lightweight Multi-Layer Perceptron (MLP) surrogate is first trained to map normalized parameters to absorption coefficient and then frozen. During diffusion training, this frozen surrogate provides physics guidance through a consistency term, while the conditional denoiser uses timestep and target-conditioned embeddings with Feature-wise Linear Modulation (FiLM) blocks under a cosine noise schedule. Two pivotal losses were examined for computing the gradients: the noise prediction loss and the physics loss carried out by the frozen surrogate model. Subsequently, The total training loss is given by

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{noise}} + \lambda\, \mathcal{L}_{\text{physics}}, \tag{1}$$

where $\mathcal{L}_{\text{noise}}$ is the denoising score-matching loss, $\mathcal{L}_{\text{physics}}$ is the MSE between surrogate-predicted and target absorption, and λ is linearly ramped over the first 40 training epochs. At inference, the model generates 20 candidate parameter sets for each target, and the best candidates are selected using TMM verification, enabling one-to-many inverse design with physical consistency.

An extensive dataset of 1,000,000 samples was generated using Latin Hypercube Sampling (LHS) within the predefined parameter bounds, each entry comprising the 20 structural parameters and the corresponding TMM-computed average absorption coefficient.

A. Conditional diffusion model and implementation

Following dataset construction, a CDM was trained on the normalised 20-parameter space. The conditional denoiser employs sinusoidal timestep embeddings and a target-conditioned embedding fused via Feature-wise Linear Modulation (FiLM) blocks, which adaptively scale and shift intermediate feature maps based on the target absorption value. A cosine noise schedule governs the forward diffusion process over $T{=}500$ timesteps. Training optimises Eq. (1) with λ ramped over 40 epochs. The forward surrogate achieves $R^2{>}0.99$, confirming its suitability as a differentiable physics proxy. At inference, 20 candidate sets are generated by independently denoising 20 Gaussian noise vectors conditioned on the same target.

B. Theoretical validation

A TMM physics engine based on [2] computes the average absorption coefficient for each of the 20 predicted parameter sets. The candidate with minimum absolute relative error relative to the target is retained, enforcing physical correctness independently of the learned model.

Fig. 1. Physics-guided Conditional Diffusion Model for inverse design of broadband low-frequency underwater acoustic metamaterials. (a) Multilayer unit-cell configuration with 20 design parameters (16 geometric, 4 material). (b) CDM architecture: frozen MLP surrogate provides physics guidance via composite loss ($\mathcal{L}_{\text{noise}} + \lambda\mathcal{L}_{\text{physics}}$) with FiLM-conditioned denoiser under cosine noise schedule. (c) Embedded design space showing structured variation with target absorption coefficient. (d) Heatmap of TMM-validated spectra across target levels 0.1–1.0. (e) Best-of-20 reconstructed absorption spectra demonstrating accurate target recovery.

III. Results and Discussion

The trained CDM was evaluated on 100,000 unseen test samples using TMM-verified best-of-20 selection. Model performance is quantified by two complementary metrics. The mean *single-sample* relative error, the raw performance of one generated design without selection is 2.9634%, establishing the intrinsic generative quality of the model. The *best-of-20* mean relative error, where the TMM physics filter selects the optimal candidate from 20 independently generated designs, is 0.1065%, with a minimum of 0.00% and a maximum of 5.0718%. The model further achieves RMSE of 0.000422 and MAE of 0.000298 on the best-of-20 selected designs (Fig. 1(e)).

IV. Conclusion

A physics-guided CDM is proposed for inverse design of low-frequency underwater acoustic metamaterials (1–1000 Hz). On 100,000 unseen samples, it achieves a best-of-20 mean relative error of 0.1065%, Root Mean Square Error (RMSE) of 0.000422, and MAE of 0.000298 using TMM-verified candidate selection. Unlike [2], the proposed CDM directly solves the inverse problem and generates 20 diverse candidate designs per target without iterative optimization. Future work will address full spectral targets and experimental validation.

***Abstract*—Active controlled metamaterials are crucial for advancement of terahertz technology. This study demonstrates actively tunable electromagnetically induced transparency, achieved by modulating phase of vanadium dioxide through temperature variation. Active transmission modulation of approximately 85% is observed. These results indicate strong potential for developing active components in toroidal terahertz photonics.**

***Keywords*— metamaterials, terahertz, active tunable metamaterial, toroidal.**

I. Introduction

Electromagnetically induced transparency (EIT) in terahertz photonics is the key research interest in recent years. It is caused by the destructive interference between the probe and pump beams and is usually explained by a three-level atomic system [1]. EIT results in a narrow transparency window in an otherwise opaque medium [2], thus it has enormous application in non-linear devices and slow light devices [3], [4], [5], [6]. The applications of traditional EIT are elusive due to rigorous conditions such as very low temperature, high-intensity laser, etc. Recently, artificially designed materials, commonly known as metamaterials (MM) are used to mimic the EIT-like effect at room temperature.

The studies so far have largely focused on the passively tunable EIT behavior. The active tunability of EIT is highly desirable for various applications, such as photoconductive material, thermally controlled superconducting metamaterials, and graphene. Numerous researchers have shown the modulation of EIT by integrating graphene-based patterns in metamaterials [7]. But very few studies focus on phase-changing materials like vanadium dioxide (VO_2).

In this paper, we experimentally demonstrated the actively controlled EIT in the THz regime. The metamaterial comprises of two toroidal resonators. Both resonators couple together and open an EIT window at 0.55 THz. A VO_2 layer is grown on quartz substrate and sandwiched between quartz and polyimide substrate. The external temperature of VO_2 is increased gradually to achieve the modulation of EIT. An on-to-off modulation is observed in simulation results.

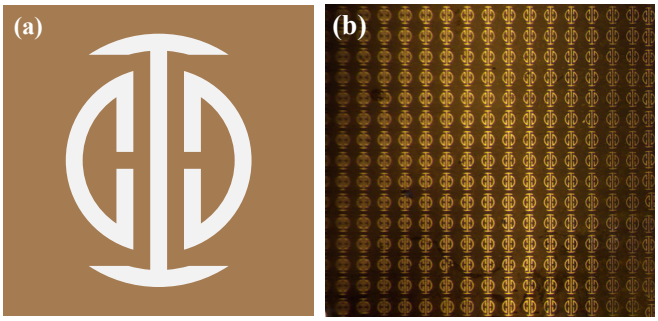

Fig. 1. (a) Unit cell geometry of the proposed metamaterial. (b) Microscopic image of fabricated metamaterial.

II. Methods

Our geometry consists of 2 main parts: firstly, the substrate and metal-based MM, the design consists of two toroidal resonators shown in unit cell (see Fig. 1(a)). These two resonators couple together and an EIT-like effect is observed. Secondly, the VO_2 layer over a quartz substrate, which is used to actively tune the EIT effect. The designed MM and the arrangement of MM, polyimide, VO_2 and quartz. The MM structure is of aluminum and has a thickness, $t = 200nm$, and VO_2 layer is 1.5 μm thick. The microscopic image of experimentally fabricated sample is shown in Fig. 1(b). The optical properties of VO_2 is described using Drude model which is expressed as [8]:

$$\varepsilon(\omega) = \varepsilon_\infty - \frac{\omega_p^2}{\omega^2 + i\gamma\omega} \tag{1}$$

$$\omega_p = \sqrt{\frac{\sigma}{\sigma_0}}\,\omega_p(\sigma_0) \tag{2}$$

Where, $\varepsilon_\infty = 12$, and ω_p is the plasma frequency, equation 1 is utilized to plot real and imaginary part dielectric constant versus frequency at different conductivities to achieve active modulation of EIT response.

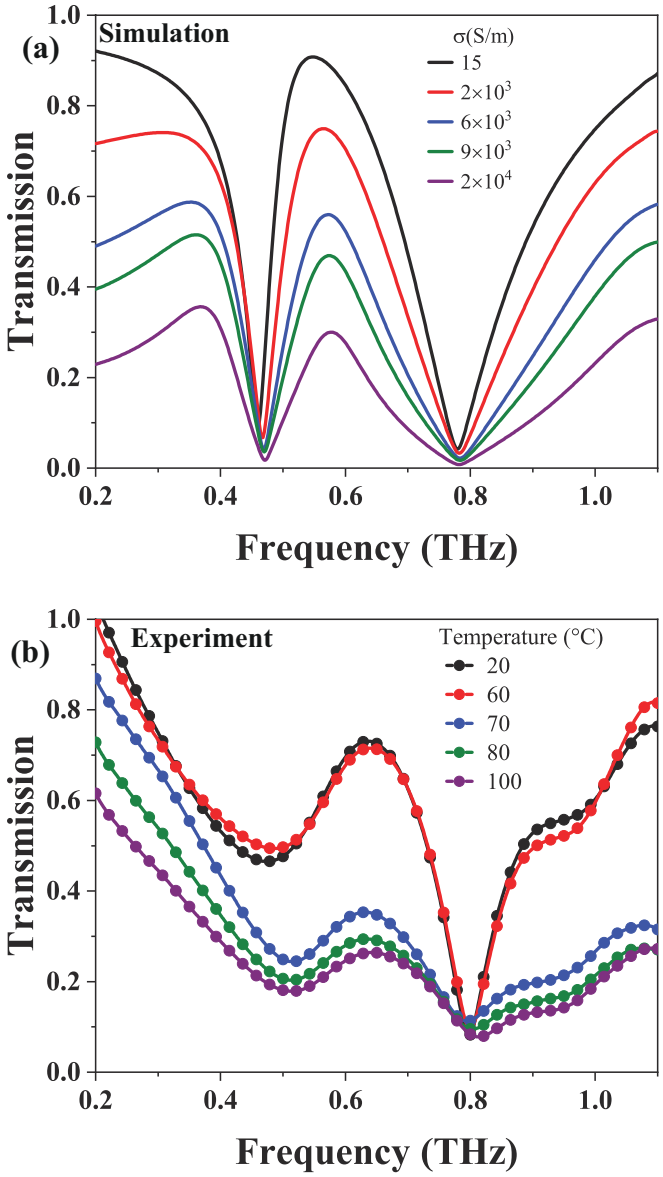

Fig. 2. (a) Modulation of Transmission with variation of conductivity in simulation. (b Modulation of transmission with variation of environmental temperature in the experiment.

III. Results and Discussion

The transmission spectrum of the complete geometry and its modulation with varying conductivity of VO_2 is depicted in Figure 2. The transmission window at 0.55 THz arises due to the frequency detuning of bright-bright mode resonators. The black solid trace represents the transmission spectrum for the proposed metamaterial (MM) at a conductivity of 15 S/m. In contrast, the violet trace shows the transmission spectrum when the conductivity of VO_2 is 20,000 S/m, representing the insulating and conductive phases, respectively. The transmission spectra for different conductivity values are illustrated in Figure 2 (a). Figure 2 (b) demonstrates experimental modulation of transmission response with varying temperature, the black circle trace shows transmission at room temperature, and the violet circle trace shows transmission at 100°C.
It clearly shows that as the conductivity of VO_2 increases, the EIT window is diminishes. This active tuning is achieved experimentally by increasing the external temperature. As we know, VO_2 is a phase transition material, and changes its phase from dielectric to conductive at a transition temperature of 67°C, which is further validated by experimental results.

IV. Conclusion

In conclusion, we experimentally demonstrated an actively tunable EIT by bright-bright mode coupling in toroidal THz metamaterials. The bright-bright mode coupling results in a narrow transparent window at 0.55 THz. Additionally, VO_2 is employed with the MM structure to actively control the EIT-like effect by varying its conductivity. In this case, the peak of the EIT window can be controlled. It is noted that the transparency peak of the EIT effect reduces from 90% at the insulating phase to 30% at the conductive phase. Ultimately, we can tune the EIT window by actively using VO2, which can be greatly utilized in the fabrication of modulators, switches, and slow light devices.

***Abstract*— We show that Lorentz-dispersive nonlinearities are essential to describe the second- and third-harmonic responses from a metal-ITO metasurface with high fidelity. Details of a nonlinear-oscillator model that yields closed form angular dependences for second- and third-harmonic generation to describe the experimentally measured angular resolved spectra are presented.**

***Keywords*— metasurfaces, nonlinearities, indium-tin-oxide, hydrodynamic model, second-harmonic generation.**

I. Introduction

Nonlinear metasurfaces offer a compact platform for frequency conversion, enabling precise control over second-harmonic and third-harmonic generation [1]. A particularly effective architecture combines plasmonic resonators with epsilon-near-zero (ENZ) media like indium tin oxide (ITO), which exhibit large, tunable nonlinear responses near their ENZ wavelength [2]. These metal-dielectric-metal structures can strongly confine optical energy and support multiple, interfering radiation pathways.

However, accurately predicting the behavior of these systems is a significant challenge. Simplified models that neglect the frequency dependence (dispersion) of the material's nonlinear coefficients, $\chi^{(2)}$ and $\chi^{(3)}$, often fail. Near the ENZ point, treating these parameters as static constants misrepresents the phase of the nonlinear polarization, leading to incorrect predictions of interference effects and the final angular emission pattern. This work investigates resonant split-ring resonator (SRR)/ITO/Au metasurfaces using a combined numerical and analytical approach.

II. Methods

The study utilized a metasurface composed of gold split-ring resonators (SRRs) fabricated on an indium-tin-oxide (ITO) film, which was deposited on a continuous gold ground plate to ensure reflection-only operation (Fig. 1). The device's nonlinear optical response was characterized using a tunable femtosecond laser in a reflection-geometry microscope. Second- and third-harmonic generation (SHG and THG) signals were collected and analyzed for various input polarizations. Angle-resolved datasets between the SRR orientation and the input laser polarization were acquired not by moving the sample, but by rotating the polarization. Rigorous calibration, background subtraction, and power-scaling tests were performed to ensure data accuracy and confirm the perturbative nature of the harmonic generation.

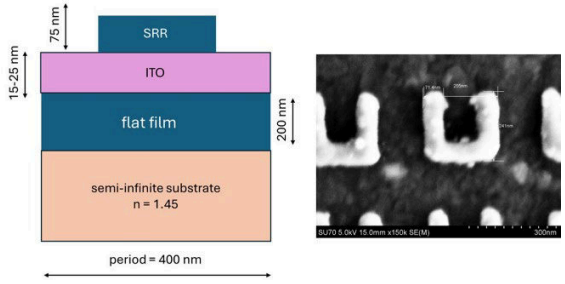

Fig. 1 Schematic of the (SRR)/ITO/Au structure along with an SEM image of the fabricated split-ring resonator.

The modeling framework employs an FDTD solver where gold is described by a nonlinear hydrodynamic model [3-4]. The crucial ITO layer is modeled with three increasing levels of fidelity: as a linear dielectric, then by adding static nonlinear susceptibilities ($\chi^{(2)}$, $\chi^{(3)}$), and finally by implementing frequency-dispersive Lorentz-pole nonlinearities.

III. Results and Discussion

A comparison between experimental second-harmonic generation (SHG) spectra and simulations reveals the critical

role of material properties in accurately modeling the metasurface's response. The experimental data shows two distinct SHG peaks corresponding to orthogonal pump polarizations (Fig. 2). Models that only account for nonlinearities from the metallic components, or that treat the indium tin oxide (ITO) layer with a simple, frequency-independent nonlinearity, fail to reproduce these results. Specifically, a model with a static, non-dispersive $\chi^{(2)}$ for the ITO layer also fails to match the measured polarization contrast and the relative amplitudes of the harmonic peaks, demonstrating that a more sophisticated description is necessary.

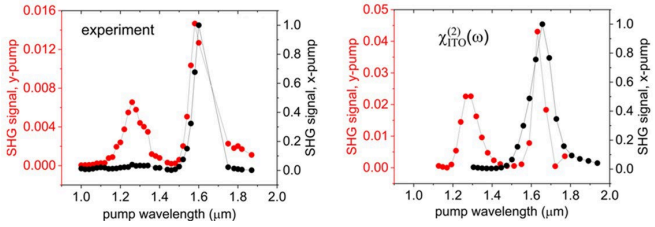

Fig. 2 Total SHG versus pump wavelength for x polarized (black circles, right axis) and y polarized (red circles, left axis) excitation. (left) experiment (right) simulations with a dispersive $\chi^{(2)}$ for ITO.

The key insight is that excellent agreement with the experiment is only achieved when the ITO's second-order susceptibility, $\chi^{(2)}$, is modeled as a dispersive, frequency-dependent parameter as described by equation 1. This advanced model correctly captures the position, relative intensity, and spectral shape of the SHG peaks.

$$\chi^{(n)}(\omega) = \frac{B_n}{\Omega_n^2 - \omega^2 - i\gamma_n\omega} \quad (1)$$

Expanding on this, we demonstrate that a model incorporating Lorentz-dispersive nonlinearities for ITO is essential to reproduce not only the spectra but also the experimentally measured angular patterns for both SHG and THG, whereas simpler, static models consistently fail. Our analysis reveals that the enhanced harmonic generation arises not from ENZ field concentration alone, but from the complex interplay between the SRR-induced modal fields and the intrinsically dispersive ITO nonlinearities [5].

To provide a physically interpretable framework, we developed a compact analytical model that treats the metasurface as a driven nonlinear oscillator. This model consists of coupled equations of motion for the x and y axes, each with distinct effective mass, damping, and restoring forces to capture the SRR's structural anisotropy. A weak cubic anharmonic potential is introduced to the system, which, when perturbed by the linear motion driven by the pump field, generates the second- and third-harmonic responses. By solving these equations perturbatively, we derive closed-form expressions for the SHG and THG intensities as functions of the input polarization angle. The most critical feature of this model is that the coefficients for the angular basis functions are treated as complex numbers. This complexity is not merely a fitting parameter but is physically significant: the magnitude and phase of each coefficient encode the intricate interference between different radiation pathways, capturing phase delays arising from material dispersion, propagation within the multilayer stack, and geometry-dependent radiation patterns. By fitting this model to the experimental data, we can extract these complex amplitudes, allowing us to deconstruct the final angular emission patterns into the fundamental contributions and their relative phases.

IV. Conclusion

In conclusion, this work demonstrates that accurately modeling the metasurface's second- and third-harmonic generation requires incorporating the dispersive nature of ITO's nonlinearities, as simpler static models fail. This approach is successful because it correctly captures the complex phase interference between different radiation pathways, which governs the observed angular emission patterns. This physical picture is further validated by a compact, driven nonlinear oscillator model that relies on complex coefficients to encapsulate the crucial phase relationships between these interfering pathways. This framework not only reconciles experiment and theory but also provides a practical route for the inverse design of metasurfaces with tailored, angle-dependent nonlinear emission.

Enhancement of Spontaneous Decay Rate in Hybrid Photonic Nanocavities

Themistoklis Deloudis[1,*], Angus Crookes [1], Angela Demetriadou [1]

[1]School of Physics and Astronomy, University of Birmingham, UK
*Corresponding author: txd383@student.bham.ac.uk

***Abstract*—Structured optical environments modify the spontaneous decay rate of quantum emitters. Ultra high emission rates are often hindered by either the diffraction limit or material losses. We design a hybrid photonic nanocavity with extreme enhancement of the spontaneous decay rate, not often seen in diffraction-limited photonic cavities. Our new design can easily form a quantum network, with applications in quantum technology.**

***Keywords*— hybrid cavities, Purcell factor, emission rate enhancement, photonic crystal, plasmonic antenna.**

I. Introduction

Optical environments modify the spontaneous emission rate of quantum emitters, either enhancing or suppressing it [1]. Spontaneous emission in a photonic environment is quantified by the Purcell factor

$$F_P^m = \frac{3}{4\pi^2}\left(\frac{\lambda_m}{n}\right)^3 Q_m Re\left[\frac{1}{\tilde{V}_m}\right] \quad (1)$$

where λ_m corresponds to the wavelength of the m^{th} photonic mode, n refers to the refractive index of the environment surrounding the emitter and Q_m,$\tilde{V}_m$ are the quality factor and the mode volume of the mode experiences, respectively.

While many different photonic environments exist, one can classify them into two broad categories: dielectric and plasmonic. Here, we concentrate on nanocavities (i.e. cavities with nanosized features). Dielectric nanocavities, for example formed with photonic crystals, retain photons for long times, but they are diffraction limited. On the other hand, plasmonic nanocavities confine light into deep subwavelength scales, but exhibit high ohmic and radiative losses. To address these limitations, hybrid photonic nanocavities have been proposed [2]. In this work, a scalable hybrid photonic design is proposed, operating in the optical frequencies which demonstrates unprecedented enhancement of the spontaneous enhancement of the spontaneous decay rate. In contrast to other hybrid designs [7], a plasmonic dimer antenna is integrated inside a photonic nanobeam, at the point where the electric field of the latter is maximum. In this way, the scattering losses are mostly mitigated, enabling simultaneously ultra-high Q factor and subwavelength mode volume to achieve extremely high Purcell factors.

II. Hybrid Cavity Design

Our design operates at 780nm and combines a periodically patterned photonic nanobeam made of Si_3N_4 [3] and a gold dimer antenna integrated in the central air hole of the former, as graphically shown in Fig. 1a) and b). The radius of each air hole is $r = 52.67$nm, while the photonic crystal lattice constant is $\alpha = 262$nm. The cavity has a constant height of $h = 300$nm and is wider in the center; namely $b_0 = 558$nm, gradually tapered down to $b_m = 458$nm to the edges. This introduces a band gap at the edges of the waveguide, preventing photons of $\lambda = 780$nm from escaping and, therefore, minimising scattering losses and forming a cavity. In the absence of plasmonic components, the nanobeam exhibits resonant cavity modes at $\lambda = 780$nm, $\lambda = 767$nm and $\lambda = 756$nm. The lowest order mode, depicted in Figure 1c), corresponds to $\lambda = 780$nm and has a quality factor $Q = 1.3 \times 10^7$ and mode volume $V = 1.1\lambda^3$. The plasmonic component is a gold dimer antenna that consists of two identical faceted spheres of radius $r_p = 24$nm and facet radius $r_f = 6$nm. The distance between the spheres is set to 1nm, which yields extremely strong electric fields. By placing a dielectric spacer of permittivity ϵ_{sp}^{rel} between the facets, we can tune the resonant frequencies of the plasmonic antenna and, thus, control the detuning with respect to the nanobeam modes.

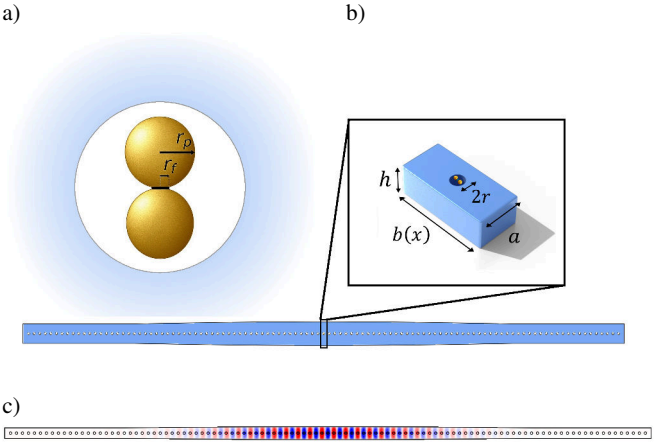

Fig. 1: a) Close up view of the central air hole of the hybrid photonic - plasmonic nanocavity. b) Depiction of the central unit cell. c) Lowest order mode of the isolated photonic nanobeam, at $\lambda = 780$nm

III. Spontaneous Decay Rate Enhancement

It is often desirable to decompose a photonic system into normal modes, especially if one wants to explore its interaction with quantum emitters. However, to account for the dispersive and lossy nature of gold, we use Quasi Normal Mode (QNM) formalism [4]. This approach allows for the computation of both the total and each QNM's contribution to the spontaneous decay rate of an emitter using [5]:

$$\frac{\gamma}{\gamma_0} = \sum_m F_P^m \frac{\Omega_m^2}{\omega} \frac{(\Gamma_m/2)^2}{(\omega-\Omega_m)^2+(\Gamma_m/2)^2} \times \left[1 + 2Q_m \frac{\omega-\Omega_m}{\Omega_m} \frac{\mathrm{Im}(\tilde{V}_m)}{\mathrm{Re}(\tilde{V}_m)}\right] \tag{2}$$

where m idexes the mode with eigenfrequency

$$\omega_m = \Omega_m - i\Gamma_m/2 \tag{3}$$

where Q_m, $\tilde{V}_m$, F_P^m referring to the quality factor, mode volume and Purcell factor defined in Equation (1) of the m^{th} mode respectively, and Ω_m and Γ_m being the resonant frequency and decay rate of the corresponding QNM [5]. The mode volume is defined as follows [5]:

$$\tilde{V}_m = \frac{1}{2\epsilon_0 n^2 \left(\tilde{\mathbf{E}}_m(\mathbf{r}_0)\cdot\mathbf{u}\right)^2} \tag{4}$$

where $\tilde{\mathbf{E}}_m(\mathbf{r}_0)$ declares the normalised electric field at $\mathbf{r}_0$, $\mathbf{u}$ is the unitary vector along the emitter's dipole moment.

Figure 2 depicts the modes of the hybrid cavity QNMs, as ϵ_{sp}^{rel} increases, with the area of each dot being commensurate with F_p, computed at the centre of the hybrid cavity, using Equations (1). The QNM splitting occurring when the detuning between the dimer and the nanobeam is low indicates that the two constituents are coupled. Examining the response of

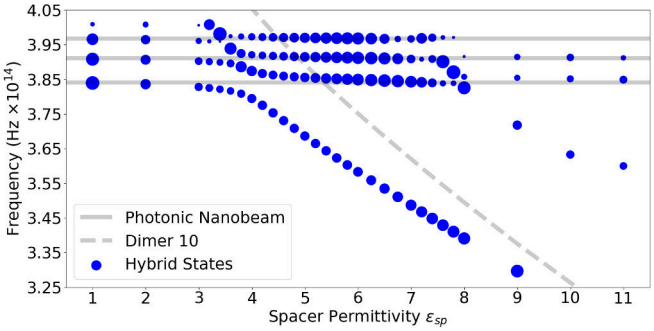

Fig. 2: Dispersion relation of hybrid QNMs in a broad range of spacer electric permittivity values. The dot size is proportional to the Purcell factor of the corresponding QNM. The spectral positions of the isolated waveguide modes and the (10) mode of the isolated antenna are added for reference.

the hybrid cavity, it clearly surpasses its isolated constituents, when these are detuned. To explicitly show this, we use Equation (2) to compute the increment of the spontaneous emission rate both for the hybrid cavity and its isolated constituents. The same rate is also computed classically by dividing the power emitted by a dipole placed in the cavity by the power it emits in free space. Figure 3 depicts how the γ/γ_0 varies throughout the red and near infrared part of the spectrum when the antenna is strongly blue - detuned with respect to the nanobeam (top panel) and when the (10) mode of the antenna is on resonance with the nanobeam (bottom panel). The former case is captured by simulating a hybrid cavity with $\epsilon_{sp}^{rel} = 1$, and results in a threefold increase of γ/γ_0 in comparison to with the isolated photonic nanobeam. The increase when the dimer and the nanobeam are brought on resonance is strongly suppressed compared to the detuned case [6].

