***Abstract*—Helmholtz resonators (HRs) are widely used as a means to achieve sub-wavelength performance in acoustic metamaterials. HRs contain compliance, mass and loss elements. The balance of the three determines resonance frequency, bandwidth and absorption. We discuss how to implement HRs for better control, robustness and performance.**

***Keywords*— Helmholtz Resonator, Acoustic Metamaterials, Viscothermal Losses.**

I. Introduction

Helmholtz resonators are based on the interplay of two fluid-filled elements: a cavity and a neck. A third element is the acoustic loss in the neck which can be assumed to be dominated by the effect of fluid viscosity. A balance of the three can provide a resonance at a given frequency with high absorption of sound. HRs resonate at frequencies corresponding to wavelengths larger than their size, making them an ideal choice for subwavelength metamaterials [1], [2].

The design of a HR for perfect absorption and wide bandwidth requires a given set of mass, compliance and resistance, which correspond to the neck, the cavity, and the acoustic losses. However, the three parameters are not independent. When the neck mass is modified, viscous losses in the neck change in a non-obvious way that depends on how its geometry is implemented [3]. Viscous losses mainly take place within a thin layer over the boundaries, with a thickness that increases as the frequency decreases [4], [5]. As the boundary layers fill the neck, losses increase, but only if the wave can propagate. Such behavior can be predicted through approximate or numerical models [2], [6]. In addition to the above, the practical construction of HRs for metamaterials is subject to fabrication tolerances. Fabrication can become cumbersome and expensive, and the result unsatisfactory if the HR is sensitive to tolerances.

This communication revises the issues associated with practical design and implementation of HRs as used in metamaterials. The goal is making the best choices for achieving good performance, manufacturability, robust geometrical tolerance and the possibility of tuning.

II. Methods and Discussion

Different HR configurations will be illustrated using a combination of lumped element models, transfer matrix method, numerical simulations and measurements. We analyze several neck geometries: i) single cylindrical tube, ii) multiple tubes or perforations, and iii) slits in different configurations.

Theory predicts that, as necks or slits get narrower, viscous and thermal boundary layers eventually merge [7]. Propagation of waves becomes heavily hindered by, mostly viscous, losses. Wide necks, on the other hand, allow propagation but losses decrease as the width becomes much larger than the boundary layers. The frequency has an inverse effect, as the boundary layer thicknesses decrease with frequency. Note that we are not considering the thermal losses in our analysis, which can be relevant for some cavity geometries at low frequencies. The choice of neck geometry controls how the viscous losses change as the acoustic mass is varied. For each neck configuration and dimensions, there is a frequency region where losses are maximized while propagation is still possible. Designing a HR with perfect or high absorption, and, at the same time, a wide bandwidth, must consider all the above factors.

III. Conclusion

We give an overview of the design choices available to the metamaterial designer and how the different geometries of HRs influence the robustness, performance and manufacturability. To this end, we study in detail the effect viscous losses for different neck geometries.

***Abstract*—We show a broadband enhancement of transmission through an opaque barrier placed at the center of a symmetric periodic waveguide. This enhancement is sensitive to subwavelength barrier displacements and, for symmetric unit cells, recurs at half-period shifts due to local symmetries.**

***Keywords*— periodic waveguides, local symmetries, transmission enhancement.**

Multiple-wave interference in complex media can lead to striking transport phenomena when the scattering region has spatial symmetries. A notable example is the enhancement of transmission through an opaque barrier placed at the center of a mirror-symmetric complex waveguide, i.e., at the global symmetry center. In such a configuration, the transmission of the complex medium can be significantly larger than that of the barrier alone. This symmetry-induced transmission enhancement has been studied in disordered diffusive waveguides [1]–[6] and has also been reported in quantum dots [7], [8]. In this work, we investigate symmetry-induced transmission enhancement in periodic waveguides. We show that it also occurs when the barrier is placed at the symmetry center of a symmetric periodic waveguide (see Fig. 1).

Fig. 1. Enhanced transmission when a barrier is placed at the center of a symmetric periodic waveguide. (a) Opaque barrier in a uniform waveguide. (b) Opaque barrier at the center of a periodic waveguide. (c) Opaque barrier at the center of a symmetric periodic waveguide.

Unlike in disordered systems, where transmission tends to vanish due to localization, the enhancement in periodic structures persists even for long structures. We also show that, as in the disordered case, the transmission enhancement is sensitive to the barrier position. A subwavelength shift of the barrier from the symmetry center leads to a drop in transmission enhancement. For periodic structures composed of symmetric unit cells, the enhancement recurs when the barrier is shifted by half a period due to local symmetries.

***Abstract*—In this work, we report the ultrafast electronic and acoustic dynamics of nanocrystalline silicon (nc-Si) thin films and membranes, investigating how structural and morphological changes impact phonon lifetimes.**

***Keywords*— gigahertz acoustic waves, nanocrystalline silicon, phonon lifetime, photoacoustics, silicon membranes, ultrafast spectroscopy**

I. Introduction

Nanocrystalline materials provide a scalable and cost-effective alternative to single-crystal counterparts, showing advantages among several technological applications [1]. In particular, nanocrystalline silicon (nc-Si) is a versatile material for high-frequency resonators, where controlling the sample morphology enables the tailoring of mechanical damping [1], [2]. Ultrafast pump-probe spectroscopy measurements have contributed significantly to the understanding of phonon dynamics in nanoscale systems [3]. Studying these temporal oscillations is of fundamental importance, as their decay rates provide insights into phonon lifetimes and energy dissipation mechanisms. Previous pump-probe studies on single-crystal silicon membranes (c-Si) have been reported [4], [5], [6], where thickness-dependent acoustic phonon frequencies and lifetimes were measured, ranging from several nanoseconds to a few picoseconds. Our work extends this investigation to nc-Si membranes and thin films. We observe that the introduction of grains, grain boundaries, random grain orientations, and degree of crystallinity has an impact on phonon dephasing time compared to c-Si.

II. Methods

The nc-Si samples were synthesized by low pressure chemical vapor deposition (LPCVD) with different annealing and deposition temperatures. To investigate the impact of morphology on electronic dynamics, acoustic modes, and lifetimes, ultrafast pump-probe measurements were performed using the asynchronous optical sampling technique. The experiments were performed at room temperature in transmission and reflection modes. The system is driven by two Ti:Sapphire oscillators operating with a repetition rate of $\sim$ 1GHz and generating 50 fs duration pump and probe pulses. The central wavelength of the pump and probe beams is slightly shifted, corresponding to 760 nm and 830 nm, respectively. The spot size of both beams is $\sim 15\,\mu$m. The fluence of the pump is $\sim 50\,\mu$J/cm^2 and that of the probe is one order of magnitude lower.

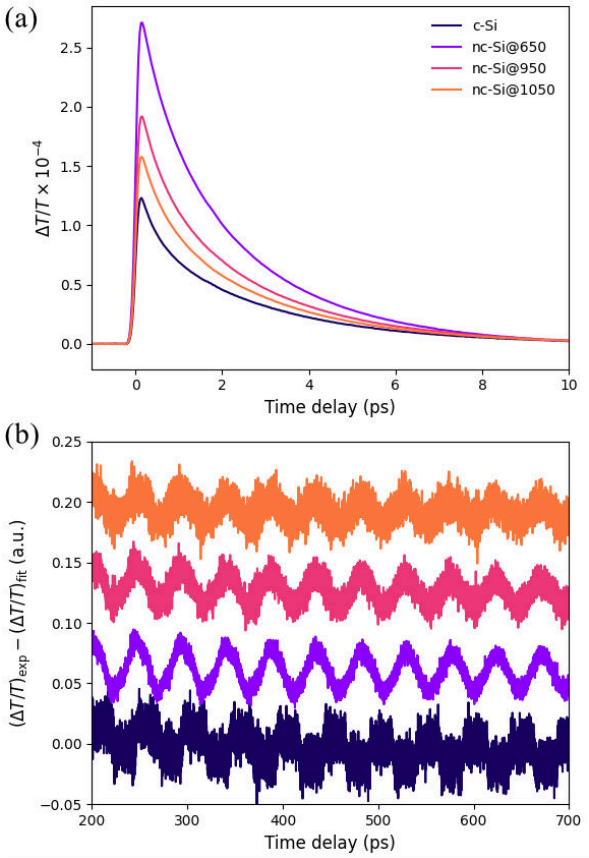

Fig. 1. Ultrafast pump-probe measurements in c-Si and nc-Si in transmision mode. (a) Time-resolved measurements within the first 10 picoseconds. (b) Time-resolved measurements with subtraction from the multiexponential fitting.

III. Results and Discussion

Ultrafast time-resolved measurements in transmission geometry are illustrated in Fig. 1, for c-Si and nc-Si membranes with different annealing temperatures (650°C, 950°C,

1050°C). A multiexponential fit was first applied to the experimental data and subsequently subtracted to isolate the underlying oscillations Fig. 1b. Then, a fast Fourier transform was performed, revealing the frequencies of the generated standing acoustic waves, which are given by [6]

$$f_n = \frac{n\, v_L}{2d}\,, \tag{1}$$

where n is an integer corresponding to the order of the mode, v_L is the longitudinal velocity, and d is the thickness. Values of around $20.5\,\mathrm{GHz}$ for c-Si and $21.3\,\mathrm{GHz}$ for nc-Si were obtained, indicating a slightly larger velocity in the nanocrystalline samples. The lifetimes of the modes for nc-Si are also observed to be smaller for nc-Si when compared to c-Si.

IV. Conclusion

We have investigated the coherent acoustic phonon dynamics of both c-Si and nc-Si samples by ultrafast pump-probe spectroscopy. We have generated and measured acoustic phonon modes, their frequency and lifetimes. From these measurements, we have retrieved the phonon velocity and lifetimes. We observe that although the phonon velocity is slightly larger for nc-Si samples when compared to that of c-Si, the phonon lifetimes are smaller. Moreover, a suppression of high acoustic modes ($n > 1$) is observed compared to c-Si.

***Abstract*— The resonant optical response of single plasmonic nanoparticles enables efficient probing of their vibrational and thermal dynamics. Ultrafast pump-probe experiments and numerical simulations reveal how these dynamics depend on nanodisk and substrate properties, and demonstrate that vibrations and cooling produce distinct spectral signatures, enabling their selective detection.**

***Keywords*— ultrafast dynamics, metal nanoparticles, single-particle time-resolved spectroscopy, vibrational modes.**

I. Introduction

The resonant optical response of plasmonic nanoparticles provides a powerful means for probing their electronic, vibrational and thermal dynamics via optical spectroscopy. Such experiments can now be performed at the single-particle level [1], providing access to far richer information than ensemble experiments, by revealing intrinsic dynamics otherwise obscured by averaging effects and by enabling a quantitative connection between these dynamics and the transient optical response they induce. This presentation reviews recent results on the vibrational and cooling dynamics of single gold nanodisks supported on various solid substrates.

II. Methods

Solutions of gold nanodisks with different average dimensions were produced via colloidal synthesis, allowing their deposition on a variety of solid substrates, including nanometrically thin membranes. Spatial modulation spectroscopy was employed to locate individual nanodisks on substrates and to measure their extinction spectra. The nanodisk ultrafast dynamics were probed using time-resolved single-particle pump-probe spectroscopy. These optical experiments were complemented by finite-element numerical simulations of the nanodisks' optical response, thermal and vibrational dynamics.

III. Results and Discussion

The results clarify how nanodisk dimensions and substrate properties influence the nanodisk vibrational and cooling dynamics. In particular, the cooling dynamics are significantly slowed on thin membranes compared to thick substrates, resulting in incomplete cooling between successive pump excitations [2]. While vibrational frequencies are primarily determined by nanodisk dimensions, the vibrational quality factors strongly depend on substrate properties, indicating that radiative effects play a major role in damping in our experiments. The transient responses associated with vibrations and cooling are markedly different: nanodisk temperature rise primarily manifests as a broadening of the surface plasmon resonance, whereas vibrations predominantly induce a spectral shift. This difference enables selective detection of these processes through appropriate tuning of the probe wavelength.

IV. Conclusion

This work highlights the strong influence of the environment on the ultrafast dynamics of nanoparticles following impulsive excitation, and demonstrates that distinct dynamical processes can be selectively probed using tunable light sources. Future goals include the detection of high-quality-factor vibrational modes and precise analysis of the transient optical response associated with vibrations.

Radiation Control in Fluid-Loaded Metamaterial Waveguides with Space and Time Modulation

Emanuele Riva[1,*], Alper Erturk[2]

***Abstract*—We investigate leaky-wave radiation in fluid-loaded elastic waveguides equipped with spatially and temporally modulated resonators. Periodic modulation induces controlled wavenumber or frequency shifts that activate radiating Floquet harmonics inside the acoustic sound cone. The resulting radiation angle is tunable and is herein engineered to steer or focus acoustic energy in the adjacent fluid. *Keywords*— leaky waves, acoustic metamaterials, space-time modulation, Floquet engineering.**

I. Introduction

When in contact with fluids, elastic waveguides naturally support leaky waves, such that guided energy continuously radiates into the surrounding medium under certain conditions. Although often regarded as a loss mechanism, leaky-wave radiation provides a powerful route toward directive emission and beam steering in submerged structures [1]. Achieving systematic and tunable control of this radiation, however, remains a central challenge. In this work, we demonstrate that spatiotemporal modulation of locally resonant metamaterials enables programmable control of leaky-wave emission. By periodically modulating the properties of resonators attached to a fluid-loaded beam, additional Floquet harmonics are generated through wavenumber or frequency conversion. These harmonics may enter the sound cone even when the underlying guided mode remains subsonic, thereby activating controllable radiation channels.

II. Dynamics of Spatially and Temporally Modulated Metamaterial

Under spatial modulation, the dispersion relation of the fluid-loaded beam with resonators becomes periodic along the wavenumber axis, and harmonic components are shifted by integer multiples of the imposed spatial periodicity, i.e. $\kappa + n\kappa_m$. Even when the fundamental guided mode remains outside the sound cone, a modulation-induced harmonic may enter it, thereby activating a radiative channel in the surrounding fluid. The resulting emission angle is directly governed by the modulation wavenumber and can be continuously tuned.

An analogous mechanism emerges under temporal modulation. In this case, frequency-shifted Floquet harmonics $\omega + n\omega_m$ are generated at fixed wavenumber [2], [3]. These harmonics also satisfy the fluid dispersion relation and radiate energy at angles controlled by the modulation frequency.

In both scenarios, the dispersion analysis, herein found through a bordered Newton-Raphson algorithm, captures the onset and direction of radiation in both configurations. The modulation parameters therefore act as programmable degrees of freedom that determine when and how guided energy is converted into leaky-wave radiation. Building on this principle, a smoothly varying spatial modulation is designed so that locally emitted wavevectors converge at a prescribed location, producing acoustic focusing in the fluid without external phased arrays or bulky gradient-index devices.

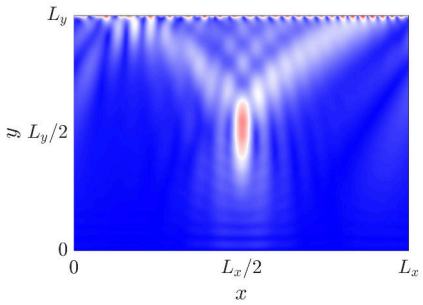

Fig. 1. RMS pressure field showing the leaky-wave-induced acoustic focusing.

III. Conclusion

Altogether, the proposed modulation strategy provides a unified way to regulate leaky-wave emission, offering direct control over radiation patterns and enabling acoustic focusing in submerged environments.

***Abstract*—We demonstrate 20 GHz phonon transport over 20 µm in a phononic waveguide based on GaAs/AlAs multilayers. By introducing two excitation laser pulses to drive distinct phonon sources, we achieve coherent control of the propagating phonons through spatio-temporal interference.**

***Keywords*— phonon transport, coherent acoustic phonons, pump-probe spectroscopy, phononic waveguides**

Controlling high-frequency acoustic phonon propagation is essential for their use in storage, processing, and filtering applications [1-3]. Ultrafast optical excitation enables the generation and detection of coherent phonons in the gigahertz to terahertz range, while pump-probe techniques provide direct access to their frequency, amplitude, and phase. Phonon propagation can be controlled by engineering structures such as phononic crystals and microcavities.

In this work, we design a ridge waveguide based on a GaAs/AlAs superlattice. Vertically, it forms a Fabry-Perot cavity with a high quality factor, confining both photons and phonons within the spacer layer [4]. This simultaneous confinement enhances the efficiency of phonon generation and detection under ultrafast laser excitation. The planar cavity is then patterned into a ridge geometry, where the air-semiconductor sidewalls provide lateral confinement and guide phonon propagation along the waveguide.

Phonon dynamics are studied using time-resolved pump-probe measurements in two configurations. When the pump and probe beams are spatially superimposed, we observe 20 GHz phonons that decay exponentially in time, confirming the generation of propagating waves. When the beams are spatially separated, phonons can be detected at distances up to 20 µm at room temperature, demonstrating their transport in the waveguide. The phonon signal is present over the entire measurement time window. This behavior results from the high-quality-factor cavity and the periodic excitation by the laser pulse train. Successive pulses repeatedly excite the phonon field, leading to a quasi-continuous phonon source in the generation region [6].

To further investigate the coherence of propagating phonons, we introduce two pump pulses to excite two spatially separated phonon sources, allowing them to interfere at the midpoint. Since the phonon phase is determined by the excitation timing, the relative phase between the two sources can be controlled by adjusting the delay between the pump pulses [5]. By sweeping this delay, we extract the phonon amplitude, which exhibits a clear interference pattern. These results show that 20 GHz phonons remain coherent after long-distance propagation and demonstrate phase control as a basis for phonon-based information processing [6].

In the future, the number of phonon sources can be increased by implementing a spatial light modulator with independent control of their intensity and phase. This would offer a route toward phonon networks for information transfer and processing in compact nanophononic devices.

***Abstract*— We examine how interface orientation affects wave transport in valley phononic crystals. Bulk dispersion calculations, supercell models, and full field simulations are used to compare junction geometries. This work provides a conservative baseline for interpreting angle-dependent transmission variations in lattice waveguides.**

***Keywords*— valley phononic crystals, interface orientation, discrete lattices, wave transport.**

I. Introduction

Mechanical lattice metamaterials provide a convenient testbed for controlling elastic and acoustic waves through engineered geometry and coupling. A key advantage of these discrete platforms is that waveguides can be formed by simple patterning choices, including interfaces between lattice domains, and the resulting guided response can be probed directly in simulations [1].

One representative route to interface-guided modes is offered by valley phononic crystals, where momentum-space features associated with inequivalent valleys can shape how waves couple across an interface. In such systems, transport is often sensitive to interface orientation [2].

For a straight interface, the tangential component of the Bloch wave vector is conserved, so transmission depends on how this conserved momentum aligns with valley features in momentum space. Rotating the interface changes the projection of these valley features, which can make intervalley coupling more or less likely, thus modifying transmission characteristics and where the field localizes along the interface. This angle dependence matters in practice because routing networks often require oblique segments rather than only high-symmetry cuts. However, systematic studies of how interface orientation influences transmission in valley phononic crystals remain limited.

In this work, we examine interface-angle-dependent transport in valley phononic crystals based on discrete mechanical lattices. We introduce a simple projection viewpoint to interpret angle-dependent trends, and we support the discussion with unit-cell calculations, supercell analysis, and full field simulations.

II. Methods

We study how interface orientation influences wave transport in a valley phononic crystal realized in a discrete mechanical lattice. The bulk lattice is kept fixed throughout, and only the interface angle is varied. Bulk dispersion calculations provide the band structure, supercell models identify interface-guided modes for each orientation, and frequency domain full field simulations are used to compare transmission and field localization. A simple projection argument based on tangential momentum conservation is included to support the interpretation.

Bulk dispersion is computed under Bloch periodic boundary conditions to locate the frequency range where valley features are present. To connect bulk characteristics to interface behavior, we construct strip supercell models that are periodic along the interface and finite across it. The resulting band structures and mode profiles are used to confirm guided interface modes and to set a consistent baseline for comparing different interface orientations.

Transport is evaluated in finite lattices with an input section, an oblique interface segment, and an output section. A time harmonic excitation is applied at the input and the steady state response is recorded. Transmission is quantified by evaluating the same response intensity at fixed cross sections before and after the junction and applying the same normalization across all angles. Field maps are also extracted to illustrate how localization changes as the interface is rotated.

To interpret the angle dependence, we adopt a geometric projection viewpoint. Because the tangential component of the Bloch wave vector is conserved at a straight interface, bulk valley features can be projected onto the interface direction. The relative alignment of these projections is taken as a qualitative guide for when intervalley coupling is more likely. This interpretation is used only to support the discussion, while the reported comparisons are based on the supercell and full field calculations.

III. Results and Discussion

Numerical results show:

- Interface-guided transport is observed for the valley phononic crystal setting, and the guided response depends on interface orientation.
- Supercell calculations confirm interface-guided modes for multiple interface directions, providing a consistent reference for comparing orientations.
- Full field simulations indicate that transmission behavior can change noticeably as the interface angle is varied, accompanied by clear changes in where the field localizes.
- Angle-dependent trends are qualitatively consistent with a geometric projection viewpoint based on the conserved tangential momentum.

IV. Conclusion

We investigated interface-angle-dependent wave transport in a valley phononic crystal realized in a discrete mechanical lattice using bulk dispersion, supercell analysis, and full field simulations. The results highlight that interface orientation can noticeably influence transmission and field localization, and a geometric projection viewpoint provides a useful way to interpret the observed trends. Future work will extend this baseline to broader routing geometries and operating conditions.

***Abstract*—This work studies how a deviatoric generalized Maxwell soil response modifies seismic metamaterial dispersion. Finite-element eigenfrequency simulations show that stiffness changes and dynamic stiffening shift modal branches at higher frequency values. The results indicate that seismic metamaterial design should account for realistic soil inelasticity, since the intented functionality may change.**

***Keywords*— seismic metamaterials, viscoelasticity, band gaps, finite element modelling, eigenfrequency analysis.**

I. Introduction

Seismic metamaterials use periodic inclusions, resonators, or structured soil domains to attenuate surface waves through scattering and band-gap formation [1], [2]. Most numerical studies assume an ideal elastic soil, although realistic seismic loading can involve damping and other inelastic effects. This work enriches the non-hierarchical unit-cell model of Miniaci *et al.* [3] by adding a dissipative generalized-Maxwell soil response. It is shown that accounting for dissipative effects results in high deviation from the intended seismic metamaterial functionality, a fact that suggests that these must be designed with care for real-case scenarios.

II. Methods

The employed finite-element model follows that reported in Miniaci et al. [3]. The soil height was set to $H = \min(L_{\max}, 8\lambda)$, with $L_{\max} = 1000$ m, reducing the original computational costs while keeping the eigenfrequency problem solvable. This setup was used to isolate the effects of deviatoric viscoelasticity and increased soil stiffness.

TABLE I
Elastic material properties and reference speeds.

Case	E MPa	ρ kg/m^3	ν	c_S m/s	c_L m/s	c_R m/s
LowE	20	1800	0.30	65.4	122.3	60.6
HighE	320	1900	0.33	251.6	499.5	234.3

The c_S, c_L, and c_R references are plotted as $f = ck_x/(2\pi)$ over $k^* = k_x/(\pi/a)$ and they are reference slopes.

For the viscoelastic cases, one Maxwell branch was introduced with

$$G_0 = \frac{E}{2(1+\nu)}, \qquad G_1 = rG_0, \qquad \tau_1 = \frac{1}{2\pi f_{relax}}, \quad (1)$$

where E is the Young's modulus, ν is Poisson's ratio, G_0 is the instantaneous shear modulus, G_1 is the shear modulus of the Maxwell branch, $r = G_1/G_0$, and τ_1 is the characteristic relaxation time of that branch. In the absence of rheological data, $r = 0.3$ was chosen as a moderate contrast: a preliminary sweep showed nearly linear modal sensitivity, with a visible frequency shift already at this value. The relaxation frequency, f_{relax}, was similarly set to 12 Hz, placing the Maxwell transition within the HighE modal window, whose first mode is near 10 Hz. It must be noted that only the deviatoric response is dissipative, while the volumetric response remains elastic. The corresponding shear modulus is:

$$G^*(\omega) = G_0 + \frac{G_1 i\omega\tau_1}{1 + i\omega\tau_1}. \quad (2)$$

Thus $G^* \approx G_0$ at low frequencies, and $G^* \to G_0 + G_1$ at high frequencies, so the model introduces both damping and dynamic stiffening.