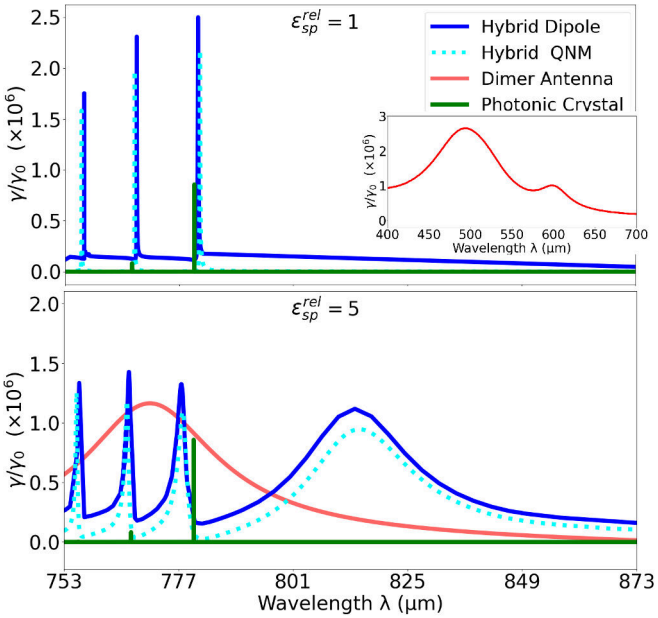

Fig. 3: Spontaneous emission rate, computed in the middle of the hybrid photonic cavity. Top panel demonstrates the enhancement achieved when the dimer antenna is blue detuned with respect to the nanobeam ($\epsilon_{sp}^{rel} = 1$). The inset depicts the isolated, spacerless antenna response. Bottom panel demostrates the case where the nanobeam being on resonance with the (10) mode of the antenna, which corresponds to $\epsilon_{sp}^{rel} = 5$. The enhancement attained with the isolated nanobeam and antenna are added for reference.

IV. Conclusion

In conclusion, we have designed a hybrid photonic nanocavity by integrating a gold dimer antenna inside a silicon nitride nanobeam to create an optical environment that significantly enhances the spontaneous decay rate of quantum emitters, operating at 780nm. This property makes it an ideal optical environment for specific quantum emitters, such as cold Rubidium atoms. The emission rate enhancement can reach as high as $2.5 \cdot 10^6$, a threefold increase in comparison to the enhancement attained by its isolated photonic waveguide. Furthermore, the size and shape of the nanocavity makes it an

excellent candidate as the building block of a long network of coupled waveguides. Atoms can be easily adsorbed to the metal surface and placed in the hot point, where the electric field and, subsequently, the emission rate enhancement is maximum. Ultimately, the geometry of the cavity makes rescaling possible, to make the device operate at different wavelengths, making it eligible for a plethora of emitters.

***Abstract*—Luminescent hybrid crystals are grown via organic ligand evaporation within a CuI-containing polymeric layer. This emissive layer can serve as defect layer in solution-processed microcavities, whose photonic bandgap and cavity mode are tuned to spectrally match the hybrid crystals emission, to the end of narrowing and enhancing it.**

***Keywords*— optical microcavities, photonic crystals, luminescence, hybrid coordination polymers.**

I. Introduction

Photonic crystals (PCs) are low-loss materials featuring periodic modulation of the refractive index, which gives rise to a photonic band gap (PBG), i.e. a frequency range in which light propagation is forbidden along specific directions and which is responsible for the PC chromatic response. The simplest examples of PCs are planar multilayer stacks of alternating dielectric layers, with high (n_H) and low (n_L) refractive indices, whose periodicity ($d_H + d_L$) is on the order of UV, visible, or infrared wavelengths. These structures are commonly referred to as distributed Bragg reflectors (DBRs). The reflectance of the first order PBG is maximized when the quarter-wavelength condition is satisfied:

$$\frac{\lambda_{PBG}}{4} = n_H d_H = n_L d_L \quad (1)$$

When the symmetry of the DBR is broken by introducing a defect layer (cavity) with a specifically designed optical thickness, allowed photonic states appear within the bandgap, giving rise to a narrow transmission peak (Fig. 1b). The thickness L_C and refractive index n_C of the cavity layer must be tuned such that the cavity supports a standing wave of wavelength λ_C comprised in the bandgap [1], according to:

$$2n_C L_C = m\lambda_C \quad (2)$$

where m denotes the cavity mode order. A microcavity (MC) is thus formed, consisting of DBRs sandwiching a defect layer in which the optical field is strongly confined. If an active emissive material is introduced into the cavity (Fig. 1a), it experiences an enhanced local electromagnetic field and a modified photonic density of states [2]. Consequently, its emission spectrum is altered, with increased intensity and spectral redistribution around the cavity resonance (Fig. 1c). To exploit this effect for applications ranging from lasing to optical sensing and filtering [2], the MC must be properly engineered such that the cavity mode spectrally overlaps the emission of the active material.

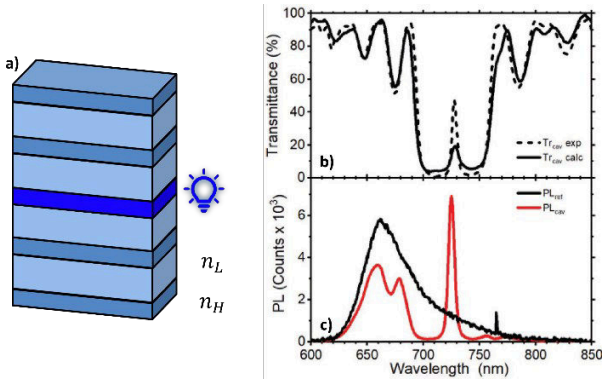

Fig. 1 Scheme of a planar MC with an emissive material embedded in the defect layer a). Experimental (continuous line) and calculated (dashed line) transmission b) and emission spectra c) of a MC (red) and a reference sample (black) for a all-polymer MC containing Perylene BisimideJ-aggregates. Adapted from [1].

Hybrid coordination polymers (HCPs) are an emerging class of materials whose photoluminescence properties can be tuned through the appropriate selection of their constituent building blocks. HCPs are coordination compounds containing inorganic clusters or inorganic polymeric subunits [3]. In these materials, the infinite repetition of the coordination entity is provided by the inorganic component, while the overall dimensionality (Fig. 2) depends on the binding sites of the organic ligand [3]. Among HCPs, copper(I) iodide-based hybrids display a wide variety of molecular structures, often showing stimuli-responsive emissive properties [3] and high luminescence efficiency [4].

In this work, luminescent copper(I) iodide hybrids are used as active materials within the cavity layer of solution-processed organic microcavities. Ligand evaporation is employed to promote crystal growth directly within the cavity layer of a pre-fabricated MC. The inherently broad emission of the HCP is

expected to be reshaped by the MC, resulting in enhanced emission intensity and spectral narrowing, potentially amplifying any stimuli-responsive behavior.

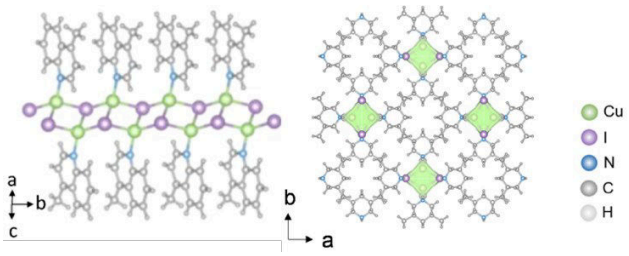

Fig. 2 Example of 1D and 2D crystal structures of Copper(I) iodide hybrids materials. Adapted from [4].

II. Methods

Wet-chemistry and solution-processing techniques are used to fabricate both the organic DBRs and the cavity layer composing the MC. The DBRs are deposited on glass substrates by dynamic spin-coating of alternating low-refractive-index (cellulose acetate, CA, in diacetone alcohol) and high-refractive-index (polyvinylcarbazole, PVK, in toluene) polymer solutions, followed by annealing at 70°C. The cavity layer is fabricated by spin-coating a CA solution in acetonitrile containing 0.1 M CuI, which acts as the inorganic node of the emissive HCP. The complete microcavity is then exposed for 24 h to vapors of an organic ligand, which binds to the CuI nodes within the cavity layer, leading to the formation of confined emissive HCP crystals. Depending on the specific HCP emission, the DBR bandgap and cavity-mode spectral positions are tuned using Eq. (1) and Eq. (2), to achieve overlap with the emission band of the hybrid crystals.

III. Results and Discussion

Fig. 3 shows the reflectance spectra of PVK:CA DBRs fabricated by spin-coating polymeric solutions with different concentrations, resulting in photonic band gaps centered at approximately 450 nm, 550 nm and 650 nm. These results demonstrate that the PBG can be continuously tuned across the visible spectrum by adjusting the layer thicknesses, enabling adaptation to the emission wavelength of a target CuI hybrid coordination polymer.

Several organic ligands capable of coordinating CuI nodes to form emissive hybrid crystals were investigated. Here, we focus on 4-methylquinoline. Fig. 4 shows the photoluminescence emission spectrum of a three-layer sample (PVK:CA–CuI:PVK) exposed to 4-methylquinoline vapors. The appearance of an emission peak at approximately 575 nm confirms the formation of emissive hybrid crystals. However, this emission is red-shifted compared to literature values [4], possibly due to polymer–crystal interactions or the formation of a different crystal polymorph. Further investigations are required to clarify this behavior. Based on the measured emission spectrum (Fig. 4, red curve), a microcavity with a cavity mode spectrally overlapping the emission was successfully fabricated (Fig. 4, black curve).

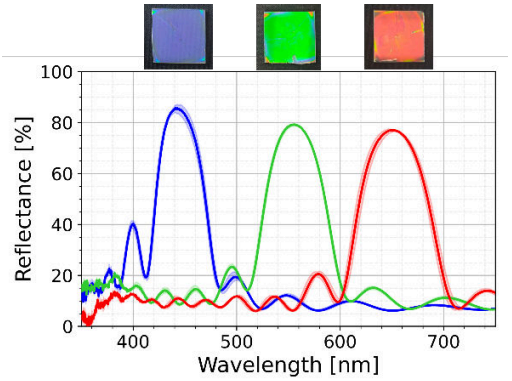

Fig. 3 Reflectance measurements of blue, green, and red PVK:CA DBRs obtained by tuning the layer thicknesses. Inset photographs show the structural color of each DBR.

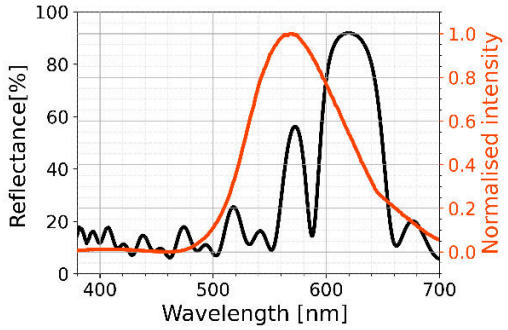

Fig. 4 Photoluminescence emission spectrum (red, excitation at 365 nm) of a PVK:CA–CuI:PVK stack after exposure to 4- methylquinoline vapors. Reflectance spectrum (black) of a microcavity engineered to spectrally match the emission band.

IV. Conclusion

We have demonstrated the formation of emissive CuI-based hybrid crystals grown directly within a CuI-containing polymeric layer via ligand evaporation. Furthermore, a solution-processed microcavity with a photonic bandgap and cavity mode spectrally overlapping the hybrid emission (~575 nm) was successfully fabricated. Future work will focus on the growth of emissive crystals directly within the cavity layer of the completed microcavity. Key-challenges include controlling ligand permeation through the DBR layers, which may alter the refractive indices and consequently the MC optical response. A carefully tuned additional annealing step, designed to preserve the emissive crystals, may promote ligand desorption from the DBRs layers and mitigate this effect.

***Abstract*— We investigate multilayer photonic crystal gratings in which stacked layers replicate a periodic surface pattern, enabling multimode waveguiding and angle-selective diffraction in reflection. An FDTD-based design approach clarifies the influence of the grating period, refractive index contrast, and layer sequence. Samples fabricated using ion beam sputtering technology experimentally confirm a narrowband, angle-selective response under oblique illumination.**

***Keywords*—photonic crystal gratings, multilayer structures, multi waveguiding, diffraction filtering, FDTD.**

I. Introduction

Unlike conventional one-dimensional gratings, Multimode Waveguiding Photonic-Crystal Gratings are periodically modulated multilayer structures that enable angular selectivity in diffraction through the combined effects of surface modulation and Bragg-type resonances. These structures can improve the spatial quality of reflected diffracted beams. Similar spatial filtering mechanisms based on periodic refractive-index modulation and photonic crystal concepts have previously been demonstrated in both transmission and reflection configurations [1-3].

In this work, we investigate multilayer photonic crystal gratings formed by depositing dielectric layers onto a corrugated substrate (see Fig. 1a). Their angular and spectral responses are analyzed using finite-difference time-domain simulations, which guide the design and fabrication of the structure.

II. Methods

Our methodology combines analytical modeling, numerical simulations, and experimental validation (see Fig. 1b) to study angular-selective diffraction and spatial filtering in multilayer photonic crystal gratings formed by periodically replicated layers on a corrugated substrate. The structure is modeled as a two-dimensional periodic system with transverse and longitudinal periods d_x and d_z.

$$\lambda_{m_x,m_z}=\frac{2d_xd_z\left(m_xd_z\sin\theta+m_zd_x\cos\theta\right)}{m_x^2d_z^2+m_z^2d_x^2},$$

The resonance conditions of the multiple diffracted and guided modes are obtained from elastic wave-vector conservation in reciprocal space, leading to a unified multimode diffraction relation which simultaneously describes Bragg resonance, when constructive interference in reflection occurs between the waves scattered by the periodic planes, transverse resonance, when the diffractive coupling condition to a transverse (lateral) mode of the structure is satisfied in reflection or transmission, and Littrow-type resonance, which occurs when both resonances occur simultaneously, sending the light back along the incident direction (see Fig. 1c); these regimes can be described through the integers m_x and m_z.

A four-wave coupled-mode formulation is further introduced to describe the interaction between the incident wave, the Bragg-backwards reflected wave, and the forward and backward diffracted waves. Most interesting for us are backward diffracted wave, which is supposed to propagate at approximately the Littrow direction. We expect that this diffraction component will lead strongest angular filtering. Based on this framework, the grating parameters are chosen to reach a multimode resonance regime.

Finite-difference time-domain (FDTD) simulations are used to validate the analytical model and to refine the design. The simulations start by defining a unit cell with the corresponding geometry and by applying Bloch boundary conditions along the periodic directions. A Broadband Fixed-Angle Source Technique (BFAST) is used to model non-normal incidence.

The multilayer thicknesses and the longitudinal period are optimized for oblique incidence using a generalized quarter-wave condition. The Nb_2O_5/SiO_2 gratings fabricated by ion beam sputtering (IBS) technology [4] were previously studied in the non-diffractive regime [3]. In this work, the diffracted light orders are experimentally characterized and compared with theoretical predictions.

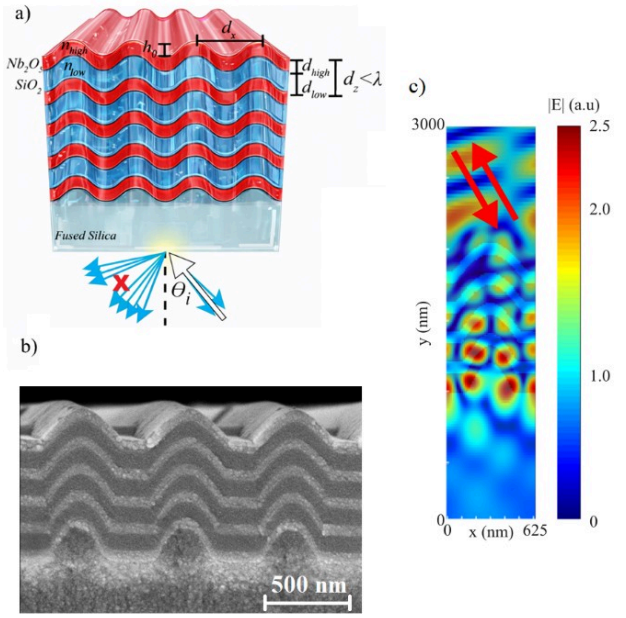

Fig. 1. (a) Schematic of multilayer grating, defining the transverse and longitudinal periods and the incidence angle. (b) Cross-sectional SEM image of the fabricated the Nb_2O_5/SiO_2 structure on fused silica substrate. (c) FDTD electric-field amplitude distribution under resonant illumination.

III. Results and Discussion

Experimental measurements at 633 nm under S polarization reveal a strong angular redistribution of the reflected and transmitted diffraction orders produced by the fabricated multilayer grating. As shown in Fig. 2, the first reflected order R_1dominates over a broad angular range around 29° - 32°, while the specular reflection R_0 is strongly suppressed in the same region.

A complementary behavior is observed for the transmitted orders, indicating efficient angular-selective coupling between reflection and diffraction channels. The total measured power remains close to 97% over the entire angular range, confirming low losses and good fabrication quality. These results demonstrate experimentally the angular-selective response and spatial filtering capability predicted by the analytical model and numerical simulations.

IV. Conclusion

We have theoretically and experimentally demonstrated angular selective diffraction and spatial filtering in multilayer photonic crystal gratings fabricated on corrugated substrates. The measured redistribution of reflected and transmitted diffraction orders and the high overall efficiency confirm the validity of the analytical and numerical design approach. These results highlight the potential of multilayer grating photonic crystals for compact diffractive and spatial filtering optical components.

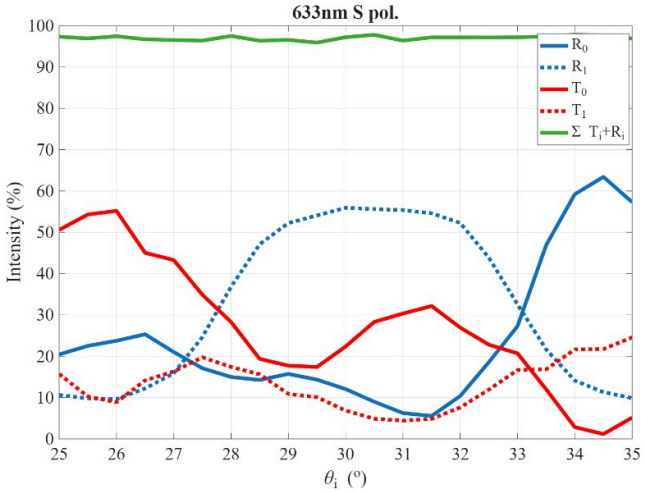

Fig. 2. Measured angular dependence of the reflected and transmitted diffraction efficiencies R_0, R_1, T_0, and T_1 at $\lambda = 633$nm under S polarization for the fabricated multilayer photonic crystal grating. The green curve shows the total measured efficiency $\sum_i (R_i + T_i)$.

I. Introduction

The current world demand for energy requires the expansion of renewable solar energy. The Space Solar Power Project aims to increase access to clean energy by harvesting power at large from space via ultra-light, efficient photovoltaic (PV) devices and transmitting it back to Earth through RF enabled wireless power transfer [1]. Luminescent solar concentrators (LSCs) are one such class of PV concentrator devices that leverages the Stokes shift [2] to achieve 10^5 times greater light concentration than traditional bulk optics methods [2]. Typically, LSCs are waveguide devices with isotropic emitters non-deterministically dispersed within a slab waveguide, such that their luminescence is transmitted via total internal reflection (TIR) to an attached PV cell. However, TIR - based strategies in the optical regime are inefficient, leading to $> 25\%$ photon loss [3].

To mitigate these losses, we propose a redesign of the LSC architecture that facilitates controlled free space optical outcoupling from the waveguide to the PV cell instead. This Emissive Luminescent Solar Concentrator (eLSC) model comprises an ensemble of quantum dots placed within a waveguide resulting in a spatially and temporally incoherent source, with a spatially isotropic emission profile. However, by coupling the quantum dot emission to a guided mode resonance, we enforce a single spatial phase profile along the aperture, thus establishing a degree of spatial coherence to an ensemble of incoherent emitters [4].The confined light is then outcoupled via a momentum matched resonant grating structure.

II. Methods and Results

The eLSC is designed to span 20 cm; 2 mirrored devices of 10 cm each. The quantum dots used are CdSe/CdS that that absorb broadly up to ~ 600 nm and emit at 635 nm ± 15 nm. The corresponding PV cell(s) is to be placed above one end (i.e., at -10 cm and $+10$ cm) of the waveguide grating structure, as seen in 1a), which then dictates two crucial design considerations: a) the grating structure must be quasi-aperiodic to outcouple light at a range of diffraction angles with respect to the PV cell and b) at each grating period, the emission profile must be asymmetric such that maximum energy is transmitted towards the closer PV cell.

To address these challenges, we use FDTD electromagnetic simulations to design the waveguide and grating structure, optimizing for maximum coupling efficiency along the optical path: quantum dots to guided mode, guided mode to free space. To evaluate the overall outcoupling performance, two orthogonally polarized dipoles were placed along the axis of the propagation, exciting both forward and backward guided modes. For the waveguide, sputtered TiO_2 $(n \sim 2.35)$ was chosen as the core, and SiO_2 $(n = 1.44)$ as the substrate for their high refractive index contrast and ease of fabrication. The waveguide dimensions were determined to be 200nm tall and 400nm wide, resulting in a unidirectional coupling efficiency of 70% and a Purcell factor of 30 for the TM polarized dipole. This indicates an enhancement of specific radiative decay channels into the guided mode, which translates to the dominance of a single mode (in this case, TM_0) within the waveguide, establishing spatial coherence to incoherent quantum dot luminescence.

To outcouple the confined light, we introduce periodic perturbations along the surface of the waveguide in the form of symmetric TiO_2 grating elements that satisfy the following phase matching condition:

$$n_{eff} \quad = \quad n_1 \sin\theta_i - m\frac{\lambda_0}{\Lambda} sin\phi, \tag{1}$$

here, n_1, n_2, n_3 refer to the refractive index of the upper cladding (in this case air), waveguide material (TiO_2), and the substrate material (SiO_2), respectively. θ_{inc} is the angle of diffraction into free space, λ_0 is the wavelength of operation. n_{eff} refers to the effective index of the mode within the waveguide medium and Λ refers to the grating period of the grating element.

Equation 1 states that the periodic perturbations of the grating supplies discrete momentum such that light confined in the guided mode, i.e., outside the light line, is folded back into the light line, allowing free space outcoupling. However, to satisfy requirement a) mentioned above, the grating period

Fig. 1. a) The overall eLSC design with quasi-aperiodic arrays of guided mode resonators. b) A single period of 660nm with 4 sub-periods, each of $\Lambda' = 165$nm. c) Asymmetric emission profile from 2 orthogonal dipole excitation d) Asymmetric emission profile from randomized, incoherent dipole sources e) 66μm aperture (= 100 periods) simulation, confirming beam steering at finite, large apertures.

must change with respect to the desired outcoupling angle (as per Equation 1), requiring a range of grating periods to cover the full range of the proposed 10 cm device while remaining optically coupled to the PV cell. Each period is thus repeated a finite number of times over few centimeters before "stepping" to the next period, creating a quasi-periodic array on the wavelength scale, and aperiodic array in the macroscopic scale 1a).

In the presence of a bi-directional guided mode, both the $+1$ and -1 diffraction conditions are satisfied, leading to symmetric transmission intensities in both directions (requirement b)). We address this issue by designing a metasurface with a blazed phase profile. By dividing a single period into n equal sub-periods, each containing a structure contributing $2\pi/n$ phase, it is possible to create a phase ramp that enhances one diffraction order, while suppressing the other, via constructive and destructive interference, respectively. Thus, for incoherent emitters with established spatial coherence via the single mode waveguide, the relative spatial/phase profile along the waveguide remains well-defined, allowing the phase ramp to create some asymmetry in the transmission intensity [5].

For our case, we divide the period into 4 sub-periods (1b)), and use a Bayesian optimization algorithm to determine the parameters of each sub-structure, optimizing for maximum transmission to the $-1(+1)$ order and penalizing transmission to parasitic orders. For the 660 nm period, the addition of the blazed phase profile demonstrated angular selectivity, and allowed for 62.5% emission into the -1 order, with the remaining 37.5% considered as loss, from the $+1$ and $0th$ order as seen in 1c).

Finally, for a more realistic model, we simulate incoherent emitters using 100 dipoles of randomized phase, polarization, and location, placed along the propagation axis of the waveguide, and the transmission to the -1 order observed. The simulation was then iterated 10 times, each with a new set of randomized dipoles, and averaged to determine the emergent behavior. Analyzing the phase contribution of the individual sub-structures revealed a low relative phase delay, with an average delay across the period of $5\pi/6$ instead of the expected 2π. Despite the lack of a phase gradient however, the device design maintained the high angular selectivity, and asymmetric emission under incoherent excitation, as seen in 1d), e).

III. Conclusion

In conclusion, we demonstrate high angular selectivity, and preferential outcoupling to the -1 order of non-equilibrium, incoherent emission. The use of a guided mode resonator facilitated the re-establishment of spatial coherence, allowing for directional emission in the visible. Further work includes expanding current models to full wave simulations, including tiling together the full aperiodic structure to demonstrate the "off axis focusing" of the diffracted beam.

***Abstract*— Whispering-gallery microresonators offer ultrasensitive optical fingerprints but can suffer from long-term spectral drifts. Combining experiments and modeling, we trace this instability to slow solvent release from quantum-dot-loaded polystyrene microparticles. Harnessing this understanding, we develop a simple stabilization protocol that locks resonances, enabling reliable WGM-based photonic labels, sensors, and microscale self-trackers.**

***Keywords*— Whispering-Gallery Modes Microresonators; Photonic labels; Optical Memory.**

I. Introduction

Whispering gallery mode (WGM) microresonators provide ultrasensitive optical fingerprints that are ideally suited for photonic labeling and for detecting minute variations in size and refractive index. These resonances arise from the repeated total internal reflection of light confined along the periphery of dielectric microstructures, resulting in long optical path lengths and high quality factors. When coupled to a luminescent gain medium, WGM microcavities can be directly probed through their emission, enabling compact and highly sensitive optical platforms with ultrasharp spectral features. Such luminescent WGM microresonators can be fabricated through self-assembly approaches, for instance by incorporating luminescent molecules or nanomaterials into dielectric microspheres.

Among the different material platforms, polymer microspheres loaded with semiconductor quantum dots represent a particularly attractive architecture. Polystyrene microbeads provide a low-cost, optically transparent, and easily processable dielectric host with well-defined spherical geometry, while quantum dots offer high photostability, size-tunable emission, and efficient coupling to cavity modes owing to their large absorption cross-section and high quantum-yields. His combination enables fully self-emissive WGM microresonators that do not require external evanescen coupling schemes and can be fabricated in a scalable and versatile way.

WGM microresonators have attracted considerable interest for applications in optical sensing, photonic tagging, and microscale tracking of physicochemical changes. In most experimental and theoretical descriptions, their optical response is implicitly assumed to be passive and reversible, governed solely by instantaneous parameters such as temperature, refractive index, and resonator geometry. Within this framework, long-term spectral drifts are typically regarded as undesirable artifacts that compromise performance and must be suppressed. However, despite their sharp spectral signatures, polymer-based WGM microresonators often exhibit pronounced thermal and temporal instabilities that limit their practical applicability. The physical origin of these drifts has remained poorly understood.

In this work, we combine experiments and modeling to show that these instabilities originate from slow internal dynamics within the microresonator material. In particular, we demonstrate that the gradual release of residual solvent trapped inside the polymer matrix during fabrication induces a continuous and irreversible evolution of the effective refractive index and a progressive shrinking of the microparticles, which can be directly monitored via WGM spectroscopy. As a result, the optical spectrum of the resonator does not solely reflect its instantaneous state, but progressively encodes information about its preparation conditions and environmental history. By identifying and controlling this mechanism, we establish a simple protocol to suppress long-term spectral drift, locking WGM resonances into stable, sharply defined modes. More broadly, our results reveal that commonly used WGM microresonators operate as non-equilibrium optical systems, in which slow internal processes couple to confined optical modes. This insight provides a new perspective on WGM resonators, advancing their reliable use as robust optical platforms, for photonic labeld, noninvasive sensors, and precise self-trackers of microscale physicochemical changes, while opening new opportunities for micro-optical memories.

II. Methods

Microresonator Fabrication: Whispering gallery

microresonators were realized by loading colloidal quantum dots into polystyrene microspheres, a widely adopted architecture for active WGM systems. The loading procedure relies on solvent-assisted diffusion of emitters into the polymer matrix, yielding intense photoluminescence coupled to high-Q optical modes.

Optical characterization: Optical spectra were acquired using high-resolution photoluminescence spectroscopy, allowing individual WGM resonances to be tracked over time with sub-nanometer precision. Measurements were performed over extended time windows (hours to days) and under controlled thermal conditions to disentangle fast thermal effects from slow temporal evolution.

III. Results and Discussion

Single-particle spectroscopy reveals that QD-polystyrene microparticles exhibit sharp and distinctive WGM fingerprints that evolve in time under ambient conditions. Monitoring the emission spectrum of an individual microparticle as a function of time elapsed after dropcasting, we initially observe a relatively low mode density, which progressively increases while displaying a systematic blueshift of the resonances (Figure 1b). This behaviour indicates a gradual modification of the optical cavity parameters, mainly associated with the change of the refractive index constrast with respect to the environment, where external solvent layers evaporate. However, the shift persists for several hours and becomes even more pronounced under mild vacuum conditions, as evidenced by the spectra reported in Figure 1c, which suggest the involvement of slow structural relaxation.

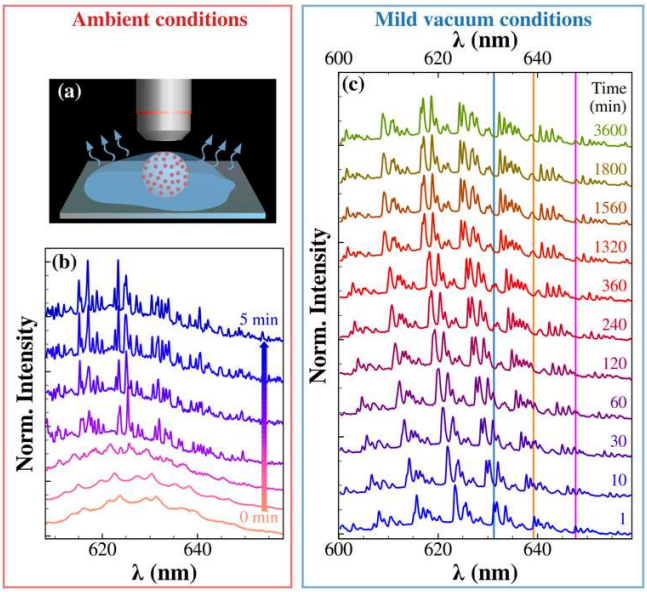

Fig. 1 (a) Illustration of the optical configuration employed to record PL spectra from a single QD-PSμP in air during solvent evaporation. (b) Temporal progression of the PL spectrum measured from the same microparticle following drop-casting under ambient conditions. (c) Time-dependent PL spectrum of an individual QD-PSµP maintained under mild vacumm (0.15 bar). Colored markers and shaded areas emphasize the systematic blueshift of three selected modes.

To elucidate the origin of this effect, the temporal evolution of WGM positions was analyzed within a model linking resonance shifts to variations in the effective refractive index and microsphere radius. The analysis corroborates a gradual shrinkage of the particle overt time, consistent with the slow release of residual solvent molecules trapped within the polymer matrix during the quantum dot loading process. As the solvent diffuses out, the the local dielecric environment experienced by the confined optical modes evolves concurrently with a reduction of the cavity size, leading to a continous and irreversible modification of the WGM spectrum.

Based on these observations, we implemented a thermal protocol aimed at accelerating solvent release to produce spectrally-stable photonic microtags. After this treatment, WGM spectra exhibit a marked suppression of long-term drift, with resonance positions remainng stable over extended measurements times and reproducible after prolonged storage, as shown in Figure 2. The thermal treatment effectively drives the system toward a steeady optical configuration, where both the internal refractive index and the resonator size reach a quasi-equilibrium state.

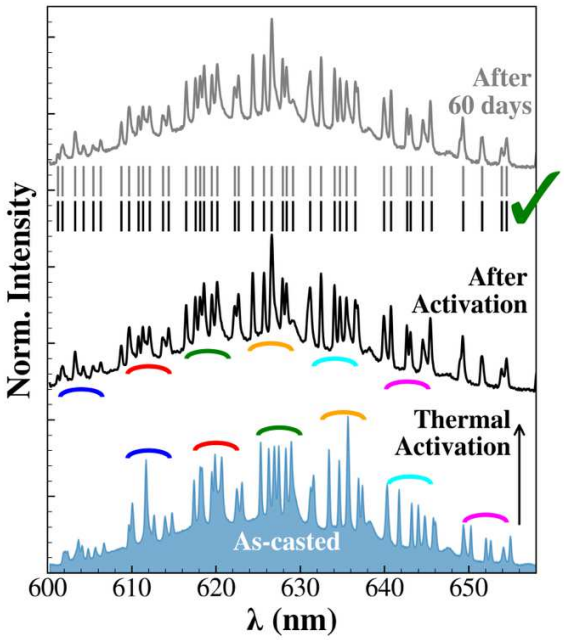

Fig. 2 µ-PL spectrum of a QD-PSµP recorded shortly after drop-casting (blue-filled) and following thermal treatment (black line), displaying a clear blueshift of the main WGM clusters (indicated by colored arcs). The gray spectrum shows the same sample measured 60 days later, after storage in ambient conditions. The WGM positions remain stable after thermal activation, making them suitable as a robust photonic barcode.

These findings reveal that polymer-based WGM microresonators operate as non-equilibrium optical systesm, in which slow internal structural dynamics are intrinsically coupled to confined optical modes. Rather than representing a limitation, this coupling can be harnessed as an additional

degree of freedom in photonic labeling and sensing, enabling microresontars whose optical spetra encode not only their present environment, but also their prior structural evolution.

IV. Conclusion

We have investigated whispering gallery modes in hybrid QD-polystyrene microparticle microcavities, showing that their unique spectral fingerprints sensitively encode environmental changes. Time-resolved tracking reveals irreversible blueshift driven by residual solvent evaporation, which are fully suppressed by a simple, thermal treatment requiring no additional fabrication steps. After stabilization, the resonators exhibit low thermal sensitivity due to near-compensation between thermal expansion and thermo-optic effects. Beyond secure photonic labeling, this platform enables noninvasive, real-time probing of structural dynamics in soft photonic materials and reconfigurable microresonators.

***Abstract*—We theoretically and experimentally demonstrate that merely tuning the spacer thickness of the bilayer photonic crystal slabs induces a topological transition from a fundamental charge ($\nu = 1$) to a high-order charge ($\nu = -2$) without modifying symmetry. This topological transistion is triggered by bilayer destructive interferences of quasi-BICs.**

***Keywords*— photonic crystal slabs, BIC, topological transitions.**

I. Introduction

Topological photonics has emerged as a vibrant frontier, with bound states in the continuum (BICs) being paradigmatic topological states in photonic crystal slabs(PhCs). BICs emerge as polarization vortices carrying quantized topological charges defined by the winding of far-field polarization vectors[4]. They have enabled numerous applications in lasing, sensing, and polarization control. Spatial symmetry strictly quantizes the charges at Γ points; e.g -symmetric systems require $\nu = 3n + 1$ ($n \in Z$)[4]. Although high-order charges such as $\nu = -2$ have been realized in C_6-symmetricstructures[1], prior works have largely isolated fundamental ($n = 1$) charges. A deterministic transition from fundamental to high-order charges—especially under preserved symmetry—remains unrealized.

Here, we theoretically propose and experimentally demonstrate symmetry-preserved tuning of at-Γ BICs in bilayer PhCs, realizing a topolgical transition from fundamental ($\nu = 1$) to high-order ($\nu = -2$) charges while maintaining C_3 symmetry[3].Via perturbation theory, we analytically reveal that destructive interference between bilayer radiation can completely suppress the first-order far-field correction upon tuning the spacer thickness. This drives a topological transition and the Q-factor scaling of near-Γ resonances changes from $\mathcal{O}^{-2}$ to$\mathcal{O}^{-4}$, with k the Bloch wavenumber. Full-wave simulations and angle-resolved measurements validate the predicted transition.

II. Theory

Figure 1(a) shows the structure of our BM. Each layer is composed of a triangular lattice of TiO_2 ($n = 2.46$) nanopillars. All the dimensional parameters for the two layers remain the same, but the top layer (tL) is shifted along the y-axis by p relative to the bottom layer (bL). The tL and bL are vertically separated by $2s$. The individual layers are governed by D_{6h} ($C_{6v} \times C_{1h}$) point group and hence support symmetry-protected at-Γ BIC, carrying polarization singularity with $\nu = +1$. The stack of the two layers breaks the C_6 and up-down mirror symmetry, resulting in the D_{3d} ($C_{3v} \times C_{1i}$) point group. Due to the symmetry breaking, the eigenstates of the two single layers, $|\mathbf{u}_{t,b}\rangle \equiv \mathbf{u}_{t,b}(\boldsymbol{\rho}, z \mp s)$, become mixed, where ($\boldsymbol{\rho}$,$z$) is the coordinate. Using group representation theory, we find that $|\mathbf{u}_s\rangle \equiv |\mathbf{u}_b\rangle + |\mathbf{u}_t\rangle$ ($|\mathbf{u}_a\rangle \equiv |\mathbf{u}_b\rangle - |\mathbf{u}_t\rangle$) is associated with the A_{2g} (A_{1u}) irreducible representation of the D_{3d} group. Therefore, $|\mathbf{u}_{s,a}\rangle$ are the eigenstates at the Γ points of the bilayer PhCs. We call photonic bands related to $|\mathbf{u}_s\rangle$ and $|\mathbf{u}_a\rangle$ symmetric band(SB) and antisymmetric band (AB), respectively. Since both $|\mathbf{u}_t\rangle$ and $|\mathbf{u}_b\rangle$ of the single layers are BICs, their linear superpositions, i.e., $|\mathbf{u}_{s,a}\rangle$, are BICs, exhibiting polarization singularity in the momentum spaces with the topological charges generally obeying $\nu = 3n + 1$ ($n \in \mathbb{Z}$) because of the C_3 symmetry. Although $|\mathbf{u}_{s,a}\rangle$ have vanished far-field radiation, the so-called quasi-BICs near the Γ point will radiate. This radiation, contributed from both the tL and bL, is expected to interfere constructively or destructively as s varies.

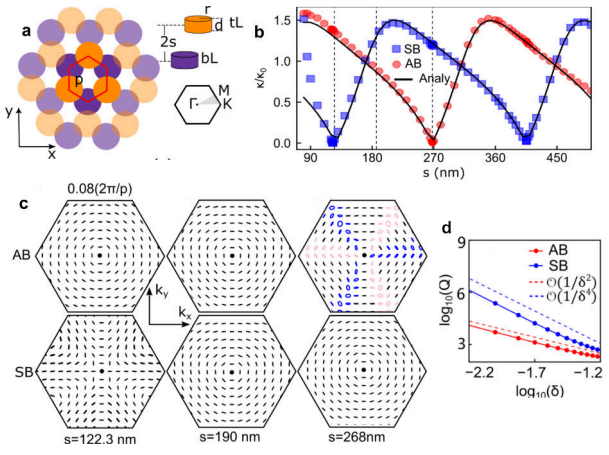

Fig. 1. **a** Schematic of the bilayer PhCs. The parameters are $r = 0.6p$, $d = 0.4p$ and $p = 300$ nm. **b** Simulated and analytical coupling coefficients for the SB and AB. **c** Polarization vector patterns of the far-field radiation from the SB and AB. **d** Q factors and their evolution trends with δ when $s = 122.3$ nm.

To reveal the interference behavior of the surrounding

radiative states around the BICs and the evolutions of the topological charges, we use perturbation theory to directly solve the far-field polarization vectors at a near-Γ Bloch wavevector $\boldsymbol{\alpha} = \frac{2\pi\delta}{p}[\ \cos\theta \quad \sin\theta\ ]^T$, where θ is the angle between $\boldsymbol{\alpha}$ and the x-axis, and δ is the perturbation parameter. We show that the $\mathbf{d}_1^+$ can be calculated from

$$\begin{bmatrix} d_{1y}^+ \\ d_{1x}^+ \end{bmatrix} = M\kappa_{s,a} \begin{bmatrix} \cos\theta \\ -\sin\theta \end{bmatrix} \tag{1}$$

where $\kappa_{s,a} = \langle \mathbf{u}_{y*}^+ | \mathcal{L}_{1x} | \mathbf{u}_{s,a} \rangle = \frac{1}{\sqrt{2}} \langle \mathbf{u}_{y*}^+ | \mathcal{L}_{1x} | \mathbf{u}_b \pm \mathbf{u}_t \rangle$ and M is a normalization parameter. The global coupling parameter $\kappa_{s,a}$ which relates the far-field polarization vectors of all the near-Γ states $|\mathbf{u}_{s,a}\rangle + \delta |\mathbf{u}_1(\theta)\rangle$ with the at-Γ states $|\mathbf{u}_{s,a}\rangle$, where θ spans 0–2π. According to Eq.(1), $\nu = +1$ ($n = 0$) for the SB and AB if $\kappa_{s,a}$ are nonzero[4]. Note that $\kappa_{s,a}$ are contributed from the tL and bL. we derive a detailed form of $\kappa_{s,a}$ to reveal how they vary with s,

$$\kappa_{s,a} = \frac{\kappa_0}{\sqrt{2}} e^{is\gamma} \frac{1 \mp e^{-i(2s\gamma+\varphi)}}{1 \mp \tilde{r}_0 e^{-2is\gamma}} \tag{2}$$

where κ_0 is the coupling coefficient of the single layer; $\varphi = \angle(r_0 - t_0)$, r_0 (t_0) is the normal reflection (transmission) coefficient of the single layer. Equation (2) indicates that when $2s\gamma+\varphi = 2N\pi$, $\kappa_s = 0$ and that when $2s\gamma+\varphi = (2N+1)\pi$, $\kappa_a = 0$, where N is an integer. We have demonstrated in theory that far-field radiation of the resonant states near BICs from two separated layers can produce destructive bilayer interference.

Figure 1(b) shows the calculated results of $\kappa_{s,a}$. The squares mark the simulated results according to the definition $\kappa_{s,a} = \langle \mathbf{u}_{y*}^+ | \mathcal{L}_{1x} | \mathbf{u}_{s,a} \rangle$. The solid curves denote the analytic results from Eq.(2), consistent with the simulation results. Our collective interference theory successfully predicts the destructive interferences at $s = 122.3$ nm for the SB and $s = 268$ nm for the AB. Figure 1(c) show the polarization vector patterns when $s = 122.3$ nm, $s = 190$ nm and $s = 268$ nm. One can find that when the destructive interference conditions are satisfied, i.e, $s = 122.3$ nm for the SB and $s = 268$ nm for the AB , the ν becomes -2 ($n = -1$). When $\kappa_{a,s}$ deviate far from zero, $\nu = +1$ ($n = 0$) for both the SB and AB. These results indicate that the topological charges can transition from $+1$ to -2 by changing s without breaking or boosting symmetry. We show in Fig.1(d) that when the condition for the destructive interferences is met, the Q factors scale with δ^{-4} near the Γ point.

III. Experiments

We fabricated the designed BMs with their spacer thickness of $s \sim 120$ nm and $s \sim 190$ nm based on the alignment lithography[2]. The scanning electron microscope (SEM) images shown in Fig.2(a) and 2(b) confirm the fine alignment and the precise control of the spacing layers. We use a commercial angle-resolved spectrometer(ARMS, Ideaoptics) to reveal the topological transition of the BICs. Figure 2(c,e) shows the measured spectra when $s \sim 120$ nm and $s \sim 190$ nm. The dispersions of the resonant modes in the SB and AB are clearly

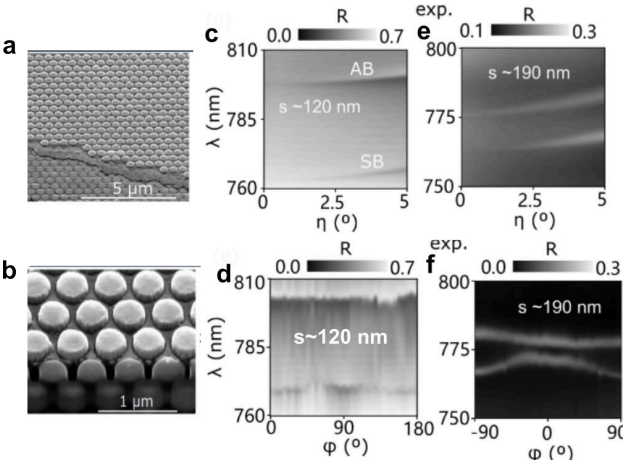

Fig. 2. **a, b** SEM images of the fabricated bilayer PhCs. **c, e** Experimental and simulated angle-resolved reflection spectra. **d, f** Experimental and simulated azimuth-angle dependence of the reflection spectra.

presented. When η approaches 0°, the Fano resonant structures disappear, indicating the existence of BICs. The resonance linewidth of the SB is noticeably narrower than that of the AB when $s \sim 120$ nm, which provides preliminary evidence for destructive interference.

We then rotated the samples and recorded the reflection spectra under the illumination of s-polarized input lights at a fixed η of 4°. The reflectance peak amplitudes scale with $R_{peak} \propto \cos^2\beta$, where β is the angle between the input light polarization and the major axis of the polarization ellipses. Consider that the sample azimuth angle is φ, the input polarization vector is then $[\ -\sin\varphi \quad \cos\varphi\ ]^T$. If the topological charge is $+1$ (-2), the polarization vectors is $[\ -\sin\varphi \quad \cos\varphi\ ]^T$ ($[\ -\cos 2\varphi \quad \sin 2\varphi\ ]^T$) and then $R_{peak} \sim 1$ ($R_{peak} \sim \sin^2 3\varphi$). Hence, as the samples are rotated by 180°, the reflectance at the resonances remains unchanged when $\nu = +1$ while R_{peak} oscillates by 3 cycles when $\nu = -2$. Figure 2(d) and 2(f) shows the measured φ-dependent reflection spectra. It can be seen that when $s = 120$ nm, the resonant peaks for the SB oscillate 3 times while those for the AB remain nearly unchanged. When $s = 190$ nm, the resonant peaks for both bands do not oscillate. These results indicate that we observed a topological transition of polarization singularities simply by changing the thickness of the BM spacer layer.

IV. Conclusion

We demonstrate theoretically and experimentally that the topological charges ($\nu = 3n + 1$) of BICs in C_3-symmetric bilayer metasurfaces can be dynamically tuned from fundamental charges ($n = 0$) to high-level charges ($n = -1$) by adjusting the spacer thickness. Our work provides a symmetry-preserved approach to control BIC topological charges and quasi-BIC Q factors, critical for tunable vortex lasers, ultrasensitive sensors, and other vortex-based devices.

Thermal simulations, including full cavity models, identify dominant dissipation pathways and relate them to thermooptic shifts and changes in transduced mechanical spectra.**

***Keywords*— optomechanics, photonic crystals, nanopillar cavities, thermal dissipation, thermo optic effect.**

I. Introduction

Nanopillar-based optomechanical cavities (OMCs) provide an attractive platform for co-localizing high-Q optical resonances with multiple mechanical modes in a sub-wavelength footprint [1]. These devices are promising for compact displacement and force sensing, as nanopillars offer high mechanical compliance while photonic-crystal confinement enables efficient optical transduction [2], [3]. While monolithic silicon implementations provide strong optomechanical performance [2], hybrid architectures integrating a silicon dioxide base on silicon-on-insulator (SOI) substrates facilitate low-loss waveguide integration and robust optical access [3]. The introduction of vertical material asymmetry and additional thermal interfaces is expected to modify heat-transport pathways.

In these high-field nanophotonic devices, residual optical absorption leads to localized heating, triggering thermo-optic (TO) shifts and free-carrier effects that distort the optical response [4]. Absorption-driven temperature gradients can also induce thermoelastic stresses and photothermal backaction, modifying the mechanical dynamics and the transduced radio-frequency (RF) spectra, with consequences for stability and calibration [5].

Thermal tuning and relaxation have been investigated in silicon optomechanical crystal cavities [6]. For nanopillar-based 1D photonic-crystal cavities, however, a quantitative identification of the dominant heat-loss pathways and their simultaneous optical and mechanical signatures remains missing.

Here we compare monolithic Si and hybrid Si/SiO_2 nanopillar cavities to identify dominant heat-loss channels. Combining power-dependent optical tuning, frequency-domain pump–probe measurements, and mechanical spectral analysis with finite-element (FEM) simulations, we connect thermal dissipation dynamics to thermo-optic shifts and changes in mechanical readout, extending beyond relaxation-focused comparisons [7].

II. Methods

A. Optomechanical cavities under study

We investigate one-dimensional photonic-crystal nanopillar cavities implemented in two material platforms: (i) monolithic silicon nanopillars and (ii) hybrid nanopillars with a silicon top segment and a silicon dioxide base on a silicon-on-insulator substrate. In both designs, the optical cavity is formed by a longitudinal modulation of the pillar geometry to create an adiabatic defect, resulting in strong optical confinement near the upper portion of the pillars and enabling optical transduction of their mechanical motion [2], [3]. Unless otherwise stated, the unit-cell geometry follows Fig. 1.

B. Experimental setup and readout

Optical and mechanical mode tuning. Optical resonances are probed with a tunable infrared laser coupled to the cavity via evanescent fiber-loop coupling (Fig. 2). Power-dependent optical tuning is obtained by monitoring the transmitted signal while sweeping the laser wavelength. Under increased optical excitation, absorption-driven heating produces thermo-optic shifts and free-carrier related effects that distort and shift silicon cavity resonances [4]. Mechanical motion is read out through optomechanical transduction of the transmitted light: the transmission is detected with a fast photodiode and the radio-frequency (RF) power spectral density is measured with a spectrum analyzer.

Frequency-domain pump–probe thermal response. Thermal relaxation is extracted using a frequency-domain pump–probe method (Fig. 3). The cavity supports at least two optical modes. A pump laser is tuned into resonance with one mode and intensity-modulated to generate periodic absorbed power and temperature modulation. A low-power probe laser is tuned to a second mode and converts the thermally-induced spectral shift into an amplitude modulation of the transmitted probe via the thermo-optic effect. The probe modulation at the pump modulation frequency is measured with a vector network

(b) Monolithic silicon nanopillar with a radius step Δr between bottom and top segments. Parameters: $t_1 = t_2 = 1500$ nm, $a = 350$ nm, $r = 105$ nm, and $\Delta r = 50$ nm (monolithic). (c) FEM simulation of the E_y field component of the fundamental TM cavity mode (side view). (d) Same for the second-order TM cavity mode, showing similar localization near the pillar top.

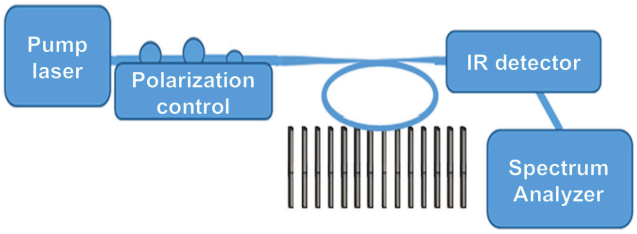

Fig. 2. Setup for optical transmission and mechanical readout under optical heating. A tunable IR laser is coupled to the cavity using a fiber-loop; the transmitted signal is detected on a fast photodiode and analyzed with a spectrum analyzer to obtain the RF power spectral density.

analyzer (VNA). We fit the magnitude response to a first-order low-pass transfer function,

$$|H(\Omega)| = \frac{1}{\sqrt{1 + (\Omega\tau_{\mathrm{th}})^2}}, \tag{1}$$

and extract τ_{th} and the cutoff frequency $1/\tau_{th} = 1/(2\pi\tau_{\mathrm{th}})$.

C. Finite-element thermal simulations

Thermal transport is modeled in COMSOL Multiphysics using time-dependent finite-element simulations (Heat Transfer in Solids),

$$\rho C_p \frac{\partial T}{\partial t} = \nabla \cdot (k\nabla T) + Q(\mathbf{r}, t), \tag{2}$$

where $Q(\mathbf{r}, t)$ represents an effective heat source associated with optical absorption localized near the upper pillar region,

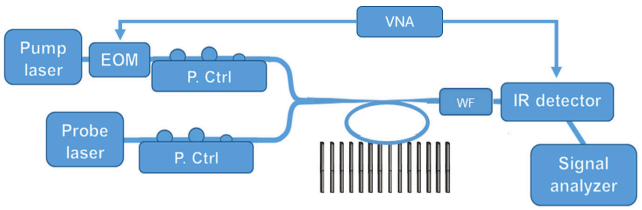

Fig. 3. Frequency-domain pump–probe setup to extract the thermal time constant. A modulated pump induces absorption-driven heating; a weak probe monitors thermo-optic detuning of a second mode. A wavelength filter separates probe and pump at the output; the VNA measures the probe magnitude response versus modulation frequency.

motivated by the optical mode localization in both platforms [2], [3]. We first employ a reduced single-pillar (unit-cell) model to capture the dominant relaxation dynamics. Simulations are run to steady state under constant heating and then the heat source is switched off to obtain the transient thermal decay. The local temperature at a monitoring point near the optical mode maximum is fitted to

$$T(t) = T_{\mathrm{amb}} + \Delta T\, e^{-t/\tau_{\mathrm{th}}}, \tag{3}$$

providing τ_{th}. To identify dominant dissipation pathways, we compare simulation variants including air-mediated dissipation (convection / heat exchange with an air domain) versus purely solid conduction through the substrate stack. We also develop full-cavity electromagnetic and thermal simulations to emulate the experimental measurements and evaluate collective effects on the entire cavity geometry.

III. Results and Discussion

A. Optical mode tuning

We characterize the optical response under increasing excitation by recording power-dependent transmission spectra of the cavity resonance (Fig. 4). For both monolithic Si and hybrid Si/SiO_2 nanopillar cavities, increasing input power induces a redshift and progressive lineshape distortion, consistent with absorption-driven heating and carrier-related nonlinearities reported in silicon photonic-crystal resonators [4], [6].

For comparable excitation conditions, the hybrid platform shows a larger effective redshift and more pronounced nonlinear distortion, suggesting a higher temperature rise at the mode location. This is consistent with reduced thermal extraction expected from the vertically asymmetric stack and additional thermal interfaces, and agrees with the slower thermal response extracted from pump–probe measurements (Sec. III-C).

B. Mechanical mode tuning

Mechanical motion is read out via optomechanical transduction of the transmitted field. Figure 5 summarizes the evolution of the transduced RF spectra under optical heating. In monolithic Si cavities, the dominant mechanical resonances remain largely stable over the explored range.