III. Results and Discussion

With respect to Miniaci et al. [3], the PML was here replaced with a low-reflecting boundary, and the use of the capped wavelength-scaled height preserves the qualitative modal structure of the reference simulation, as shown in Fig. 1(a-b). Thus, it yields the same result of the reference, though saving computational time; this is a validation step, not the main physical result.

TABLE II
Progressive modelling changes and observed trends.

Case	Main observation
Reference elastic	Baseline elastic modal structure.
No PML	Similar branches; lower computational time than Ref.
LowE viscoelastic	Modest upward shift from frequency-dependent shear stiffness.
HighE elastic	Shift from about 2.5–6 Hz to about 10–25 Hz.
HighE viscoelastic	Preserved structure with a moderate shift for $r = 0.3$, $f_{relax} = 12$ Hz.

Adding viscoelasticity to the LowE model modestly shifts the modal branches upward, consistent with the high-frequency Maxwell limit where the effective shear stiffness approaches $G_0 + G_1$. Increasing elastic stiffness has a stronger effect: the HighE elastic case shifts the spectrum from about 2.5–6 Hz to 10–25 Hz. In the viscoelastic case, $f_{relax} = 12$ Hz avoids a fully high-frequency asymptotic response, while

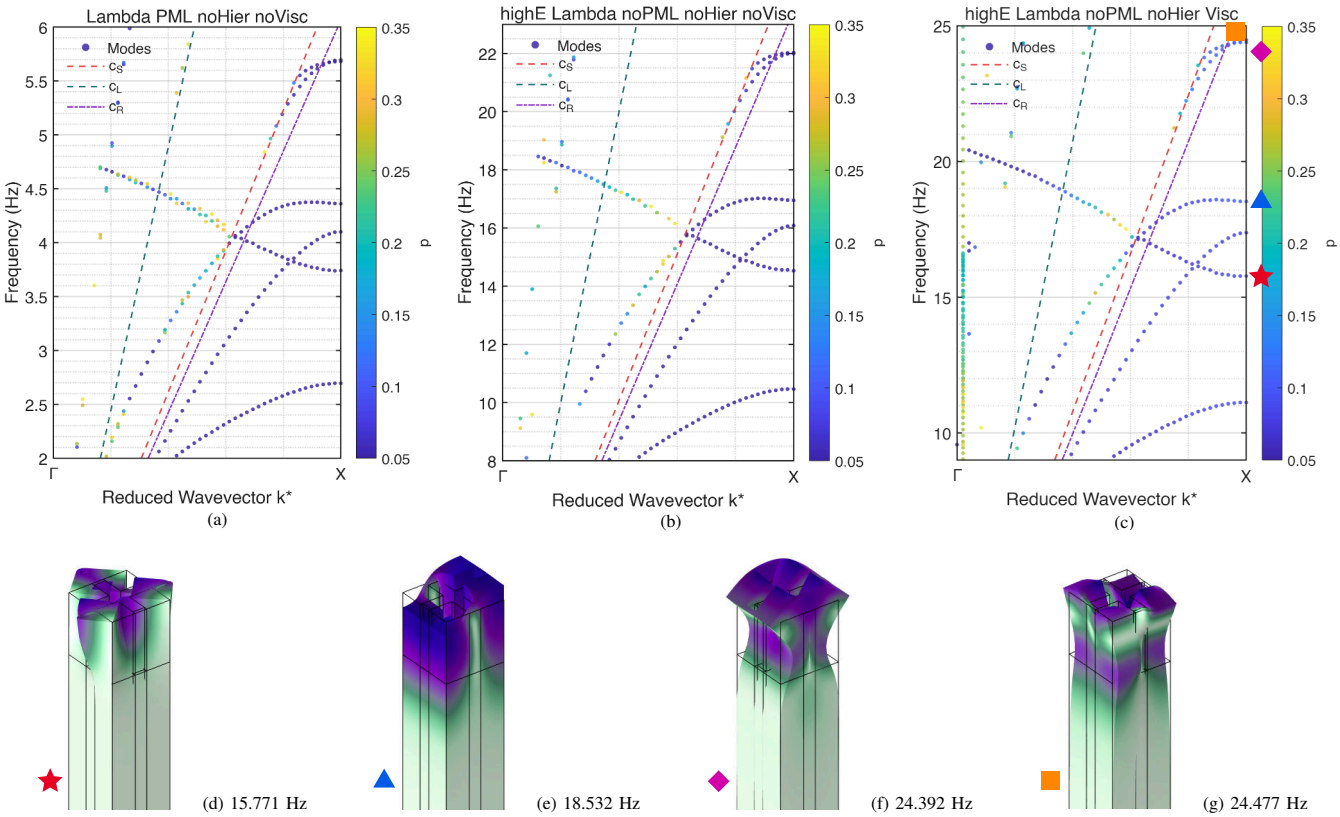

Fig. 1. Eigenfrequency results and selected HighE viscoelastic mode shapes, filtered based on the p-value. Panel (a) reports the reference elastic case; panels (b,c) use $H = \min(L_{\max}, 8\lambda)$, $L_{\max} = 1000$ m. Panel (c) uses $r = 0.3$ and $f_{relax} = 12$ Hz. Panels (d)–(g) show representative modes at X.

$r = 0.3$ gives a moderate visible deviation from the elastic diagram, Fig. 1(c). Table II separates numerical validation from stiffness and viscoelastic effects.

Stronger preliminary viscoelastic cases showed a small splitting of two modes nearly coincident in elastic simulations. This may reflect damping-induced lifting of an accidental degeneracy, although mesh/solver convergence is needed before interpreting its magnitude quantitatively.

The modal shapes in Fig. 1(d)–(g) were extracted at $k = 2$, i.e., at X along Γ–X. The deformation is localized near the surface, with out-of-plane and mixed character comparable to the surface-mode shapes reported in Miniaci *et al.* [3]. The frequency range is shifted upward by the HighE material and Maxwell-branch stiffening.

IV. Conclusion

The proposed simplified model shows the same behavior of Miniaci *et al.* [3]: the same general band-gap behavior and distinction between strongly excited, mainly out-of-plane SAW-type modes and weakly excited modes remain. In the HighE configuration, these features shift upward due to increased stiffness and Maxwell-branch dynamic stiffening. Thus, higher-order effects must be considered with due care for the faithful design of seismic metamaterials. Future works will consider plasticity and dissipative effects.

Coupled Inertial Amplification and Local Resonance Band Gaps

Cetin Yilmaz[1,*]

[1]Department of Mechanical Engineering, Bogazici University, Istanbul, Turkey
*Corresponding author: cetin.yilmaz@bogazici.edu.tr

***Abstract*—Band gaps below the Bragg limit can be generated through local resonance and inertial amplification methods. A lever-type inertial amplification mechanism with a local resonator at its tip is analyzed. Due to their coupling, a single band gap is formed below what could be achieved by the individual mechanisms.**

***Keywords*— elastic metamaterials, local resonance, inertial amplification, coupling.**

I. Introduction

Phononic band gaps are typically generated through Bragg scattering or local resonance methods. The lowest frequency Bragg gap is centered around the ratio of the wave speed in the lattice to the lattice constant. By contrast, the local resonance approach can produce band gaps at much lower frequencies. However, achieving wide gaps at low frequencies with this method requires the use of large resonator masses [1].

An alternative band gap generation technique is inertial amplification. In this approach, amplified motion of small masses increases the effective inertia of the lattice, thereby producing low-frequency band gaps. Unlike the two conventional methods, this technique enables the formation of wide, low-frequency gaps without increasing the overall mass or reducing the stiffness of the lattice [2,3]. Bridge-type amplification mechanisms are usually utilized to generate the amplified inertial forces that result in low-frequency band gaps [2–8]. Alternatively, effective inertia of a structure can also be increased by lever-type amplification mechanisms [9–12].

Inertial amplification and local resonance methods can be used together to obtain wide band gaps at low frequencies. By using local resonators and bridge-type inertial amplification mechanisms in a periodic structure, double attenuation peaks in a band gap can be achieved [13-14].

In this study, a 1D periodic structure with a unit cell containing a lever-type inertial amplification mechanism with a local resonator at its tip will be investigated. Dispersion plot of the 1D periodic structure will be obtained to compare band gaps arising solely from inertial amplification, solely from local resonance, and from the combined effect of inertial amplification and local resonance.

II. Method

Consider the 1D periodic structure in Fig. 1. The unit cell of this periodic structure contains a lever-type inertial amplification mechanism with a local resonator at its tip.

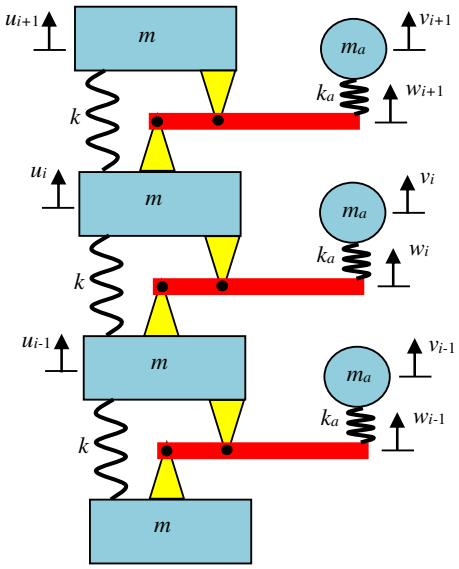

Fig 1 1D periodic structure with a unit cell containing a lever-type amplification mechanism with a local resonator at its tip.

The lever with length l_1 is assumed to be rigid and massless. Hinge spacing of the lever is l_2 and the amplification ratio is defined as $\alpha = l_1/l_2$. Assuming small amplitude motion for the lever, tip displacement of the lever (w_i) can be obtained in terms of u_i and u_{i-1} as $w_i = \alpha u_i - (\alpha - 1)u_{i-1}$. Hence, there are two independent degrees-of-freedom of the i^{th} unit cell, i.e., u_i and v_i. By applying Bloch boundary conditions, u_{i+1} and v_{i+1} can be obtained in terms of u_i and v_i as

$$u_{i+1} = u_i e^{j\gamma a} \tag{1}$$

$$v_{i+1} = v_i e^{j\gamma a} \tag{2}$$

where γ is the wave number and a is the lattice constant. Then, the equation of motion of the unit cell can be obtained as

$$M\ddot{\boldsymbol{x}} + K\boldsymbol{x} = \boldsymbol{0} \tag{3}$$

where

$$\boldsymbol{x} = \begin{bmatrix} u_i \\ v_i \end{bmatrix} \tag{4}$$

$$M = \begin{bmatrix} m & 0 \\ 0 & m_a \end{bmatrix} \tag{5}$$

$$K = \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & k_a \end{bmatrix} \tag{6}$$

$$K_{11} = 2k + k_a(2\alpha^2 - 2\alpha + 1) - \left(k + k_a(\alpha^2 - \alpha)\right)(e^{j\gamma a} + e^{-j\gamma a}) \tag{7}$$

$$K_{12} = -k_a(\alpha - (\alpha - 1)e^{j\gamma a}) \tag{8}$$

$$K_{21} = -k_a(\alpha - (\alpha - 1)e^{-j\gamma a}) \tag{9}$$

Assuming harmonic motion with frequency ω, Eq. (3) can be solved to obtain the two branches of the dispersion curve.

III. Results and Discussion

The model in Fig. 1 can show an inertial amplification induced gap if $k_a \to \infty$ and $\alpha > 1$, a local resonance gap if k_a is finite and $\alpha = 1$, and a coupled inertial amplification and local resonance gap if k_a is finite and $\alpha > 1$.

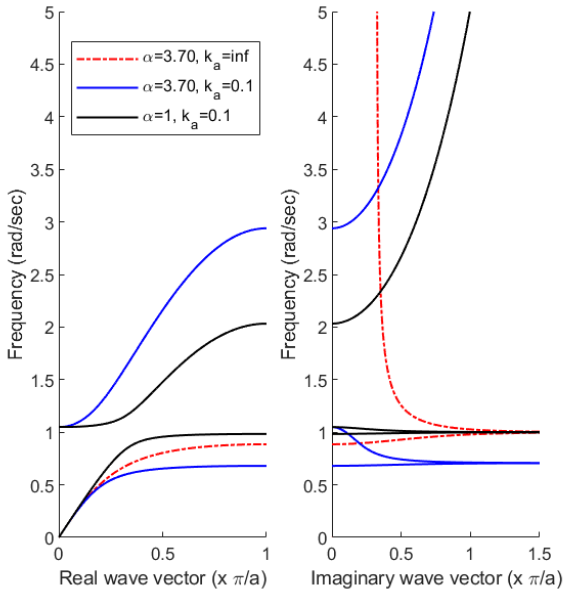

Fig 2 Complex band structure of the 1D lattice (a) Real wave vector. (b) Absolute value of the imaginary part of the complex wave vector.

Fig. 2 shows the complex band structure of this lattice for three different cases. In all cases, $m = 1$kg, $m_a = 0.1$kg and $k = 1$N/m. If $k_a \to \infty$ and $\alpha = 3.7$, a semi-infinite inertial amplification induced gap appears with a lower limit of 0.885rad/s. Peak attenuation is achieved at 1rad/s. If $k_a = 0.1$N/m and $\alpha = 1$, a narrow local resonance gap appears between 0.983-1.05rad/s. Although the peak attenuation is achieved at the same frequency (1rad/s), inertial amplification induced gap starts at a lower frequency (0.885rad/s) and extends to infinity. If $k_a = 0.1$N/m and $\alpha = 3.7$, a wide coupled gap appears between 0.68-1.05rad/s. Unlike the earlier two cases, peak attenuation is achieved at 0.707rad/s. Hence, the coupled inertial amplification and local resonance gap has the same upper limit as the local resonance gap (1.05rad/s), but its lower limit (0.68rad/s) is lower than that of the inertial amplification gap (0.885rad/s). The coupled band gap produced by the lever-type inertial amplification mechanisms and local resonators in this study shows a single attenuation peak, unlike the bridge-type amplification mechanisms combined with local resonators, which yield double attenuation peaks [13–14].

IV. Conclusion

Dispersion relation of a 1D periodic structure with a unit cell containing a lever-type inertial amplification mechanism with a local resonator at its tip is obtained. This structure displayed an inertial amplification induced gap, a local resonance gap or a coupled inertial amplification and local resonance gap depending on the parameters of the unit cell. It is shown that a wide band gap at low frequencies can be obtained due to coupling.

***Abstract*— A coupled-resonator phononic cis-polyacetylene, presenting a two-fold topological transition is studied experimentally. The artificial molecule is governed by a tight-binding model similar to that of condensed matter. The design was done through numerical simulations using finite elements. The machined molecule was characterized using acoustic resonant spectroscopy.**

***Keywords*— metamaterials, phononic crystals.**

I. Introduction

Polyacetylene is an organic polymeric molecule formed by a chain of carbon atoms with alternating double and single bonds between them; each carbon atom is also bonded to a hydrogen atom. This polymeric molecule is important due to its conductive properties. Is conductive properties yield multiple applications in microelectronics of organic compounds. This molecule can be found as the cis-polyacetylene and trans-polyacetylene isomers; the cis isomer is depicted in Fig. 1 (a). Recently, some of us found that cis-polyacetylene presents a twofold topological phase transition ruled by the third-nearest-neighbor hoppings [1].

II. Artificial molecule

This transition presents a Dirac cone and two different topological phases to each side. In this work we present experimental evidence of this transition using a coupled-resonator phononic molecule (CRPnMo) [2,3]. The artificial molecule is formed by resonators joined by finite phononic crystals (FPnCs). When a normal-mode frequency of the resonator falls within the gap of the FPnC the wave amplitude localizes in the resonator and evanescently decays along the FPnCs. When a second resonator is added, the normal modes couple evanescently emulating the quantum tunneling. This coupling gives rise to a tight-binding regime of elastic waves equivalent to that of condensed-matter physics. An image of the CRPnMo used is given in Fig. 1 (b).

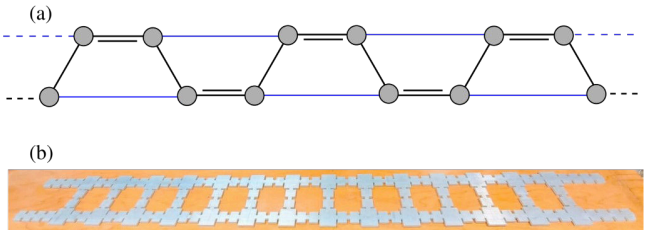

Fig. 1 Schematic representation of cis-polyacetylene with first- and third-nearest-neighbors hoppings. (b) Coupled-resonator phononic molecule of cis-polyacetylene.

III. Results and Discussion

The measured spectrum of the coupled-resonator phononic molecule of Fig. 1 is given in Fig. 2. One can observe in this figure that the level density at the center of the band is almost constant. This is in agreement with the existence of a Dirac cone. Results of the topologically protected states will be given elsewhere.

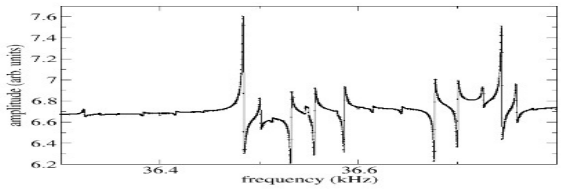

Fig. 2 Measured transmission of a coupled-resonator phononic cis-polyacetylene molecule. In this case a band is apparent. The first- and third-nearest-neighbor hoppings in the molecule are the same.

IV. Conclusion

We have measured the twofold topological phase transition predicted recently by some of use. Evidence of the Dirac cone is give. The topologicaly protected states will be shown elsewhere. The experimental results confirm the appearance of the Dirac cone as well of the topologically protected states.

Non-reciprocal communication with signal amplification

Xinxin GUO[1,*], Zhenwei Xu[1], Ulrich Kuhl[2]. Nicolas Noiray[1,*]

[1]ETH Zürich, Department of Mechanical and Process Engineering, CAPS laboratory, 8092 Zürich, Switzerland

***Abstract*—In this work, we present a compact acoustic circulator that enables signal-amplified non-reciprocal transmission of time-varying information via binary encoding. The nonlinear synchronization between the input wave and a spinning limit cycle is leveraged, leading to strong non-reciprocity not only in transmitted energy but also in information accuracy.**

***Keywords*— information transport, non-reciprocal transmission, dynamic synchronization, limit cycle.**

I. Introduction

Current research in metamaterials has broken the reciprocity in achieving various types of asymmetric wave manipulation. However, in the field of communications and information processing, relevant advances, such as the development of programmable and coding metamaterials, have hardly been explored at the intersection with non-reciprocity. To unlock this limitation, we design a compact acoustic circulator based on the synchronization mechanism [1] and investigate the non-reciprocal transmission of time-varying information.

II. Results and Discussion

Figure. 1 shows the experimental communication results based on the realization of a 3D-printed acoustic circulator. The information is first encoded into a binary stream (Fig. 1b), with bits 0 and 1 mapped to two frequencies ω_1 and ω_2, respectively. ω_1 and ω_2 are chosen near the frequency that yields the optimal non-reciprocal transmission. The resulting frequency-modulated input signal p_1 is sent to port 1 of the circulator. The signals transmitted to ports 2 and 3 are illustrated in Fig. 1c. The asymmetric transmission behaviors of the circulator result from the synchronization of the spinning limit cycle with the input wave p_1. As such, the time-varying information can equally be transmitted non-reciprocally. The signal p_2 received at port 2 is significantly amplified in magnitude compared to the input p_1, thanks to the energy fed by the synchronized limit cycle. Unsurprisingly, it allows the input message to be accurately decoded. However, at port 3, transmission is nearly forbidden due to the non-reciprocal responses of the circulator. The magnitude of p_3 drops to the level of stochastic noise generated by airflow. In this case, the information extraction completely fails as a result of its nonlinear coupling with noise.

III. Conclusion

In this study, we demonstrated signal-amplified non-reciprocal transmission of time-varying information through a compact acoustic circulator. We exploited the synchronization between the input acoustic wave and a flow-driven spinning limit cycle, which endows transmission with strong non-reciprocity while compensating for losses by extracting energy from the limit cycle. Based on binary encoding, our results show that the input information is transmitted with complete accuracy and signal amplification in one direction. In contrast, in the other direction, it is fully erased due to its significantly low transmission level and the nonlinear coupling with flow-induced stochastic noise. Our designed acoustic circulator not only allows steady-state transmission analysis but is also suitable for dynamic wave manipulations.

Fig. 1. Non-reciprocal communication: experimental results. **a** The designed acoustic circulator, with an inner diameter of 5 cm. **b** The time-varying input information sent to port 1. **c** Information extraction from signals transmitted to ports 2 and 3, respectively.

*Corresponding author: xonics@tongji.edu.cn

***Abstract*— Spin angular momentum was long deemed exclusive to transverse electromagnetic waves, while longitudinal acoustic waves, elastic waves and phonons were regarded as spinless. Based on a series of theoretical and experimental studies, we establish a unified framework covering acoustic spin, elastic spin and phonon spin. We prove that longitudinal and hybrid longitudinal–transverse vibrational waves carry intrinsic spin, and reveal hybrid spin, anomalous spin–momentum locking, universal geometric relations among spin, energy flux and reactive power. Experiments confirm the existence of acoustic spin and elastic spin, and realize chiral transport, symmetry-selective wave routing, topological valley–spin coupling and parity–frequency–space programmable control. We further extend spin physics to phonons, uncover chirality-induced phonon spin selectivity and collective-interference-induced circular dichroism. Our works reshape the fundamental understanding of spin in structured waves and topological metamaterials, and lays the foundation for the emerging field of spin phononics.**

***Keywords*— metamaterials, acoustic, elastic, phononic, spin.**

I. Introduction

Spin angular momentum is a core property of wave physics and quantum technology. For decades, the conventional view held that only transverse waves possess spin, excluding longitudinal acoustic, elastic and phonon systems. This paradigm limited the development of spin-based wave manipulation in acoustics, mechanics and condensed matter physics. Our group has systematically explored the spin of vibrational waves from theory to experiment, extending macroscopic acoustic and elastic spin to microscopic phonon spin, forming a complete research chain from fundamental discovery to applied mechanism. This report reviews the unified physical origin, key phenomena and applications from acoustic spin, elastic spin to phonon spin.

II. Methods

We combine theoretical derivation, numerical simulation, experimental measurement and first-principles calculation. Based on classical field theory and Noether's theorem, we derive the spin angular momentum density of elastic and acoustic waves, and extend the theory to phonons via second quantization. We design acoustic spin torque measurement, chiral elastic meta-sources and near-field acoustic structures to observe spin and directional transport. We construct metasurface waveguides, topological phononic crystals and parity–frequency–space modulated phononic circuits to realize spin-dependent chiral control. We also use quantum perturbation methods to analyze local and collective interference phonon spin.

III. Results and Discussion

We first predicted the intrinsic spin of elastic waves, breaking the traditional belief that only transverse waves have spin. Elastic waves contain both longitudinal and transverse components, producing hybrid spin from their cross coupling, which leads to the anomalous spin–momentum locking in surface elastic waves. We then experimentally observed acoustic spin by measuring spin-induced mechanical torque, and realized direct excitation and detection of elastic spin using chiral meta-sources, confirming spin–momentum locking in Rayleigh and Lamb waves.

We derived universal geometric relations linking acoustic spin, energy flux and reactive power, providing a general principle for spin-based wave control. By breaking structural symmetry, we achieved acoustic spin transport in metasurface waveguides and symmetry-selective directional excitation in near-field acoustics. Introducing topological design, we realized valley–spin locked chiral coupling in valley phononic crystals with robust anti-backscattering transport, and further established multi-dimensional programmable wave routing in parity–frequency–space phononic circuits.

We extended the spin framework to microscopic phonons and established the unified symmetry between elastic spin and phonon spin. Via elastic spin–orbit interaction, we revealed chirality-induced phonon spin selectivity for selective spin excitation. More importantly, we discovered the collective interference nature of phonon spin: phonon angular momentum includes both local atomic vibration and nonlocal collective interference between sublattices. This collective effect induces strong circular dichroism in chiral crystals, contributing over 95% in chiral quartz, linking phonon spin to optical response and multi-physical field coupling.

IV. Conclusion

This work systematically establishes the unified theory of acoustic spin, elastic spin and phonon spin, overturning the

conventional view that longitudinal waves and phonons are spinless. Key advances include intrinsic spin, hybrid spin, anomalous spin–momentum locking, universal geometric relations, topological valley–spin control, chirality-induced phonon spin selectivity and collective-interference phonon spin. These findings create the new field of spin phononics, offering new principles for topological metamaterials, chiral acoustics, topological phononics, quantum information and precision sensing.

Wide-area Topological Higher-order Modes in Heterostructured Kagome Phononic Crystal

Yusuke Hata, Yuri Fukaya, Kenji Tsuruta*

Department of Electrical and Electronic Engineering
Okayama University, Japan

***Abstract*— We designed wide-area elastic waveguides based on higher-order topological modes in a heterostructured Kagome lattices consisting of trivial and nontrivial domains. We numerically demonstrated that interface modes as well as corner modes are broadened leading to more efficient energy storage than at the corners of the conventional structure.**

***Keywords*— elastic-wave device, phononic crystal, topological insulator.**

I. Introduction

Topological phononic crystal (TPnC), which is an artificial elastic structure to imitate a topological insulator have attracted increasing attention due to their robust boundary modes against defects, disorders, and bends with nearly zero energy dissipation even at GHz frequencies [1]. In addition to the primary boundary modes, higher-order topological state (HOTS) emerging at lower dimension in TPnCs is expected to extend the functionality of elastic devices to store elastic energy at a designated region. However, HOTS is only available at narrow boundaries, hindering its use in devices where the energy carried by phonon is converted to electrical one.

Recently, wide-area topological waveguide, which is composed of a symmetric structure surrounded by two symmetry-broken structures , has been proposed in a photonic system as a candidate of devices transporting large photonic energy [2]. Here, we proposed a heterostructured TPnC with wide-area HOTSs, which is easily excited by an external load, and applied it to an energy storage device.

II. Heterostructure Design

The unit cell of the Kagome lattice we adopted is made of aluminum alloy consisting of three hexagonal sites and intra- and inter-bonds. The topological corner modes have been shown to emerge when the intra-cell bond is smaller than the inter-cell bond [3].

III. Energy Storing With Heterostructure

The left panel of Fig. 4 shows the displacement field of the eigenmode in the conventional structure. The mode localizes at the corner of the internal domain, and decays rapidly away from the corner. In contrast, the mode profile is broadened uniformly in the corner region of the mid-domain inserted between the trivial and nontrivial regions of the heterostructure, as shown in the right-panel of Fig. 4. We calculate the ratio of the stored energy in the region surrounded by the dashed lines. The energy stored at the extended corners is 79.3% of the total energy, while only 21.6% of the total energy is concentrated at the corners of conventional structure.

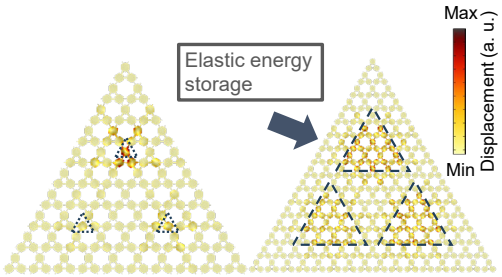

Fig. 1 The displacement field of eigenmodes calculated by finite element analysis. Triangles with dashed lines denote the corner area of conventional (left) and proposed (right) structure, respectively.

IV. Conclusion

We designed a heterostructured TPnC with Kagome lattice to broaden the area of topological corner states. By inserting the mid-domain that has a symmetric structure between the non-trivial and trivial domains, we demonstrated that the proposed structure stored significantly larger elastic energy at extended corner regions than the conventional structure. This study may open new strategies for efficient elastic energy storage and/or energy harvesting.

***Abstract*—We reveal unconventional topological states driven by beyond-nearest-neighbor interactions, inaccessible to conventional winding-number methods. We introduce a local winding-number characterization derived from Berry connections and validate it experimentally using laser-assisted measurements on designed metamaterials, confirming the method's predictive power for complex topological phases.**

***Keywords*— beyond-nearest-neighbor interactions, topological states, local winding number, Berry connection, phononic crystals.**

I. Introduction

Topological mechanical metamaterials and phononic crystals enable robust wave manipulation through topologically protected boundary states (TPBS) dictated by bulk–edge correspondence. A canonical example is the one-dimensional Su–Schrieffer–Heeger (SSH) model [1], in which alternating spring stiffnesses generate distinct topological phases identified by winding numbers that quantify TPBSs [2]. While most studies consider only nearest-neighbor interactions, our recent work shows that beyond-nearest-neighbor (BNN) couplings fundamentally alter the topological landscape, producing unconventional dispersion and new boundary phenomena [3], [4]. We demonstrate that, in such systems, the number of TPBSs is governed not by global winding numbers but by *local* winding numbers extracted from the Berry connection [5], which correspond directly to the Jackiw–Rebbi (JR) indices associated with JR zero modes [6].

II. Methods

Conventional winding number n, which predicts the number of TPBSs in the SSH model can be computed directly from the stiffness matrix $C(k)$ as

$$n = \int_{-\pi/a}^{\pi/a} \frac{1}{4\pi i} \mathrm{tr}[\sigma_3 C'^{-1} \partial_k C'] dk, \tag{1}$$

where σ_3 is the third Pauli matrix, and C' is the effective Hamiltonian, defined as:

$$C'(k) = C(k) - (c_1 + c_2)\sigma_0, \tag{2}$$

with σ_0 the identity matrix, k the wave number, and c_1, c_2 the alternating interaction strengths.

However, with BNN coupling, the global winding number n no longer predicts the correct number of TPBSs. To capture the correct topological behavior, we examine the Berry connection,

$$B(k) = \frac{1}{4\pi i} \mathrm{tr}[\sigma_3 C'^{-1} \partial_k C'], \tag{3}$$

which is the integrand of n in Eqn. 1. As the BNN coupling strength c' increases, the difference in $B(k)$ between the two phases of the unit cell (i.e., when $c_1 > c_2$ and $c_1 < c_2$) generated by flipping the nearest-neighbor interactions evolves, as shown in Fig. 1. The emergence, number, and positions

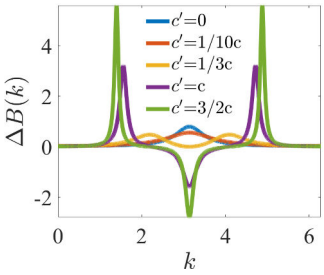

Fig. 1. (a) $\Delta B(k)$ with various c'.

of peaks and valleys in $\Delta B(k)$ correspond to local winding numbers of ± 1, and these match the predictions of the Jackiw-Rebbi theory, confirming their topological origin.

III. Results and Discussion

Although the global winding-number difference between the two topological phases remains $\Delta n = 1$, suggesting a single TPBS at the domain interface, the full supercell phonon-dispersion calculation reveals a different picture. When $c' > \frac{c_1+c_2}{6}$, three TPBSs emerge (Fig. 2). These three states correspond directly to the two peaks and one valley of $\Delta B(k)$ in Fig. 1, each carrying a local winding number of ± 1. Their spatial decay rates extracted from the eigenmodes precisely match the widths of these features in $\Delta B(k)$, confirming their topological origin. Experimental measurements obtained using a scanning laser Doppler vibrometer further verify the presence of all three TPBSs in our 3D-printed lattices.

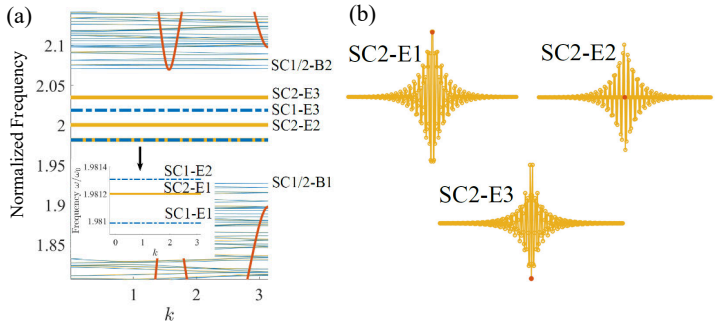

Fig. 2. (a) Phonon dispersion showing the triple topological states when $c' = \frac{c_1+c_2}{2}$. (b) Mode shapes of the three topological states.

IV. Conclusion

We have demonstrated that beyond-nearest-neighbor interactions cause the global winding number to fail in predicting the number of TPBSs in SSH lattices. To address this breakdown, we introduce a new topological characterization – local winding numbers derived from the Berry connection – which correctly captures the full set of boundary states.

***Abstract*— The fine fabrication of metalens allows the leverage of spatial multiplexing to manipulate multi-channel ultrasonic beams independently. We experimentally demonstrate four-channel ultrasonic Bessel vortex beams as examples, showcasing great agreement with simulation results on topological charge and radiation direction. Our work offers more possibilities in designing functional ultrasound devices.**

***Keywords*— acoustic metalens, ultrasonic vortex beams, spatial multiplexings.**

I. Introduction

Acoustic vortex, with the characteristic of the helicoidal wavefront, have been widely studied due to its fascinating properties, such as orbital angular momentum (OAM) and the singularity of zero intensity [1]. Many efforts have been devoted to the generation of acoustic vortex via feasible strategies. However, the efficient generation of multi-channel and multi-directional vortex beams in water via a single, passive device remains an open challenge, primarily due to the difficulties in decoupling spatial information in each channel.

II. Methods

Our methodology relies on the precise manufacturing that allows the adjacent pixel of the metalens to be assigned independently [2]. Thus, the generate non-diffraction ultrasonic vortices can carry different topological charges and spatial orientations. For a case containing 4 channels, the phase profile for individual channels (i=1,2,3,4) can be expressed as:

$$\varphi_i = m_i\theta + k_0 \sin\alpha \sqrt{x^2+y^2} - k_0(x\cos\beta_i + y\cos\gamma_i) \quad (1)$$

where $k_0 = 2\pi f/c_0$ represents the wavenumber in water, and f, c_0 denote the ultrasonic frequency and the sound speed in water, respectively. The azimuthal angle θ is defined by $\tan\theta = y/x$. Parameter α denotes the base angle required for generating ultrasonic Bessel beams. β and γ correspond to the angles between the beam propagation axis and the positive x-axis and y-axis, respectively.

During experiments, working frequency is 2 MHz. The measured sample is designed as a 40 mm × 40 mm square. It is fabricated via 3D printing technology using a photopolymer resin (HTL resin) with a printing resolution of 10μm.

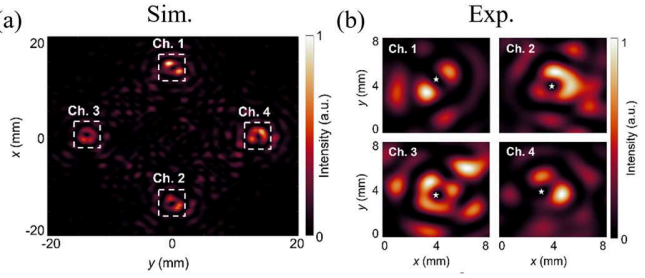

Fig. 1 The Generation of multi-channel ultrasonic Bessel vortex beams. (a) The simulation results. (b) The measured results.

III. Results and Discussion

From Fig. 1, the comparison between simulations and measurements shows that the ultrasonic beams propagate as predicted, each beam carries a donut-like pattern. Moreover, we can assign different or even higher order topological charge to the channels, which can be validated in phase distributions.

IV. Conclusion

We propose a MHz-band ultrasonic metalens that encodes four-channel phase information into a single device through spatial multiplexing, while maintaining ultrasonic field fidelity. This work may inspire more functional ultrasonic devices.

Abstract— Investigation of the interaction between elastic surface waves and nano-cylinder scatterers to identify resonant regimes and thereby extract crucial transport parameters in multiple scattering experiments aimed at exploring two-dimensional sub-diffusive Anderson localization. Using a Ti:Sapphire pump-probe setup we recorded spatial maps of the displacement on Au membranes and films.

***Keywords*— Picosecond ultrasonics, Surface acoustic waves, Lamb waves, Rayleigh waves, Resonant scattering**

In this work, we experimentally investigate the scattering properties of resonant microdisks with the objective of creating and characterizing a multiple-scattering acoustic medium. Using picosecond ultrasonics in a pump–probe configuration, we generate surface elastic waves through an opto-thermo-elastic mechanism and detect them via two interferometric techniques: a Sagnac interferometer for guided Lamb waves in membranes, and a Michelson interferometer for Rayleigh waves on bulk substrates. The microdisks consist of gold cylindrical resonators deposited either on silicon nitride membranes or on SiO_2 substrates.

We first characterize the free propagation of Lamb and Rayleigh waves, extracting dispersion relations that reveal the presence of several guided modes, including the antisymmetric A_0 and symmetric S_0 Lamb modes. We then investigate the interaction between these waves and individual gold microdisks. Although the scattered field is initially hidden within the dispersive incident wavefront, spectral filtering in the (k,ω) domain enables us to isolate a backward-scattered component. Its frequency content exhibits a set of discrete resonances, which we attribute to resonant modes of the cylindrical microresonator. The observed resonant peaks agree with theoretical predictions, confirming the excitation of transverse acoustic modes confined within the microdisk.

This study demonstrates that single microdisks act as efficient resonant scatterers for GHz surface waves. Their well-defined modal structure makes them promising building blocks for engineered multiple-scattering media, opening new perspectives for acoustic wave control, disorder-induced transport phenomena, and the realization of phononic systems operating in the gigahertz regime.

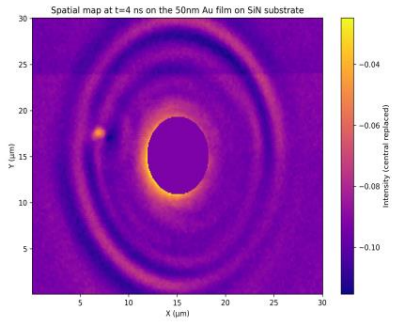

Figure 1: A (30 by 30µm) spatial scan of a Rayleigh wave with a lateral precision of 125nm at t= 4ns.

Figure 1 shows the spatial map of the out-of-plane displacement on the SiN/Si substrate. The gold cylinder appears as a bright yellow spot on the left, due to its locally enhanced reflectivity. From that point, a circular scattered wave-front propagates outward.

Omnidirectional and anomalous acoustic absorption with an array of wiremeshes

Juan Pablo Escudero[1], Jean-Philippe Groby[1], Vincent Pagneux[1,*]

[1]Laboratoire d'Acoustique de l'Université du Mans (LAUM), UMR 6613, Institut d'Acoustique - Graduate School (IA-GS), CNRS, Le Mans Université, France
*Corresponding author: vincent.pagneux@univ-lemans.fr

***Abstract*— This study investigates the acoustic absorption of a rigidly-backed, periodic layer of inclined ultrathin resistive wiremeshes, aiming for strong performance across wide frequency and incidence-angle ranges. Results reveal omnidirectional absorption in subwavelength bands at high resistivity, and omnidirectional broadband absorption at medium resistivity, Anomalous scattering behaviors is also discussed.**

***Keywords*— Acoustic absorbers, wiremesh, broadband, omnidirectional.**

I. Introduction

One way to efficiently absorb acoustic waves is to combine both impedance matching and a loss mechanism to dissipate energy. Broadband angular impedance matching is generally challenging. However, for an interface between a homogeneous half-space and a periodic array of inclined thin wiremeshes, the reflection vanishes not only for waves traveling parallel to the plates, but, more remarkably, also for waves arriving at the mirror-symmetric angle, a consequence of reciprocity. In this work, our goal is to use this result to achieve broadband and omnidirectional absorption with rigid backing.

II. Methods

Our setup is depicted in Figure 1. An plane wave is incident on on array of ultra thin wiremeshes with rigid backing (Figure 1(a)). This problem can be directly solved numerically and as well through effective medium approximation Figure 1(b). It is then possible to investigate the absorption as a function of the parameters of the array (angle of the wiremeshes, resistance of the wiremeshes, thickness h versus periodicity of the array d) and of the angle of incidence [1].

III. Results and Discussion

Numerical results show:

- a resistive configuration capable of strongly absorbing acoustic energy over a wide omnidirectional broadband absorption
- a less resistive configuration capable of strongly absorbing acoustic energy at all angles of incidence for a specific subwavelength thickness

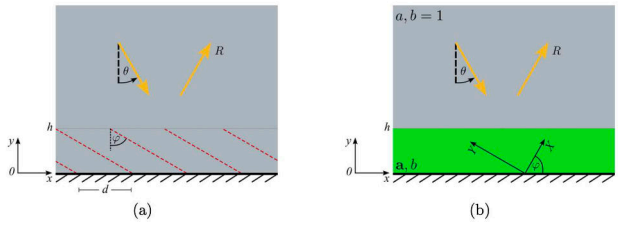

Fig. 1 (a) Reflection problem of an array of wiremeshes (in red dashed) with rigid backing. (b) Effective medium modelling of the setup

IV. Conclusion

We studied a rigidly-backed layer of inclined periodic resistive wiremeshes, analyzed numerically and via an effective medium model. Two configurations are identified: one optimized for strong all-angle absorption at a specific subwavelength thickness, and one for broadband omnidirectional absorption. Both come with large inclination angles, offering new routes toward perfect omnidirectional absorbers.

Finite-Size Effects in Mechanical Metamaterials: The Role of Interfaces

Svenja Hermann

Technische Universität Dortmund, Germany
*Corresponding author: svenja.hermann@tu-dortmund.de

***Abstract*— C Mechanical metamaterials offer new possibilities for controlling vibrations and sound transmission through engineered band gaps. In building acoustics, they are a promising approach to improve noise insulation in lightweight wall systems, where low- and mid-frequency vibrations are difficult to mitigate with conventional materials. However, metamaterial design is typically based on infinitely periodic unit cells, while real applications involve finite structures connected to surrounding components. In this talk, we investigate how interfaces influence the vibration damping performance of finite-sized metamaterial panels. Using numerical simulations of sandwich-like assemblies, we analyze the role of material and free interfaces as well as the geometry of the connected plates. The results show that interface configuration significantly affects energy transmission and must be considered in the design of metamaterial-based structures for vibration mitigation.**

Mode conversion for elastic waves via temporal interfaces

***Abstract*— We demonstrate perfect mode conversion between longitudinal and transverse elastic waves using an isotropic-anisotropic-isotropic temporal interface. This phenomenon arises from distinct phase accumulation of the two eigenmodes. For physical realization, a piezoelectric lattice with shunting circuits is proposed. These findings provide a new route for wave control via temporal interfaces.**

***Keywords*— mode conversion, temporal interface, elastic waves, anisotropy, time-varying modulation**

I. Introduction

In recent years, time-varying metamaterials have introduced an additional degree of freedom beyond spatial structuring. Temporal modulation can relax constraints imposed by time-reversal symmetry and energy conservation, thereby enabling wave phenomena and functionalities inaccessible in stationary media. Consequently, increasing attention has been devoted to time-varying systems across elasticity, acoustics, and photonics [1].

A temporal interface is formed by an abrupt change in material properties occurring on a timescale much shorter than a wave period, serving as the temporal analogue of a spatial interface. Although a variety of novel wave phenomena have been reported in electromagnetic systems [2,3], studies on temporal interfaces for elastic waves remain very limited. Moreover, the complex polarization characteristics and mode coupling inherent to elastic waves pose substantial challenges for both theoretical and experimental realization in time-varying elastic systems.

Here, perfect mode conversion between longitudinal (P) and shear (S) waves are achieved through an isotropic-anisotropic-isotropic temporal interface. We also develop a temporal transfer matrix method (TTMM) to analyze temporal multilayer structures and propose a two-dimensional piezoelectric lattice with external circuits for physical realization.

II. Methods

We consider an infinite and spatially homogeneous two-dimensional (2D) elastic medium in the plane-strain state with a constant mass density ρ. The elasticity of the medium varies in time: the elasticity tensor initially $\mathbf{C}$ takes the value $\mathbf{C}^0$, undergoes instantaneous changes to $\mathbf{C}^1$ at an instant t_1, and reverts to $\mathbf{C}^0$ at $t = t_2$, as illustrated in Fig.1. The initial and final media are assumed to be isotropic in elasticity, while the middle layer exhibits orthotropic elasticity. Without loss of generality, the principal axes of the orthotropic medium are set to align with coordinates (x, y).

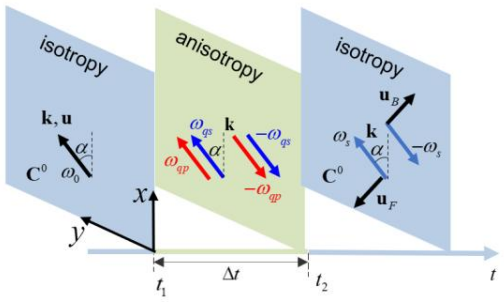

Fig. 1 Schematic of mode conversion through the temporal structure. ω_0 denotes the angular frequency for incident wave. Arrows aligned with or opposite to the wavevector $\mathbf{k}$ indicate waves with positive or negative frequencies. $\boldsymbol{u}_F$ and $\boldsymbol{u}_B$ represent the displacement vectors of the forward and backward waves in the end layer, which are perpendicular to $\mathbf{k}$.

A plane longitudinal wave with incident angle α and wavevector $\mathbf{k}$ travels in the initial layer, as shown in Fig.1. This temporal multilayer structure can be solved analytically using the temporal transfer matrix method (TTMM). For a given layer, $\mathbf{k}$ is conserved across the temporal interface due to spatial homogeneity, while the frequency changes as a result of temporal discontinuity. The converted frequencies are determined by the temporal Snell's law, while the amplitudes of the temporally scattered waves follow from the continuity of displacement $\mathbf{u}$ and momentum $\mathbf{p}$ across the temporal interface, which constitute the temporal boundary conditions.

In the final layer, there are four wave components, namely the forward and backward P and S waves. Their amplitudes can be expressed as

$$\begin{cases} F_p = M_{11}A_0, \quad F_s = M_{21}A_0 \\ B_p = M_{31}A_0, \quad B_s = M_{41}A_0 \end{cases} \tag{1}$$

where M_{ij} are the components of the temporal transfer matrix $\mathbf{M}$, and A_0 denotes the amplitude of the incident wave. Therefore, the analytical solutions for complete mode conversion from P wave to S wave can be obtained when $F_p = B_p = 0$. This condition yields

$$\begin{cases} \sin\beta_{qp} = \sin\beta_{qs} = 0 \\ \cos\beta_{qp} = -\cos\beta_{qs} \\ 2A_{12}\sin(2\alpha) + \cos(2\alpha)(A - B) = 0 \end{cases} \tag{2}$$

where α is the incident angle, $\beta_{qp} = \Delta t\omega_{qp}$ and $\beta_{qs} = \Delta t\omega_{qs}$. Here, $\Delta t = t_2 - t_1$ is the time duration of the orthotropic layer, while ω_{qp} and ω_{qs} are the angular frequencies of the quasi-longitudinal and quasi-shear waves, respectively. The coefficients A_{12}, A and B are determined by the components of $\mathbf{C}^1$ (see [4] for details). Eq. (2) provides the parameter conditions for achieving complete mode conversion at arbitrary incident angles, except for the cases $\alpha = 0$ and $\alpha = \pi/2$.