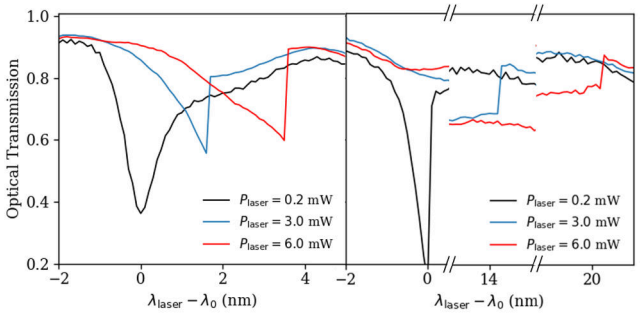

Fig. 4. Power-dependent optical transmission spectra for monolithic Si and hybrid Si/SiO_2 nanopillar cavities. Increasing excitation induces a redshift and lineshape distortion consistent with absorption-driven thermal effects and carrier-related nonlinearities.

In hybrid Si/SiO_2 devices, most resonances remain stable; however, selected modes exhibit reproducible frequency upshifts as optical heating is increased. This behavior is unexpected and is currently under investigation. When two resonances approach each other, we observe signatures consistent with mode hybridization (avoided crossing), which becomes more apparent as heating modifies mechanical detuning (Fig. 6).

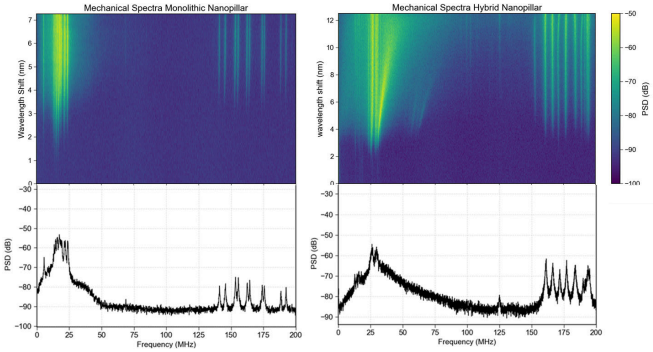

Fig. 5. Mechanical spectra under optical heating for monolithic Si and hybrid Si/SiO_2 cavities.

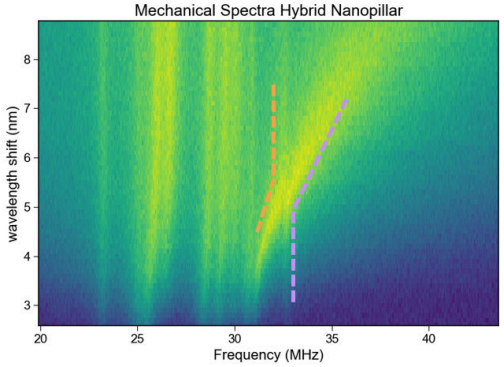

Fig. 6. Example of two mechanical resonances approaching and exhibiting an avoided-crossing-like behavior consistent with mode hybridization.

C. Thermal relaxation measurements

Heat dissipation is quantified with a frequency-domain pump-probe method. Figure 7 shows the probe magnitude response versus modulation frequency, which is fitted to a first-order low-pass fit [8], yielding $1/\tau_{th} \sim 11$ MHz (monolithic Si) and $1/\tau_{th} \sim 2$ MHz (hybrid Si/SiO_2), a markedly slower thermal response in the hybrid platform.

Figure 8 shows the time-domain FEM transients on a reduced unit-cell model, which provide consistent values ($f_c \sim$ 7.67 MHz and $\sim$ 2.22 MHz), supporting the observed trend.

FEM control simulations indicate that, in the hybrid geometry, heat dissipation through the base of the pillar is greatly obstructed by the low thermal conductivity of SiO_2, leading to a much slower conduction-only decay. When an air domain is included, heat exchange with air significantly accelerates the relaxation, becoming a major contribution to the effective decay rate (Fig. 9).

Full-cavity coupled electromagnetic and thermal simulations are being developed to capture the coupled thermal–optical dynamics and collective effects in the complete cavity.

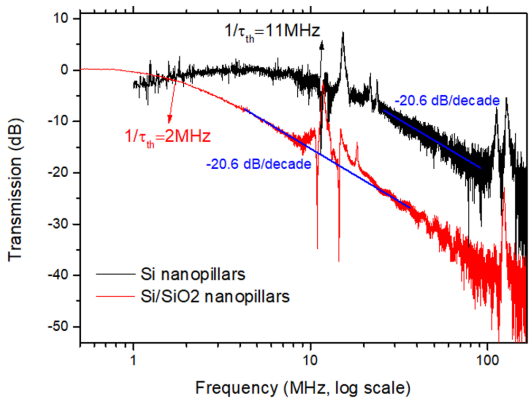

Fig. 7. Frequency-domain pump–probe thermal response for monolithic Si and hybrid Si/SiO_2 nanopillar cavities. The probe magnitude response shows a first-order roll-off, from which an effective thermal relaxation rate is extracted.

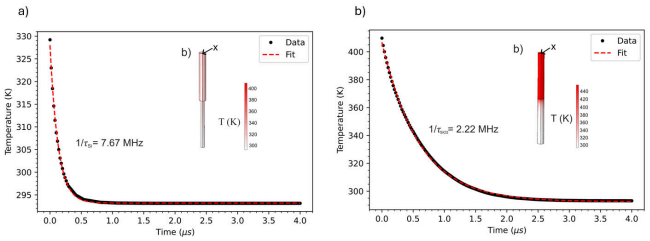

Fig. 8. The average temperature of the top of the nanopillar as a function of time for both geometries.

IV. Conclusion

We compared monolithic Si and hybrid Si/SiO_2 nanopillar optomechanical cavities under absorption-driven heating. Pump–probe measurements and FEM transients show a slower

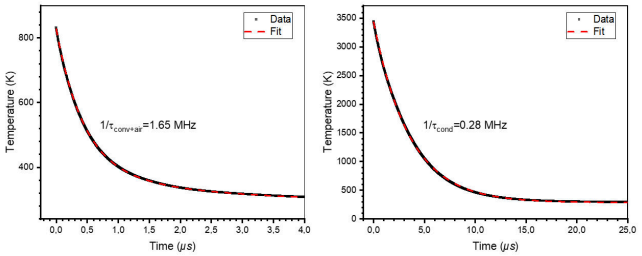

Fig. 9. FEM dissipation rate for (a) air domain enabled (convection/air exchange) and (b) purely solid conduction.

thermal response in the hybrid platform, consistent with reduced heat extraction through the SiO_2 segment. This enhanced thermal response correlates with larger optical resonance shifts and with mode-dependent changes in the transduced mechanical spectra, highlighting the role of the material stack in thermal–optical–mechanical behavior.

***Abstract*—We present a dual-ridge unit cell enabling deterministic, independent tuning of guided-mode resonance frequency and linewidth. A closed-form parametric search space maps geometry to spectral metrics, removing trial-and-error. The framework supports multi-metric design and uncovers emergent non-Hermitian and topological features, including exceptional points and Fermi arcs.**

***Keywords*— metamaterials, guided-mode resonance, photonic crystals, dual-ridge unit-cell.**

I. Introdunction

Guided-mode resonances (GMR) near the second-order band-gap condition are of particular interest because they can yield strong spectral signatures such as near-unity reflection/transmission, symmetry-protected bound states in the continuum (BIC), and topological edge states under near-normal incidence.

However, practical GMR device design frequently requires the independent tuning of multiple spectral metrics. To increase degrees of freedom, designers typically introduce additional parameters such as material index, ridge height, and layer thickness. Nevertheless, it remains difficult to predict and decouple each parameter's influence on resonance position and linewidth, which makes optimization slow and frequently suboptimal.

Here, we present a comprehensive study of dual-ridge compound unit cells and propose a deterministic tuning strategy based on a coupled-mode-theory (CMT) model with closed-form geometric relations. We further validate the feasibility of the method through rigorous numerical analysis.

II. Simplified Model Description

Our model is based on the CMT formulation introduced by Kazarinov and Henry [1]. For the considered geometry, the coupled-mode description reduces to an eigenvalue problem of the form

$$\mathbf{H}|\psi\rangle = (\omega - \omega_{\mathrm{B}})|\psi\rangle, \tag{1}$$

for GMR state $|\psi\rangle = [a_+\ a_-]^{\mathrm{T}}$, where $a_\pm$ denote the amplitudes of guided modes propagating along $\pm x$. Here, ω_{B} is the frequency corresponding to the second-order Bragg condition of the guided mode, and the effective Hamiltonian is written as

$$\mathbf{H} = \begin{bmatrix} vk+\delta & m_+ \\ m_- & -vk+\delta \end{bmatrix}. \tag{2}$$

where v is group velocity of the guided mode and k is Bloch wave vector along x. The two counter-propagating guided modes couple to each other through second-order Bragg reflection with rates $m_\pm$.

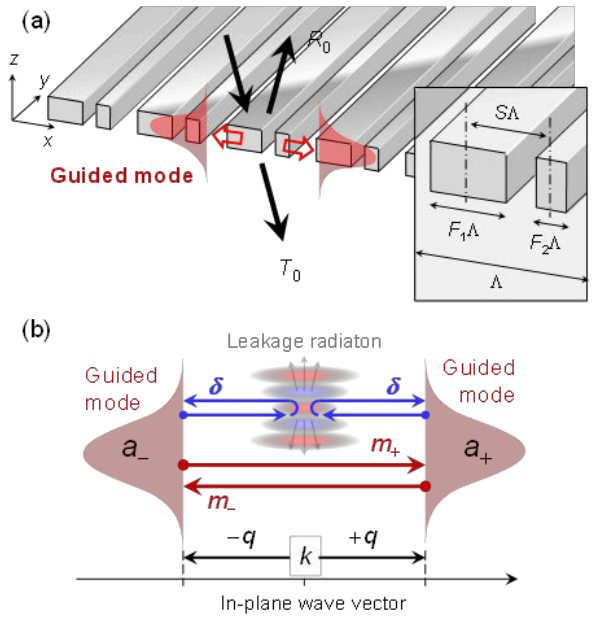

Fig. 1. GMR in dual-ridge compound unit-cell structure.

Importantly, $m_\pm$ and the detuning parameter δ are directly linked to the unit-cell geometry, enabling geometry-driven

design strategies that target the band-gap width and linewidth in a controlled manner. They can be expressed using the Fourier coefficients $\{\varepsilon_n\}$ of the dielectric function in the grating region as

$$m_{\pm} = \varepsilon_{\pm 1}{}^{2}\kappa_1 - \varepsilon_{\pm 2}\kappa_2 , \tag{3}$$

$$\delta = \varepsilon_{+1}\varepsilon_{-1}\kappa_1 , \tag{4}$$

where κ_1 and κ_2 are diffraction-rate coefficients associated with the first- and second-order diffraction processes of the guided mode, respectively. Detailed expressions are provided in our previous work [2].

To exploit a convenient constant-F subspace, we introduce the ridge-width difference factor $\chi = F_1 - F_2$, which sets the individual fill factors as by $F_1 = (\mathrm{F}-\chi)/2$ and $F_2 = (\mathrm{F}+\chi)/2$, together with the ridge center-distance factor S. With these parameters, the real and imaginary parts of the Fourier coefficients $\{\varepsilon_n\}$ admit explicit expressions:

$$\mathrm{Re}(\varepsilon_{n\neq 0}) = \frac{2\Delta\varepsilon}{n\pi}\sin\left(\frac{n\pi \mathrm{F}}{2}\right)\cos\left(\frac{n\pi\chi}{2}\right)\cos\left(n\pi S\right), \tag{5}$$

$$\mathrm{Im}(\varepsilon_{n\neq 0}) = \frac{2\Delta\varepsilon}{n\pi}\cos\left(\frac{n\pi \mathrm{F}}{2}\right)\sin\left(\frac{n\pi\chi}{2}\right)\sin\left(n\pi S\right). \tag{6}$$

Substituting these relations into the model equations yields closed-form expressions for the linewidth ω_g and the linewidths $\Delta\omega_{\pm}$, which can be conveniently visualized on the χ-S plane. The independent-control scheme is then constructed by using gradient directions or equi-level contours of ω_g and $\Delta\omega_{\pm}$, as described next.

III. Rigorous Numerical Analysis

To quantify the degree of independent tunability, we define the parametric-gradient cosine $c_{\pm}$ on χ-S plane as

$$c_{\pm} = \frac{\nabla\omega_g \cdot \nabla\Delta\omega_{\pm}}{|\nabla\omega_g||\nabla\Delta\omega_{\pm}|}, \tag{7}$$

where the parametric gradient operator is $\nabla = \mathbf{e}_{\chi}(\partial/\partial\chi)+\mathbf{e}_S(\partial/\partial S)$. Independent control is poorly achievable in regions where $c_{\pm} \approx \pm 1$ while maximally efficient for $c_{\pm} \approx 0$.

We further demonstrate several practical examples of independent parametric control in Figs. 2(c)–3(e). Figure 2(c) shows a band-gap-preserving linewidth modulation. The angle-resolved transmittance spectra simultaneously visualize the dispersion bands and their linewidth distributions. Notably, the dispersion curve remains nearly fixed while the linewidth varies substantially. In Fig. 2(d), we highlight a particularly strong linewidth modulation: the linewidth changes by a factor of 65 while the resonance wavelength remains fixed at 1.259 μm. Conversely, resonance-position tuning with nearly fixed linewidth is also readily achievable, as shown in Fig. 2(e), where the linewidth is maintained at 0.5 nm while the resonance wavelength shifts from 1.247 μm to 1.297 μm.

Importantly, these demonstrations are achieved while holding other structural parameters constant, including the net fill factor F, period, and ridge height. Therefore, the dual-ridge compound unit-cell approach enables highly efficient and practical independent control of GMR metrics.

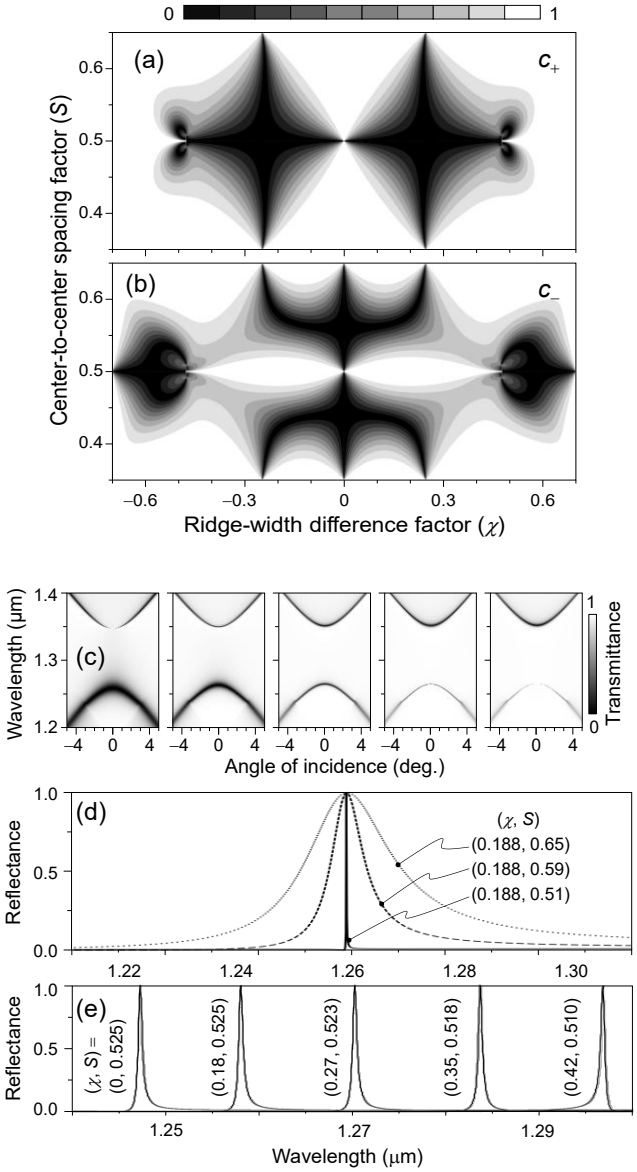

Fig. 2. Fully independent parametric control of resonance position and linewidth.

IV. Additional Feature: Fermi Arc Condition

Beyond independent tunability, the χ-S maps reveal additional emergent features. In the distributions of $\Delta\omega_{\pm}$, we observe arc-like loci where the linewidths of the upper and lower bands coincide, i.e., $\Delta\omega_{+} = \Delta\omega_{-}$. These loci are indicated by the blue curves in Fig. 3(a). Within the simplified model of Eqs. (1)–(4), these arcs correspond to a loop defined by the condition $\mathrm{Im}(m_{+}m_{-}) = 0$, which can be expressed in terms of the Fourier coefficients $\{\varepsilon_n\}$ as

$$\mathrm{Re}(\kappa_1) = \mathrm{Re}(\varepsilon_2 / \varepsilon_1^{\,2})\kappa_2 \,. \tag{8}$$

Using Eqs. (5) and (6), this condition can be evaluated explicitly on the χ-S plane, producing the loop shown in Fig. 3(a). Here we note that κ_1 is generally complex-valued, whereas κ_2 is purely real for lossless structures, which is used in deriving Eq. (8). As a result, nearly uniform linewidth can be obtained across the entire GMR bands, as illustrated in Fig. 3(b) (angle-resolved transmittance) and Fig. 3(c) (reflection spectra). Remarkably, an extremely narrow resonance can persist over a broad range of incident angles and wavelengths, which occurs for parameter sets on the blue segment of the loop in Fig. 3(a).

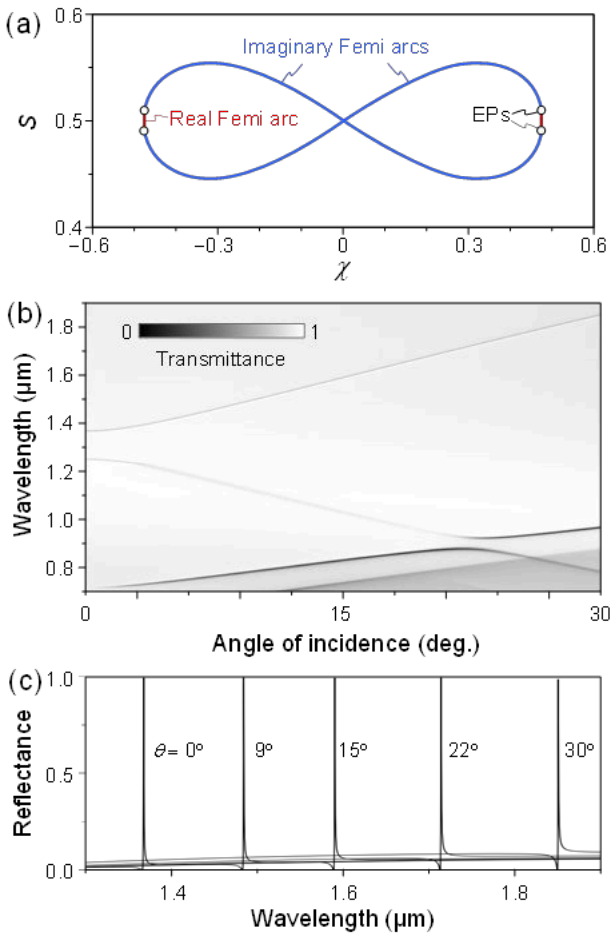

Fig. 3. Fermi arcs in GMR spectra.

V. Conclusion

We have presented a comprehensive description of key GMR metrics in explicit terms of unit-cell design parameters and proposed a deterministic design methodology for targeted resonance properties. In particular, a dual-ridge compound unit cell enables fully independent tuning of dispersion-band location and resonance linewidth, offering a highly efficient approach for practical GMR devices such as filters, sensing templates, and surface-emitting light sources.

Moreover, we find that the dual-ridge design provides direct access to emergent physics associated with non-Hermitian dynamics and topological wave effects, including EP singularities, Fermi arcs, and band-topological phase transitions. These advantages originate from enhanced parametric controllability over the complex-valued Fourier coefficients $\{\varepsilon_n\}$, which fundamentally determine the coupling strengths and phases of elementary diffraction processes. This framework can be further extended to develop new GMR elements involving BICs, topological localization, beam shaping, and related functionalities.

***Abstract*— We propose a design framework for controlling topologically protected edge states, illustrated by Tamm Plasmon Polaritons in 1D planar photonic crystals. By emulating Weyl points in synthetic-parameter space, robust interface modes can be engineered on demand. This strategy opens up new pathways toward resilient, multifunctional photonic platforms.**

***Keywords*: topological photonics, photonic crystal, topological edge states, synthetic space.**

I. Introduction

Topologically protected edge states are typically associated with Weyl points—three-dimensional band degeneracies originally identified in semimetals and defined in momentum space. While such features are conventionally studied in fully three-dimensional systems, it has recently been shown that analogous topological singularities can be engineered in synthetic parameter spaces constructed from controllable structural or temporal degrees of freedom [1].

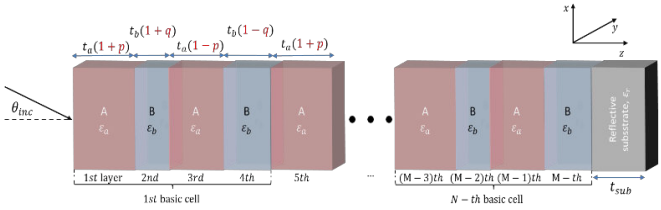

Fig. 1 Schematic of a parametrized 1D topological PC emulating Weyl point.

Here, we introduce a systematic design approach that enables controlled realization of topologically protected edge states, which we demonstrate by example of topologically-protected Tamm Plasmon Polaritons existing at the interface between a parametrized PC (depicted in Fig.1) and a highly reflective substrate/superstrate. The method is based on the approach proposed by Wang et al. [2] and emulates a Weyl point in a one-dimensional periodic system with a parametrized four-layer unit cell composed of materials A and B (isotropic or anisotropic).

II. Design Approach

By independently tuning two unit-cell geometrical parameters and combining them with a wavevector component, we construct an effective three-dimensional synthetic space. Within this space, linear band degeneracies emerge, accompanied by characteristic phase vortices in the reflection response.

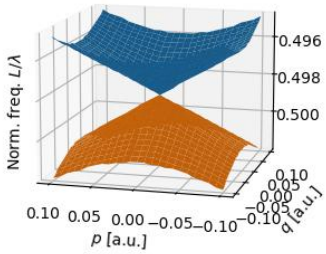

Fig. 1 Linear degeneracy around for a wave of Weyl frequency in the assumed synthetic space

Importantly, this synthetic-space framework serves not merely as a theoretical construct but as a predictive design tool: it directly determines the conditions under which robust interface states fulfill the resonance condition and must arise in real space. In particular, we demonstrate how these synthetic Weyl points guarantee the formation of topologically protected Tamm plasmon polaritons at the boundary between the photonic crystal and a reflective truncation. The approach therefore provides an intuitive and scalable route for engineering high-quality, polarization-independent interface resonances with built-in robustness against structural perturbations.

III. Results and Discussion

The results presented confirm that the synthetic-space design framework provides direct control over the formation and physical properties of topologically protected interface states. The first set of colormaps (Fig. 3(a–c)) illustrates transmission, reflection, and absorption as functions of the synthetic-space parameters p and q.

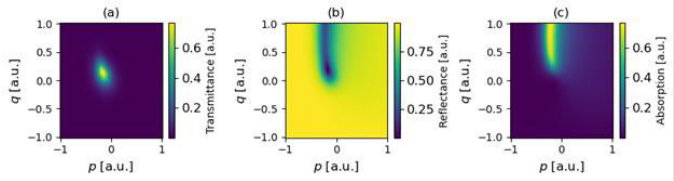

Fig. 3 Colormaps of power transmission (a), reflection (b), and absorption (c) plotted vs. synthetic space parameters.

Distinct arc-like regions are visible in all three maps, corresponding to Fermi-arc states that originate from the emulated Weyl point in synthetic space. These arcs indicate parameter combinations for which a robust interface resonance exists. Importantly, while the reflectance map exhibits a clearly defined dip along the arc, corresponding to the presence of the interface state, the transmission and absorption maps reveal that the energy redistribution between these channels strongly depends on the chosen synthetic-space coordinates.

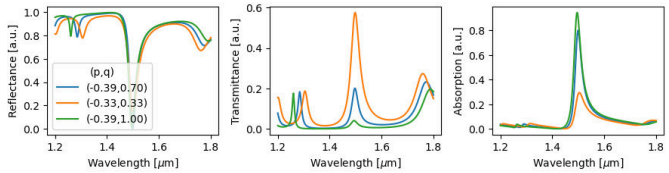

Fig. 4 Spectra of transmission (a), reflection (b) and absorption (c) for different *pq* pairs.

The corresponding spectral responses shown in the Fig. 4, further clarify this behavior. For different synthetic-space parameters located along the Fermi arc, a reflectance minimum is preserved at approximately the same spectral position, confirming the topological nature of the interface state. However, the depth and spectral redistribution of energy between transmission and absorption vary significantly. In some configurations, the interface state is predominantly absorptive, whereas in others it enables enhanced transmission. This demonstrates that the proposed approach does not merely guarantee the existence of a state but allows its optical properties to be engineered.

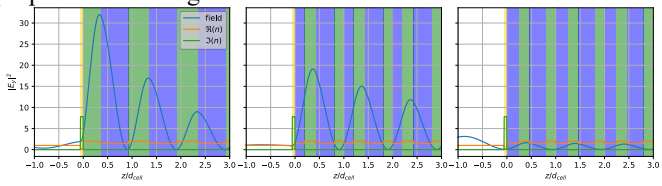

Fig. 5 Field distribution for absorption-dominated (a), transmission-enhanced (b) and weakly confined configuration (c).

Along with transmission and absorption, spatial field distributions can also be engineered by an appropriate choice of synthetic-space parameters, see Fig. 5. The results show strong localization of the electromagnetic field at the interface, characteristic of a Tamm plasmon polariton. Crucially, the magnitude and spatial profile of the local field enhancement differ across parametrizations. By appropriately selecting the synthetic parameters, one can tailor the degree of field confinement and peak intensity while maintaining the reflectance dip associated with the topological state. This capability is particularly attractive for enhancing nonlinear effects and optimizing sensing performance while maintaining the guaranteed existence of the interface state.

IV. Conclusion

This work demonstrates that topology in photonics can move beyond an abstract concept toward function-driven design. By emulating Weyl points in a synthetic parameter space, we transform a simple one-dimensional multilayer into a platform where the existence of interface states is guaranteed by topology, yet their functionality remains fully engineerable. The resulting Tamm plasmon polaritons combine robustness with tunability: the reflectance dip persists as a topological invariant, while transmission, absorption, and local field enhancement can be deliberately tailored through synthetic-space parameter selection. Rather than designing resonances that must be delicately optimized and are vulnerable to fabrication imperfections, we begin with a state that is topologically secured and subsequently tailor its propertties. In this sense, synthetic space becomes a powerful design framework for creating robust and customizable photonic responses. The implications extend beyond the specific system studied here. In sensing, topologically protected resonances provide stable spectral markers whose field enhancement can be engineered for maximum interaction with active or analyte materials [3]. In nonlinear photonics, controllable interfacial confinement enables enhanced Kerr or saturable effects, paving the way for intensity discriminators, compact optical limiters, and elements for all-optical signal processing [4]. Looking forward, expanding the synthetic-space concept to alternative parameter manifolds—including gain–loss balance, anisotropy, temporal modulation, electrostatic bias, or nonlinear coefficients—opens the possibility of topology tailored to functionality. Extension to two-dimensional photonic configurations further enriches the design landscape, enabling directional robustness, higher-order topological states, and scalable integration within photonic circuits.