III. Results and Discussion

As a relevant example, we consider a scenario where the excitation is chosen as the 10-cycle harmonic line source modulated by a Gaussian envelope, as illustrated in Fig.2 (a). The frequency of the incident P wave is set to 0.5 kHz , and the incident angle is $\alpha = \pi/6$. The material parameters of the initial and final isotropic layers are taken as $\lambda = 1$ GPa , $\mu = 1$ GPa, $\rho = 10^3$ kg/m^3, while C_{66} is fixed at C_{66}=1 GPa for the orthotropic layer. Based on Eq. (2), it can be determined that $\Delta t = 1.861$ ms, $C_{11} = 1.053$ GPa and $C_{22} = 10.160$ GPa for the appearance of perfect mode conversion.

Wave propagation under the above parameters is simulated using the Finite-Difference Time-Domain (FDTD) method, and the results are reported in Fig.2.

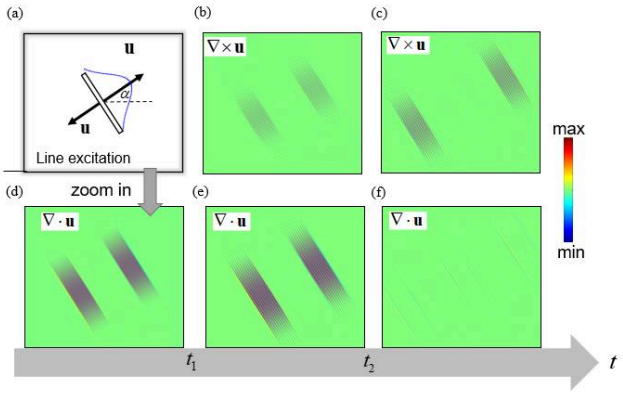

Fig. 2 FDTD results in the temporal slab: (a) the simulation model for FDTD; (b) The divergence component of displacement fields at t_1=40 ms; The curl and divergence components of displacement fields at (c,d) 40.93 ms and (e,f) 60 ms.

In Fig.2, the snapshots of the curl and divergence components of displacement field at 40 ms ($t = t_1$), 40.93 ms ($t_1 < t < t_2$) and 60 ms ($t > t_2$) are provided in Fig.2 (b-f), respectively. The incident longitudinal wave (Fig.2 (b)) undergoes the mode conversion in the orthotropic medium as shown in Fig.2 (c,d). After the sudden change at $t_2 = 41.86$ ms, the divergence component in Fig.2 (f) vanishes, signifying that the incident wave has been converted into a pure S wave. Moreover, examples of perfect S-to-P can also be found in [4].

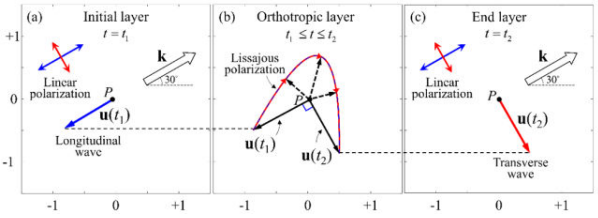

Fig. 3 The particle polarization trajectories in the regime of (a) $t \le t_1^-$, (b) $t_1^+ \le t \le t_2^-$ and (c) $t \ge t_2^+$

To elucidate the physical mechanism underlying complete mode conversion, we analyze the polarization trajectories of particles upon the sudden change of material properties. Initially, the displacement for a material point P is in align with $\mathbf{k}$, corresponding to a longitudinal polarization (Fig.3 (a)). Following the sudden transition to the anisotropic medium at $t = t_1$, both $\mathbf{k}$ and the displacement vector $\mathbf{u}(t_1)$ are preserved, while the superposition of qP and qS eigenmodes with distinct frequencies gives rise to a Lissajous-type polarization (Fig.3 (b)). After accumulating a relative phase shift over the temporal slab, $\mathbf{u}(t_2)$ becomes vertical to $\mathbf{k}$ at t_2, leading to a purely transverse polarization once isotropy is restored (Fig.3 (c)).

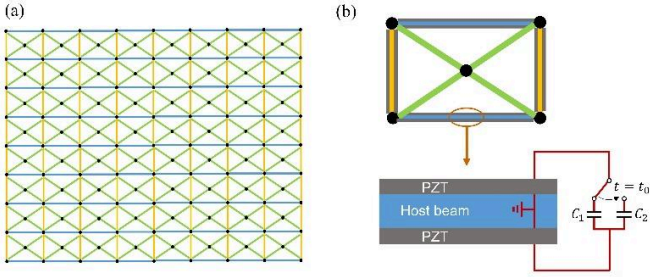

Fig. 4 (a) Schematic of a periodic square lattice structure for physical realization of medium systems with temporal interfaces, and (b) its unit cell consisting of piezoelectric composite structures shunted with the external circuit

Isotropic-anisotropic-isotropic temporal interfaces can be physically realized by two-dimensional lattice structures involving piezoelectric materials and shunting circuits, as sketched in Fig. 4. Each unit cell consists of a piezoelectric composite beam with a sandwiched configuration, where two piezoelectric patches are symmetrically bonded to both sides of a host beam and connected to an external shunting circuit containing a capacitance. By designing piezoelectric composite beams in two perpendicular directions, overall elastic properties of lattice structures can be manipulated to fulfill either isotropic or anisotropic elasticity. In addition, the modulus property can be dynamically modulated by temporally changing the circuit elements. For example, the temporal interface at time $t = t_0$ can be realized by switching the capacitance of value C_1 to a different one C_2. The structured materials presented in Fig. 4 are designed based on realistic materials, and provide a feasible platform for experimental realization of elastic temporal interfaces.

IV. Conclusion

We have demonstrated complete mode conversion between P and S waves through an isotropic-anisotropic-isotropic temporal slab, which is validated by the FDTD method. The results show that the key mechanism underlying perfect mode conversion lies in the distinct phase accumulation of two eigenmodes supported by the orthotropic material. Our findings reveal the interaction mechanism between elastic waves and time-varying materials, and provide both analytical and numerical tools for analyzing elastic waves in temporal solids. Future work will extend to the experimental validation of mode conversion via temporal interface.

***Abstract*—We report the flat-band skin effect (FBSE) in 1D non-Hermitian lattices, driven by the spectral topology of surrounding dispersive bands. The FBSE was experimentally observed in a non-Hermitian mechanical lattice. Our work reveals unique non-Hermitian localization and offers new perspectives on wave propagation.**

***Keywords*—mechanical metamaterials, non-Hermitian phononics, non-Hermitian skin effect, localized sates.**

I. Introduction

Non-Hermitian physics has fundamentally extended the study of open systems, most notably through the non-Hermitian skin effect (NHSE). In this work, we investigate one-dimensional (1D) non-Hermitian lattices hosting an ideal flat band, where we identify a distinct flat-band skin effect (FBSE) that transforms compact localized states (CLSs) into edge modes under open boundary conditions (OBCs).

Crucially, while conventional NHSE arises from a band's intrinsic topology, the FBSE is dictated by the point-gap topology of the surrounding dispersive manifold. This coupling causes the FBSE to counterintuitively vanish under high non-Hermiticity. We experimentally validate these findings using an active mechanical lattice, offering new insights into inter-band topological phenomena with broad implications for non-Hermitian metamaterials and photonics.

II. Methods

We investigate a 1D Lieb model characterized by a zero-energy flat band arising from an $(M-1)$-dimensional null space. The system is described by the Bloch Hamiltonian $H(k)$,

$$H(k)=\begin{pmatrix} 0 & t_1-\gamma_1+t_2e^{-ik} & t_2-\gamma_2 \\ t_1+\gamma_1+t_2e^{ik} & 0 & 0 \\ t_2+\gamma_2 & 0 & 0 \end{pmatrix}, \tag{1}$$

which incorporates reciprocal hopping $(t_{1,2})$ and non-reciprocal terms $(\gamma_{1,2})$, all of which are purely real.

While the Hermitian gap between the flat and dispersive bands remains robust unless the Hamiltonian itself vanishes $(t_1 = t_2 = 0)$, the introduction of non-Hermiticity facilitates line-gap closures. Specifically, these closures occur at $k = \pm\pi$ and $k = 0$ when the non-reciprocity balances the hopping parameters, satisfying critical conditions derived from $E(k) = \pm\sqrt{\Delta - (\gamma_1^2+\gamma_2^2) - 2i\gamma_1 t_2 \sin k}$ and $\Delta = t_1^2+2t_2^2+2t_1t_2cosk$. Furthermore, under OBC, the N-fold degeneracy of the flat band manifests as CLS-like wavefunctions that are localized across the bulk, enabling the engineering of diverse wavefunction profiles through linear combinations of eigenmodes.

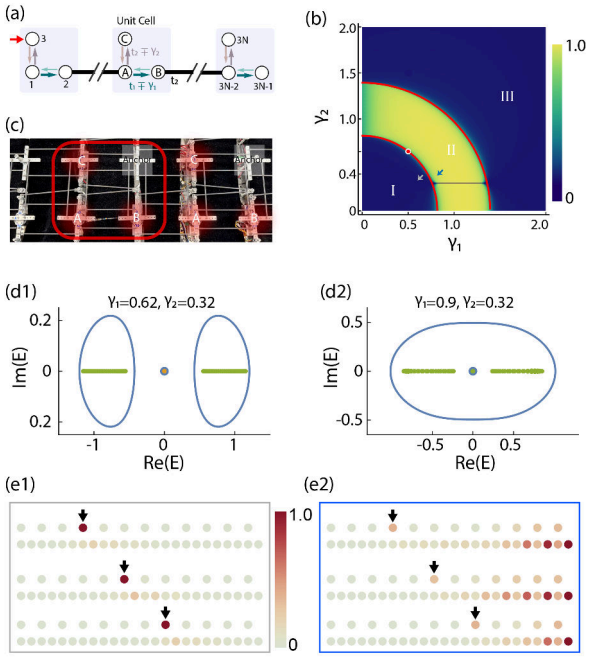

Fig. 1. (a) Schematic of 1D non-Hermitian flat-band model. (b) The averaged responses χ of the OBC flat band computed through the Green's function. (c) The active mechanical lattice realizing the non-Hermitian flat-band model. (d) and (e) Complex eigenenergy and steady-state responses of the flat band $(f = 10.9\text{Hz})$ under different parameters.

To characterize the spatial profiles of the flat-band modes, we employ the Green's function $\hat{G}(E_\eta) = (E_\eta - H_{OBC})^{-1}$ as a basis-invariant probe. Specifically, by setting the excitation energy to $E_\eta = 0 + i\eta$ with a vanishingly small imaginary part (we use $\eta = 10^{-20}$ in our numerical simulations), the source selectively targets the flat-band manifold, ensuring that the resulting response accurately reflects the characteristics of these zero-energy modes. The normalized spatial response $|R\rangle = \hat{G}(E_\eta)|s\rangle$ is generated from a source $|s\rangle$ at the first unit cell. We quantify the localization through the spatial centroid

$$\chi = \sum_n (n/3N)|R_n|^2, \tag{2}$$

where $\chi \approx 0$ indicates bulk-localized modes and $\chi \approx 1$ signifies the FBSE. The calculated $\chi(\gamma_1, \gamma_2)$ map in Fig. 1(b) reveals a well-defined regime where the response concentrates at the right boundary, providing clear evidence for the emergence of FBSE.

To elucidate the physical origin of the observed responses, we analyze the eigenvectors of zero-energy flat-band under OBC. These modes span an N-dimensional null space, $\ker(H_{OBC})$, where the right eigenvectors (REVs) typically manifest as bulk-localized, CLS-like states. The emergence of the FBSE is fundamentally understood through the Lehmann spectral representation of the Green's function:

$$G(E_\eta) \approx \sum_n \frac{|\psi^R_{0,n}\rangle\langle\psi^L_{0,n}|}{E_\eta}, \tag{3}$$

which highlights the critical role of the biorthogonal duals, or left eigenvectors (LEVs). In the FBSE-free regimes (Regions I and III), LEVs and REVs remain spatially co-localized. Conversely, within the FBSE regime (Region II), specific LEVs undergo exponential localization at the left boundary with significantly enhanced amplitudes, while their corresponding REVs still evenly in the whole bulk. This biorthogonal disparity ensures that even bulk-like excitations are projected onto boundary-dominant modes, thereby driving the non-Hermitian FBSE.

Our analysis reveals that the FBSE regime is strictly congruent with the regions where the line gaps of the dispersive bands close [Fig. 1(b)], marking a departure from standard non-Hermitian bulk-boundary correspondence. This phenomenon is rooted in an unexpected link to the point-gap topology of the surrounding manifold: the FBSE emerges only when the zero-energy flat band is enclosed within the complex spectral loops formed by the dispersive bands under periodic boundary conditions. Consequently, as further non-Hermiticity reopens the line gap, the flat band exits the spectral loop and the FBSE subsequently vanishes. This unique interplay—where the localization of a parameter-invariant flat band is dictated by the topology of its adjacent dispersive bands—constitutes a novel feature of non-Hermitian spectral topology that has been previously overlooked

III. Results and Discussion

We experimentally implement the proposed model using a versatile active mechanical lattice [Fig. 1(c)], an experimental platform engineered for the high-fidelity realization of non-Hermitian Hamiltonians. The system comprises 36 spring-coupled rotational oscillators organized into 12 unit cells, where non-reciprocal coupling is synthesized via programmable brushless DC motors driven by active feedback control. To target the flat-band manifold, all oscillators are precisely calibrated to a degenerate resonant frequency of $f_0 = 10.9$ Hz, corresponding to the zero-energy mode of the system.

The emergence of the FBSE is demonstrated by probing the steady-state spatial response under local harmonic excitation at site C. In Region I ($\gamma_1 = 0.62, \gamma_2 = 0.32$), where the FBSE is theoretically absent, the energy remains confined in the immediate vicinity of the source [Figs. 1(d1, e1)], characteristic of conventional localized modes. Conversely, upon tuning the parameters to Region II ($\gamma_1 = 0.9, \gamma_2 = 0.32$), the spatial profile undergoes a dramatic transition: the response concentrates predominantly at the right boundary. This boundary-dominant localization persists irrespective of the excitation position, providing robust experimental evidence for the non-Hermitian FBSE in the mechanical lattice.

IV. Conclusion

In summary, this work elucidates a novel FBSE that differs fundamentally from standard NHSEs in dispersive systems. Beyond theoretical insights, our findings offer significant potential for the development of advanced photonic devices and topological metamaterials.

***Abstract*—We investigate transient growth in the Hatano-Nelson model with uniform loss. By analyzing the nonnormality of the Hamiltonian, we identify a boundary separating the regions of transient amplification and monotonic decay. Notably, increasing only the system size N can trigger a transition between the two regions.**

***Keywords*—Lattice dynamics, Non-Hermitian skin effect, Transient growth.**

I. Introduction

Over the last few years, non-Hermitian systems have attracted significant interest due to their unique properties, such as the non-Hermitian skin effect [1]. A paradigmatic system hosting the skin effect is the Hatano-Nelson model [2], which has lately been experimentally implemented in the fields of acoustics [3] and photonics [4]. While much attention has been given to the spectral properties of the Hatano-Nelson model — particularly its extreme sensitivity to variations in the boundary conditions [1]— the transient dynamics of this model have received much less attention, even though this system offers a rich landscape for exploring amplifying effects [5], [6], [7].

In this work, we investigate the transient growth in the Hatano-Nelson model with uniform loss [Fig. 1(a)]. First, we show that different initial conditions lead to significantly different growth experiences before the eventual decay [Fig. 1(b)]. Second, we identify a boundary separating the regions of transient amplification and monotonic decay [Fig. 1(c)].

II. Model

We study wave evolution in a Hatano-Nelson (HN) lattice with N sites, with the dynamics given by

$$\dot{\boldsymbol{\psi}} = -i\mathbf{H}\boldsymbol{\psi} \tag{1}$$

where $\boldsymbol{\psi} = \begin{pmatrix}\psi_1 & \psi_2 & \cdots & \psi_N\end{pmatrix}^T$ and ψ_i is the wave field in the i^{th} site. Moreover, dot denotes differentiation with respect to time t and $\mathbf{H}$ is the non-Hermitian Hamiltonian

$$\mathbf{H} = \begin{pmatrix} -i\gamma & e^{h} & 0 & \cdots \\ e^{-h} & -i\gamma & e^{h} & \cdots \\ 0 & e^{-h} & -i\gamma & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix}. \tag{2}$$

where h is the coupling asymmetry between left and right sites and γ is the uniform loss applied to each site [Fig. 1(a)]. The solution of the wave evolution is given by

$$\boldsymbol{\psi}(t) = e^{-i\mathbf{H}t}\boldsymbol{\psi}(0) \tag{3}$$

with $\boldsymbol{\psi}(0)$ being the initial excitation in the lattice.

III. Results

A. Transient Growth and Nonnormality

Because the coupling is nonreciprocal ($e^{h} \neq e^{-h}$) , the Hamiltonian $\mathbf{H}$ is a nonnormal matrix, meaning $[\mathbf{H}, \mathbf{H}^{\dagger}] \neq 0$. This nonnormality allows for transient growth [8], [9], [10], [11], a phenomenon where the power $E(t) = \sqrt{\sum_{i=1}^{N} |\psi_i(t)|^2}$ of an initial excitation increases transiently in time before eventual decay. The maximum possible amplification is defined by the 2-norm of the propagator matrix $||e^{-i\mathbf{H}t}||$ [Fig. 1(b)–black line]. Moreover, as shown in Fig. 1(b), the system's growth experience is highly dependent on the initial conditions. Different initial states—such as a single-site excitation or a Gaussian beam—lead to distinct amplification curves. Crucially, the optimal right SVD vector, defined as the right singular vector of the propagator matrix $e^{-i\mathbf{H}t}$ associated with its largest singular value, is guaranteed to experience the highest possible amplification [11].

B. Boundary of Transient Amplification

A central focus of our study is to identify the boundary that separates regions of transient amplification from regions of monotonic decay. This transition is determined by analyzing the eigenvalues of the Hermitian matrix $\mathbf{B} = \frac{\mathbf{A}+\mathbf{A}^{\dagger}}{2}$ [11], where $\mathbf{A} = -i\mathbf{H}$. The boundary occurs when the maximum eigenvalue, λ_{max}, equals zero.We have derived an analytical expression for this boundary. By setting $\lambda_{max} = 0$, we find that for a constant loss γ, the critical coupling asymmetry h is given by

$$h = \sinh^{-1}\left[\frac{\gamma}{2\cos(\frac{\pi}{N+1})}\right]. \tag{4}$$

This result, illustrated in Fig. 1(c), demonstrates that increasing the system size N alone can trigger a transition from monotonic decay to transient growth, highlighting the sensitivity of the model to the system size.

IV. Conclusion

In this work, we demonstrated that an initial excitation in the Hatano-Nelson model with uniform loss exhibits transient growth before asymptotic decay due to the presence of coupling asymmetry. We also showed that this growth dependents on the spatial structure of the initial excitation. Finally, we identified the boundary in the (N, h) parameter space that defines the transition from a regime of transient growth to one of monotonic decay, highlighting the sensitivity of the system to its size.

Fig. 1. (a) Schematic of the Hatano-Nelson lattice with N sites, featuring nonreciprocal couplings e^{h}, e^{-h} and uniform loss γ. (b) Transient growth of the wave field norm $||\psi(t)||$ for different initial excitations: single-site (blue), Gaussian beam (green), and optimal right SVD vector (red). The black line denotes the 2-norm of the propagator $||e^{-i\mathbf{H}t}||$, representing the maximum possible amplification. Parameters: $\gamma = 1$, $N = 30$, and $h = 0.55$. Inset: Spatial profiles of the initial excitations. (c) Phase diagram in the (N, h) parameter space for $\gamma = 1$. The solid white line represents the analytical boundary given in Eq. (4), separating the regions of transient growth and monotonic decay.

Elastic Willis Metamaterials: Parameter Characterization and Wave Matching Application

Joo Hwan Oh[1]

[1]Department of Mechanical Engineering, Seoul National University, Republic of Korea
*Corresponding author: ojh86@snu.ac.kr

***Abstract*— This paper presents complementary studies on elastic Willis metamaterials. First, a parameter retrieval method considering mode coupling in elastic solids is proposed for analyzing complex elastic Willis metamaterials. The proposed method can characterize arbitrary Willis metamaterials with mode conversion. Then, wave matching application with Willis metamaterials is introduced.**

***Keywords*— metamaterials, Willis metamaterials, retrieval method, wave matching.**

I. Introduction

Willis metamaterials are elastic metamaterials exhibiting bianisotropic coupling between stress-velocity and momentum-strain fields [1,2]. This coupling, known as Willis coupling, gives rise to unique wave phenomena absent in conventional materials. Willis coupling in elastic media presents greater complexity due to the coexistence of longitudinal and shear wave modes and the associated mode coupling between them.

Despite growing interest, two fundamental challenges have prevented progress in this field. First, characterizing elastic Willis metamaterials through effective parameter retrieval is significantly more difficult than in acoustic or electromagnetic systems, particularly when mode coupling is present. Existing retrieval methods developed for acoustic metamaterials is not applicable when applied to general elastic cases containing mode coupling. In this presentation, a novel retrieval method with mode coupling is addressed. Additionally, the practical utility of Willis coupling in wave matching is introduced as one of the meaningful applications.

II. Methods

We propose a numerical retrieval method which can handle the full complexity of elastic Willis metamaterials including simultaneous mode coupling and Willis coupling [3]. The key strategy is to leverage eigen-decomposition on transfer matrix of Willis metamaterials. In elastic wave systems, transfer matrix is the matrix relating the state field vector at the interface of intermediate materials to the state field vector at the other interface. This matrix contains the information about wave propagation in the medium, thus it can be decomposed by the matrix composed of eigenvector of each propagating wave's mode like $T = MNM^{-1}$. For numerically retrieving effective parameters of Willis metamaterials, the numerical simulation with finite element method is conducted, then the scattering parameters such as reflection and transmission coefficients are measured. From the scattering parameters, transfer matrix can be calculated, then the effective parameters are retrieved by decomposing transfer matrix. The detailed procedures will be introduced in the presentation.

III. Results and Discussion

The process of validation is shown in the following cases

- Asymmetrically layered media with no mode coupling, but Willis coupling (Fig. 1)
- Asymmetric mass spring system with no Willis coupling, but mode coupling (Fig. 2)
- Asymmetric continuum structure with Willis coupling and mode coupling simultaneously (Fig. 3)

In two cases of layered medium and mass-spring systems, the effective parameters can be theoretically calculated, which validated the retrieving methods applied to numerical simulations. As can be seen in Figs. 1 and 2, the effective parameters can be retrieved by the proposed method. These results validate that the proposed retrieval method is effective to address the elastic metamaterials with Willis coupling and mode coupling simultaneously.

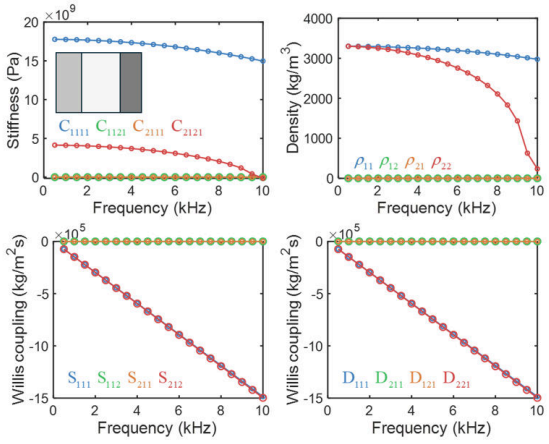

Fig. 1 The retrieved effective parameters of the layered medium.

Finally, the retrieving method was applied to complex continuum Willis metamaterials which have both Willis coupling and mode coupling simultaneously. The retrieved parameters are shown in Fig. 3. Then, the effectiveness of the proposed method was validated by comparing it with the homogenized models as described in Fig. 4. The displacement field contours are well-matched each other, which proved the validity of the proposed retrieving method.

In addition to the characterization of elastic Willis metamaterials, wave matching application will be introduced in the presentation.

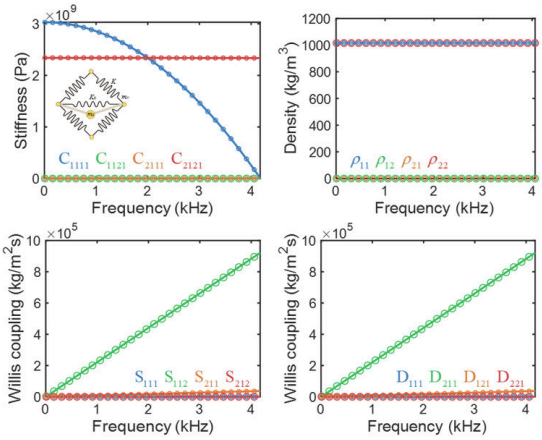

Fig. 2 The retrieved effective parameters of the mass-spring system.

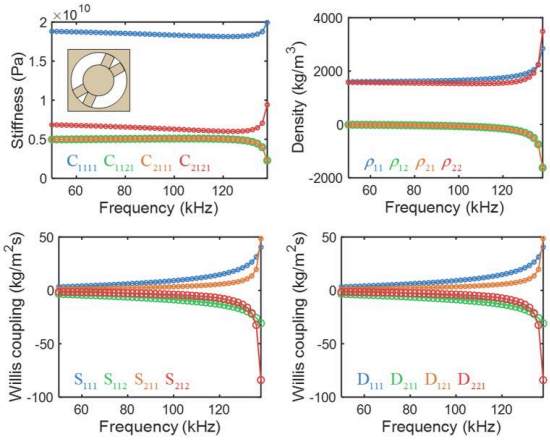

Fig. 3 The retrieved effective parameters of the continuum structure.

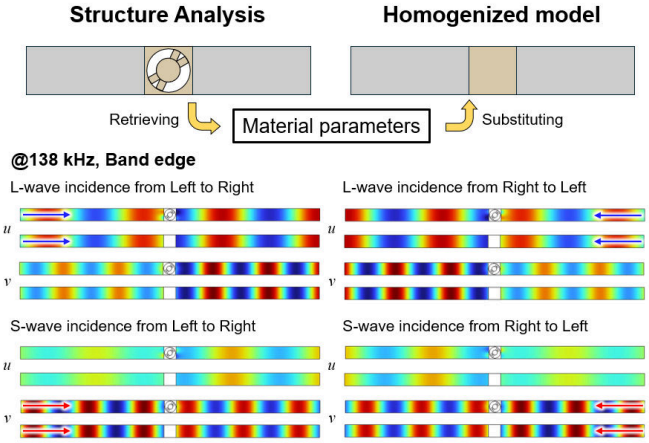

Fig. 4 The validation of the retrieving method with homogenized models.

IV. Conclusion

We have proposed a novel characterization method for retrieving the effective parameters of general elastic Willis metamaterials with Willis coupling and mode coupling simultaneously. We believe that this characterization method broadens the research area of Willis metamaterials containing mode coupling. Finally, as one of the useful applications of Willis metamaterials, wave matching application with Willis metamaterials will be introduced in the presentation.

***Abstract*—Nanocrystalline silicon is a promising material for nano-opto-electro-mechanical metamaterials to be integrated into information and communication technology platform. The preparation of nanocrystalline silicon has an impact on properties associated with grain sizes and grain boundaries, which influence the mechanical quality factor of one-dimensional nanoresonators, among others.**

***Keywords*— nanocrystalline silicon, metamaterials, optomechanics, NOEMS.**

I. Introduction

Nanocrystalline silicon (nc-Si) is a novel material consisting of randomly oriented Si grains, so that it has an isotropic behavior [1]. Developed for MEMS applications in the 1980's [2], it has been recently considered as a possible material for optomechanical devices and circuits.

II. Methods

Nc-Si is produced by low pressure chemical vapour deposition (LPCVD) and consequent annealing of 220 nm of amorphous silicon on a silicon dioxide layer, which in turn is on a crystalline silicon (c-Si) substrate. The annealing temperature ranges from 650°C to 1050°C. During the annealing, nucleation and growth of nanocrystallites take place, resulting in a material as the one reported in Fig. 1.

The thermal annealing process determines the mean grain size and grain size distribution, impacting the electronic, optical and mechanical properties of nc-Si, which can be tuned by varying the annealing parameters [3]. These impact thermal transport [4] and, consequently, the performance of devices [5]. The isotropy of nc-Si has been demonstrated by an inelastic light scattering investigation [1].

The structural information is one example of characterisation needed to unravel the high mechanical quality factors of optomechanical nc-Si metamaterial devices compared to similar devices fabricated in silicon-on-insulator (SOI) [6]. The sizes of the nanocrystallites have been investigated by dark-field TEM images acquired at different diffraction areas through the hollow-cone technique [7], so that nanocrystallites with different orientations could be revealed. Complementary Raman spectroscopy characterization has provided insights about the grain size distributions at different annealing temperatures.

The devices under investigation consist of suspended nanobeams, which act as photonic-phononic one-dimensional

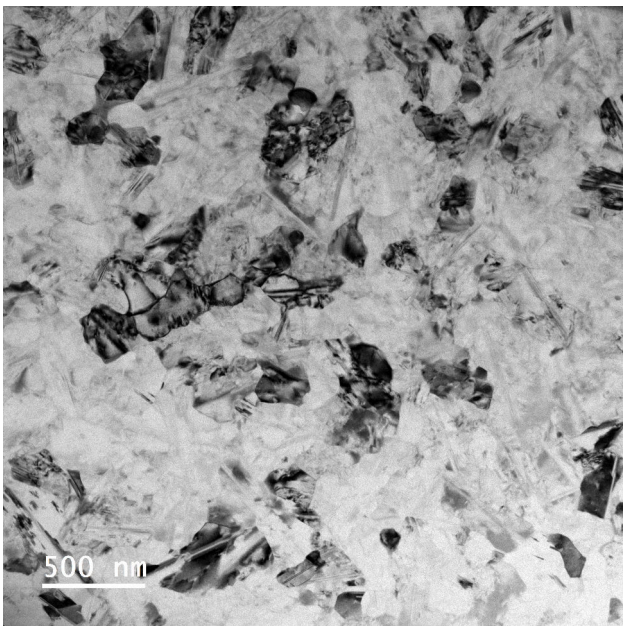

Fig. 1. TEM image of nc-Si.

structures working at hypersonic frequencies. In such devices photons and phonons are confined in a central cavity. The performance of these devices is determined not only by the material properties, but also by the device design. Two examples of nc-Si nanobeams are shown in Fig. 2.

Such devices are characterized by the fiber-loop method: the light from a tunable laser is sent into a tapered fiber which is arranged in order to have a loop, which is approached to the device so that both the photonic and phononic modes of the device are excited.

III. Results and Discussion

The resulting average grain size is larger for higher annealing temperatures (57.5 $\pm$ 2.5 nm and 53.4 $\pm$ 2.2 nm for 950°C and 1050°C, respectively) rather than the lowest annealing temperature (33.5 $\pm$ 0.7 nm for 650°C). The different average grain size determines a different volume of grain boundaries, which is crucial to understand electron and phonon transport in the material. The grain boundaries play a key role because they are expected to host a relatively high number of electronic

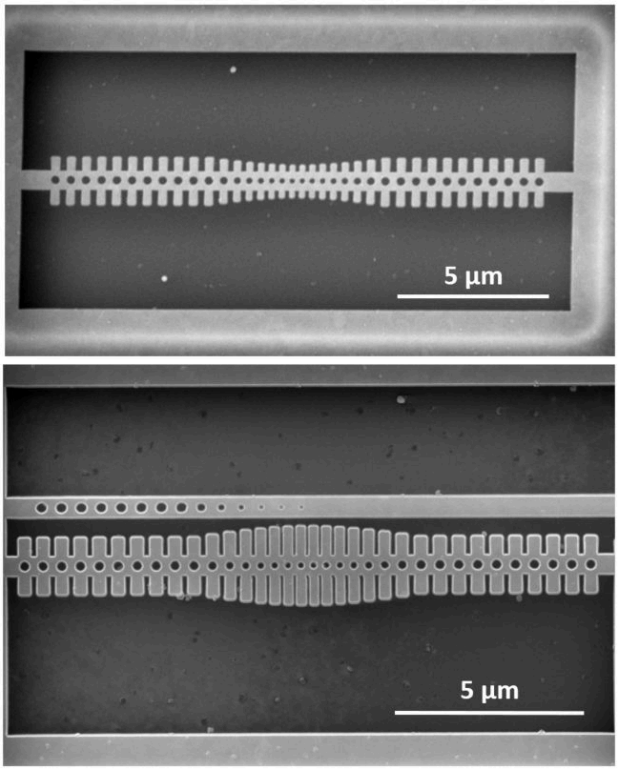

Fig. 2. SEM images of optomechanical nc-Si nanobeams. Top: device operating at a mechanical frequency of 4 GHz. Bottom: device operating at a mechanical frequency of 2 GHz and coupled to a waveguide.

gap states, which in turn affect the optical absorption, in particular the efficiency of one- versus two-photon absorption. However, the actual mid gap states densities are difficult to be determined. In some cases, the grain boundaries appear amorphous; in other cases, the grain boundaries exhibit 3-5 atomic planes.

Raman spectroscopy characterization has revealed that a reduction of the annealing temperature leads to a blueshift of the LO-TO Raman modes, accompanied by a significant broadening on the low-frequency side. Such spectral asymmetry arises from enhanced phonon confinement due to smaller grain sizes and larger grain boundary volumes [3].

The nc-Si nanobeams showed phonon lasing at MHz frequencies and, in some cases, at GHz frequencies. The typical behaviour of such devices is reported in Fig. 3.

The impact of different nc-Si fabrication parameters and of variability of critical dimensions in the performance of the devices is being assessed in both material properties and device performance.

IV. Conclusion

Further structural and optical analysis of nc-Si will shed light on the interplay among electrons, photons and phonons in the material, specifically regarding the role of nanocrystallites and grain boundaries in absorption and dissipation mechanisms at the nanoscale. This knowledge, combined with

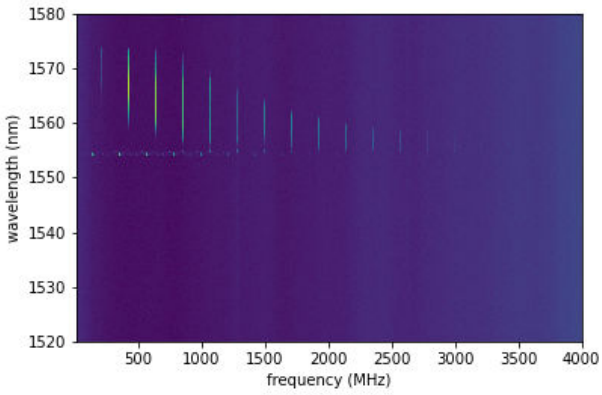

Fig. 3. Spectrogram of the light reflected from the cavity as the laser wavelength is swept from 1520 to 1580 nm at 15 mW. The bright features reveal regimes of coherent mechanical oscillations (phonon lasing) and self-pulsing in the intracavity fiels as the laser is tuned across the optical cavity resonance.

the comparison of the behaviours of devices fabricated from different nc-Si and with different deterministic fabrication variability parameters, will be crucial for a much improved understanding of losses, variability and device integration technology.

***Abstract*—Acoustic metamaterials enable tailored manipulation of sound waves, yet their extension to aeroacoustic environments remains challenging due to background flow effects. This work investigates spacetime curvature arising from non-uniform flows and spatially varying properties in phase-gradient metasurfaces, providing insight toward robust design of fully integrated aeroacoustic metamaterials.**

***Keywords* — metacontinua, metasurfaces, spacetime curvature, coordinate transformations**

I. Introduction

Metamaterials have revolutionised the concept of wave control, spreading across all branches of physics and engineering where manipulation of waves is desired. This rapid expansion has been enabled by the symmetries in the structure of the differential operator that governs wave propagation, which break down in the presence of a background flow. Indeed, the introduction of metamaterials in aeroacoustic environments requires, in principle, the redesign of the device, as it must account for the change in the mechanism of propagation of the perturbation. So far, the only way to do so is to embed the characteristics of the aerodynamic field directly in the metacontinua design and, thereby, tune the components derived through standard acoustic procedures [1]. The mathematical architecture allowing the manipulation of the material properties relies on the spacetime formalism, where the propagation of any scalar field can be described in a conservative form of the differential governing equation [2]. Therefore, moving in the *pseudo*-Riemannian manifold of the acoustic spacetime, it is possible to address the change in the mechanism of propagation due to convection with the generation of spacetime curvature [3]. Nonetheless, another source for deviating from flatness appears when the medium of propagation displays space-varying distributions of its mechanical properties, which is exactly what happens when metamaterials appear in the scene. This work analyses these aspects aiming to provide deeper insight into both effects toward the derivation of a more robust design for aeroacoustic metamaterials.

II. Methods

The methodology relies on the mathematical structure of the acoustic spacetime, where the notion of point is replaced by that of an *event* indicated by $\boldsymbol{\xi} = (c_0 t, x_1, x_2, x_3)$, and where the propagation of acoustic waves is governed by

$$\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\partial_\nu p\right) = 0, \tag{1}$$

being $\boldsymbol{\partial}$ the four-dimensional nabla operator, and where $g^{\mu\nu}$ are the components of the contravariant metric tensor that specify the mechanism of propagation, with g its reciprocal determinant. The shape of the metric tensor indicates the kind of propagation that we are observing. The possible scenarios could be: (i) a metric tensor with constant components, (ii) a metric tensor with event-dependent components. The case (i) results in a flat Minkowskian spacetime, whereas scenario (ii) might be associated with curved acoustic spacetime. Specifically, case (ii) can be addressed to the case of a propagation within a medium displaying non-uniform anisotropic properties or to the presence of a non-uniform background flow. However, the event-dependence of the $g^{\mu\nu}$ components is a necessary requirement but not sufficient for spacetime curvature.[4]. In fact, the local differential properties of the spacetime can be fully described by the Riemann tensor

$$R^\rho_{\sigma\mu\nu} = \partial_\mu\Gamma^\rho_{\nu\sigma} - \partial_\nu\Gamma^\rho_{\mu\sigma} + \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\sigma} - \Gamma^\rho_{\nu\lambda}\Gamma^\lambda_{\mu\sigma}, \tag{2}$$

which is a fourth-order tensor, whose interpretation is in general non-trivial. The Ricci tensor $R_{\sigma\mu} = R^\rho_{\sigma\mu\nu}$ and the Ricci scalar $R = g^{\sigma\mu}R_{\sigma\mu}$ are the first and second contraction of the Riemann tensor in Eq. (2), respectively, and can be used to have hints about the local spacetime geometry at the cost of losing some information. However, the Ricci scalar provides an overall description of the total amount of spacetime curvature that we might have, and a case where $R \neq 0$ represents the scenario in which we have some source of spacetime curvature in our domain. Specifically, anisotropic non-uniform media or non-uniform background flows generally lead to event-dependent metric components and may generate non-vanishing spacetime curvature. In such cases, the acoustic propagation path follows the geodesics of the effective metric, which may deviate from straight Euclidean paths. This aspect becomes relevant if one considers the propagation of the acoustic wave within a metamaterial: the possibility of achieving exotic wave manipulations derives from the definition of a suitable tailored spatial distribution of the material parameters. Therefore, an acoustic metamaterial can be described through an extended version of the continuum model, named *metacontinuum* [5], where the propagation of the acoustic perturbation is governed by

$$K\nabla\cdot\left(\boldsymbol{S}\boldsymbol{\rho}^{-1}\boldsymbol{S}\partial p\right) - \partial_{tt}p = 0, \tag{3}$$

where the desired distribution of parameters is embedded in the definition of an anisotropic stiffness, with an elasticity tensor provided by $\boldsymbol{C} = K\boldsymbol{S} \otimes \boldsymbol{S}$, and an anisotropic inertia $\boldsymbol{\rho}$. The key point in deriving aeroacoustic metacontinua designs is to recognise that Eq. (3) can be recast into the spacetime as Eq. (1), and, thanks to its conservative form, spacetime coordinate transformations can be used to tune the metacontinuum parameters from a static design to an aeroacoustically efficient one [1], as

$$\boldsymbol{g}_c = \boldsymbol{\Lambda}^{-1}\boldsymbol{g}\boldsymbol{\Lambda}^{-T}, \tag{4}$$

where $\boldsymbol{g}_c$ indicates the convected metric tensor obtained thanks to the spacetime mapping provided by $\boldsymbol{\Lambda}$. The Jacobian matrix in Eq. (4) enables the inclusion of the background flow characteristics directly into the metacontinuum design. Consequently, the approach for inducing convection in a region originally quiescent is limited solely by the capability of capturing the convective effects, and a transformation capable of encompassing general flow conditions is not known so far. As a consequence, deviations from the aeroacoustic benchmark will always appear, nevertheless, they could be reduced by combining together different spacetime mappings [6].

Results and Discussion

Due to the intrinsic analytical approximations of the methodology for deriving an aeroacoustic metacontinua design, efficient designs for practical aeronautical applications may be sensitive to variations of the operative conditions in which the device operates. For this reason, the present work investigates the spacetime curvature that can be generated by the presence of a metacontinuum with tailored distributions of the material properties, and by the presence of convection. A deeper understanding of spacetime curvature may provide a useful indicator for quantifying the benefit of deriving a spacetime-corrected design for each specific test case. The methodology will be assessed through its application to a phase-gradient metasurface whose design is defined to obtain extraordinary reflection. Specifically, the architecture of the metadevice will be replaced by the equivalent metafluid model with the spacetime adapted design obtained via Eq. (4). The analytical approach will ensure the computational cost saving and while enabling a direct assessment of the curvature-induced deviations from the aeroacoustic benchmark, thereby providing guidance for the development of more robust spacetime-corrected designs.

Acoustic Purcell effects in phase-transitioning nanodroplets

Chengzhi Shi[1,*]

[1]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, USA
*Corresponding author: czshi@umich.edu

Abstract— Microscale ultrasound devices are increasingly important for medical diagnostics and targeted therapies, yet achieving strong acoustic output at small scales remains challenging. Conventional strategies, including transducer arrays and MEMS components, often fail to satisfy the stringent requirements of compactness, flexibility, and power efficiency necessary for wearable applications. These challenges arise from fundamental trade-offs between miniaturization, acoustic intensity, and biological safety. We present a new strategy that leverages the acoustic Purcell effect, enabled through specially engineered perfluorocarbon nanodroplets (PFCnDs) designed to boost ultrasound emission. A theoretical framework for nanodroplet-enhanced Purcell effect is developed and experimentally confirmed through ultrasound emission measurements—the first demonstration of its kind. By tailoring the acoustic environment around the droplets, we achieve an acoustic Purcell factor normalized by droplet diameter (APF/D) of $1.6\times10^{5} \pm 2.6\times10^{2}$ m^{-1}, surpassing previous acoustic Purcell designs by two orders of magnitude. Furthermore, tunable droplet size and concentration allow precise control over Purcell-enhanced pressure radiation, mediated by the acoustic density of states. In B-mode imaging, PFCnDs operating in the Purcell-enhanced regime deliver a 42 ± 1.4 dB contrast gain relative to conventional ultrasound, arising from enhanced acoustic scattering. This work establishes a nanoscale acoustic Purcell framework for efficient ultrasound emission and marks a key advance toward integrating nanophononic design with high-contrast, ultrasound-based biomedical diagnostics and therapeutic platforms.

Generalization of exceptional point: high-dimensional coalescing non-Hermitian spaces

Guancong Ma

[1]Department of Physics, Hong Kong Baptist University, Kowloon Tong, Hong Kong, China
*Corresponding author: phgcma@hkbu.edu.hk

***Abstract*— We present the generalization of exceptional point, called "exceptional deficiency," characterized by the coalescence of two high-dimensional non-Hermitian linear spaces. At this condition, exceptional physics appears over a spectral continuum without fundamental limitations on bandwidths. The exceptional deficiency is experimentally realized using an active phononic crystal.**

***Keywords*—exceptional points, non-Hermitian skin effects, phononic crystals.**

Exceptional points (EPs) are spectral singularities in non-Hermitian systems, at which individual eigenvalues and eigenvectors become identical. The successful realization of EPs in diverse physical systems, such as photonics, acoustics, cold atoms, and superconducting circuits, has triggered tremendous interest in fundamental physics and inspired a vast array of novel applications. However, as the term "exceptional" suggests, EPs are usually isolated spectral points. Consequently, functionalities rooted in EPs face several inherent limitations, such as narrow bandwidth. Here, we present a generalization of the concept of EPs characterized by the coalescence of multi-dimensional Hilbert subspaces and overlapped spectra. This condition is denoted as "exceptional deficiency." When this happens, two Hilbert subspaces of identical but arbitrarily large dimensions exactly align, accompanied by the coincidence of their spectra. Consequently, the full Hilbert space is highly defective by "missing" half of its span. In the meantime, the spectrum is entirely composed of EPs. The condition of exceptional deficiency can be reached in a large variety of systems. Intriguingly, the exceptional deficiency can break the bulk-edge correspondence of non-Hermitian skin effects, which relates nontrivial point-gap topology to the existence of skin modes. As a consequence, we find that the exceptional deficiency underpins new non-Hermitian phenomena characterized by the synergy of skin effects and propagation.

The exceptional deficiency is experimentally realized using a non-Hermitian phononic lattice consisted of two unidirectionally coupled one-dimensional chains. The results also reveal new ways for flexible localization control [1].

On the Quest of a Boundary Integral Formulation for Aeroacoustics of Metacontinua in Curved Spacetime

Umberto Iemma[1,*] and Giada Colombo[1]

[1]Department of Civil, Computer Science and Aeronautical Technology Engineering, Roma Tre University, Italy
*Corresponding author: umberto.iemma@uniroma3.it

***Abstract*—Boundary Integral Equation (BIE) methods represent an indispensable tool in computational aeroacoustics and acoustic metamaterial design. They basically rely on the self-adjointness (*i.e.*, Hermitianity) of the linear differential operator governing the phenomenon, which is verified when the acoustic perturbation propagates ina medium at rest or moving as a uniform stream. However, when sound propagation occurs in the presence of a non–uniform background flow or within a metacontinuum with spatially varying mechanical properties, the Hermitianity of the differential operator is lost and a pure BIE cannot be derived. This contribution focuses on the conceptual and mathematical challenges associated with the identification of an effective, design–oriented strategy to derive an integral equation formulation valid on a curved spacetime. It is shown how the non-Hermitian nature of the generalised spacetime D'Alembertian prevents the construction of a pure boundary integral formulation, and possible strategies based on boundary–field formulations or tangent spacetime approximations are discussed, outlining a path towards a general integral method for curved spacetime acoustics easily integrable with the existing integral formulations for aeroacoustic analysis.**

***Keywords*— metacontinua, aeroacoustics, boundary integral equation method, curved spacetime**

I. Introduction

Green's functions constitute the cornerstone of integral equation methods in acoustics, enabling compact formulations for scattering, radiation and metamaterial design. For homogeneous media in static condition or moving as a uniform stream, closed-form fundamental solutions exist and allow the reduction of the governing equations to boundary-only formulations.

In aeroacoustic configurations, however, sound often propagates within complex aerodynamic flows. The situation is made even more complex when the propagation domain is occupied by a non-uniform medium, such as the case of engineered metacontinua. A direct consequence of this is that the performance of metadevices designed under quiescent assumptions decays dramatically. At the same time, the non–uniform convection and the gradients of the metacontinuum properties compromise the validity of the static Green's functions and, as a consequence, prevent or limit the applicability of the BIE widely adopted in aeroacoustics. Recent developments have shown that all these effects can be consistently interpreted within a spacetime framework, where both background flow and metamaterial properties act as geometrical distortions of the acoustic spacetime. Aim of this work is to explore approaches and strategies capable to recover, at least partially, the effectiveness of boundary integral methods by reducing the contribution of field integrals (computationally critical for large domains) or relaying on the approximation of the equations on the local tangent, Minkowskian space.