Ultimately, this approach bridges abstract topological physics and practical device engineering. It suggests a future in which photonic components are not merely optimized against imperfections, but are fundamentally designed to be robust, adaptable, and multifunctional by construction.

***Abstract*—We study two atoms coupled to a continuum and analytically reveal a mechanism for selective dissipation induced by external driving. By tuning only the driving parameters, an undriven atom can decay remotely while the driven atom remains long-lived. Numerical simulations demonstrate controllable switching between dissipation and suppression.**

***Keywords*— quantum photonics, Floquet engineering, dissipation control, waveguide QED**

I. Introduction

Structured photonic environments provide powerful platforms for controlling dissipation [1], [2]. In systems such as photonic crystal waveguides, coupled-resonator optical waveguides, and waveguide-QED platforms, the finite bandwidth of the continuum and the density of states near band edges strongly modify radiative processes, giving rise to a variety of open-system dynamics including non-Markovian effects and bound-state formation [2], [3]. If the lifetime of a particular state among multiple discrete degrees of freedom coupled to such a continuum can be selectively controlled, it would be useful for tasks such as state initialization and reset.

Periodic driving provides an additional control knob for this purpose [4]. Within Floquet theory, a time-periodic Hamiltonian is described in an extended Hilbert space [5], where the drive creates additional channels in the energy structure of both discrete states and the continuum [6], [7]. As a result, dissipation pathways that do not exist in the static system may be opened or closed.

In this work, we consider a minimal model consisting of two atoms (discrete states) coupled to a one-dimensional tight-binding continuum, where only one of the states is subjected to a time-periodic modulation of its transition energy. Using the Wannier–Stark basis, we construct the Floquet Hamiltonian and analyze the complex spectrum by the Brillouin–Wigner–Feshbach projection method [8]. We show that, by tuning only the parameters of the external drive while keeping all system parameters fixed, it is possible to selectively induce dissipation either in the driven state or in the undriven state.

II. Theoretical Formulation

We consider a Fano–Anderson-type model [9] in which two discrete states $|d_A\rangle$ and $|d_B\rangle$ are coupled to a one-dimensional tight-binding continuum, while only A is subjected to periodic driving. In the Bloch basis $|k\rangle$, the time-dependent Hamiltonian is written as

$$\hat{H}(t) = \hat{H}_{\rm tb} + \hat{H}_{\rm d}(t) + \hat{H}_{\rm int} \tag{1}$$

$$\begin{cases} \hat{H}_{\rm tb} \equiv \displaystyle\int_{-\pi}^{\pi} dk\, \varepsilon_k |k\rangle\langle k|, \qquad \varepsilon_k = -\beta\cos k, & (2)\\ \hat{H}_{\rm d}(t) \equiv (e_A + \alpha\cos\omega t)\,|d_A\rangle\langle d_A| + e_B|d_B\rangle\langle d_B|, & (3)\\ \hat{H}_{\rm int} \equiv \dfrac{g_A}{\sqrt{2\pi}}\displaystyle\int_{-\pi}^{\pi} dk\ (|d_A\rangle\langle k| + \text{H.c.}) \\ \qquad\quad + \dfrac{g_B}{\sqrt{2\pi}}\displaystyle\int_{-\pi}^{\pi} dk\ (|d_B\rangle\langle k| + \text{H.c.})\,. & (4) \end{cases}$$

Here, β is the parameter that determines the bandwidth of the static continuum. The bare energies e_A and e_B are placed outside this band. The constants g_A and g_B denote the coupling strengths of A and B to the continuum, respectively. Throughout this work we mainly focus on the weak-coupling regime, $g_A \sim g_B \sim g \ll \beta$. The drive amplitude and frequency are denoted by α and ω, and we define $\chi \equiv \alpha/\omega$.

To exploit the time periodicity, we introduce the extended Floquet space and use the Fourier basis $|\cdot, n\rangle\!\rangle \equiv |\cdot\rangle \otimes e^{in\omega t}$ with Floquet index n [6], [7]. For the driven state A, we further introduce the Wannier–Stark basis

$$|\phi_A^{(n)}\rangle\!\rangle = \sum_{\nu} J_{n-\nu}(\chi)\,|d_A, \nu\rangle\!\rangle, \tag{5}$$

where $J_n(\chi)$ is the Bessel function of the first kind. Using this basis, the Floquet Hamiltonian $\hat{\mathcal{H}} = \hat{H}(t) - i\partial_t$ can be decomposed, in the same way as the original Hamiltonian [10], as

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{\rm tb} + \hat{\mathcal{H}}_{\rm d} + \hat{\mathcal{H}}_{\rm int}. \tag{6}$$

$$\begin{cases} \hat{\mathcal{H}}_{\rm tb} = \displaystyle\sum_n \int_{-\pi}^{\pi} dk\,(\varepsilon_k + n\omega)\,|k, n\rangle\!\rangle\langle\!\langle k, n|, & (7)\\ \hat{\mathcal{H}}_{\rm d} = \displaystyle\sum_n (e_A + n\omega)\,|\phi_A^{(n)}\rangle\!\rangle\langle\!\langle \phi_A^{(n)}| \\ \qquad\quad + \displaystyle\sum_n (e_B + n\omega)\,|d_B, n\rangle\!\rangle\langle\!\langle d_B, n|, & (8)\\ \hat{\mathcal{H}}_{\rm int} = \dfrac{g_A}{\sqrt{2\pi}}\displaystyle\sum_{n,n'}\int_{-\pi}^{\pi} dk\, J_{n'-n}(\chi)\left[|\phi_A^{(n')}\rangle\!\rangle\langle\!\langle k, n| + \text{H.c.}\right] \\ \qquad\quad + \dfrac{g_B}{\sqrt{2\pi}}\displaystyle\sum_n\int_{-\pi}^{\pi} dk\ [|d_B, n\rangle\!\rangle\langle\!\langle k, n| + \text{H.c.}]\,. & (9) \end{cases}$$

As shown in Fig. 1, the continuum forms the band $[-\beta + n\omega, \beta + n\omega]$ in the nth Floquet mode, while the discrete ladders of A and B appear at $e_A + n\omega$ and $e_B + n\omega$, respectively. The ladder of A can couple different Floquet modes through the Bessel weight $J_{n'-n}(\chi)$, whereas the ladder of B remains mode-diagonal, namely $|d_B, n\rangle\!\rangle$ couples only to $|k, n\rangle\!\rangle$. Therefore, B cannot change the Floquet index by itself, and in order to reach an open continuum band in a neighboring Floquet mode, it must pass through the driven ladder of A. In the following, the complex spectrum of the Floquet Hamiltonian is analyzed by the Brillouin–Wigner–Feshbach projection method [8]; a finite imaginary part of the A-like or B-like pole corresponds to decay of the corresponding state. Within the projection formalism, the A-like and B-like poles are obtained from the projected resolvent in the discrete subspace.

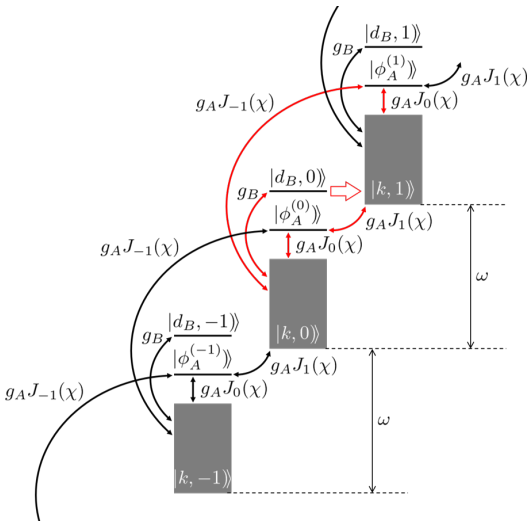

Fig. 1. Schematic energy structure in the physical and extended Floquet representations. The tight-binding continuum forms a finite band in each Floquet mode, while the driven discrete ladder $\{|\phi_A^{(n)}\rangle\!\rangle\}$ couples to different Floquet modes with Bessel-weighted amplitudes $J_{n'-n}(\chi)$. The undriven ladder $\{|d_B, n\rangle\!\rangle\}$ couples to the continuum without changing n. This structure allows photon-assisted pathways, mediated by the driven ladder, that connect the undriven state to a neighboring continuum Floquet mode.

III. Results and Discussion

We now interpret the two representative cases shown in Fig. 2 on the basis of the energy structure in Fig. 1. As a time-domain observable, we use the survival probability

$$P_X(t) = |\langle d_X | U(t,0) | d_X \rangle|^2 \tag{10}$$

for the initial state $|d_X\rangle$ $(X = A, B)$, where $U(t,0)$ is the time-evolution operator associated with the time-dependent Hamiltonian $\hat{H}(t)$. The numerical results are obtained by direct integration of the time-dependent Schrödinger equation. The common parameters are $\beta = 1$, $e_A = 1.25$, $e_B = 1.30$, and $g_A = g_B = 0.05$. In this case, the continuum band in the nth Floquet mode is $[-\beta + n\omega, \beta + n\omega]$.

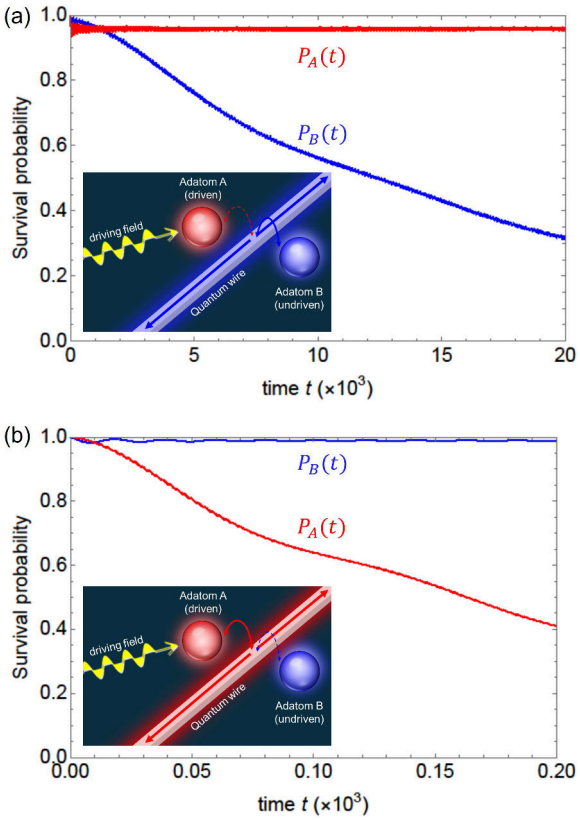

Fig. 2. Selective dissipation controlled by local driving. (a) Remote dissipation of the undriven state: $P_A(t)$ remains close to unity while $P_B(t)$ decays for $\omega = 2.3025$ and $\chi = 1.08$. (b) Switching and suppression of the remote channel: choosing χ near the first zero of J_0 suppresses the decay of B, while the driven state A decays for $\omega = 2.2$ and $\chi = 2.40$. The internal parameters are $\beta = 1$, $e_A = 1.25$, $e_B = 1.30$, and $g_A = g_B = 0.05$.

We first consider the condition corresponding to Fig. 2(a), namely $\omega = 2.3025$, $\chi = 1.08$. In this case, the lower edge of the first Floquet mode is very close to e_B. By contrast, e_A is still below this edge, so A is not yet sufficiently inside the open continuum band. Moreover, for $\chi = 1.08$, the product $|J_0(\chi)J_1(\chi)|$ is large, so the weight of the indirect pathway for B is strong. Therefore, as can be read from the energy diagram in Fig. 1, the undriven state $|d_B, 0\rangle\!\rangle$ first couples to $|k, 0\rangle\!\rangle$ with amplitude g_B, then to the driven ladder state $|\phi_A^{(0)}\rangle\!\rangle$ with amplitude $g_A J_0(\chi)$, and finally to the continuum state $|k, 1\rangle\!\rangle$ in the first Floquet mdoe with amplitude $g_A J_1(\chi)$. The effective amplitude of this remote pathway is thus weighted by $g_A^2 g_B J_0(\chi) J_1(\chi)$. Once this channel is open, the B-like pole acquires a finite imaginary part. Accordingly, the induced linewidth appears at order $O(g_A^4 g_B^2)$, namely $O(g^6)$ for $g_A \sim g_B \sim g$. In contrast, A is still far from an open dissipation channel into which it can decay directly. As a result, in Fig. 2(a), the driven state A remains long-lived, while only the undriven state B decays appreciably.

We next consider the condition corresponding to Fig. 2(b), namely $\omega = 2.2$, $\chi = 2.40$. In this case, both e_A and e_B lie inside the continuum band of the first Floquet mode.

From the energy structure alone, both A and B may appear energetically allowed to decay. However, when the pathway structure in Fig. 1 is also taken into account, their behaviors are very different. Since A can directly transition from $|\phi_A^{(0)}\rangle\rangle$ to $|k,1\rangle\rangle$ with amplitude $g_A J_1(\chi)$, the A-like linewidth appears at $O(g^2)$, and $P_A(t)$ indeed decays rapidly. On the other hand, the dominant indirect pathway of B is proportional to $J_0(\chi)J_1(\chi)$. Under this condition, $J_0(\chi) \simeq 0$, so that its principal pathway is closed. Therefore, although B is located near the continuum band of the first Floquet mode, the main photon-assisted pathway leading to that dissipation channel is supplessed. Consequently, in Fig. 2(b), A decays, whereas the remote dissipation of B is suppressed and B remains long-lived.

These two results show that which state decays is determined not only by simple energetic overlap, but also by whether the Floquet pathway leading to the corresponding continuum band is actually open. While A can decay at low order because it can directly cross Floquet modes under the drive, B depends on an indirect pathway mediated by A, so its dissipation can be selectively opened or closed by changing only the drive condition.

IV. Conclusion

In this work, we theoretically studied a system in which only one of two discrete states coupled to a finite-band continuum is subjected to local periodic driving. Starting from the Hamiltonian in the k-representation, we described the Floquet Hamiltonian in terms of $\hat{\mathcal{H}}_{\rm tb}$, $\hat{\mathcal{H}}_{\rm d}$, and $\hat{\mathcal{H}}_{\rm int}$ using the Wannier–Stark basis, thereby making clear which Floquet modes couple to which discrete states. Furthermore, by means of the Brillouin–Wigner–Feshbach projection method, we analyzed the complex spectrum associated with the A-like and B-like poles. This analysis shows that the linewidth of the driven state appears at low order through a direct pathway to an open Floquet mode, whereas the linewidth of the undriven state arises from a higher-order photon-assisted pathway mediated by the driven state.

In particular, when the energy of the undriven state is located near an open continuum band in a neighboring Floquet mode, especially near its edge, and at the same time the driven state is arranged so as not to decay directly, only the undriven state undergoes remote dissipation. By contrast, when an open Floquet mode is directly available for the driven state, while the dominant indirect pathway for the undriven state is suppressed by a Bessel weight such as $J_0(\chi) \simeq 0$, only the driven state decays and the remote dissipation of the undriven state is supplessed. Direct numerical integration of the time-dependent Schrödinger equation clearly reproduced both of these selectively dissipative situations.

These results show that Floquet analysis together with complex-spectrum analysis provides a quantitative understanding of how local periodic driving remotely controls the dissipation of an undriven state coupled to a common continuum. The mechanism presented here offers a useful design principle for state-selective reset and dissipation engineering in structured photonic environments.

Nonlinear Topological States in Photonic Crystals: Modal Structure and Intensity-Dependent Optical Response

***Abstract*— We theoretically investigate how Kerr-type nonlinearity modifies topological Bloch and interface states in 1D and 2D photonic crystals, and how these changes manifest in intensity-dependent transmission and reflection characteristics.**

***Keywords*: topological photonics, photonic crystal, topological edge states, nonlinear optics.**

I. Introduction

Topological photonics offers a powerful paradigm for controlling light via states robust against structural disorder. In photonic crystals (PhCs), this allows for the engineering of protected edge and interface states. Utilizing synthetic dimensions enables the realization of these phenomena even in 1D systems, leading to highly localized optical modes, such as topological Tamm plasmon polaritons (TPPs) [1]. Integrating Kerr-type optical nonlinearity, particularly through graphene in the terahertz (THz) regime enables dynamic, intensity-dependent control over the spectral position of these states. Despite rapid advancements, the interplay between topology and nonlinearity remains only partially understood, especially regarding how nonlinear effects modify the underlying modal structure. In this work, we present a theoretical investigation of nonlinear topological PhCs in 1D and 2D configurations. We analyze the formation of topological interface states within synthetic parameter spaces and examine how Kerr nonlinearity influences their transmission and reflection properties.

II. Numerical Analysis

The numerical framework combines rigorous frequency-domain techniques to investigate the interplay between photonic topology and Kerr-type nonlinearity. First, the linear dispersion characteristics, including the engineering of topological bandgaps and the exploration of synthetic parameter spaces, are calculated using the Plane Wave Expansion Method (PWEM) [6]. By solving the electromagnetic eigenvalue problem, PWEM allows for the precise identification of frequency regimes supporting protected edge and interface states. To evaluate optical response and the excitation of highly localized modes, such as TPPs, we employ the Transfer Matrix Method (TMM) for strictly 1D stratified configurations and Rigorous Coupled-Wave Analysis (RCWA) for structures with 2D lateral periodicity [7]. Crucially, to accurately model the intensity-dependent Kerr nonlinearity elements, the scattering algorithms are augmented with a self-consistent spatial discretization scheme. Because the nonlinear dielectric response is linked to the spatially varying local electric field intensity, the nonlinear regions are subdivided into a series of the sub-layer stripes (Fig. 1) along the propagation axis [5]. Within each stripe, the optical properties are assumed to be locally uniform and are iteratively updated based on the confined field distribution. This iterative feedback loop ensures self-consistency between the internal electromagnetic field profile and the material's dynamic response.

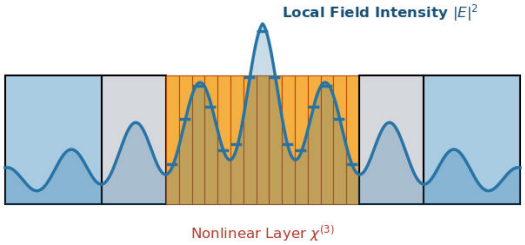

Fig. 1 Spatial discretization of the nonlinear layer in the 1D model, comparing the continuous field profile with its piecewise-averaged approximation for each strip.

By correlating these rigorously calculated nonlinear transmission and reflection spectra with the PWEM-derived band structures, we can directly map how incident light intensity modulates the spectral position and coupling conditions of the topological interface states.

III. Results and Discussion

Here, we analyze a 1D photonic crystal truncated with a nonlinear defect layer based on graphene. The basic cell of the considered structure consists of 4 layers of two dielectric materials and thickness that are parametrized with geometrical parameters p and q, which allows to obtain a synthetic parameter space with so-called Fermi-arc states translated into

real-space TPPs [2]. To establish the topological nature of our structure, we first calculated the linear band dispersion. As shown in Fig. 2, the cross-section of the dispersion relation with the assumed synthetic space (for a $q = 0$) exhibits a Dirac-like linear degeneracy at the intersection between the first and second bands, signifying the presence of a Weyl point. Subsequently, numerical simulations (Fig. 3) of a state belonging to the Fermi arc, arbitrarily chosen to be at p=-0.53 q=1.00, reveal a non-monotonic, intensity-dependent transmission response. At low optical intensities, a clear transmission channel emerges. However, due to the dispersive Kerr-type nonlinearity of graphene, increasing the incident intensity dynamically shifts the phase of the reflected waves. This effect bends the transmission channel and leads to an abrupt suppression of transmittance, driving the device into a highly reflective state.

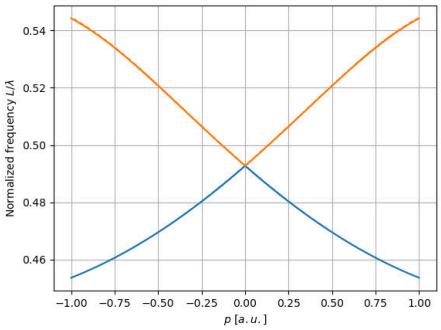

Fig. 2 Calculated band structure exhibiting a Dirac-like degeneracy. The linear crossing signifies a topological phase transition.

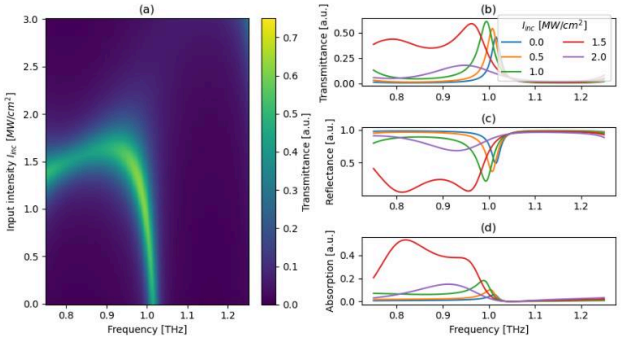

Fig. 3 (a) Transmittance colormap plotted as a function of frequency and incident intensity. Spectral characteristics of (b) transmittance, (c) reflectance, and (d) absorption for selected incident intensities

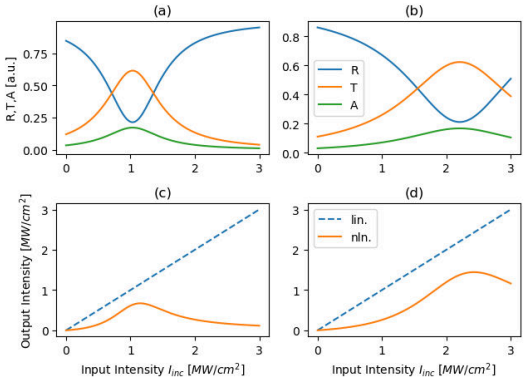

Fig. 4 Power-limiting performance of the proposed structure. Relative redistribution of optical power among reflectance, transmittance, and absorption (a, b), and absolute output versus input intensity characteristics (c, d) for two different graphene electrostatic biasing levels.

Importantly, this power-limiting threshold can be actively tuned via electrostatic biasing of the graphene layer; higher bias voltages decrease the effective nonlinear sensitivity, shifting the cut-off to higher incident intensities. These characteristics demonstrate the platform's potential as a compact, electrically tunable nonlinear distributed Bragg reflector (DBR), highly suitable for optical power limiting and passive pulse shaping in THz laser cavities.

IV. Conclusion and Future Outlook

We theoretically demonstrate the dynamic, intensity-dependent control of TPPs in THz photonic crystals utilizing the ultrafast Kerr nonlinearity of integrated graphene. By combining PWEM with self-consistent nonlinear TMM/RCWA models, we capture the spectral modulation of these robust interface states, driven by strong local-field enhancement. The observed interplay between topological protection and nonlinear field confinement provides a versatile platform for active nanophotonic devices. These include ultrafast optical limiters, all-optical switches, and highly sensitive, label-free THz sensors based on novel intensity-interrogated detection schemes.

While the present study focuses on 1D structures, ongoing work extends this framework toward higher-dimensional photonic crystals, where richer topological phenomena and additional degrees of freedom are expected to emerge. In particular, future efforts will emphasize a more comprehensive analysis of the underlying modal structure, including Bloch, edge, and interface states in 2D systems, and their role in shaping nonlinear optical response. These directions will be further explored and presented during the conference.

Abstract — We demonstrate coherence-controlled holographic microscopy (CCHM) as a robust tool for creating experimental metasurface building block libraries. By measuring the experimental response of TiO_2 nanostructures across varying wavelengths, polarizations, and numerical apertures, we identify critical discrepancies between simulations and real-world performance caused by fabrication-induced internal voids in modified damascene nanofabrication process.

Keywords — metasurfaces, holographic microscopy, TiO_2 nanostructures, phase characterization, building block library.

I. INTRODUCTION

Optical metasurfaces are next generation for state-of-the-art free-space and on-chip devices. While dielectric materials like TiO_2 and Si have pushed light-scattering efficiencies over 90%, their design often relies solely on numerical simulations (FDTD, RCWA). These simulations frequently overlook real-world fabrication imperfections, such as rounding, size deviations, surface roughness, or material density variations.

Existing characterization methods, such as far-field intensity inspection, evaluate overall response but fail to identify specific sources of functional imperfections. While scattering-type scanning near-field optical microscopy (s-SNOM) offers high resolution, it is limited by slow imaging speeds and small fields of view. In this work, we propose coherence-controlled holographic microscopy (CCHM) as a practical, single-snapshot alternative for establishing experimental libraries that account for all fabrication and material imperfections.

II. METHODS

Our experimental setup utilizes a modified CCHM (based on the Telight Q-Phase microscope) [1]. The system was modified with a monochromator for wavelength sweeps (600–740 nm) and a rotatable linear polarizer. This configuration provides amplitude and direct phase imaging using light of arbitrary spatial and temporal coherence. We compare the experimentally acquired data with commercial FDTD (Lumerical) and RCWA (Python [2]) implementations.

Sample Fabrication: Anisotropic TiO_2 building blocks, pictured in Fig. 1, were fabricated on a fused silica substrate using electron beam lithography and atomic layer deposition (ALD), similar to [3]. The sample consists of 20×20 µm fields with widths and lengths ranging from 130 to 330 nm, a constant period of 450 nm, and a height of 500 nm. Fabrication accuracy was verified via Atomic Force Microscopy (AFM) and SEM.

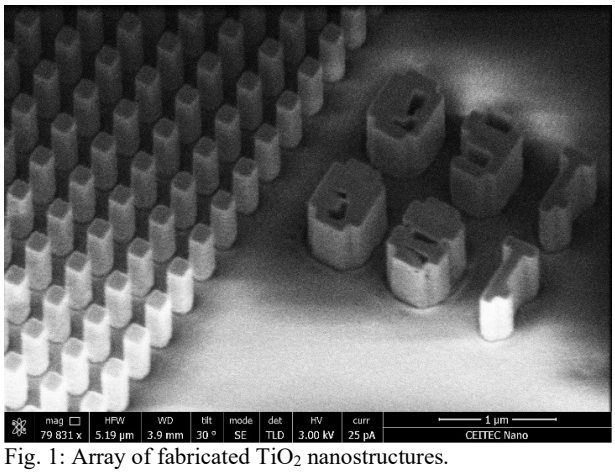

Fig. 1: Array of fabricated TiO_2 nanostructures.

III. RESULTS AND DISCUSSION

Wavelength Dependence

We conducted a spectral sweep from 600 to 740 nm. As can be seen in Fig. 2, the experimental phase values are found to saturate at 1.25 π, whereas numerical simulations (RCWA/FDTD) predicted coverage up to 2π. This discrepancy is critical for forward design, as simulated half-wave plates (HWPs) may only function as quarter-wave plates (QWPs) in practice.

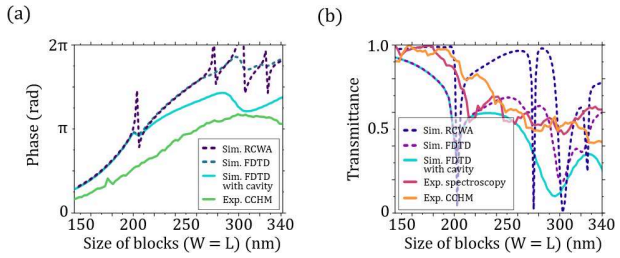

Fig. 2: Comparison of experimental and simulated a) phase and b) amplitude response.

Identification of Internal Voids

Investigation into the phase discrepancy revealed that it was not caused by changes in the material's dielectric function or rounding of edges. Instead, Focused Ion Beam (FIB) cross-sections confirmed the formation of hollow spaces within the high-aspect-ratio nanostructures. These voids, caused by limited ALD precursor diffusion, significantly reduce the phase shift and shift resonant spectral positions.

Polarization and Numerical Aperture Effects

Including the linear polarizer showed a polarization sensitive phase response of the nanostructures, proving the versatility of the CCHM. Furthermore, experimental testing showed that varying the numerical aperture of the condenser lens (0.05 to 0.5) had an insignificant impact on the phase response, suggesting the robustness of the building blocks under varying illumination conditions.

IV. CONCLUSION

We have demonstrated that CCHM is an effective and robust tool for validating metasurface building blocks. By identifying systematic fabrication defects like internal voids that are invisible to non-destructive techniques, CCHM allows for the creation of experimental true response "metalibraries". This approach is essential for high-performance metasurface design, ensuring that fabricated devices meet their intended phase and amplitude specifications and can also be used for metasurface validation.

***Abstract*— We demonstrated angle-resolved spectroscopy as precise, non-invasive metrology for characterizing self-assembled 2D photonic crystals in close-packed and non-close-packed states. By analyzing diffraction, retroreflection, and interference, we retrieved the structural parameters and effective refractive indices. This framework overcomes limitations of electron microscopy, such as need for conductive coatings and vacuum conditions.**

***Keywords*— 2D photonic crystal, self-assembly, angle-resolved spectroscopy, diffraction, retroreflection**

I. Introduction

Self-assembled two-dimensional colloidal spheres, which function as 2D photonic crystals, play a significant role in nanophotonics [1], [2]. In this work, polystyrene (PS) sphere monolayers were fabricated via interfacial self-assembly, which offers a superior approach for large-scale production on a wide range of substrates [3]. Reactive ion etching (RIE) is employed to transform polystyrene (PS) monolayers from the close-packed (CP) state to the non-close-packed (NCP) state [2]. While these systems are often characterized by electron microscopy, the need for conductive coatings and a vacuum environment limits usability. Since the optical properties of these 2D photonic crystals are strictly dependent on the lattice geometry and effective refractive index[4], spectroscopy offers a strong pathway to solve the inverse problem. By systematically analysing the spectral response of these 2D photonic crystals, one can rigorously deduce the underlying structural and optical parameters non-invasively. However, interpreting the spectral response is non-trivial, as it involves an interplay of three optical phenomena: lattice diffraction [5], thin-film interference [6], and guided-mode resonances [7]. Since the substrate's refractive index is higher than the PS monolayer's effective refractive index ($n_{Si} > n_{eff}$), the optical modes along the monolayer are not entirely confined and may leak into the substrate, resulting in leaky mode resonances (LMR) [8]. These LMRs are often accompanied by broad interference and diffraction patterns, making it challenging to distinguish resonant features against the background.

II. Methods

In the present work, we fabricated PS sphere ($\approx 1000\ nm$) monolayers on silicon substrates via surfactant-assisted self-assembly at the air-water interface [9]. Further, we generated a library of NCP test structures with varying sphere size (d_f) through RIE. To characterize the complex optical response of the PS monolayers, we used three complementary geometries: fixed-incidence diffraction, retroreflection, and symmetric reflection (Fig. 1). Through this approach, we distinguished the respective contributions of diffraction, retroreflection, and thin-film interference.

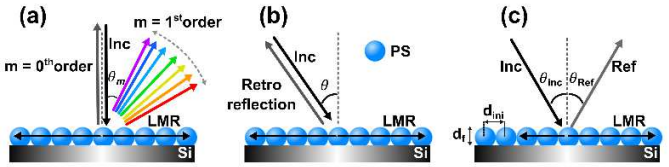

Fig. 1. Schematic representation of the optical measurement geometry exploring (a) diffraction, (b) retroreflection, and (c) interference phenomena in a PS monolayer deposited on a silicon substrate. Here, LMR refers to leaky mode resonance.

III. Results and Discussion

First, by tracking the angular evolution of the dominant diffraction peak, the iridescence of the 2D photonic crystals was quantified (Fig. 2 a and b). Second, to uniquely extract the lattice parameter and identify the underlying lattice symmetry, we fit the grating phase-matching condition to the angular dispersion of multiple orders in retroreflection spectra (Fig. 2 c). Finally, by performing a global fit of the theoretical thin-film model to multi-order symmetry reflection spectra (Fig. 2 d), we determined the evolution of the reduced sphere size (d_f) and effective refractive index (n_{eff}) as a function of etch duration.

Finally, we identified the anomalous spectral dips observed across the aforementioned optical spectra as LMR (Fig. 2 b - c). We compared the optically retrieved structural parameters with field emission scanning electron microscope (FESEM) data, demonstrating that the proposed method is a cost-effective, robust, and non-invasive alternative for precise structural characterization. From Fig. 3, we observed that the geometric sizes extracted from FESEM (black circles) exhibit a systematic offset of about $115\ nm$ ($\approx 11\%$) compared to the optical measurements (black triangles). This deviation is attributed to calibration issues and charging-induced edge blooming in FESEM. Furthermore, the discrepancy in the n_{eff}

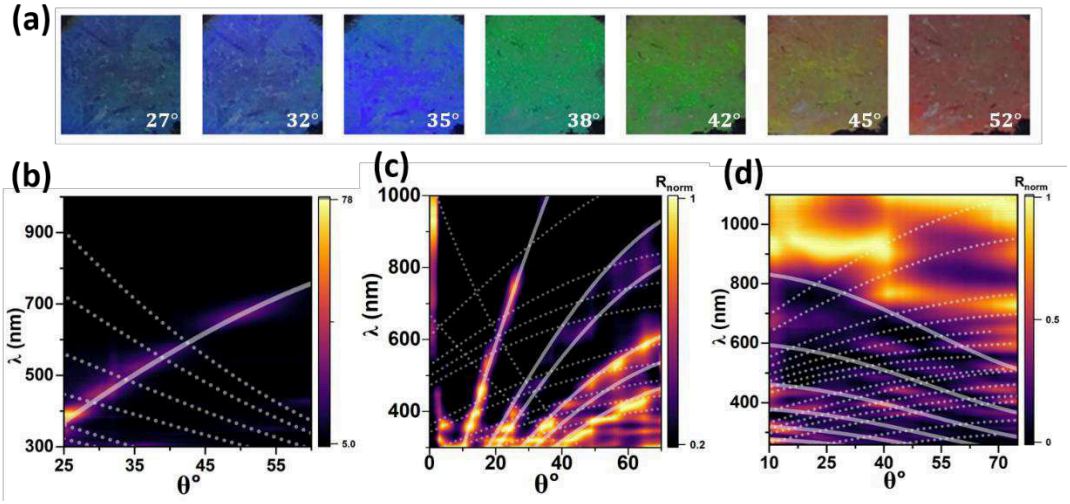

Fig. 2. (a) Photographs of the PS monolayers captured by varying the camera viewing angle (θ_m) for fixed-incidence ($\theta_{ini} = 0°$). The field of view of each images is 1.5×1.5 cm^2. Color maps indicate the experimental spectra of (b) diffraction, (c) retroreflection, and (d) symmetry reflection. (b-c) continuous lines are the analytical phase-matching and thin-film fits, while the dotted lines are plotted from the LMR dispersion relation.

increases significantly with RIE duration (from $\Delta n_{eff} \approx 0.03$ in the CP state to $\Delta n_{eff} \approx 0.09$ after 420 s of RIE) is attributed to the anisotropic nature of the etching process.

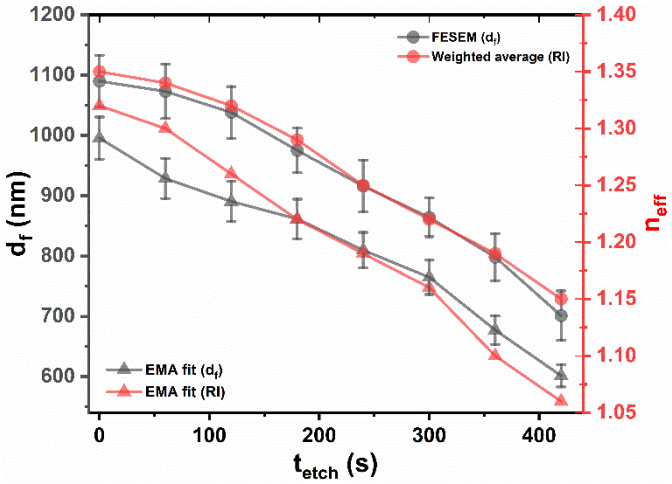

Fig. 3. The sphere size (d_f) and effective refractive index (n_{eff}) obtained from FESEM images and the weighted average index are compared with values obtained from the analytical thin-film model for different RIE durations.

IV. Conclusion

In this work, we have demonstrated a facile, non-invasive, and robust approach to measure the lattice periodicity, effective refractive index, and reduced sphere size of a 2D photonic crystal with angle-resolved optical spectroscopy. We quantified the iridescence using fixed-incidence surface diffraction. Using the retroreflection geometry, the lattice symmetry and the lattice parameter of the colloidal assembly are precisely determined. The evolution of the reduced sphere size and effective refractive index with respect to etching duration was rigorously quantified by globally fitting the interference spectra obtained in symmetric reflection geometry. Furthermore, the anomalous spectral dips observed in all these optical phenomena are attributed to leaky mode resonances. Using the appropriate dispersion relation, the dispersive trajectories of these LMR resonances for multiple reciprocal lattice vectors were accurately predicted. The lattice periodicity obtained from three different optical studies is in excellent agreement with the manufacturer's specifications. Our study highlights a significant discrepancy between sphere sizes measured via FESEM and those retrieved optically. We attributed this discrepancy to calibration issues and charge-induced blooming in FESEM. The identification of the leaky-mode resonance signatures in all three optical phenomena provides a comprehensive understanding of the electromagnetic modes supported by 2D photonic crystals. Since colloidal monolayers are increasingly used as a sacrificial mask in NSL, our non-invasive optical approach serves as an essential quality-control step, ensuring the integrity of sphere geometry and lattice order. Beyond static structural characterization, this framework can be extended to real-time monitoring of lattice evolution under external stimuli, including mechanical strain, thermal expansion, and chemical-induced swelling. Our findings establish that angle-resolved spectroscopy serves not only as an alternative to electron microscopy but also as a versatile metrology platform for the development of active photonic sensors.

***Abstract*— Direct laser writing continues to develop for photonic applications. The technique can produce complex structures using low refractive index polymer materials. The superimposed phase grating structure presented demonstrates improved colour saturation across the visible spectrum, with examples shown at 390 nm, 470 nm and 700 nm.**

***Keywords*— Structural Colour, Direct Laser Writing, Phase Grating, Optimization Algorithm.**

I. Introduction

Square wave gratings have been proven to be ideal candidates for producing structural colour using two photon polymerization [1]. Previous works have investigated the characteristics of these gratings as well as their applications for sensing in liquid and vapour environments [2][3]. Transmission in certain wavelength ranges can require pillars of 4 µm or taller with pillar widths of 0.5 µm. Such large height-width aspect ratios are challenging to achieve from a fabrication standpoint and are less robust. Taller pillars also support more colours in their zeroth order modes which affects the purity of colour achievable. The superimposed grating design is motivated by producing transmission within the visible spectrum range with improved colour purity at all wavelengths. This implies that there is a minimized number of spectral components transmitted outside a given colour range. The structure presented comprises a superposition of multiple phase square wave gratings which cause constructive interference to produce a saturated form of the desired wavelength while destructively interfering to suppress contributions from any other part of the visible spectral range. This superimposed grating design allows for the fabrication of structures with smaller pillar heights proportional to the pillar widths which has the added benefit of improving the ease of fabrication along with achieving more spectrally pure and saturated structures.

II. Methods

Our methodology integrates Finite-Difference Time-Domain (FDTD) simulations, a Particle Swarm Optimization (PSO) algorithm, and experimental feedback to design the optimal structures needed to produce saturated colour at each targeted wavelength. The gaussian spectra with a full width half maximum of 23.5 nm centered at the target wavelengths (Fig. 1a) are plotted on a CIE 1931 chromaticity diagram which provides target chromaticity coordinates (x_t, y_t) for each wavelength. The zeroth order transmission spectrum for the optimized gratings is computed using Lumerical with a minimum mesh step of 0.125 nm and a step time less than 0.06 fs, these designs are optimised using the dimension limitations imposed by the two-photon lithography method. The cost function to be minimized is defined as the Euclidean distance between the target and simulated chromaticity coordinates:

$$Cost = (x - x_t)^2 + (y - y_t)^2 \qquad (1)$$

where x denotes the simulated x coordinate, x_t the target x coordinate, y the simulated y coordinate, and y_t the target y coordinate. As can be seen in Fig 1.b, the closer the optimized transmissions (white dots) are to the target spectra (black dots), the lower the value of the cost function.

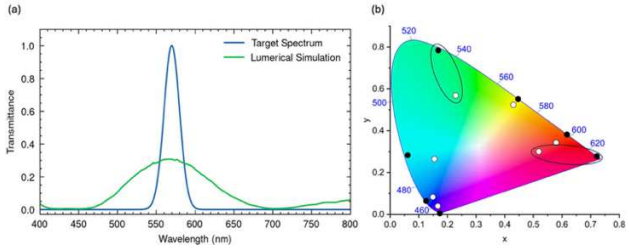

Figure 1: (a) Target spectrum in blue and optimised spectrum in green produced by the zeroth order of a superimposed grating designed to achieve yellow (570 nm), (b) The target colour is represented by black dots and the colour of the optimised structure is represented by white dots.

III. Results and Discussion

A schematic of the superimposed phase grating design is given in Fig. 2a. It is composed of elementary square gratings of various heights, generating multiple filters simultaneously. Pillars 1, 2, 4 and 5 have an identical width of 0.75 µm (labelled w1, w2, w4 and w5), pillar 3 has a width (w3) of 1 µm and hence the gap between pillar 3 and 4 or pillar 3 and 2 is 1 µm. The total of these widths gives a period of 6 µm. The height of pillars 2 and 4 (h2 and h4) are identical, the height of pillars 1 and 5 (h1 and h5) are also identical and finally pillar 3 has a height denoted by h3. With this approach, there are only three degrees of freedom, the heights h1, h2 and h3. This number is motivated by simplicity in the fabrication and keeping the computation time relatively short. The dimensions of the fabrication are verified experimentally using SEM as seen in Fig. 2b.

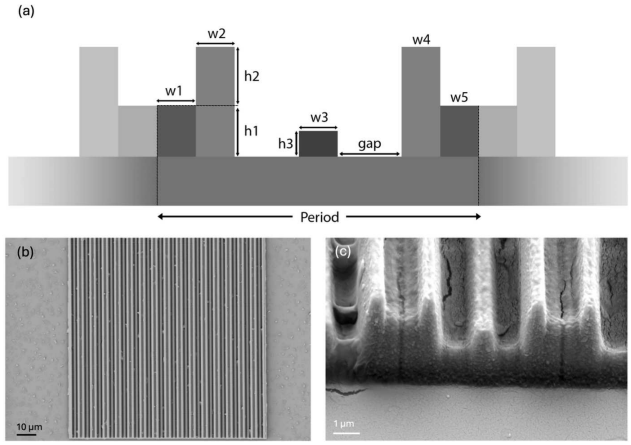

Figure 2: (a) Simple schematic of superimposed gratings with 3 pillars of height h1, h1 + h2 and h3 respectively. SEM images show (b) a top-down view of the superimposed grating for 470 nm and (c) 45-degree view of superimposed grating for 470 nm.

Experimental characterization is carried out using optical measurements taken on a home-built angle resolved setup to capture zero-order transmittance spectra for both the square wave grating and superimposed grating designs at 390 nm, 470 nm and 700 nm. The images of the gratings in transmission are obtained using a 4x objective lens coupled with a microscope focused into a CCD camera [3].

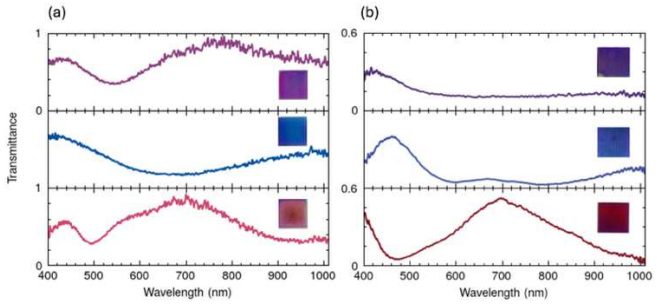

Figure. 3: (a) Comparison between the square wave and (b) superimposed grating zeroth-order transmission spectra for 390 nm, 470 nm and 700 nm, respectively.

Fig. 3 shows a comparison between the square wave grating zeroth-order transmissions and that of the superimposed gratings. We can clearly see from the experimental spectra that the contributions of other wavelengths have been greatly reduced leading to better agreement between fabrication and targeted wavelength. In the case of square wave gratings, the 700 nm fabricated sample lacks a distinct red colour and instead appears pink to the eye as there are larger contributions being made by wavelengths such as 470 nm contributing to a colour mixing affect between red and blue. Samples such as 390 nm have a clearly defined peak at 390 nm in both square wave and superimposed gratings but the superimposed grating design has managed to entirely suppress any wavelength higher than 500 nm meanwhile the square wave grating has a secondary more intense peak at 700 nm and beyond, leading to a colour mixing of purple and red.

Finally, we compared the height width aspect ratio and cost function for both experimental designs.

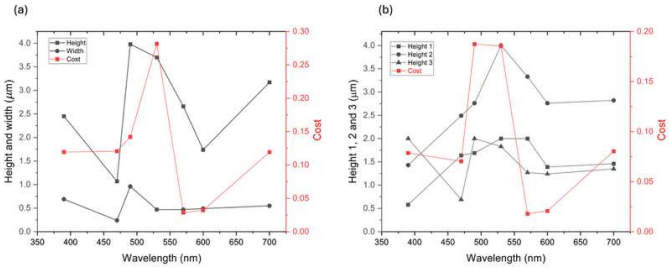

Figure 4: Dependence of the heights h, h1, h2, h3 and the cost function value as a function of wavelength for the (a) square wave and (b) superimposed grating.

In the case of the square wave grating at 390 nm, 470 nm and 700 nm the cost function value is 0.119, 0.121 and 0.119, respectively, whereas for the superimposed grating a lower cost function value is achieved of 0.079, 0.070 and 0.080 respectively, clearly demonstrating that the zeroth order transmissions realized by this novel design are closer to the target spectrum.

IV. Conclusion

In this work, we have demonstrated the design and experimental realization of polymer-based phase gratings by direct laser printing optimized for colour-selective transmission using a PSO algorithm coupled to rigorous FDTD simulations. The optimization strategy, based on minimizing the Euclidean distance between simulated and target spectra in the CIE 1931 colour space, enabled precise tuning of grating geometries to achieve desired chromatic responses.

***Abstract*— Wrinkle-mediated plasmonic metasurfaces provide a scalable route to anisotropic light-matter interaction without complex lithography. Here, large-area 1D plasmonic gratings fabricated via mechanical instabilities and oblique-angle metal deposition are presented. Surface plasmon polaritons and localized plasmon modes enable deformation-stable optical sensing and photoresponsive device functionalities.**

***Keywords*— wrinkled plasmonic metasurfaces, surface plasmon polaritons, localized surface plasmon resonances, anisotropic optical response, photoresponsive devices.**

I. Introduction

Large-area plasmonic metasurfaces can exhibit strong, tunable light-matter interactions, with applications in optical sensing and photodetection. However, conventional top-down nanofabrication techniques, such as electron-beam lithography, can impose severe limitations on scalability and throughput, which is why cost-effective, scalable alternative fabrication strategies are often sought. In this regard, wrinkling induced by mechanical instabilities in elastomeric substrates has emerged as an attractive bottom-up approach for realizing periodic 1D surface relief gratings over centimeter-scale areas [1,2]. By combining metal deposition, such wrinkled templates can produce continuous and discrete plasmonic metasurfaces that support surface plasmon polariton (SPP) and localized surface plasmon resonance (LSPR) modes, respectively. These wrinkle-mediated architectures offer a versatile platform for engineering anisotropic optical responses and photoresponsive functionalities without relying on complex lithographic processes.

II. Methods

We fabricated wrinkled templates by plasma-oxidizing elastomeric substrates, thereby inducing periodic surface modulations via controlled mechanical instabilities [1,2]. The wrinkle periodicity and amplitude were tuned through plasma exposure conditions and substrate parameters. Plasmonic metasurfaces were realized by oblique angle deposition (OAD) of metallic layers on top of these wrinkled substrates under both normal and oblique incidence, to further ensure the selective formation of surface- and edge-dominated plasmonic gratings [1]. The wrinkle fabrication process, resulting surface morphology, and subsequent plasmonic grating formation are schematically summarized in Fig. 1.

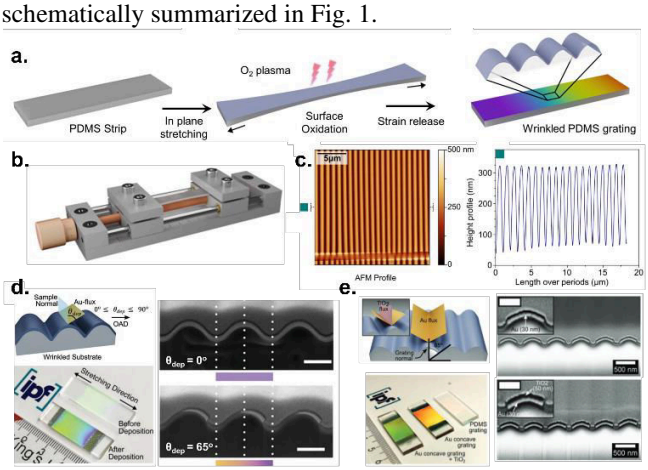

Fig. 1. Wrinkle fabrication, surface topology, and plasmonic grating formation. (a) Schematic illustration of wrinkled PDMS fabrication via in-plane stretching, O2 plasma oxidation, and strain release. (b) Custom-built stretching device used [3]. (c) Surface topology of wrinkled PDMS showing an AFM height map and the corresponding line profile extracted along the indicated direction [1]. (d) Wrinkled PDMS as a template for plasmonic grating fabrication, showing OAD of metal layer and centimeter-scale uniformity. Corresponding FIB-SEM cross-sections show Au surface gratings deposited at 0° and Au edge gratings deposited at 65° [1]. (e) Formation of concave plasmonic gratings using symmetric OAD at 65°. Photographs of large-area samples and cross-sectional SEM images show concave Au and Au/TiO2 gratings, with insets highlighting a single grating period [3].

For photoresponsive device architectures, we fabricated metal-semiconductor hybrid gratings by integrating plasmonic metals with further deposited semiconductor layers to allow electrical readout of plasmon-induced photoresponses [3]. Optical characterization was performed using polarization-resolved UV-visible-NIR spectroscopy to probe anisotropic plasmonic resonances. We conducted photoresponse

measurements under controlled illumination conditions with different excitation wavelengths, including angular dependence. Finite-difference time-domain simulations were employed to analyze electromagnetic field distributions and plasmonic mode characteristics [1-3].

III. Results and Discussion

Wrinkle-mediated plasmonic metasurfaces exhibit pronounced anisotropic optical responses arising from their 1D periodic geometry. Depending on the deposition configuration, the metasurfaces supported propagating SPP modes along continuous metallic features or LSPR-dominated modes localized at metal edges [2]. Polarization-resolved spectroscopy revealed distinct resonance features associated with these plasmonic modes, with strong sensitivity to incident light polarization and wavelength. Figure 2 provides an overview of the functional performance of the wrinkled plasmonic metasurfaces, including refractive index sensing and photoresponsive device operation.

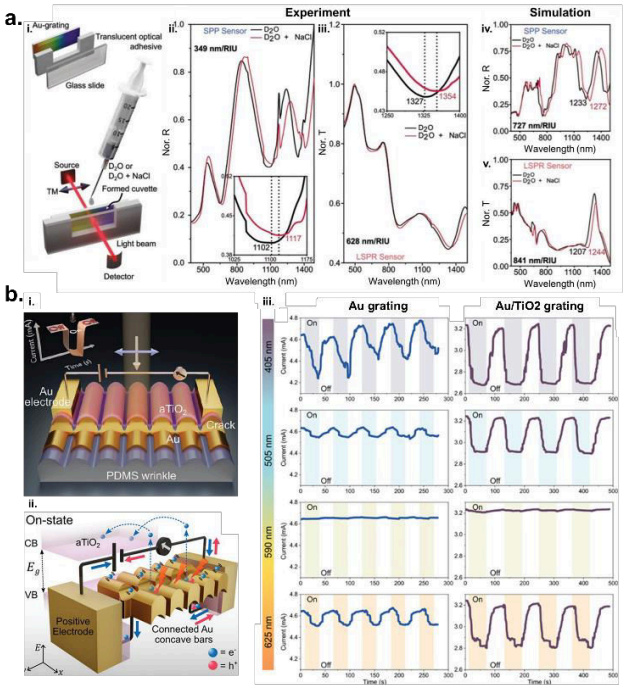

Fig. 2. Plasmonic sensing and photoresponsive behavior of wrinkled plasmonic metasurfaces. (a) RI sensing study, showing the cavity-based liquid measurement setup, experimentally measured spectral shifts of SPP modes in Au surface gratings and LSPR modes in Au edge gratings upon RI variation from D2O to D2O + NaCl, along with FDTD simulations [1]. (b) Photoresponsive device operation based on wrinkled plasmonic gratings, showing the device architecture with Au and Au/TiO2 concave bars forming the active channel between electrodes, the operating principle illustrated by band alignment and hot-electron-mediated charge transport under illumination, and time-dependent photocurrent responses for different LED excitations, where shaded regions indicate periods of light exposure [3].

Importantly, the plasmonic response of the wrinkled metasurfaces remained stable under mechanical deformation, enabling deformation-tolerant optical sensing [1]. Changes in the surrounding refractive indices led to measurable shifts in plasmonic resonance positions, demonstrating the suitability of these metasurfaces for large-area, flexible optical sensing applications.

Beyond passive sensing, metal-semiconductor wrinkled gratings also exhibited pronounced photoresponsive electrical behavior under illumination [3]. The interconnected plasmonic structures facilitate efficient light absorption and hot-carrier generation, resulting in a measurable photoresistive response. The interplay between plasmonic excitation, charge transport across metal-semiconductor interfaces, and carrier recombination dynamics governed the magnitude and sign of the photoresponse. These results established wrinkle-mediated plasmonic metasurfaces as a versatile platform for photoresponsive devices combining anisotropic optical functionality with electrical readout.

IV. Conclusion

Overall, these wrinkle-mediated plasmonic metasurfaces provide a scalable and lithography-free route to large-area photoresponsive devices with anisotropic optical and electrical properties. By exploiting mechanically induced surface instabilities and controlled metal deposition, plasmonic metasurfaces supporting SPP and LSPR modes are realized with high robustness and deformation stability. This approach offers a general framework for future plasmonic sensing and photoresponsive technologies based on large-area metasurfaces.