II. Methods

Introducing spacetime coordinates

$$\xi_\mu = (c_0 t, x_1, x_2, x_3), \tag{1}$$

the acoustic field can be written in covariant form as

$$\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}\, g^{\mu\nu}\partial_\nu\phi\right) = 0, \tag{2}$$

where $g^{\mu\nu}$ is an effective acoustic metric and $g = \det(g_{\mu\nu})$. For convective propagation, mixed space–time components of the metric encode the background velocity field, while anisotropic and inhomogeneous metacontinua modify the spatial part of the metric. Event–dependent variability of these quantities implies curvature of the associated acoustic spacetime.

In homogeneous isotropic media, the Green's function of the Helmholtz operator is available in closed form and forms the basis of classical boundary element methods. For anisotropic but homogeneous media, fundamental solutions can still be constructed explicitly, embedding anisotropy directly into the Green's function [3]. These anisotropic Green's functions, however, implicitly assume a flat spacetime, corresponding to a constant metric tensor. As a result, they fail to capture the effects of spatially varying flow fields or material parameters, which are responsible for acoustic spacetime curvature.

In curved acoustic spacetime, the Green's function would formally satisfy

$$\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}\, g^{\mu\nu}\partial_\nu G\right) = \delta(\xi - \xi^*). \tag{3}$$

Closed-form solutions are available only for highly symmetric metrics[4], not relevant for realistic aeroacoustic configurations. In any such a case, G does not satisfy anymore the reciprocity condition, $G(\xi, \xi^*) \neq G(\xi^*, \xi)$. As a consequence, the presence of curvature prevents the reduction of the governing equations to a pure boundary formulation. Indeed,

the lack of a Green's function adapted to curved acoustic spacetime explains the progressive degradation of classical integral formulations in aeroacoustic metacontinuum problems. Boundary-only representations become incomplete, and equivalent source terms associated with curvature must be retained. Volume contributions associated with metric variations cannot be eliminated, inducing major numerical inconveniences that make integral formulations no longer competitive with respect to the filed methods like finite–element or finite-difference methods.

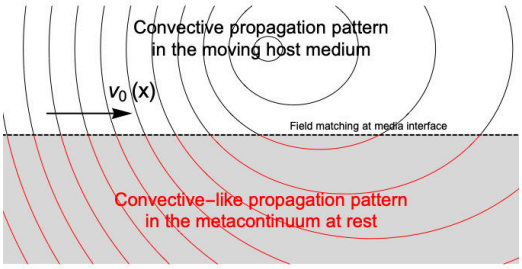

Fig. 1. A qualitative sketch of propagation patterns matching at the interface between a flowing medium and a *convective* metadevice.

III. Results and Discussion

In order to recover the potential of the integral formulations for this class of problems, two main directions appear viable: *i)* improve the numerical efficacy of boundary–field integral formulations, where volume terms are explicitly included, by enhancing the information retained in the boundary terms through the derivation of an appropriate Green's function capable to capture a general anisotropic behaviour, and, when applicable, by integration by parts of the volume terms; *ii)* explore the possibility of local approximations based on the projection of the non–Hermitian differential operator on the tangent (flat, *i.e.,* Minkowskian) spacetime. Aim of the present research is to face this challenge exploring both the approaches. In the present paper, we explore the structure of boundary–field integral equations derived from different forms of Eq. 2, rewritten by moving on the RHS all the terms inducing spacetime curvature, thus interpreting them as equivalent sources of a perturbation propagatimng on a flat equivalent spacetime. Starting from the assumption that the metric can be decomposed as $\boldsymbol{g} = \boldsymbol{g}_{\mathsf{F}} + \boldsymbol{g}_{\mathsf{C}}$, where $\boldsymbol{g}_{\mathsf{F}}$ represents the projection of $\boldsymbol{g}$ on the local tangent Minowskian spacetime, Eq. 2 can be rearranged as

$$\boldsymbol{\partial} \cdot \left(\boldsymbol{g}_{\mathsf{F}}^{-1} \boldsymbol{\partial} \varphi\right) = -\frac{1}{\sqrt{-g}} \boldsymbol{\partial} \cdot \left(\sqrt{-g}\, \boldsymbol{g}_{\mathsf{C}}^{-1} \boldsymbol{\partial} \varphi\right) - \frac{\boldsymbol{\partial}\sqrt{-g}}{\sqrt{-g}} \cdot \boldsymbol{g}_{\mathsf{F}}^{-1} \boldsymbol{\partial} \varphi, \tag{4}$$

where the spacetime–bending terms are treated as sources. Here, the operartor of Eq. 4 is reduced to the one of Stevenson's equation [3], for which a free–space Green's function exists. A similar procedure will be applied to the most general form of the convective wave equation governing the propagation within a medium in arbitrary motion. The fundamental underlying theory will be presented and discussed within the technology framework of aeronautical engineering. A preliminary numerical assessment of very simple benchmarks will be also presented.

Band-structure calculations of phononic crystals in the hard-scatterer limit

Arkadii Krokhin*, Dmitrii Shymkiv

Department of Physics,University of North Texas, USA
*Corresponding author: arkadii.krokhin@unt.edu

***Abstract*—It is well known that the hard-scatterer limit leads to the appearance of non-physical features in the band structure of phononic crystals when calculated numerically using the plane-wave expansion method. We show that these numerical difficulties arise from a mathematical singularity in the corresponding eigenvalue problem for sound wave.**

***Keywords*— plane wave expansion, singular matrix.**

The hard-scatterer limit is not a purely mathematical abstraction. A phononic crystal composed of metal scatterers in air provides a very close physical realization of this limit, since the ratio of acoustic impedances is $Z_{metal}/Z_{air} \sim 10^5$. As shown in Fig. 1, numerical calculations of the band structure in the limit of infinite scatterer density $\rho_{sc} \to \infty$, contain flat bands that are apparently non-physical. The number of these non-physical flat bands increases drastically with the number of plane waves. Here we show that the errors observed in numerical calculations of the phononic crystal band structure originate from a singularity in the underlying eigenvalue problem.

In the plane-wave basis, the wave equation for the pressure field in a phononic crystal can be written as

$$\sum_{\mathbf{G}'} \rho^{-1}(\mathbf{G}-\mathbf{G}')(\mathbf{k}+\mathbf{G})\cdot(\mathbf{k}+\mathbf{G}')p_{\mathbf{k}}(\mathbf{G}') = \omega^2 \sum_{\mathbf{G}'} \lambda^{-1}(\mathbf{G}-\mathbf{G}')p_{\mathbf{k}}(\mathbf{G}'), \quad (1)$$

where $\rho^{-1}(\mathbf{G})$ and $\lambda^{-1}(\mathbf{G})$ are the Fourier coefficients of the inverse density and inverse elastic modulus respectively. For simplicity we consider a phononic crystal composed of fluids. The Fourier coefficients $\rho^{-1}(\mathbf{G})$ (and $\lambda^{-1}(\mathbf{G})$) are expressed through the structure factor $F(\mathbf{G}) = V_c^{-1}\int_{V_{sc}} e^{-i\mathbf{G}\cdot\mathbf{r}}d\mathbf{r}$ yielding

$$\rho^{-1}(\mathbf{G}) = (\rho_{sc}^{-1}-\rho_b^{-1})F(\mathbf{G}) \underset{\rho_{sc}\to\infty}{\to} -\frac{1}{\rho_b}F(\mathbf{G}), \quad (2)$$

$$\rho^{-1}(0) = \frac{f}{\rho_{sc}} + \frac{1-f}{\rho_b} \underset{\rho_{sc}\to\infty}{\to} \frac{1-f}{\rho_b} = \frac{1-F(0)}{\rho_b}, \quad (3)$$

where ρ_b is the density of the background fluid and f is the filling fraction of the scatterers. Equations (2) and (3) can be rewritten in matrix form as

$$\rho^{-1}(\mathbf{G}-\mathbf{G}') = \frac{1}{\rho_b}\left[\hat{I} - F(\mathbf{G}-\mathbf{G}')\right], \quad (4)$$

where $\hat{I}$ denotes the identity matrix of infinite order.

The structure factor $F(\mathbf{G})$ can be regarded as the Fourier coefficient of a piecewise function $F(\mathbf{r})$, which equals 1 inside the scatterers and 0 elsewhere within the unit cell. It is therefore clear that $F(\mathbf{r}) = F^2(\mathbf{r}) = F^3(\mathbf{r}) = \ldots$. When rewritten in Fourier space, this property implies $\det F(\mathbf{G}-\mathbf{G}') = 1$. Moreover, all eigenvalues of the matrix $F_{\mathbf{G}\mathbf{G}'}$ are equal to 1, i.e., it is a *unipotent* matrix. Notably, this is a purely geometrical property of a periodic lattice and is independent of the material properties of its constituents.

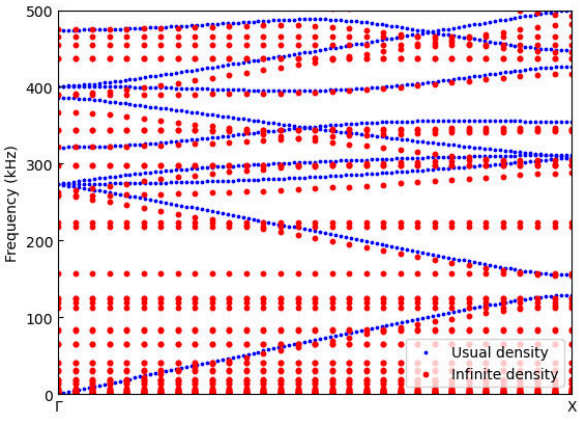

Fig. 1. Band structure of a phononic crystal of cylinders of infinite density in water.

It follows from the properties of a unipotent matrix that $\det\left[\hat{I} - F(\mathbf{G}-\mathbf{G}')\right] = 0$. Applying this result to Eq. (4), we find that $\det\rho^{-1}(\mathbf{G}-\mathbf{G}') = 0$, implying that the eigenvalue problem in Eq. (1) involves a non-invertible matrix. It is straightforward to show that the kernel matrix $\rho^{-1}(\mathbf{G}-\mathbf{G}')(\mathbf{k}+\mathbf{G})\cdot(\mathbf{k}+\mathbf{G}')$ is also singular. In numerical implementations, Eq. (1) is solved using a finite number of plane waves. In this case, the determinant of $\rho^{-1}(\mathbf{G}-\mathbf{G}')$ remains finite but small. Although the matrix is formally invertible, it becomes ill-conditioned, meaning that its output is highly sensitive to small rounding errors in the input. This sensitivity leads to numerical instability. In conclusion, the appearance of numerous spurious roots in the calculated band structure of a phononic crystal with hard scatterers can be traced to the singularity of the matrix $\rho^{-1}(\mathbf{G}-\mathbf{G}')$.

I. Introduction

The concept of topological insulator originally established in the quantum materials physics has been extended to various field of physics. It turns out that the concept is closely related to the wave nature of the phenomena in question, and not restricted in the quantum physics. In acoustics, even in the classical non-quantum regime, robust topologically protected robust wave propagation has been observed in topological phononic crystal waveguide structures[1].

In this paper, we study the acoustic wave propagation in two-dimensional topological phononic crystal, including topological waveguide and cavity, using our developing time-resolved two-dimensional optical imaging technique.

II. Methods

The phononic crystal structure is formed on a thin GaAs slab of thickness 1.0 μm[2] . The crystal itself is a hexagonal array of air holes. The unit cell of the crystal has the three-fold symmetry consisting of a center large circular hole with three lobe holes as shown in Fig. 1 (a). By rotating the hole structure clockwise (CW) or counter-clockwise (CCW) with respect to the axis perpendicular to the slab at the center of the hole by a small angle ($\alpha = \pm 5°$), the degeneracy at the Dirac cones at K and K' points in two-dimensional **k**-space is solved to form a phononic band gap, and the topologically non-trivial modes, so called valley topological modes, appear. At the interface between the CW and CCW rotated region, a localized interface mode (waveguide mode) appears within the opened gap by the bulk-edge correspondence. The appeared interface mode is supposed to be topologically protected and to show robust propagation of the acoustic waves. Figure 1 (b) shows an example of the structure we study. The black part consists of the CCW rotated unit cells, whereas the red part consists of the CW rotated unit cells. The whole structure has the plus shaped interfaces between CW and CCW regions.

The inter-digital transducer (IDT) is formed outside of the phononic crystal region. By applying radio frequency voltage to the IDT electrodes, the Lamb-like acoustic waves in the frequency range approximately from 475 MHz to 505 MHz are introduced into the phononic crystal region. The resulted acoustic field in the phononic crystal region is monitored by the laser pulses with picosecond temporal width using an optical interferometer which is sensitive to the surface normal displacement in picometer regime[3], [4] The typical measured area is around 100×100 μm^2.

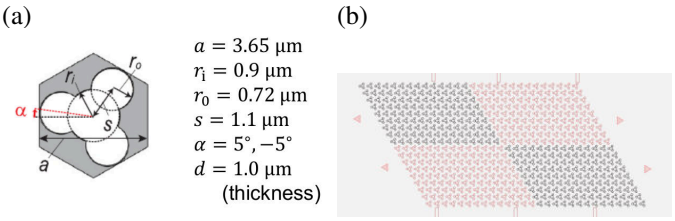

Fig. 1. (a) Unit cell geometry of the topological phononic crystal. (b) Schematic diagram of the entire structure of the phononic crystal with topological waveguide. Black part:$\alpha = -5°$ (CCW rotation), red part: $\alpha = +5°$ (CW rotation).

We also image the acoustic field with the pulse light excitation. Though the excitation efficiency is lower than above mentioned IDT excitation, the pulse excitation has an advantage of the broad band excitation (typically up to or beyond 1 GHz) comparing to the limited accessible range pre-determined by the IDT period[5].

III. Results and Discussion

Figure 2 shows an example of the measurement result, a snapshot image of the acoustic field excited by the IDT at 481.0 MHz[6]. The plane acoustic wave is incident to the phononic crystal region from the left hand side. The frequency 481.0 MHz is in the band gap of the phononic crystal, and no bulk waves penetrate into the phononic crystal. However, a localized wave propagating is clearly observed at the interface between the regions of $\alpha = \pm 5°$. It also shows a sharp turn at the corner (actuary the cross) with high efficiency > 90 %. It also shows the horizontally propagating localized wave is inhibited to to proceed across the cross because of the reversed configuration of the CW and CCW region in that part. This is another striking feature of the topologically protected mode.

IV. Conclusion

The time-resolved two-dimensional optical imaging of acoustic waves propagating on the topological phononic crystal is achieved. The excitation is done both electronically

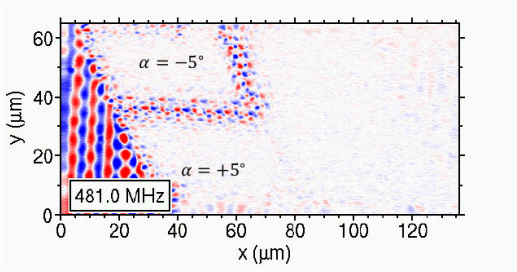

Fig. 2. A snapshot of the acoustic field on the phononic crystal waveguide. The plane wave at 481.0 MHz is incident from the left hand side.

at single frequency and optically in broad frequency band. The result shows the robust wave-guiding protected by the topological nature of the structure clearly. The method would pave a road to getting deeper understandings of the physics of acoustic waves in topological structures.

***Abstract*— We report optical pump probe measurements of surface acoustic waves in patterned silicon. Ordered hole arrays support long lived symmetry protected resonances, while disordered structures exhibit broadband trapping of acoustic waves in the gigahertz range. These results demonstrate complementary mechanisms for controlling phonon confinement using order and disorder.**

***Keywords*— phononic crystals, surface acoustic waves, disorder, bound states in the continuum, ultrafast acoustics.**

I. INTRODUCTION

Controlling elastic waves at the microscale is a central objective in phononics and acoustic metamaterials. Periodic structures, or phononic crystals, enable band engineering and wave confinement through Bragg scattering, while disordered systems can induce localization via multiple scattering. In parallel, bound states in the continuum (BICs), originally introduced in quantum mechanics, have recently attracted attention in acoustics as a route to achieve long-lived resonances embedded within radiative continua.

Surface acoustic waves (SAWs), and in particular Rayleigh modes in Silicon, provide an ideal platform to explore these phenomena in the GHz regime. However, experimental access to both ordered and disordered regimes within the same framework remains limited. Here we investigate the generation and confinement of SAWs in patterned silicon surfaces combining periodic and disordered hole arrays.

II. METHODS

The samples consist of arrays of circular holes with diameter 2 µm and lattice parameter 5 µm fabricated on silicon substrates. Two types of structures are studied: ordered periodic lattices and disordered arrays with controlled positional randomness.

Surface acoustic waves are generated via thermoelastic excitation using a pulsed optical pump. The resulting dynamics are probed using a time-resolved optical pump–probe setup with beam-deflection detection, providing sensitivity to local surface slope and displacement.

The temporal signals are analyzed in both time and frequency domains to extract spectral content in the 0.5–3 GHz range. The experimental configuration allows direct comparison between ordered and disordered geometries under identical excitation and detection conditions.

III. RESULTS AND DISCUSSION

In periodic structures, we observe narrow spectral features corresponding to long-lived acoustic modes. These resonances are consistent with symmetry-protected quasi-bound states in the continuum (quasi-BICs), where radiation losses are suppressed due to symmetry mismatch with the far field. The measured lifetimes and spectral selectivity indicate strong confinement despite the absence of a full bandgap.

In contrast, disordered structures exhibit broadband acoustic trapping over the 0.5–3 GHz range. The lack of translational symmetry leads to multiple scattering and spatial confinement of Rayleigh waves, resulting in extended dwell times without sharp spectral selection. The observed behavior is consistent with disorder-induced localization and does not require fine tuning of structural parameters.

These results demonstrate that both regimes can be exploited to tailor acoustic confinement depending on the desired spectral response.

***Abstract*— An inverse design framework of acoustic metasurfaces for color holographic imaging is established based on the optimization method. The frequency-selective elements with the required phase-shift and transmittance are customized. The layout of the elements is optimized to achieve color holographic imaging. The design is verified through numerical simulations and experiments.**

***Keywords*— metasurface, acoustic holography, color imaging, inverse design.**

I. Introduction

An acoustic metasurface [1], a kind of two-dimensional metamaterials with microstructures of subwavelength, provides a platform for holographic imaging [1]. Although several published literatures focused on this topic [2], no color imaging has been reported. In this paper, we develop a customized inverse design of acoustic metasurfaces for color holographic imaging.

II. Methods

As shown in Fig. 1, a targeted color picture is first decomposed into a superposition of monochrome targeted imagines of three primary colors (red, green and blue) corresponding to three frequencies. Then an acoustic metasurface which can modulate the waves of three frequencies independently is designed to reconstruct three monochrome holographic imagines of three colors. Finally, the color imagine can be obtained by superimpose the three monochrome imagines. The mapping relationship from the metasurface to the holographic plane are established by using Huygens-Fresnel's principle. We obtain the distributions of phase and amplitude on the metasurface for the three frequencies. An optimization method is proposed to customize 80 types of elements with phase-shifts of $2n\pi/8$ (n=0~7) and transmission coefficients of $m/10$ (m=1~10) for each frequency. It is noted that elements are frequency-selective. That is to say, each element can transmit the wave of one frequency but block the waves of the other two frequencies. The layout of the elements with different phase shifts and transmittances is optimized to achieve holographic image.

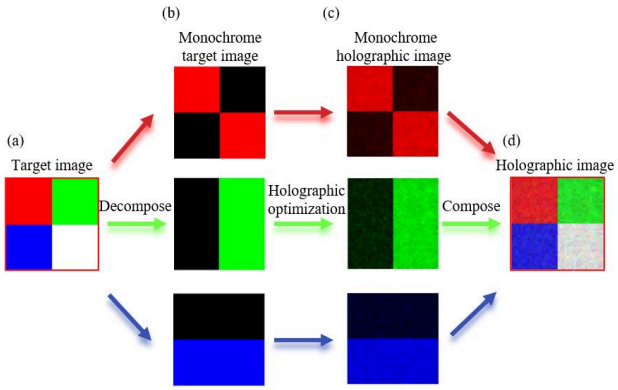

Fig. 1 Color holographic imaging.

III. Results and Discussion

As an example, the metasurface is designed for color holographic imaging of the eye part of the oil painting "Woman with a Hat and Fur Collar". Numerical simulation and experimental measurement are conducted and show agreement.

IV. Conclusion

Both numerical and experimental results show the validity of the proposed design methodology.

Odd active solids

Anton Souslov[1,*],

*Corresponding author: as3546@cam.ac.uk

***Abstract*—This work focuses on novel phenomena and design principles for active materials with so-called odd elastic moduli, which are composed of non-reciprocal springs. Our results point to the design of novel soft machines at the macroscale, and guide the miniaturization of non-reciprocal metamaterials to the colloidal scale.**

I. Introduction

Active solids consume energy to allow for actuation and shape change not possible in equilibrium. As a consequence, they exhibit anomalous elasticity due to their far-from-equilibrium nature. We discover anomalies in the continuum description of non-reciprocal odd active solids, a ubiquitous class of active materials.

II. Results and Discussion

In our work on *more is less* [1], we find that as microscopic activity increases, macroscale active response can vanish below an active percolation transition. This work considers how both periodic and disordered structures exhibit this transition and discuss its microscopic origins and dynamical implications.

Another example of recent developments in this field is the formation and coarsening of dynamical patterns when active solids undergo instabilities [2]. These patterns arise in large-scale, inertial systems, and can be understood as a chiral and inertial version of so-called Type-II instabilities of pattern forming systems. Similarly to other Type-II instabilities, these patterns coarsen to system size, but uniquely in these systems, inertia, chirality, and non-linearity conspire and result in unique coarsening dynamics and steady-state phenomena associated with these solids.

III. Conclusion

Our results unveil surprising facets of active matter, offering new principles for engineering materials and locomotion far from equilibrium [3], [4].

***Abstract*— We investigate topological properties of phononic waveguide interfaces, demonstrating robust propagation with negligible backscattering at gigahertz (GHz) frequencies. Forward and backward wavevector components are distinguished using Spatial Fourier transform thus, enabling the evaluation of backscattering and verification of the robustness of the excited topological mode.**

***Keywords*— topological, gigahertz, phononic crystals.**

I. Introduction

Topological waveguides have recently emerged as a powerful platform for controlling elastic waves due to their unique properties like unidirectionality, robustness, backscattering-free propagation in the presence of structural defects [1-3] thus, making them attractive for device applications [3-5]. With the ongoing device miniaturization and the push toward higher operating frequencies, the GHz regime has become increasingly important [5, 6].

II. Design of the Topological Waveguide

Motivated by this, we propose phononic topological waveguides based on a hypersonic phononic crystal structure consisting of patterned plates and exhibiting Dirac gaps ~ 13-14 GHz. The unit-cell of the phononic valley Hall crystal (PVHC) comprises two rounded triangles made of silicon (Fig.1(a)). For $\Delta r = 0$, a degeneracy exists at $f \sim 13.3$ GHz (Fig. 1(b), left), which is lifted when $r_1 \neq r_2$ as shown for Δr=0.04a in Fig. 1(b), right. The nontrivial topology of the PVHC is confirmed by calculating the Berry curvature and valley Chern numbers. Then, the waveguide is constructed by using two PVHCs of distinct topological nature: PVHC I (Δr=0.04a) and PVHC II (Δr= -0.04a). The supercell for the bridge big-big (BB) type waveguide is shown in the inset of Fig. 1(c).