***Abstract*—Current realisations of perovskite whispering-gallery mode resonators suffer from relatively low quality factor, restricted coupling geometries, and instability in air. We present a high-Q hybrid microcavity platform that addresses all three of the bottlenecks in state-of-the-art perovskite resonators, providing a route to accessing the promising optical properties of perovskites.**

***Keywords*— whispering-gallery resonators, perovskites, fabrication, ion migration**

I. Introduction

Metal halide perovskites, have recently been established as promising emergent materials for optics and photonics due to their large refractive index [1], high photoluminescent quantum efficiency [2], and strong reported third-order optical nonlinearity [3], [4]. These qualities make perovskites interesting candidates for use in devices that facilitate high intensity fields at low powers, such as whispering-gallery mode (WGM) resonators [5]. To date, works have realised perovskite optical resonators via solution-processed crystals grown on substrate; however, WGM resonators fabricated so far have been subject to relatively low quality factor (Q-factor) on the order of $\sim$1000 and are limited to relatively inefficient free-space coupling of light into the cavity [6], [7], [8]. Additionally, the sensitivity of perovskites to air exposure, which has been shown to cause optical degradation [9], poses an additional engineering challenge; however, in other perovskite devices such as solar cells, encapsulation of the perovskite layer has been shown to result in substantial improvements to device lifetime [10].

Here, we iterate on the perovskite WGM devices demonstrated thus far by integrating a solution-grown lead-halide perovskite with a silica template of few-micron wall thickness to produce a hybrid layered core-cladding structure. A diagram of our device is given schematically in figure 1 [11]. Our fabricated WGM resonators support higher Q-factor operation than previous demonstrations of devices composed solely of perovskite, and permit evanescent coupling of light into the cavity via tapered optical fibre. These qualities allow us to explore the effect of photo-induced ion migration, which is a unique effect in perovskites which has been previously identified to occur over timescales on the order of seconds to minutes [12]. In our devices, this effect results in a time-dependent modulation of the measured transmission spectrum. Additionally, our device geometry offers encapsulation of active region of the resonator, protecting it from the environment.

II. Methods

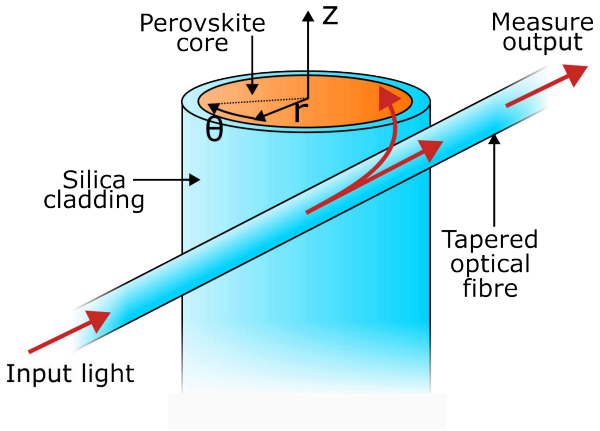

Fig. 1. Schematic representation of perovskite-based WGM resonator, showing perovskite core surrounded by thin silica layer, shown with tapered optical micro-fibre for coupling of light. Shown with cylindrical coordinates system with radial (r), azimuthal (θ), and axial (z) directions.

The silica cladding templates used here were fabricated from commercially available Polymicro fused silica capillary tubing. To prepare the capillary, a multi-stage heat-and-pull tapering process was used, employing both an electric arc and a butane flame along with translational stages to reduce the outer diameter of the capillary by over an order of magnitude to $\sim$50 µm and below. This allows for the tuning of resonator parameters such as free spectral range (FSR) as well as reduces the thickness of the external silica layer, promoting mode localization to the perovskite core. A precursor solution of $MAPbBr_3$ was drawn into the templates via capillary action, from which crystals were grown using an inverse temperature crystallization process [13], resulting in a layered core-cladding structure.

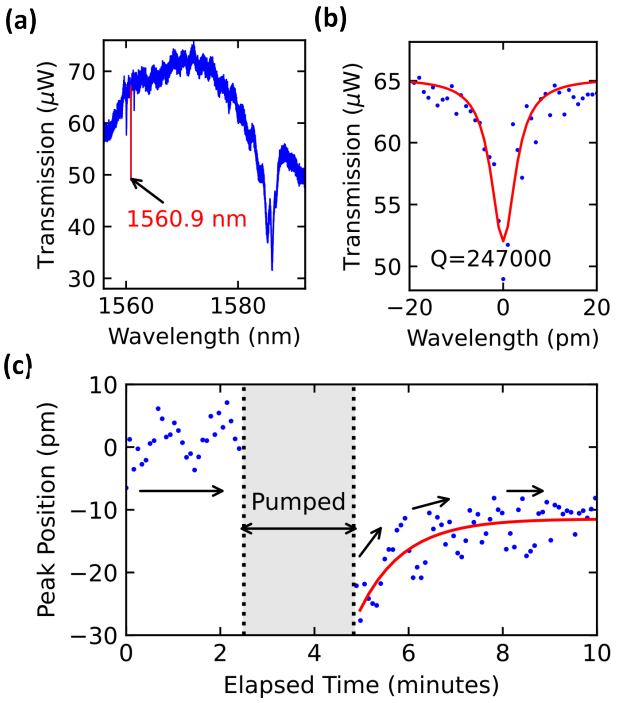

Fig. 2. Transmission spectrum characterisation of $MAPbBr_3$ WGM resonator, with highlighted high-Q mode (a). Lorentzian fit to highlighted mode, adjusted such that the center of the peak is located at zero wavelength, producing estimated Q-factor of 247000 (b). Time-dependent measurement in $MAPbBr_3$ WGM resonator, showing modulation of central peak position as a function of time before and after being pumped with high power pulsed source (c).

III. Results and Discussion

The fabricated $MAPbBr_3$ WGM resonators are characterised using a bespoke mode-hop free telecommunications characterisation rig, which employs a continuous-wave source of 400 kHz bandwidth tunable in the 1520-1630 nm range. The cross-section of the silica wall is sufficiently narrow so as to allow light to be introduced to the perovskite core via evanescent coupling from a tapered optical fibre (TOF) of diameter $\sim$1 μm. To produce a transmission spectrum, the TOF is pumped with the tunable source whilst positioned close enough to the resonator to induce coupling. The output power of the TOF is measured whilst scanning the wavelength of the tunable source to produce the transmission spectra such as the one shown in figure 2(a). To assess the performance of the device, the resonance peak located at 1560.9 nm is fitted with a Lorentzian, which is shown in figure 2(b). In doing so, a Q-factor of 247000 is identified.

To examine the role of the presence of the perovskite core in device operation, a resonator was pumped with high power light from a transform-limited pulsed source with a central wavelength of 1560 nm, a pulse width of 200 fs, and a repetition rate of 80 MHz. It was noted that, rather than returning to their original spectral position after the pump was switched off, the resonances had translated to a position that was blue-shifted from their original values. Such a measurement is given in figure 2(c). After being pumped for a duration of $\sim$2 minutes, the peak position was displaced to a position of -30 pm relative to its original value. Then, over a period of five minutes, the peak recovers to a position of -10 pm. The experimental data are fitted to an exponential model yielding a time constant of 56 s. This behaviour can be attributed to refractive index modulation caused by ion migration taking place within the core.

IV. Conclusion

In this work we have iterated upon methods for the fabrication of perovskite waveguide devices, presenting WGM resonators comprising a hybrid layered silica-perovskite structure. In our devices, we demonstrate a resonance with a Q-factor of 247000, exceeding previous examples of perovskite WGM resonators by approximately two orders of magnitude, as well as the ability to affect the transmission spectrum over protracted time periods via refractive index modulation as a result of ion migration in the perovskite core.

***Abstract*— We investigate gas-phase catalyst etching of silica glass under reduced pressure for metalens fabrication. Vacuum conditions improve etching uniformity by enhancing reactive gas diffusion, while reducing etch rate. High-aspect-ratio, vertically etched nanoscale structures with excellent uniformity are demonstrated, indicating suitability for visible and ultraviolet metalens applications.**

***Keywords*— Metalens, glass, dry etching.**

I. Introduction

Metalens fabricated using nanoscale fabrication technologies have attracted attension as nest generation optical elements because they can realize small and thin optical components. In infrared region, these have been achieved by silicon processed by using semiconductor processes and have been applied as sensing devices such as thermal camera[1] and LiDAR[2]. More recently, metalens for visible and more high frequency light are proposed. Especially, silica glass has been investigated as a promising substrate material in ultraviolet region.[3]

Reactive ion etching (RIE) is generally used to fabricate fine structures in silica glass. However, since the mask material is simultaneously etched by ion bombardment during the RIE process, achieving vertical sidewall is challenging. On the other hand, the verticality of the meta-atoms which are components of metalens affects the optical performance of the metalens. Therefore, in order to realize metalens targeting ultraviolet region, process technology capable of forming vertical fine structures with high-aspect-ratio is required.[4]

We have reported a new anisotropic etching process for SiO_2 materials, using catalyst and HF gas. This process enables vertical etching independent of conventional selectivity etching ratio by inducing a localized reaction at the interface between the catalyst and the surface of SiO_2 substrate. As a result, it is expected that nanostructures with high verticality suitable for meta-atom can be fabricated.[5]

Because the etching reaction occurs in the gas-phase catalyst etching without plasma, etching properties are expected to be controlled by the gas environment conditions. In this study, we investigated the effects of process gas pressure on etching rate and its uniformity in gas-phase catalyst etching assuming eight-inch-scale process.

II. Methods

Silica glass substrates were prepared and cleaned by ultraviolet ozone treatment for 15 minutes. Then the substrates treated by hexamethyldisilazane and coated with photoresists which is positive-tone novolac type (THMR-iP5700, Tokyo Ohka Kogyo, Japan) at 3000 rpm for 30 s. Micrometer-scale patterns (~10 μm) and nanoscale line patterns were exposed on the substrate using a maskless photolithography system (DL-1000A2, Nano System Solutions, Japan). The patterns were developed by using an alkaline developer solution (NMD-W, Tokyo Ohka Kogyo, Japan). Subsequently, the substrates were cleaned by ultraviolet ozone treatment again to remove organic contaminants from the surface without the photoresist.

The gas treatment was carried out using a tube furnace equipped with a vacuum system. The samples were placed on the furnace and heated to above 200 °C. A mixture of HF and N_2 was introduced into the furnace for from 5 minutes to 60 minutes. After the treatment, photoresist was removed by O_2 plasma treatment.

The etched structures were observed by a scanning electron microscope (SU8000, Hitach, Japan).

III. Results and Discussion

Figure 1 and Figure 2 show cross-sectional image of the etched structure and the depth distribution of the patterns respectively. Vertical hole structure without noticeable tapering is observed in Figure 1. The standard deviation of the etched depth was approximately 2.5% relative to the average as shown in Figure 2. In gas-phase catalyst etching, HF is consumed on the contact interface through inside of the catalyst in the reaction. Therefore, gas exchange must occur at the catalyst surface located at the bottom of etched holes. The reduced-pressure atmosphere enhances the diffusion of reactive gas species in the chamber and the bottom of etched feature. The gas concentration becomes uniform immediately in such reduced-pressure atmosphere. Therefore, it allows that fresh HF gas is supplied effectively and stably to all reactive areas.

Figure 3 shows the etching rate under atmospheric pressure and at 250 Torr. The rate under vacuum conditions decreases to approximately 20% of that at atmospheric pressure. Since the amount of HF per volume decreases in reduced-pressure atmosphere, the number of times it comes into contact with the catalyst decreases. This indicates that the etching reaction depends on the supply of HF and its speed is determined by the contact frequency between HF and the catalyst.

Figure 4 presents a cross-sectional image of a nanoscale pitch line structure fabricated by gas-phase catalyst etching under vacuum conditions. The achieved aspect ratio is approximately 10. All nanoscale features are etched uniformly with high vertically, demonstrating that the gas-phase catalyst etching enables the formation of high-aspect-ratio nano structures with high uniformity.

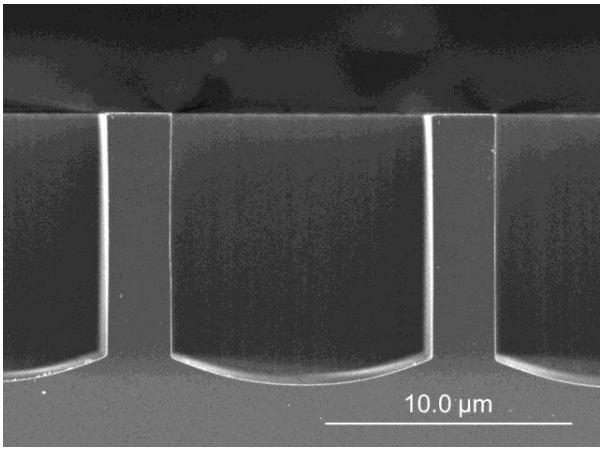

Figure 1. Cross sectional scanning electron microscopy (SEM) image of etched the micro-scale structures by gas-phase catalyst etching.

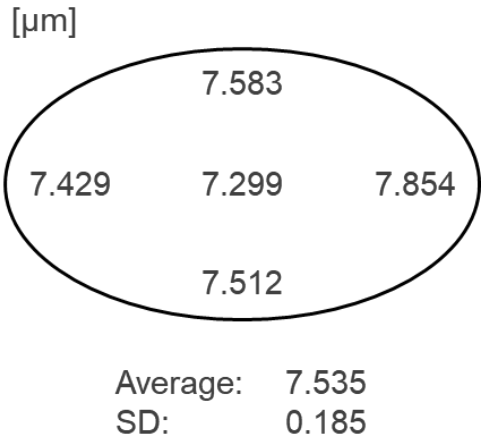

Figure 2. Depth distribution of the micro-scale structures in eight inches area.

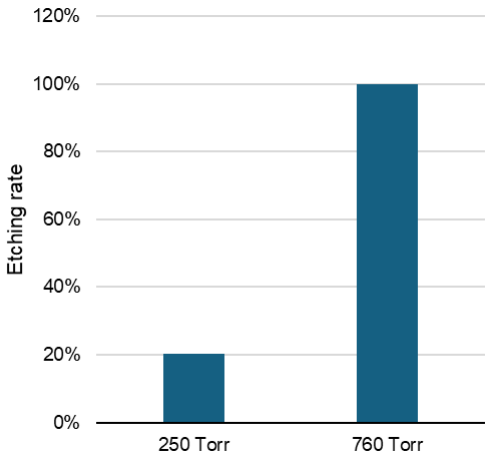

Figure 3. Etching rate of the micro-scale structures under atmospheric pressure and 250 Torr.

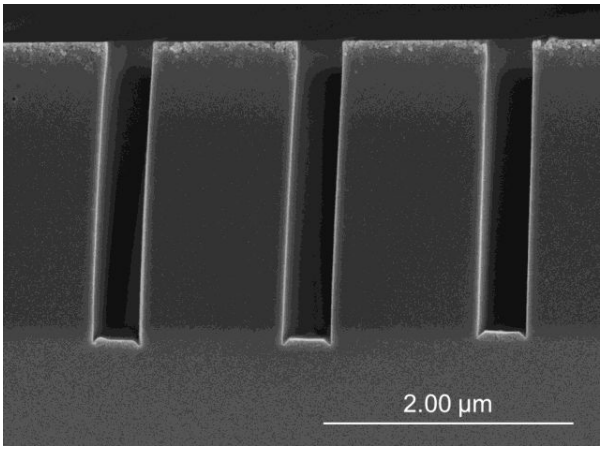

Figure 4. Cross sectional SEM image of a nano scale pitch line structures by gas-phase catalyst etching.

IV. Conclusion

We have demonstrated gas-phase catalysts etching under vacuum atmosphere and shown that the process enables the fabrication of vertical nanoscale structures with high uniformity. This technology is expected to contribute to metalens for visible or ultraviolet regions.

Abstract— We present an automated scanning electron microscopy workflow for quantitative characterization of nanostructured metamaterials. The approach combines layout-based navigation, robust alignment, and autofocus to enable reproducible wafer scale measurements. Experiments demonstrate high throughput acquisition, consistent critical dimension (CD) extraction, and statistical analysis capabilities suitable for metamaterial design, fabrication optimization, and process monitoring.

Keywords— metamaterials, scanning electron microscopy, automated metrology, nanostructures, wafer-scale characterization.

I. Introduction

Scanning electron microscopy (SEM) remains a key technique for critical dimension measurements and nanoscale structural inspection in modern nanofabrication workflows [1]. While dedicated CD-SEM systems provide highly automated and precise metrology [2], their cost and limited versatility restrict widespread use, particularly in shared research facilities. Consequently, conventional SEM platforms are still frequently operated manually, limiting throughput and reproducibility. These limitations are especially relevant for nanostructured metamaterials, where functionality is critically governed by geometric fidelity and dimensional variability. Systematic and reproducible SEM-based characterization is therefore essential for validating fabricated structures. Software-defined SEM metrology platforms extend conventional SEM platforms toward high-throughput measurement systems, enabling layout-based navigation, automated image acquisition, and direct image-to-layout comparison.

II. Methods

The automated SEM imaging and metrology workflow was implemented using a commercial SEM (Zeiss Gemini 560) with metrology upgrade kit (GenISys InSPEC software), which provides digital interfacing with conventional SEM, including stage control, scan coordination, and detector signal access. The platform enables layout-based navigation, automated alignment, and reproducible image acquisition across large sample areas. Image-to-layout matching allows direct comparison between fabricated nanostructures and nominal metamaterial target design. Geometric parameters are extracted relative to intended layout features, enabling systematic evaluation of dimensional deviations, process variation bands, and spatially resolved fabrication changes.

III. Results and Discussion

Automated image acquisition enables statistically meaningful characterization of fabricated metamaterial arrays. Image-to-layout comparison reveals systematic deviations from nominal geometry, while aggregated datasets support quantitative evaluation of process variation bands. Spatial trends and dimensional distributions provide direct feedback for fabrication optimization, device reproducibility, and tolerance-based metamaterial design.

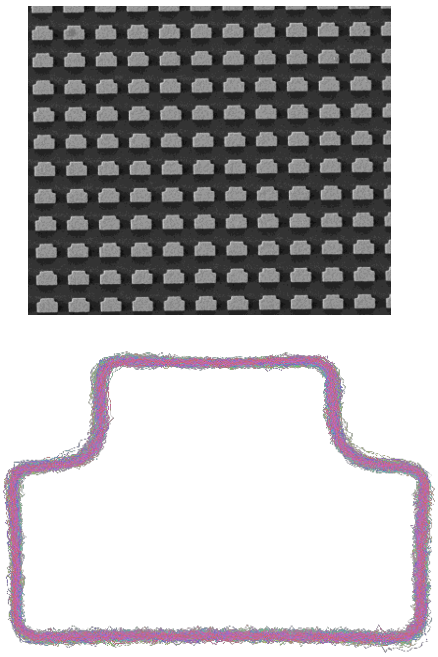

Fig. 1 Top view SEM image of metastructures (top) and superposition of extracted contours (bottom).

Structural variability and layout comparisons:

- Extracted structural contours are aggregated and centered to construct process variation tolerance bands (Fig. 1)
- Waferscale uniformity is evaluated through image-to-layout matching, incorporating systematic corrections including lateral shift, scaling, and rotation (Fig. 2)
- Direct quantitative comparison with layout primitives enables evaluation of dimensional bias and variability (Fig. 3 and Fig. 4)

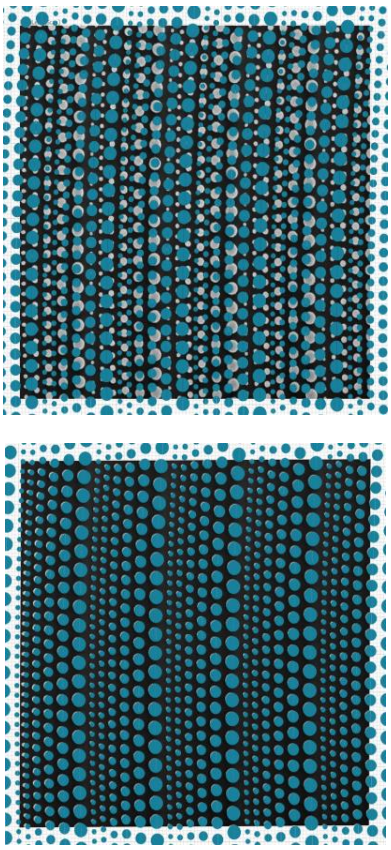

Fig. 2 Image-to-layout comparison before (top) and after (bottom) shift, scaling, and rotation corrections applied to metalens structure

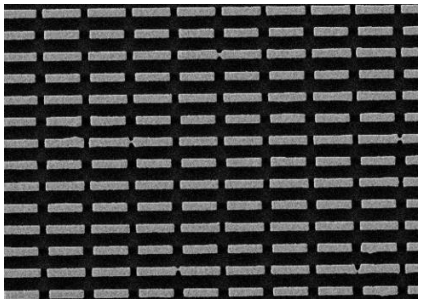

Fig. 3 Top view SEM image of rectangular metastructures

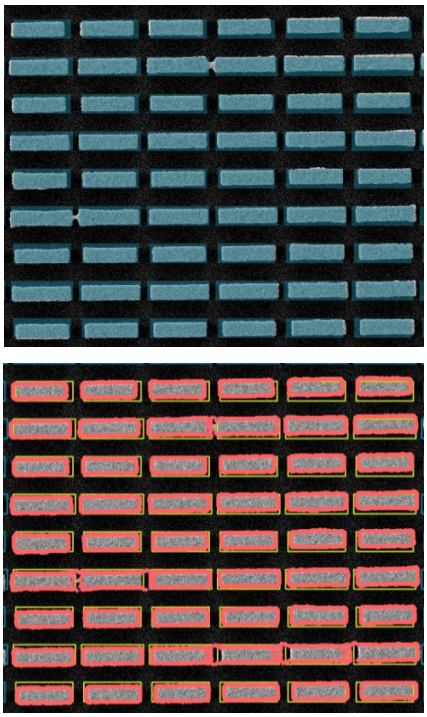

Fig. 4 Layout-overlaid SEM image from Fig 3. (top) and contour-based comparison with layout primitives (bottom).

Table 1 CD bias and variation relative to layout primitives

Width (µm)	Height (µm)	Width Bias (nm)	Width σ (nm)	Height Bias (nm)	Height σ (nm)
0.764	0.260	-50.4	7.1	-58.1	4.3
0.830	0.260	+12.5	94.0	-55.9	2.9

Table 1 summarizes the quantitative deviations obtained from comparison with layout primitives, including design bias and variability metrics relevant for lithography feedback.

IV. Conclusion

Automated SEM-based metrology provides a scalable and reproducible approach for wafer-scale characterization of nanostructured metamaterials using conventional SEM. The demonstrated workflow enables high-throughput data acquisition and statistical analysis, supporting reliable evaluation of pattern fidelity and process variation effects. Beyond the discussed results, the methodology offers a pathway toward advanced characterization capabilities, including edge roughness analysis, feature placement, and advanced layout comparison like EPE. The framework further supports curvilinear geometries and contour export into layout files, enabling direct integration with electromagnetic simulations.

***Abstract*— A robust multi-distance phase retrieval system based on optical field scanning is presented to characterize meta-lens phase modulation. Validated in the near-infrared spectrum, our method analyzes focal length, aberrations, and defect impacts. We also demonstrate phase variation across different media (air vs. ethanol), offering a straightforward tool for metalens optimization.**

***Keywords*— Phase retrieval, meta-lens, computational imaging.**

I. Introduction

Meta-lenses are highly efficient, compact optical metasurfaces capable of modulating the amplitude, phase, and polarization of incoming light. While their design and fabrication have seen significant advancements, characterization techniques remain limited. Precise measurement of phase distribution is crucial for evaluating and optimizing meta-lens performance, yet direct measurement in the optical frequency band is challenging. Traditional methods like light field scanning and electron microscopy fail to simultaneously capture localized optical field modulation and structural topography. Furthermore, existing phase measurement techniques, such as quadriwave lateral shearing interferometry (QLSI) and off-axis interferometry, are constrained by low energy utilization, complex optical setups, and strict coherence requirements. To address these challenges, we introduce a meta-lens phase-measurement system based on multi-distance phase retrieval (MDPR). This method effectively calculates the phase distribution by measuring light intensity across various distances on the sample's exit plane, offering a simpler and more robust alternative. We evaluate the system's convergence and noise sensitivity. Using this MDPR approach, we successfully measured the phase distributions of a near-infrared (NIR) meta-lens and a 405 nm metalens immersed in ethanol. The retrieved phase data enables the precise calculation of wave aberrations and other critical parameters.

II. Methods

The multi-distance phase retrieval (MDPR) system addresses the fundamental computational holography problem of determining missing phase information from intensity measurements. It achieves this through measurement encoding, capturing intensity distributions at various distances governed by free-space angular spectrum diffraction. In practice, a collimated laser illuminates the sample, and a sequence of intensity images is captured at equal intervals moving away from the surface.

Mathematically, the imaging process can be expressed as

$$\boldsymbol{y} = |\boldsymbol{A}\boldsymbol{x}|^2, \tag{1}$$

where $\boldsymbol{x}$ denotes the complex amplitude modulation of the sample, and $\boldsymbol{y}$ denotes the intensity profile captured by the camera. $\mathbf{A}$ denotes the linear measurement operator which is calculated based on the angular spectrum propagation and can

be further expressed as$\boldsymbol{A} = \boldsymbol{F^{-1}H_lF}$, where $\boldsymbol{F}$and$\boldsymbol{F^{-1}}$denote the Fourier transform and inverse Fourier transform, respectively. The transfer function at a given distance l is given by

$$\boldsymbol{H}_l(f_x, f_y) = \begin{cases} exp\left(j\frac{2\pi}{\lambda}l\sqrt{1-\lambda^2 f_x^2-\lambda^2 f_y^2}\right), & f_x^2+f_y^2 \le \frac{1}{\lambda^2}, \\ 0, & \text{otherwise}, \end{cases} \quad (2)$$

where f_x and f_y denote the spatial frequency coordinates.

To retrieve the phase, the system utilizes an iterative algorithm based on far-field amplitude-only speckle transfer. The core process unfolds in a continuous sequence of steps. First, a random complex field is initialized at the sample plane and propagated forward to the N measurement distances. Second, at each distance, the calculated phase is retained while the computed intensity is replaced with the physically measured intensity. Next, these N updated fields are propagated back to the sample plane and averaged to integrate the multi-distance information. Finally, the measured sample surface intensity is incorporated using a Kalman filtering method to refine the averaged field. By continuously repeating these steps—aided by double-feedback and selective filtering of erroneous images—the algorithm progressively converges to the meta-lens's true complex optical field, as shown in Fig. 1.

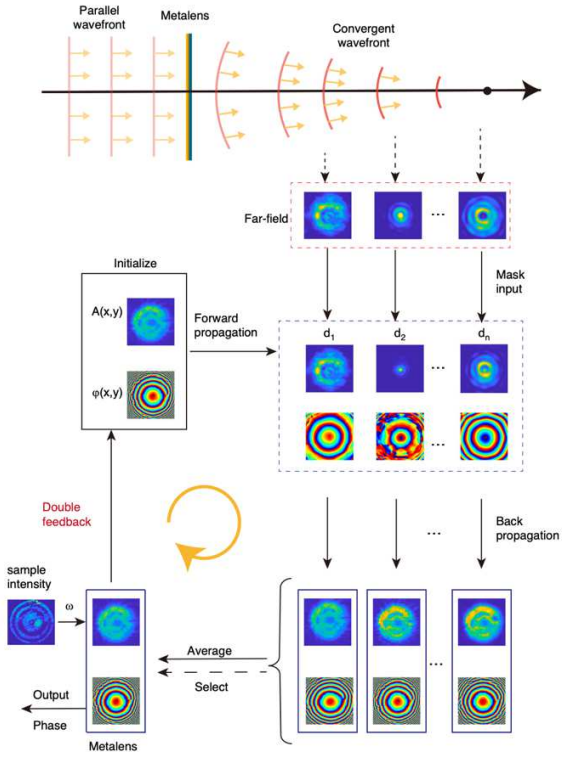

Fig. 1 Algorithmic flowchart for phase retrieval from intensity images captured at different positions

III. Results and Discussion

Two identical 1560 nm meta-lenses (design focal length 220 μm, NA 0.2) are evaluated using a supercontinuum laser. One sample contained physical defects (scratches, stains, layer penetrations), while the other was defect-free. Using 30 scanned images, the system successfully retrieved the phase distributions for both samples, revealing stark differences in their key performance metrics. Physical defects significantly hampered focusing efficiency, dropping it from 0.51 in the defect-free sample to just 0.27. Furthermore, the actual focal lengths shifted to 250 μm for the defective lens and 243 μm for the defect-free one. Consequently, the defective lens exhibited a higher wave aberration variance (0.13 compared to 0.06) and a correspondingly lower Strehl ratio (0.86 versus 0.94). The retrieved phase maps allowed us to directly correlate physical anomalies with specific aberrations. Broad stains caused significantly lower-order spherical aberrations (the 9th Zernike term), whereas localized scratches had minimal impact on these modes. Additionally, even the defect-free sample exhibited high-order spherical aberrations (the 16th term) induced by the inherent 0-2π phase jumps in the meta-lens design, as shown in Fig. 2.

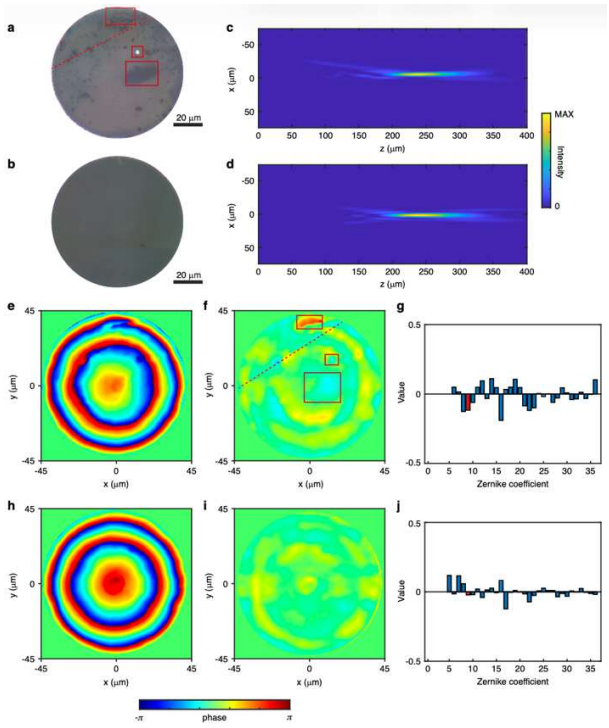

Fig. 2 Phase measurement for meta-lens working at 1560 nm. a, b Optical microscope images depicting the sample with defects and the defect-free sample. c, d Experimentally measured optical eld distributions for the sample with defects and the defect-free sample. Phase distribution, wave aberration, and Zernike expansion coefficients are illustrated for the sample with defects in (e–g) and the defect-free sample in (h–j)

IV. Conclusion

In this study, we developed a multi-distance phase retrieval (MDPR) system to measure meta-lens phase distributions. By extracting phase from intensity maps, our approach minimizes

laser coherence requirements, allowing versatile applications across various wavelengths and working mediums. We successfully demonstrated this by measuring near-infrared meta-lenses, subsequently deriving critical optical properties like focal length and wave aberration. Additionally, we quantified the phase modulation variations of a meta-lens operating in ethanol versus air. Finally, we introduced a simulation-based paradigm to analyze the system's convergence and robustness, ensuring adaptable stability and data reliability for characterizing diverse meta-lens samples.

***Abstract*—A single-layer model is proposed to extract effective optical constants of multilayer thin films from transmittance spectra. Applied to MoO_3/WO_3 bilayers, the method accurately describes the optical response and shows excellent agreement with effective-medium theory, providing a simple approach for photonic and electromagnetic applications.**

***Keywords*—multilayers, optical constants, thin films, photonic applications, effective medium.**

I. Introduction

A multilayer is an ordered array of thin films deposited on substrates or certain functional elements. The properties of these structures can be controlled via the choice of materials comprising the films, resulting in unique mechanical, thermal, and optical characteristics that have profound potential in various fields of science and engineering. Multilayers are crucial elements in several applications, including microelectronics, anticorrosion coatings, sensors, and thermal barrier coatings [1-4]. Such multilayer systems are also of significant interest in photonic and optoelectronic applications, where precise control of light–matter interaction is essential. However, the focus of this work is on the optical applications of multilayers, which include anti-reflection coatings, highly reflective coatings, beam splitters, interference filters, and X-ray imaging [5-7]. Traditionally, these coatings have been deposited on lenses, mirrors, prisms, and other optical substrates and integrated into optical elements and instruments such as telescopes, microscopes, diffraction gratings, interferometers, and laser output couplers. Recent optical applications of multilayers include antireflection coatings in solar cells [8] and extreme ultraviolet lithography [9], transparent electrodes [10], high-capacity optical data storage [11], tunable optical filters [12], spatial filtering (imaging) [13], optical sensors [14], electrochromic applications [15], and smart windows [16]. Multilayer optical coatings are based on interference of light rays reflected from the interfaces between constituent layers, which can be designed to yield constructive or destructive interference, thereby enhancing or suppressing reflection from (or transmission through) the multilayer structure at a specific wavelength or over a band of wavelengths [17]. Therefore, the performance of a multilayer is dependent on the following properties of its layers: their number, composition, periodicity, refractive index, and thickness; performance also depends on the angle of incidence of light [7]. The design and fabrication of multilayers for optical applications necessitate accurate knowledge of the optical constants (refractive index and extinction coefficient) of the layers. Optical modeling of multilayers has been established using the transfer matrix method, which is based on Fresnel coefficients that connect electromagnetic field components at an interface [18,19]. The transfer matrix method requires precise knowledge of the optical constants and layer thicknesses to calculate the system's transmittance and reflectance. The values of these parameters are optimized to maximize or minimize the optical function over the desired wavelength range. Here, the inverse problem is investigated, in which the measured normal-incidence transmittance is used to determine the effective optical constants and thickness of a multilayer using a single-layer model. Instead of using a priori knowledge of the optical constants to design a multilayer system for specific performance, the optical performance of an existing system is examined. The proposed model is applied to a bi-layer consisting of a molybdenum oxide (MoO_3) film deposited on a tungsten oxide (WO_3) film. The validity of this methodology is verified using the effective-medium theory. The proposed model simplifies the optical characterization of complex multilayer photonic structures, particularly when the number of layers or their nature is unknown. Furthermore, the model is easily extendable to any number of layers.

II. Experimental Details

Thin film deposition was carried out in a Leybold L560 system using thermal evaporation from a molybdenum boat. The starting materials were 99.99% pure powders of WO_3 or MoO3. Three sets of samples were prepared: pure WO_3 thin films, pure MoO_3 thin films, and MoO_3/WO_3 multilayer thin films. The multilayer was deposited using two boats without breaking the

Proceedings of META 2026 · Dublin, Ireland · 14–17 July 2026 · ISSN 2429-1390 · pp. 1770–1775

vacuum: first, a WO_3 layer was deposited on the substrate, followed by a MoO3 layer. The system was initially pumped to a base pressure of 2×10^{-5} mbar. Prior to evaporation, the powders were slowly outgassed. Deposition was performed on unheated fused-silica and tantalum substrates; the latter were used for chemical analysis. To ensure better film uniformity, the substrates were rotated during deposition. The evaporation rate (0.2 nm/s) and film thickness were controlled using a quartz crystal (QC) thickness monitor. For all layers, the thickness set by the QC was 150 nm. However, the real thickness was found by optical fitting.

X-ray diffraction revealed that all of the films were amorphous. The chemical properties of the single films were studied using X-ray photoelectron spectroscopy (XPS) performed in a Thermo Scientific Escalab 250Xi spectrometer equipped with a monochromatic Al K_α (1486.6 eV) X-ray source. To minimize electrostatic charging of the samples, the films deposited on the tantalum substrates were used for XPS analysis. The surface carbon 1s peak at 284.5 eV was used as the binding energy reference. For the multilayer film, the elemental distribution across the film thickness was obtained by a sequence of ion etching followed by XPS measurements. Etching was performed using a 2-keV Ar+ ion beam, and the ion current at the sample surface was less than 1 μA. The optical properties of the films were determined by measuring their normal-incidence transmittance over the wavelength range 200–800 nm using a Jasco V-570 spectrophotometer.

III. Results and Discussion

Chemical Properties:

The tungsten XPS W 4*f* core level spectrum consists of two sublevels ($4f_{5/2}$ and $4f_{7/2}$) due to spin-orbit splitting, as shown in **Fig. 1a**. In order to determine the binding energies of these peaks, the spectrum was fitted using a non-linear least squares algorithm with a Shirley background and a Gaussian-Lorentzian mixed line shape. The binding energies of the W $4f_{7/2}$ and the W $4f_{5/2}$ peaks were 36.0 eV and 38.1 eV, respectively. These values are identical to those of tungsten in the W^{6+} oxidation state (WO3) [20], indicating that our tungsten oxide films were stoichiometric. Similarly, the molybdenum XPS Mo 3*d* core-level spectrum consists of two sublevels ($3d3/2$ and $3d_{5/2}$) due to spin-orbit splitting (**Fig. 1b**). The binding energies of the Mo $3d5/2$ and Mo $3d_{3/2}$ peaks were 232.7 eV and 235.8 eV, respectively. These values are in close agreement with those of molybdenum in the Mo^{6+} oxidation state (MoO_3) [20]. Therefore, our molybdenum oxide films were stoichiometric. The O 1*s* spectrum (**Fig. 1c**) of both oxides was resolved into two components. The first is a low-binding-energy (LBE) component, which is attributed to oxygen bound to W or Mo. The second high-binding-energy (HBE) component may be attributed to oxygen species (such as water vapor or OH species) adsorbed at the film surface.

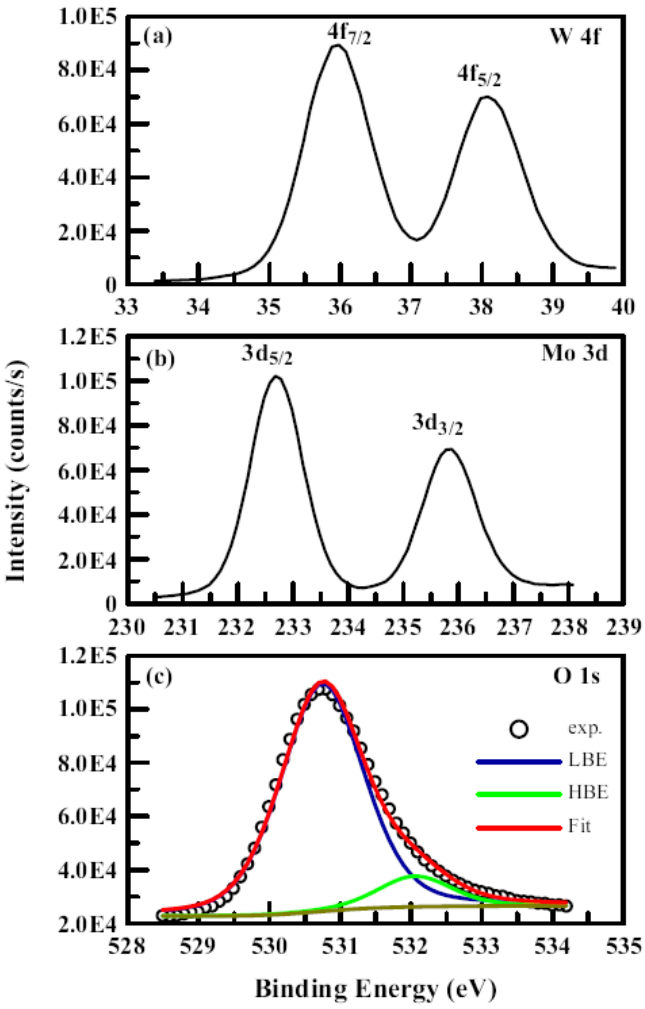

Fig. 1: XPS spectra of the pure oxide (single-layer) films: (a) W 4*f* core-level spectrum of the WO3 film; (b) Mo 3*d* core-level spectrum of the MoO3 film; (c) O 1*s* core-level spectrum, resolved into its two components.

The binding energies of these two components were 530.7 ± 0.1 eV, and 532.0 ± 0.1 eV, for the LBE and HBE components, respectively.

XPS depth profiling was used to investigate the spatial distribution and diffusion of the metals (W or Mo) across the multilayer structure. Several tungsten XPS peaks overlap with those of molybdenum or tantalum. Therefore, the Mo 3*d* and W 4*d* peaks were selected for our depth profile investigation. These two peaks are well separated, yet they are very close in binding energy. This situation makes it possible to simultaneously monitor their evolution as a function of etching time, as shown in **Fig. 2**. To achieve a better fit, it was necessary to deconvolute each of these peaks into five components (**Fig. 2**). The area under each peak (i.e. the sum of the areas of the five components) was used as a measure of the concentration of the metal at that depth. Etching was conducted until no signal was observed from the W 4*d* peak. The relative concentration of each metal was normalized with respect to the maximum intensity obtained for that metal, and the results are shown

in Fig. 3. It is evident from this Figure that the interface between the two layers was not sharp, and inter-diffusion of WO_3 and MoO_3 occurred, which resulted in a junction layer that accounted for nearly 1/6 of the total thickness of the multilayer structure. Etching the molybdenum oxide layer took less time because the Mo etching rate (0.44 nm/s) was higher than that of W (0.33 nm/s) [21].

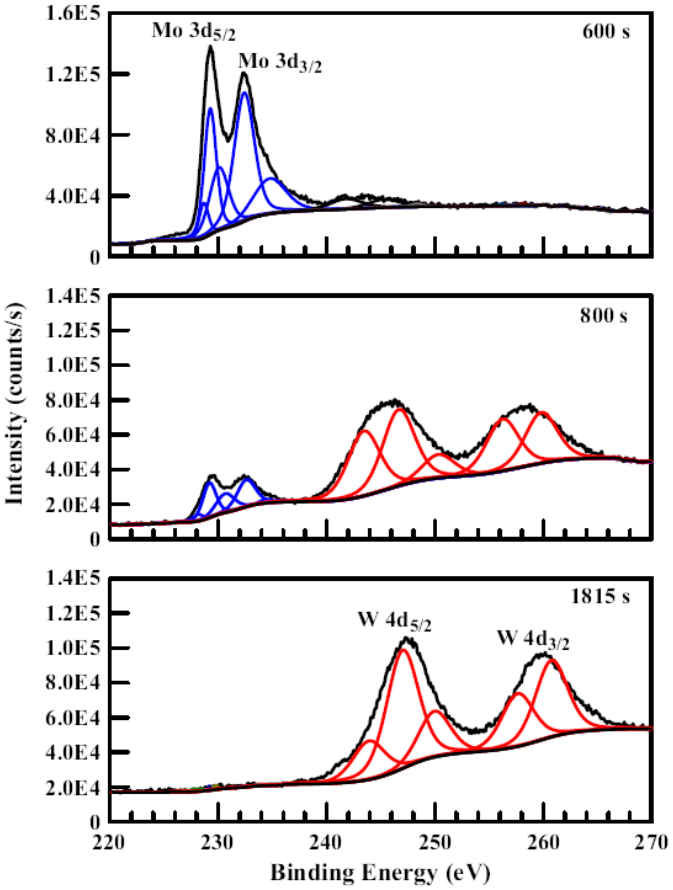

Fig. 2: X-ray photoelectron spectra of the multilayer structure in the W 4*d* and Mo 3*d* core level regions showing the evolution of the spectra as a function of etching time. The black curve is the experimental spectrum, and the blue and red curves indicate the component peaks under each spectrum.

Optical Properties:

The normal-incidence transmittance spectra of the films are shown in Fig. 4. The films were transparent throughout the visible region. These spectra were used to extract the optical constants of the films. In the transparency region of the films (wavelength, $\lambda \geq 400$ nm), the transmittance (T) spectra of the single films were fit using the formula for the transmittance of a thin film on a transparent substrate [22,23]:

$$T = \frac{16\, n_s(n^2+k^2)\beta}{A + B\beta^2 + 2\beta\left[C\cos\left(\frac{4\pi nd}{\lambda}\right) + D\sin\left(\frac{4\pi nd}{\lambda}\right)\right]} \qquad (1)$$

with

$$B = [(n-1)^2 + k^2][(n-n_s)^2 + k^2]$$
$$C = -(n^2 - 1 + k^2)(n^2 - n_s^2 + k^2) + 4k^2 n_s$$
$$D = 2kn_s(n^2 - 1 + k^2) + 2k(n^2 - n_s^2 + k^2)$$

where n, k, and d are the refractive index, extinction coefficient, and thickness of the film, respectively, n_s is the refractive index of the substrate, and $\beta = exp(-4\pi kd/\lambda)$. In order to fit the experimental transmittance spectra using Eq. (1), models for the dispersion of n and k must be used. The refractive index of the films was modeled using a Cauchy dispersion formula:

$$n(\lambda) = n_0 + \frac{A_1}{\lambda^2} + \frac{A_2}{\lambda^4} \qquad (2)$$

where n_o, A_1, and A_2 are constants. The extinction coefficient of the films was modeled by an exponential law for absorption below the band gap:

$$k = k_o + k_1 e^{-\kappa\lambda} \qquad (3)$$

where k_o, k_1, and κ are constants. Such an equation for k can account for band-tail absorption as well as absorption due to scattering and defects. The least-squares method was used to fit the experimental transmittance spectra of the single films using Eq. (1), with Eqs. (2) and (3) as the models for the optical constants. The fitting parameters were n_o, A_1, A_2, d, k_o, k_1, and κ. The best-fit parameters are listed in Table 1, and were used to calculate the optical constants of the films, as shown in Fig. 5. The accuracy of this technique is ± 0.02 for n, ± 2×10^{-4} for k, and ± 10 nm for d. Our values of the refractive index were comparable to those previously reported for MoO_3 and WO_3, as shown in Fig. 5.

Optical Properties of Multilayers – Effective Layer Method

The multilayer is treated as a single layer with effective optical constants (n_{eff} and k_{eff}) and overall thickness d_{eff}. The single-layer model (Section 3.2) was used to fit the experimental transmittance spectrum of the multilayer, with (n, k, d) replaced with (n_{eff}, k_{eff}, d_{eff}). An excellent fit of the experimental transmittance spectrum was noted, as shown in Fig. 6, and the corresponding best-fit parameters are listed in Table 1. The effective optical constants of the multilayer using this method are shown in Fig. 7 and are compared with those of the single films.

The effective refractive index of the multilayer is assumed to lie between those of the individual layers and is largely influenced by the layer adjacent to the substrate. The reason for this trend is that the difference in the refractive index (Δn) between WO_3 and the substrate is larger than Δn between WO_3 and MoO_3. In the visible region, the extinction coefficient of the multilayer was higher than that of the single layers. This could be due to light scattering at the junction layer. Given the thicknesses of the single layers found in Section 3.2 (Table 1), the overall thickness of the multilayer should be 232 nm. However, the effective thickness obtained from the fit was 183 nm. X-ray photoelectron spectroscopy depth profiles (Fig. 3) indicated that the thickness of the junction layer between MoO_3 and WO_3 was approximately ⅙ of the total thickness. Therefore, the effective thickness of the multilayer is ⅚ × 232 = 193 nm, which is close to the value of 183 nm obtained from the fit.

The validity of the new model was tested using effective-medium theory, which was developed to study the dielectric properties of heterogeneous media consisting of several phases or components [26]. This theory has also been used to investigate the effective optical properties of multilayers [27-

29]. Several effective medium models have been developed, including the parallel model and the series model [26]. In the parallel model, the effective dielectric function (ϵ_{eff}) is treated as a linear combination of the dielectric functions (ϵ_1, ϵ_2) of the two layers [26]:

$$\epsilon_{eff} = \xi_1\epsilon_1 + \xi_2\epsilon_2 \quad (4)$$

where ξ_j is the contribution of the j^{th} layer to the total dielectric function, such that

$$\xi_1 + \xi_2 = 1$$

The series model expresses the effective dielectric function as [26]:

$$\frac{1}{\epsilon_{eff}} = \frac{\xi_1}{\epsilon_1} + \frac{\xi_2}{\epsilon_2} \quad (5)$$

These equations can be expressed for the refractive index by noting that the complex dielectric function ($\tilde{\epsilon} = \epsilon_r + i\epsilon_i$) and the complex index of refraction ($\tilde{n} = n + ik$) are related by $\tilde{\epsilon} = \tilde{n}^2$, where ϵ_r and ϵ_i are the real and imaginary parts of the dielectric function. Therefore, $\epsilon_r = n^2 - k^2$ and $\epsilon_i = 2nk$. For the region of interest ($\lambda \geq 400$ nm), $k^2 \ll n^2$, and thus $n^2 \approx \epsilon_r$. The parallel and series models can then be written, respectively, as:

$$n_{eff} = \sqrt{\xi_1 n_1^2 + \xi_2 n_2^2} \quad (6)$$

$$n_{eff} = \left[\frac{\xi_1}{n_1^2} + \frac{\xi_2}{n_2^2}\right]^{-1/2} \quad (7)$$

Both models were applied to fit the effective refractive index of the multilayer, taking n_{eff} from **Fig. 7**, and n_1 (MoO_3) and n_2 (WO_3) from **Fig. 5a**. Excellent fits were obtained, with ξ_1 = 0.45 ± 0.05 and ξ_2 = 0.55 ± 0.02.

Bandgap

The band gap of a semiconductor is closely related to its band structure. It is also related to the optical constants via the absorption coefficient (α), given by $\alpha = 4\pi k/\lambda$. The absorption coefficient of the films was calculated using the equation: $\alpha = (1/d)\ ln\ (1/T)$. For semiconductors with indirect bandgaps, such as MoO_3 and WO_3 [30,31], the absorption coefficient is related to the band gap (E_g) via the relation $\sqrt{\alpha E} = b\ (E - E_g)$ where b is a constant, and E is the incident photon energy. The band gap of the films was obtained by plotting $(\alpha E)^{1/2}$ vs. E (Tauc plot), as shown in **Fig. 8**. Extrapolation of the linear portions of the curves to the energy axis yielded the band-gap values. The band gap values were 2.75, 3.29, and 3.06 eV for MoO_3, WO_3, and multilayer thin films, respectively. These values are close to those reported in the literature for MoO_3 [30] and WO_3 [31] thin films. The multilayer film assumed a band gap value that was intermediate between those of MoO_3 and WO_3, which may be written as:

$$E_g\ (multilayer) = \eta_1\ E_g(MoO_3) + \eta_2\ E_g(WO_3) \quad (8)$$

with η_1 = 0.45 and η_2 = 0.55, the same as obtained for the refractive index using effective-medium theory.

IV. Conclusion

A new model was proposed to determine the optical properties of a multilayer structure. This model uses the equation for the transmittance of a single layer to derive the effective optical constants of the multilayer, free of considerations of the individual layers comprising the structure. The model was applied to a two-layer system consisting of the dielectrics MoO_3 and WO_3. The structural, chemical, and optical properties of the single films were investigated, and the individual dielectric layers were found to be stoichiometric and transparent. Moreover, the optical constants of these layers were determined. Elemental depth profiling was used to probe the distribution of the elements across the thicknesses of the films in the multilayer structure, and this analysis revealed a significant overlap between the two layers. The new model was then used to obtain the effective optical constants of the multilayer. The validity of the new model was tested on the basis of effective-medium theory, which indicated an excellent fit to the experimental transmittance spectrum using the obtained optical constants. Finally, the band gaps of the films were determined, and the

multilayer structure yielded an intermediate band gap that was consistent with effective-medium theory.

Session Index

Plenary Presentations 98
Keynote Presentations 104
Tutorial 142
Hybrid Nanomaterials and Metastructures for Photonics, Sensing and Energy 144
New trends in nanophotonics and advanced materials 242
Advanced passive and active metasurfaces and zero-index materials 461
Chirality, magnetism, and magnetoelectricity: Separate phenomena and joint effects in metamaterial structures 509
Phononics and acoustic metamaterials 606
Advanced Techniques for Computational Electromagnetics 675
Metamaterials: novel trends and applications 746
Parity-Time and quasi-normal modes in Photonics, Plasmonics, Acoustics 778
New Advances in Metamaterials and Their Functional Applications 793
Chiral fields and ultrafast chiral spectroscopy 798
Functional materials for tunable and reconfigurable photonics 823
Quantum metaphotonics 856
Enhanced light-matter interactions: fundamentals and sensing applications 862
Bio-Inspired Nanophotonics 896
When ‘meta' meets ‘materials': innovative materials, fabrication, functionalities 909
Non-Hermitian Photonics - Topological, Disordered and Quantum systems 936
Nano-Lasers, Spasers, and Nanostructures with Quantum Elements 953
Plasmonics and Nanophotonics: Fundamentals and Applications 972
Commercialization of Metasurface and Nanophotonic Devices 988
Towards chiral and magnetoelectric quantum electrodynamics 1008
Plasmonic Nanomaterials for Bio-diagnostics, Environmental Monitoring and Food Safety 1038
Metamaterials and Metasurfaces as Platforms for Next-Generation Electromagnetics: Fundamentals, Applications and Future Trends 1087
Topological Insulator Metamaterials 1100
Inverse design, topology optimization, and machine learning 1111
Quantum Matter and Dynamics in Hybrid Metamaterial Platforms 1123
Nonlocal and nonlinear nanophotonics 1127
New trends in light-matter interaction at the nanoscale 1178
Surface-Enhanced Raman Scattering: Integrating Theoretical and Experimental Perspectives 1218
Nanoscale Phononics : Energy Transport, Light-Matter Coupling, and Emerging Applications 1237
Cavity Quantum Materials and Polaritonic Devices: From Microscopic Theory to Functionality 1272
META Quantum Nanophotonics Workshop 1280
Plasmonics and Nano-Optics 1292
Nanophotonics and Plasmonics Applications: Optical Antennas, Quantum Photonic Devices, and Beyond 1304
Chiral and Hyperbolic Metamaterials 1314
Metasurfaces: Flat Optics, FSS, HIS, and Beyond 1320
Metamaterial-Based Devices 1340
Photonic Crystals and Electromagnetic Bandgap Structures 1348
Symposia, Special-Session and Workshop Posters 1356
Plasmonics, Nano-Optics and Nanophotonics 1521
Metamaterials, Metasurfaces and Their Applications 1612
Photonic Crystals, Lasers and Photonic Devices 1717
Micro/Nano Fabrication and Characterization 1748

Country Index