III. Results and Discussion

The dispersion diagram for the bridge BB interface (Fig. 1(c)) reveals the presence of topological edge modes within the band gap. To assess the robustness of these modes, transmission is analyzed through a linear and a Z-path waveguide (Fig. 1(d)). For this, a point source is introduced near the input and the transmission is monitored along the waveguide path. The displacement field distributions (Fig. 1(f) and 1(g)), displays stronger confinement of field at the interface which is indicative of edge mode propagation.

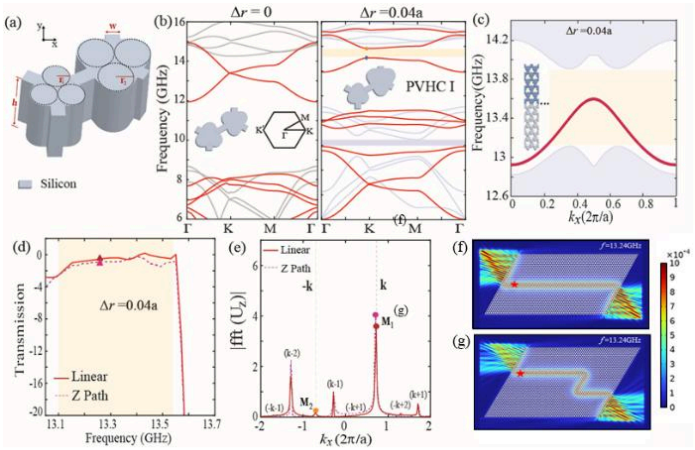

Fig. 1 (a) Unit cell for PVHC (a=381 nm, r_1=0.11a and r_2 = 0.15a). (b) Dispersion for Δr = 0, Δr = 0.04a. (c) Dispersion for Bridge BB interface (inset: Supercell). (d) Transmission for linear and Z-path waveguide. (e) Spatial Fourier spectra for linear (solid curves) and Z waveguide path (dashed curves) at f = 13.24 GHz for Δr =0.04a. (f) Comparison of forward and backward propagating wavevector magnitudes for a band of frequencies within the topological bandgap. Displacement field maps for (g) Linear and (h) Z-path waveguide. Red stars mark the position of the source.

Further insights into robustness are obtained through spatial Fourier transform (SFT) analysis (Fig. 1(e)). The Fourier spectra (Fig 1(e)) exhibits a dominant forward peak (k) along with negligible backward component (-k) for both waveguide paths confirming robust transport of the edge modes. This SFT analysis is extended across frequencies within the topological bandgap and the forward and backward magnitudes are compared. For an asymmetry of $\Delta r \approx 0.04$a, a bandwidth ~0.3 GHz of robust transport with minimal backscattering is observed. Additional studies are performed for different cases

of asymmetry as well as waveguide interface configurations. The results are significant for the design of low-loss GHz phononic device applications.

IV. Conclusion

We demonstrate robust phonon propagation with negligible backscattering using phononic topological waveguides at GHz frequencies. An asymmetry of $\Delta r \approx 0.04a$ yields a ~0.3 GHz bandwidth of robust transport with minimal backscattering. Our findings offer valuable insights for designing low-loss phononic devices at GHz frequencies.

***Abstract*— We experimentally investigate a MEMS-based topological elastic wave coupler using the quantum valley Hall effect. By utilizing frequency-dependent wave localization at bridge boundaries, we achieve continuously tunable transmission coefficients within a bandgap. Furthermore, we successfully demonstrate topologically protected digital data transfer using frequency shift keying modulation within this coupler.**

***Keywords*— phononic topological insulators, wave coupler, microelectromechanical systems.**

I. Introduction

Topological insulators have significantly advanced classical wave systems by enabling unique phenomena such as robust and unidirectional wave propagation along protected interfaces [1]. These characteristics are highly promising for the development of high-efficient and robust integrated circuits across various domains, including optics, electronics, and acoustics. Active tunability in topological circuit elements such as wave couplers is significant to achieve multifunctional circuit systems. However, the topological protection, which has been considered as a unique advantage of topological wave systems, has prevented us from continuously and actively tuning the wave state at topological interface modes by external stimulus in a single structure.

In this work, we experimentally demonstrate a microelectromechanical system (MEMS)-based continuously tunable topological wave coupler utilizing the quantum valley Hall effect (QVHE). By designing the coupler consisting of two adjacent bridge boundaries with frequency-dependent wave localization, we achieve continuously tunable transmission coefficients from a single input port to two separate output ports within a single bulk bandgap. Furthermore, we demonstrate topologically protected digital signal transfer using a frequency shift keying (FSK) in the frequency dependent coupler. In our demonstration, the topological wave coupler works as a signal receiver, filter, and demodulator. The results show a data-transfer capability close to the theoretical channel capacity limit, paving the way for robust and highly efficient topological applications with high-functionality such as information communication and signal processing systems.

II. Methods

The study comprehensively implemented numerical simulations, microfabrication, and experimental evaluation of the topological MEMS coupler. Numerical models consisting of single crystal silicon structure were designed by using COMSOL Multiphysics 6.2 to follow QVH scheme. Dispersion diagrams were calculated for unit cells and supercells to identify the topological interface modes within a bandgap ranging from 305 kHz to 375 kHz.

The devices were fabricated on a silicon-on-insulator (SOI) substrate using electron beam lithography and reactive ion etching with the Bosch process. The resulting 23×23-unit cell structure features two adjacent topological waveguides with bridge boundary as shown in Fig. 1. To characterize the wave propagation, mechanical vibrations were electrostatically excited using a driving electrode in a high-vacuum chamber (2.0×10^{-5} Pa) to minimize viscosity damping. The out-of-plane displacement profiles were measured using a laser Doppler vibrometer. The detailed fabrication process and measurement setup are shown in our previous reports [4-6].

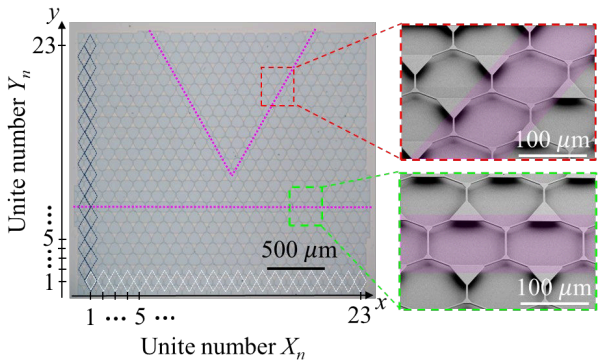

Figure 1: Top-view of the MEMS-based frequency-dependent topological wave coupler. The magenta lines represent the topological waveguides. SEM images in the right-upper and -lower panels show the enlarged views of the parts of the waveguides.

For the digital communication demonstration, binary FSK

was employed with carrier frequencies $f_1 = 315$ kHz and $f_2 = 360$ kHz. The output kinetic energy at each port was evaluated to determine the bit error rate (BER) and channel capacity, following Shannon's theorem to quantify the maximum mutual information of the topological channel.

III. Results and Discussion

Figures 2(a) and 2(b) show the experimental kinetic energy maps on the topological coupler for $f_1 = 315$ kHz and $f_2 = 360$ kHz. For the lower frequency, the elastic wave strongly localized on the V-shaped topological waveguide resulting in that the elastic wave passes through from port 1 to port 2 without coupling with the straight topological waveguide. On the other hand, when the driving frequency is high, we see the wave propagation from port 1 to port 3 by coupling with the V-shaped and straight waveguides. The coupling between the two waveguides is attributed to the frequency-dependent localization of the topological edge mode at the bridge boundaries, which enables us to continuously tune the coupling strength between them without breaking topological protection. Indeed, Fig. 2(c) shows the frequency spectrum of the output energy at ports 2 (red circles) and 3 (blue triangles) relative to the energy at port 1. As the frequency increases, the output energy at ports 2 and 3 continuously decreases and increases, respectively.

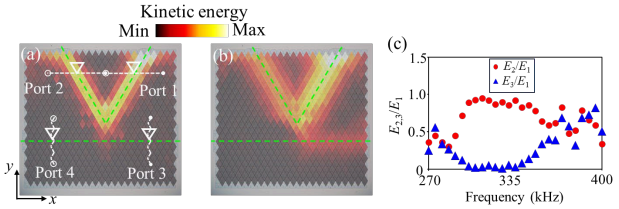

Figure 2: Two-dimensional kinetic energy maps in the topological wave coupler for (a) low and (b) high frequency. (c) Experimental frequency spectrum of the output energy at ports 2 and 3 relative to that of port 1.

Furthermore, we demonstrate digital information transfer using FSK. By assigning two frequencies ($f_1 = 315$ kHz and $f_2 = 360$ kHz) to binary states, we successfully transmitted digital signals through the coupler. Figure 3 shows the frequency response of the input signal and output kinetic energy at ports 2 and 3. The output energy at each port follows the frequency changes of input signal, indicating that the frequency-modulated digital signal is demodulated as a signal amplitude. These results indicate that the proposed coupler not only provides tunable wave routing but also serves as a robust platform for high-integrity topological communication.

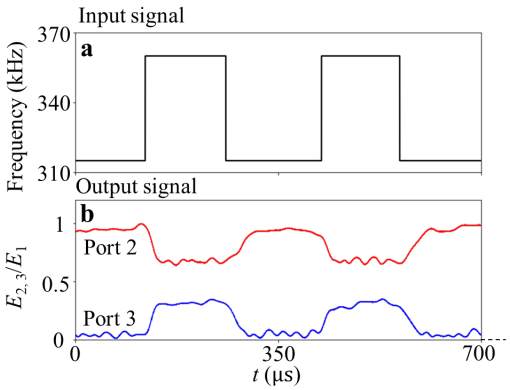

Figure 3: (a) Frequency of the input signal from port 1. (b) Output signals at ports 2 and 3. In the coupler, the frequency-modulated signal is demodulated to amplitude of mechanical vibration.

IV. Conclusion

We experimentally demonstrated a MEMS-based topological coupler with continuously tunable transmission coefficients based on the quantum valley Hall effect. By utilizing frequency-dependent wave localization at bridge boundaries, the coupler achieves tunable wave splitting within a single bandgap. Furthermore, we successfully implemented digital data transfer using frequency shift keying, achieving a channel capacity close to the theoretical limit. These results provide a robust platform for integrated topological circuits, paving the way for advanced signal processing and secure communication.

Helmholtz Resonator-Induced All-Angle Self-Collimation in Square-Lattice Sonic Crystals

David Ramirez Solana, Muhammad Gulzari*

[1]School of Civil Engineering, University College Dublin, Ireland
*Corresponding author: muhammad.gulzari@ucd.ie

***Abstract*— Over the past three decades, phononic crystals and acoustic metamaterials have revolutionized the control of acoustic waves, enabling unprecedented sound manipulation through engineered structural periodicity and local resonances. In this work, we demonstrate that Helmholtz resonators (HRs) embedded within square-lattice sonic crystals (SCs) can induce all-angle self-collimation (AASC) of acoustic waves over broad frequency ranges—a phenomenon previously achievable only in rectangular lattices or with elliptical scatterers. Using finite element simulations and experiment, we investigate two types of locally resonant sonic crystals (LRSCs) incorporating HR-based scatterers with distinct resonant frequencies: one with a resonance in the wavelength regime (termed LRSC-Type A) and another with a lower local resonance frequency (LRSC-Type B). The LRSC-Type A configuration exhibits wideband AASC within the third band, covering 66.5% of the bandwidth (520 Hz). In contrast, LRSC-Type B demonstrates frequency-sensitive super-collimation (FSSC) and AASC in the fourth band, with a bandwidth of 22.86% (190 Hz). Frequency response analyses of finite supercell arrays confirm robust collimation performance for incident angles up to 85°. These findings underscore the unique capacity of Helmholtz resonators to enable AASC in symmetric lattices, opening new possibilities for directional sound control, low-loss acoustic waveguides, non-diffractive beam shaping, and high-resolution acoustic imaging systems.**

***Keywords*— All-Angle Self-Collimation, Acoustic metamaterials, Sonic crystals, Helmholtz resonators**

I. Introduction

Since Helmholtz first discovered the resonance phenomena in resonators and proposed an equation to describe it over 160 years ago [1], Helmholtz Resonators (HRs) have become a cornerstone in acoustic wave control [2]. They have been widely used for sound absorption [3], reflection [4], and focusing phenomena [5], [6]. However, their potential for collimating acoustic waves has remained almost unexplored, despite the extensive study of periodic HR arrangements, especially within phononic crystals [5], [7], [8]. In the broader context of periodic acoustic materials, phononic crystals (PnCs) and their air-based counterparts, Sonic Crystals (SCs) [9], have emerged as versatile platforms for controlling sound propagation. These structures, characterized by periodic arrangements of high-contrast scatterers in a host medium, exhibit Bragg bandgaps (Bragg BGs) arising from destructive interference phenomena [10], [11]. For more information, read [12].

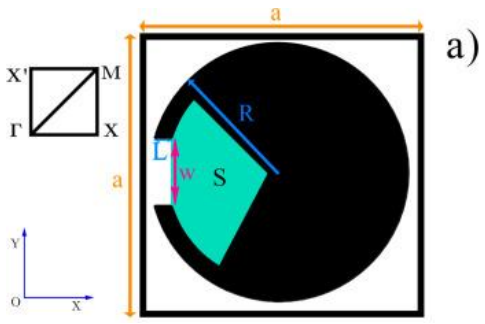
II. Methods

We consider a two-dimensional SC composed of a periodic square-lattice arrangement of scatterers, each embedded with a HR. To analyse the acoustic wave propagation, we examine the unit cell depicted in Fig. 1a, which consists of a scatterer with an outer radiussR and a single aperture forming the HR. Periodic boundary conditions are applied along the X- and Y-directions to model an infinite periodic structure and to compute its dispersion characteristics. The lattice constant is denoted by a, and the wavevector is swept along the boundary of the irreducible Brillouin zone (BZ) in reciprocal space [13].

The resonator within each scatterer is defined by three geometric parameters: the neck length L_n (corresponding to the wall thickness, i.e., the difference between the outer and inner radii), the neck width w_n, and the inner surface area of the cavity S_c. The fundamental resonance frequency of the HR is given by [1]:

$$f_{HR} = \frac{c}{2\pi}\sqrt{\frac{\omega}{L_{eff}S}}$$

where $L_{\text{eff}} = l_n + \delta l_n$ is the effective length of the neck, and $\delta l_n = \alpha w_n$ represents the end correction. The factor α accounts for the abrupt change in cross-section at the neck–cavity interface and typically ranges between 1.3 and 1.7 for circular geometries [14]. In our two-dimensional model, however, α is found to be 2.73, which deviates from the conventional range due to the planar nature of the simulation domain.



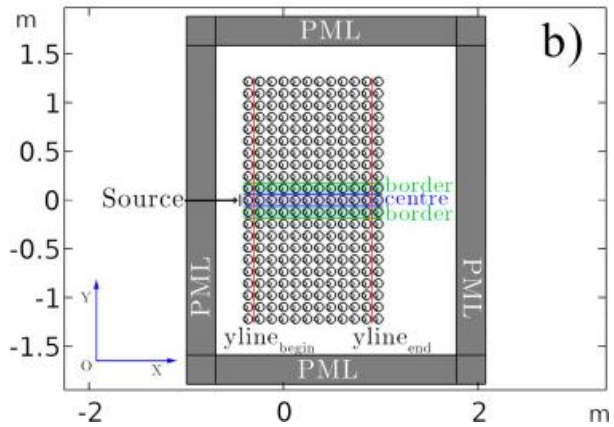


Fig. 1 (a) (a) Diagram of a unit cell comprising a cylindrical scatterer embedded with a HR, illustrating the wave propagation directions along the X and Y axes of the first Brillouin zone. Relevant geometric parameters—external radius R, neck length L, mouth width w, and cavity surface area S—are indicated. (b) Finite SC supercell array employed in numerical simulations. The blue central row marks the location where a line source, with a length equal to the lattice constant a, emits the acoustic wave. Green rows denote the lateral border regions used to evaluate the acoustic pressure relative to the collimation zone. Dashed lines P_1 (near the first column) and P_2 (near the last column) indicate the positions where the total acoustic pressure is monitored along the propagation axis. Perfectly matched layers (PMLs) of thickness 0.20 m are applied on all boundaries surrounding the LRSC to absorb outgoing waves and minimize reflections at the edges of the computational domain. This model is employed to validate all-angle self-collimation (AASC) phenomena under various excitation angles.

III. Results and Discussion

This section analyzes the band diagrams and EFCs obtained from the infinitely periodic unit cell structure of the LRSC. The vertical flat lines in the EFCs across the entire BZ correspond to eigenfrequencies that exhibit AASC. In Figs. 2a and 2b, the purple rectangles indicate the AASC frequency ranges. According to the literature, even though some frequencies in the upper part of the positive EFCs exhibit curved regions, they still support AASC [15-16]. These minor curvatures represent propagation slightly tilted toward the horizontal axis (ΓX), inducing focusing effects that help suppress wave diffraction. Furthermore, as previously reported by Rumpf et al. [63] and as will be discussed in detail in Section "*All-angle Self-Collimation* and *Frequency Sensitive Super-Collimation*", the flattest EFC region does not always yield optimal collimation.

Figs. 2-3 summarizes the EFC zones exhibiting self-collimation at specific angles (pink: LASC) and over full angular ranges (purple: AASC) for the 3rd and 4th bands of the proposed LRSCs: scatterers with $f_{HR} > f_{Bragg}$ and $f_{HR} < f_{Bragg}$. The $f_{HR} > f_{Bragg}$ case exhibits AASC in a narrow frequency region close to the origin of the BZ, while the $f_{HR} < f_{Bragg}$ case exhibits AASC over a broadband frequency region. The characteristics of AASC are analyzed by examining the shape of EFCs near the BZ origin $(0, 0)$ and as they extend toward the edge at $X(\pi/a, 0)$.

Since LASC is not the primary focus of this study, the LASC observed in the 4th band of the $f_{HR} > f_{Bragg}$ case (see Fig. 2d)—a small region near the BZ origin—will not be discussed further.

The following subsections examine two AASC cases in detail: first, a narrower yet still substantial frequency range in the $f_{HR} > f_{Bragg}$ configuration, demonstrating both AASC and FSSC phenomena; and second, the exceptionally broadband AASC observed in the $f_{HR} < f_{Bragg}$ case.

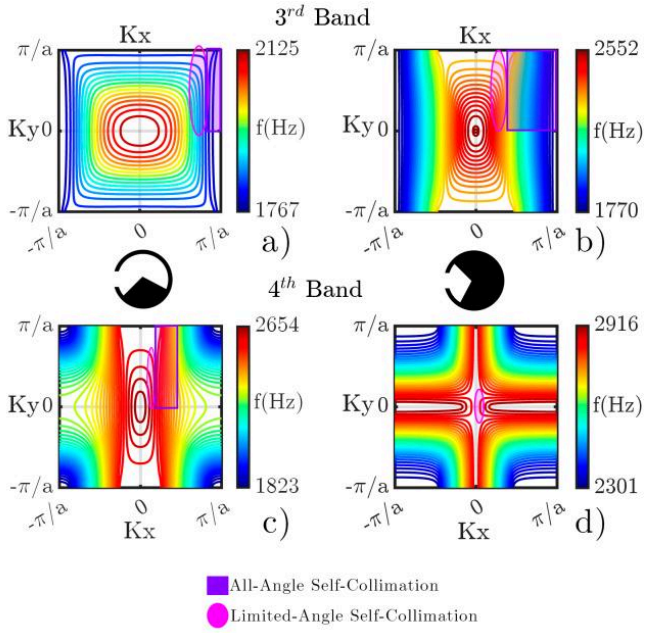

Fig. 2: Equi-frequency contours (EFCs) for the third and fourth bands of locally resonant sonic crystals (LRSCs) with Helmholtz resonator Type I ($f_{HR} > f_{Bragg}$) and Type II ($f_{HR} < f_{Bragg}$). Purple rectangles indicate all-angle self-collimation (AASC) frequency regions, while pink highlights limited-angle self-collimation (LASC) ranges. The shape and position of the EFCs are visualized, emphasizing the emergence of AASC in the Type II (broadband, third band) and Type I (narrowband, fourth band) configurations. These contours illustrate the rationale for selecting operating regimes for robust acoustic wave collimation and summarize the key findings on the band dependence of locally resonant (LR)-induced phenomena.

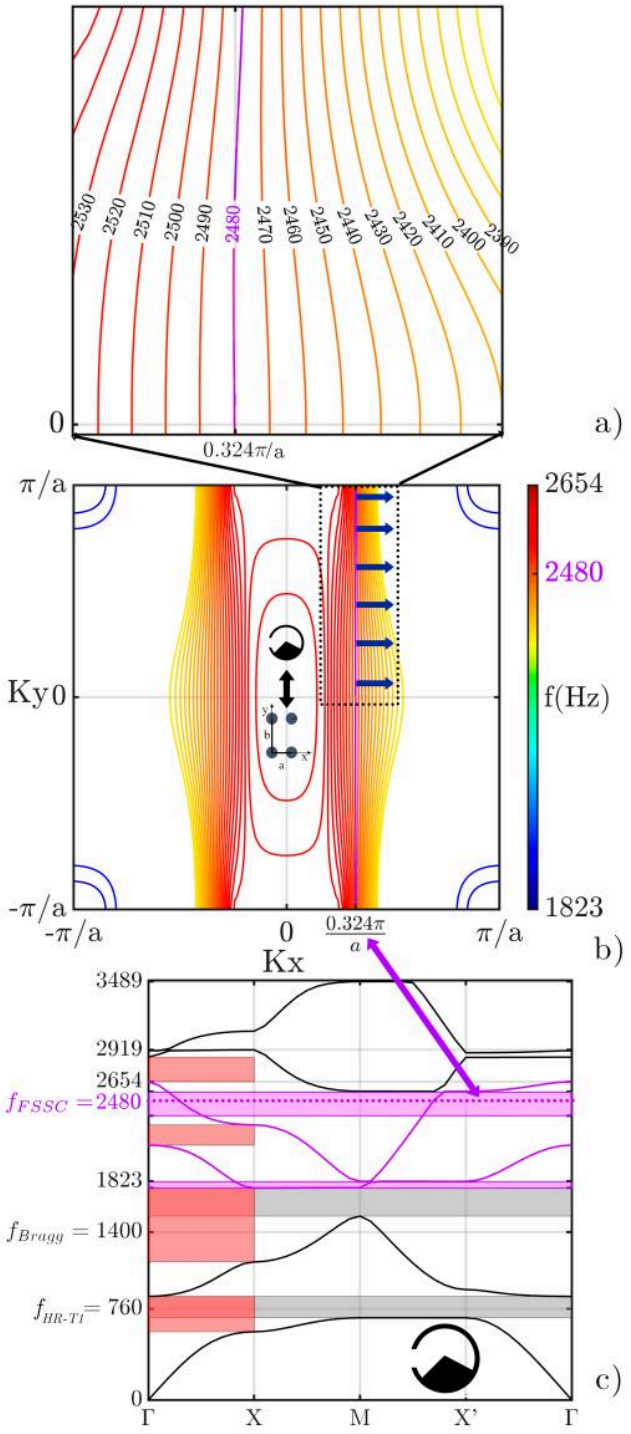

Fig. 3: (a) Magnified view of the fourth band frequency range (2290–2550 Hz) showing EFC transitions from convex to flat (at 2480 Hz) to concave geometry, with the flat EFC enabling frequency-sensitive super-collimation (FSSC). The full range supports AASC. (b) Selected EFCs of the fourth band, highlighted in blue (lower edge) and warm colors (near the FSSC frequency). (c) Band structure diagram presenting locally resonant bandgaps (LR-BGs) shaded in gray and directional Bragg bandgaps (Bragg-BGs) shaded in red. Purple highlights denote AASC regions, and the dashed purple line marks the FSSC frequency. Key frequencies—including those associated with periodicity (f_{Bragg}), local resonance ($f_{\text{HR-T1}}$), and FSSC—are explicitly annotated. Together, these panels analyze the coexistence and necessary conditions for FSSC within the fourth band, with reference to Van Hove singularities, saddle points, and relevant group velocity vectors.

IV. Conclusion

In summary, we have demonstrated that embedding Helmholtz resonators (HRs) in a square-lattice sonic crystal (SC) enables all-angle self-collimation (AASC) without requiring lattice deformation or axis elongation, and with a low filling fraction of 0.44. The emergence of AASC in locally resonant SCs (LRSCs) originates from a symmetry-breaking mechanism that induces anisotropy in the effective density and bulk modulus tensors. Specifically, the phase shift introduced by local resonance generates direction-dependent lattice constants, leading to anisotropic effective material parameters. This anisotropy modifies the dispersion relation, causing the equi-frequency contours (EFCs) to become entirely flat across the Brillouin zone (BZ). These flat EFCs sustain AASC over wide frequency ranges, representing a significant advancement over previous designs that relied on rectangular or inherently anisotropic lattices.

The physical mechanism underlying this behavior is linked to tuning the local resonance (LR) frequency above and below the first directional Bragg bandgap, creating broad frequency regions in which the group velocity remains perpendicular to the wavefronts. In addition to AASC, we report the observation of frequency-sensitive super-collimation (FSSC)—a phenomenon previously identified only in photonic systems—characterized by a flat EFC flanked by convex and concave EFCs in close proximity. The ability to control acoustic wave propagation through LRSCs without uniaxial elongation opens promising avenues for practical applications.

In defence and security, AASC structures could enable stealth communication or directed acoustic energy transfer. In telecommunications, they offer a viable route toward low-loss acoustic wave guiding in compact devices. In biomedical engineering, precise control of ultrasonic beams via self-collimating metamaterials could enhance imaging resolution or enable non-invasive therapeutic energy focusing. These findings position HR-based square lattices as a robust and versatile platform for broadband acoustic wave control, ready for integration into real-world technologies.

Although elastic wave propagation was not modelled and purely rigid scatterers were assumed, this work also expands practical applications toward tunable focusing devices. Future research will aim to establish an analytical relationship between the lattice aspect ratio η (i.e., for rectangular lattices) and the resonance frequency f_{HR} of LRSC scatterers. Additionally, experimental validation of the AASC phenomenon is planned as a key direction for subsequent work.

***Abstract*—Single MoS_2 nanotubes are examined using ultrafast, non-contact all-optical photoacoustic microscopy with picosecond temporal and submicron spatial resolution. Elastic modes in the tens of GHz are observed, and their dependence on structural features provides insight into the nanotubes' mechanical properties and internal morphology.**

***Keywords*—MoS_2 nanotube, GHz, acoustics, nano-resonator, ultrafast, microcopy, Young modulus.**

MoS_2 in its two-dimensional (2D) form has attracted significant research interest, including studies of its mechanical response at frequencies in the tens of GHz and beyond [1, 2]. Despite its technological relevance, the mechanical behavior of one-dimensional MoS_2 nanotubes remains comparatively underexplored. This is mainly due to (i) morphological variability among nominally identical nanotubes, (ii) limited knowledge of their internal radii [3], and (iii) the challenge of accessing radial eigenmodes in the tens of GHz range, corresponding to oscillation periods of tens to hundreds of picoseconds. Addressing these challenges requires an ultrafast, time-resolved, non-contact microscopy technique capable of probing both internal morphology and mechanical response at the single-nanotube level [4].

This talk reports on the nanomechanical dynamics of individual multiwalled MoS_2 nanotubes using ultrafast, all-optical photoacoustic microscopy. The method combines picosecond temporal resolution with submicron spatial precision, enabling the excitation and detection of vibrational modes in isolated nanostructures. By avoiding ensemble averaging, direct correlations between structural characteristics and vibrational response are established, revealing modes that remain undetected in bulk measurements. Elastic eigenmodes in the tens of GHz range are identified and analyzed as a function of nanotube dimensions, providing quantitative insight into their hypersonic elastic properties. Furthermore, the approach enables estimation of internal radii, which are not readily accessible through conventional techniques.

More broadly, this presentation demonstrates the effectiveness of ultrafast all-optical spectromicroscopy as a non-invasive tool for nanoscale metrology. It enables detailed characterization of both mechanical properties and morphology in individual one-dimensional nanostructures, while offering new insights into the intrinsic mechanical behavior and internal structure of MoS_2 nanotubes.

***Abstract*— We report self-organized multimode phonon lasing in a silicon optomechanical nanobeam driven by intrinsic optical self-pulsing. Strongly competing mechanical modes are simultaneously amplified without external modulation, producing periodic, quasi-periodic, and chaotic dynamics. The results establish self-induced coherent pumping as a compact route toward integrated multi-frequency phononic sources.**

***Keywords*— optomechanics, nonlinear dynamics, phonon lasing, silicon photonics, multimode oscillations.**

I. Introduction

Nonlinear optomechanical systems provide a powerful platform for controlling light–matter interactions and generating coherent mechanical motion. Multimode phonon lasing is particularly attractive for multi-frequency signal generation and wave-based information processing, yet it is generally hindered by strong mode competition. Existing approaches rely on external modulation or engineered frequency separation, increasing system complexity. Here we demonstrate a self-organized mechanism enabling multimode phonon lasing in a silicon nanobeam, where intrinsic optical nonlinearities generate coherent pumping capable of synchronizing multiple mechanical oscillators.

II. Methods

The platform consists of a silicon optomechanical crystal nanobeam supporting a confined optical mode coupled to several flexural mechanical resonances. Continuous-wave optical excitation is delivered via tapered-fiber coupling.

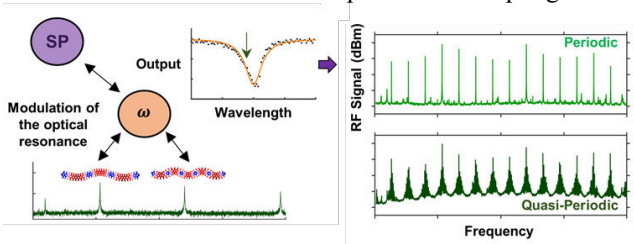

Fig. 1 A silicon optomechanical nanobeam generates self-sustained phonon lasing in multiple competing mechanical modes via self-pulsing,

Self-pulsing dynamics arise from the interplay between free-carrier dispersion and thermo-optic effects, producing a nonlinear limit cycle that modulates intracavity power. This modulation generates radiation-pressure forces that coherently drive the mechanical modes. The system is described by coupled nonlinear equations including optical, thermal, carrier, and mechanical dynamics, solved numerically to map the accessible dynamical regimes.

III. Results and Discussion

By tuning laser detuning, the system exhibits a rich nonlinear landscape including: single-mode phonon lasing, stable multimode lasing (Fig.1 top-right), quasi-periodic dynamics (Fig.1 bottom-right) and chaotic multimode states.

Remarkably, two strongly competing in-plane flexural modes simultaneously reach self-sustained oscillation under continuous-wave excitation. The adaptive self-pulsing cycle dynamically synchronizes with mechanical perturbations, enabling coherent pumping even when modal frequencies are not harmonically related. RF spectra reveal frequency-comb formation and sideband generation associated with nonlinear multimode interactions. Numerical simulations reproduce the experimental phase transitions and confirm the role of self-pulsing as an internal synchronization mechanism.

IV. Conclusion

We demonstrate a compact self-organized mechanism for multimode phonon lasing in an integrated silicon optomechanical platform. Intrinsic nonlinear dynamics enable coherent pumping that overcomes mode competition without external control, opening new opportunities for chip-scale multi-frequency phononic sources and nonlinear RF photonic systems.

***Abstract*—The set of eigenstates is numerically calculated for a disordered phononic crystal with an axis of mirror symmetry. The states are well localized due to strong disorder in orientation of asymmetric scatterers. However, mirror symmetry allows either symmetric or antisymmetric solutions that leads to two localized peaks for each eigenstate.**

***Keywords*— phononic crystals, disorder, symmetry.**

I. Introduction

The eigenstates in a one-dimensional disordered potential are exponentially localized. Two identical samples can form a disordered medium with mirror symmetry, for which the binary correlator of the potential, $< V(x)V(-x) >= V_0^2$ remains nonzero even as $x \to \infty$. At the same time, two neighboring points located on the same side of the symmetry axis are uncorrelated, $< V(x)V(x') >= 0$. The presence of long-range correlations in the absence of short-range correlations leads to an interesting manifestation of Anderson localization, accompanied by symmetry-induced antilocalization.

II. Results and Discussion

The solutions of a wave equation with a symmetric potential are either even or odd functions. In a 1D disordered structure, eigenstates appear as randomly centered peaks. A wave excited at any of these peaks decays exponentially with the localization length $l(\omega)$. However, in a medium with symmetric disorder, a perturbation peaked at a point x extends toward the center of the sample with an amplitude $\sim e^{-|x|/l}$. After passing through the center, the wave amplitude begins to grow, reaching its initial value at the symmetric point $-x$. This behavior of point excitations was demonstrated in a chain of LC circuits with random resonant frequencies [1]. Symmetry-induced enhancement of wave transmission through a diffusive sample was reported in Ref. [2]. Here, we report the symmetry-induced antilocalization effect in acoustics.

The sample used for numerical calculations and experiments is shown in Fig. 1. The scatterers are steel rods with circular-sector cross sections. The rods are periodically arranged in the transverse plane but randomly oriented along the length of the waveguide, producing one-dimensional disorder with a mirror-symmetry axis marked by the horizontal red line. The eigenfrequency spectrum consists of a set of doublets corresponding to even and odd eigenstates. One even eigenstate at $f = 430$ kHz is shown in Fig. 1.Two peaks separated by an exponentially weak pressure region demonstrate Anderson localization caused by random scattering in a one-dimensional structure, together with antilocalization imposed by mirror symmetry. A short pulse applied at one of the eigenstate maxima oscillates between the two peaks, mimicking the dynamics of a quantum particle in a symmetric double-well potential. In the experiment, these oscillations are strongly suppressed by thermo-viscous losses.

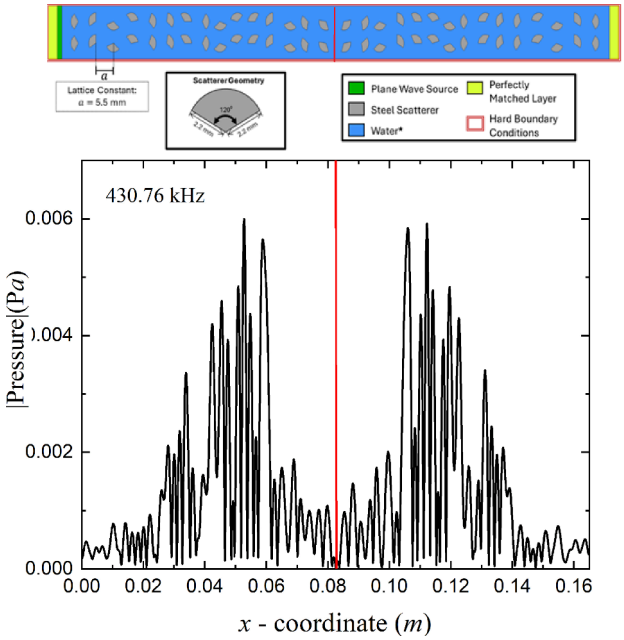

Fig. 1. Phononic crystal with symmetric disorder and distribution of pressure produced by a source with diameter 3 mm located at $x = 0.44$m.

***Abstract*— We demonstrate an efficient and broadband nanoscale electromechanical phonon point source which can be integrated into optomechanical nanobeams or used to excite topological phononic structures. The properties have been investigated by extensive FEM simulations and verified experimentally by vibrometry and electrical measurements.**

***Keywords*— nanophononics, optoelectromechanics, topological phononics.**

I. Introduction

Compact phonon sources are essential in nanomechanical, optoelectromechanical and currently also in topological applications [1,2,3]. Here, we introduce a nanoscale broadband freestanding bulk acoustic wave (BAW) transducer that can act both as a phonon source and a detector.

II. Fabrication and Characterisation

Extensive finite element method (FEM) simulations were carried out to estimate the performance of the BeamBAW transducers. Based on the simulations, test devices were made using standard CMOS compatible cleanroom processes, The devices are 8 µm tall and 7 µm wide triangular resonators with the centre frequency at 4.5 GHz, integrated into silicon nanobeams. The devices were characterized by vibrometry and RF measurements.

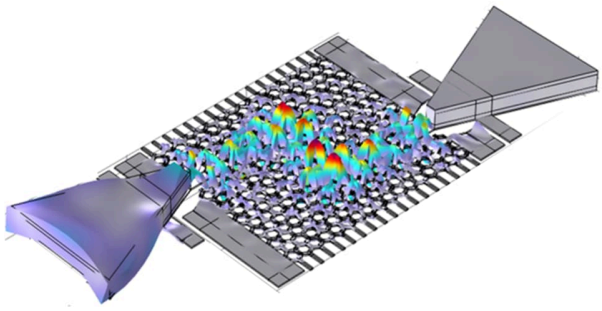

Fig. 1 FEM simulation of phonons excited by a BeamBAW transducer propagating through a topologically protected Z path.

III. Results and Discussion

Simulations show that the test transducers can generate mechanical energy flux into an integrated nanobeam up to 10 GHz frequencies. The coupling efficiency approaches 90 % with optimized supporting beams which minimise the mechanical power leaking to the substrate. In addition, simulations show that the transducers can be used to excite topologigal structures (Fig. 1).

Electrical measurements prove that the centre frequency is at 4.6 GHz. Mechanical signals generated by one transducer in the range of 4.4-4.7 GHz were detected by another transducer after travelling across a 50 µm long freestanding nanobeam. Furthermore, vibrometry shows coupling from the transducer to a nanobeam at around 2 GHz.

IV. Conclusion

We have demonstrated an efficient nanoscale phonon source which can be integrated into nanomechanical structures. FEM simulations confirm the broadband operation, supported by experimental results at around 2.0 GHz and 4.5 GHz by vibrometry and electrical measurements.

Eigenmode steering with time-varying acoustic metamaterials

Wai Chun Wong, Gregory J. Chaplain, Jensen Li*

Department of Physics and Astronomy, University of Exeter, United Kingdom

* j.li13@exeter.ac.uk

***Abstract*— We introduce a spatiotemporal gain-loss framework for eigenmode steering in coupled acoustic resonators. Cross-coupled feedback conserves total energy while directing the system toward selected modal states. Temporal modulation enables programmable transitions and energy routing, offering a route to reconfigurable metamaterials and analog information processing.**

***Keywords*— acoustic metamaterials, time-varying metamaterials, gain–loss engineering, eigenmode steering.**

I. Introduction

Time varying metamaterials provide new opportunities for controlling wave dynamics beyond passive structures. Temporal modulation can produce novel phenomena such as frequency conversion and time analogues of spatial interference, as demonstrated experimentally in optical systems [1]. These developments highlight the potential of dynamic media for manipulating wave propagation.

Here, we present a spatiotemporal gain loss framework for deterministic eigenmode steering in coupled acoustic resonators. Cross-coupled gain-loss feedback conserves total energy while guiding the system toward a selected eigenmode. Temporal modulation further enables programmable transitions between modal states and controlled redistribution of energy between resonators.

II. Methods

We consider three coupled acoustic resonators labeled a, b, and c. Their slowly varying modal amplitudes $\psi = (\psi_a, \psi_b, \psi_c)^T$ evolve according to $i\frac{d}{dt}\psi = H\psi$, where H contains resonator coupling and nonlinear gain–loss feedback. The Hamiltonian can be written as $H = H_{\text{eff}} - iGI$, where the effective linear Hamiltonian governing the modal structure is

$$H_{\text{eff}} = \frac{1}{2}\begin{pmatrix} ig_a & -\kappa/2 & -\kappa/2 \\ -\kappa/2 & ig_b & -\kappa/2 \\ -\kappa/2 & -\kappa/2 & ig_c \end{pmatrix},$$

I is the identity matrix and the nonlinear biasing diagonal matrix is GI where

$$G = \frac{1}{2E}(g_a \mid \psi_a \mid^2 + g_b \mid \psi_b \mid^2 + g_c \mid \psi_c \mid^2),$$

with $E = \mid \psi_a \mid^2 + \mid \psi_b \mid^2 + \mid \psi_c \mid^2$. The nonlinear diagonal term regulates the total amplitude but does not modify the eigenvectors of H_{eff}. Consequently, the eigenmodes of H_{eff} determine the attractor states toward which the system evolves. In theory, the system is designed to converge to the eigenvector whose associated eigenvalue has the largest imaginary part. The normalization term G ensures that the total energy E remains conserved during the evolution.

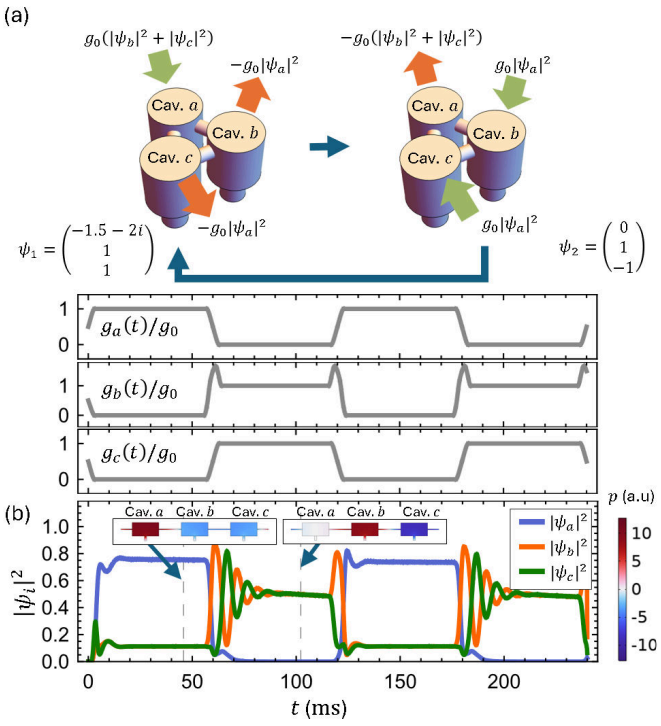

Fig. 1 Assisted eigenmode steering enabled by spatiotemporal gain modulation. (a) Time-dependent gain configuration applied to three coupled acoustic resonators. A transient perturbation breaks symmetry between cavities. (b) Simulated modal intensities showing successful transition from the initial eigenmode to the target antisymmetric mode, demonstrating symmetry-assisted energy redistribution.

III. Results and Discussion

Figure 1 demonstrates eigenmode steering using the spatiotemporal gain protocol illustrated in Fig. 1a. In the first phase, the gain configuration $(g_a, g_b, g_c) = (g_0, 0, 0)$ drives the system toward the eigenmode dominated by resonator a. The protocol then switches to $(0, g_0, g_0)$, whose effective Hamiltonian supports a target antisymmetric eigenmode with opposite phases in resonators b and c. In both phases, the selected modes correspond to the eigenvector associated with the eigenvalue having the largest imaginary part, resulting in relative amplification compared with the other eigenmodes.

Under ideal symmetry, the transition from the initial state to this target mode is inhibited because the two states have different parity with respect to the exchange of resonators b and c. To assist the transition, a transient perturbation is applied to the gain of one cavity during the switching stage, as illustrated in Fig. 1a. The resulting modal evolution is shown in Fig. 1b. After the spatiotemporal perturbation, the system converges toward the target eigenmode, with energy redistributed equally between resonators b and c (with opposite phases) while resonator a is suppressed. We note that the proposed gain–loss feedback and temporal modulation could be implemented experimentally using active acoustic resonators with digital feedback control [3].

IV. Conclusion

We have presented a spatiotemporal gain–loss framework for eigenmode steering in coupled acoustic resonators. By designing the gain distribution and temporal protocol, the system deterministically evolves toward selected eigenmodes while conserving total energy. This approach may enable programmable wave control, analog information processing, and new computation protocols in active metamaterial platforms.

***Abstract*— Free electrons enable mapping and controlling nanoscale optical fields, advancing spatiotemporal and spectral microscopy. While analytical methods suffice for simple geometries, complex structures require numerical simulations. We discuss advanced techniques to simulate electron-light interactions illustrated through phenomena such as the generation and probing of non-classical light states.**

***Keywords*— computational electromagnetic, nonlinear optics, free electrons.**

Free electrons have emerged as a powerful tool to map and manipulate optical fields, providing exciting prospects to investigate new quantum phenomena and push the resolution of spatiotemporally and spectrally resolved microscopy. Advances in this field rely strongly on our understanding of the interaction between free electrons and nanoscale optical fields. Much progress has recently been gained by utilizing analytical methods when the electron interacts with optical fields in the presence of relatively simple material geometries. However, numerical electromagnetic simulations are generally needed for more complex structures. In this presentation, we will discuss several recent examples of applications of surface-integral techniques for simulating the interaction between free electrons and nanoscale optical fields. Furthermore, we will show that, by understanding classical optical fields and their interaction with free electrons, we can equally describe quantum interactions, whereby non-classical light states are generated or externally provided. We will discuss a general protocol to investigate the noted quantum effects based on classical electromagnetic simulations.

Computational Nanophotonics for AR Optics: From Performance Targets to Artifact-Robust Designs

Christina Spaegele[1]

[1]Meta, United States
cspaegele@meta.com

Abstract: Nanophotonic optics have the potential to enable compact, lightweight AR displays by enhancing wavefront control in wearable devices. This talk links AR system requirements to nanostructure design, discusses performance and fabrication challenges, and presents examples of nanophotonic design approaches developed to overcome artifacts and meet demanding AR display standards.

Immersive AR technology aims to revolutionize digital interaction by seamlessly embedding information into our everyday surroundings. Achieving this requires display systems that are virtually invisible to the user, ensuring content integration without compromising natural vision. These goals translate into demanding optical targets, including a wide field of view, support for focus cues, a sunglasses-like form factor, and efficiency compatible with all-day wear.

Despite strong recent progress, meeting the combined requirements for compactness, visual fidelity, power efficiency, and cost will depend on continued advances in materials, optoelectronics, and photonics. Nanophotonic elements are appealing because they can enable thinner, lighter optics and more precise control of light propagation. However, their expanded degrees of freedom present significant practical challenges, including sensitivity to manufacturing tolerances and artifact pathways that can dominate perceived image quality. This talk reviews how computational nanophotonic design can translate AR system-level requirements into practical, manufacturable nanostructured optics, emphasizing artifact-robust performance under fabrication constraints and illustrating these ideas with representative design examples.

Topologically structured doughnuts: optical skyrmions, superoscillations, and axion probes

Nikitas Papasimakis[1,*]

[1]Optoelectronics Research Centre, University of Southampton, UK
*n.papasimakis@soton.ac.uk

***Abstract*— This talk will present recent developments on spatiotemporally structured toroidal pulses including their topological properties, exotic field configurations, superoscillatory behaviour, and non-trivial light-matter interactions.**

***Keywords*— toroidal pulses, superoscillations, optical skyrmions**

Toroidal light pulses, space-time nonseparable solutions to Maxwell's equations, were predicted in 1996 [1] and only recently observed [2]. A broader class of supertoroidal pulses was discovered [3] with intriguing topological structure reminiscent of skyrmions in condensed matter. Such pulses can exhibit exotic propagation properties, such as non-diffraction over arbitrary distances and energy transfer reminiscent of "vortex streets" in fluid dynamics [4]. Moreover, the spatiotemporal structure of supertoroidal pulses can lead to unusually rapid local temporal and spatial oscillations, a phenomenon termed space-time superoscillations [5]. Finally, superpositions of toroidal pulses are shown to be maximally chiral with parallel electric and magnetic field components. Finally, promising applications of toroidal pulses in telecommunications, metrology, and spectroscopy will be discussed.

A Universal Scattering Anomaly near Bound States in the Continuum

Jiaxin Zhou[1], Ya Yan Lu[1,2,*]

***Abstract*—A bound state in the continuum (BIC) is an eigenmode with a frequency in the radiation continuum. When the system with a BIC is perturbed, scattering problems may exhibit unusual wave phenomena referred to as scattering anomalies. We identify a new and universal scattering anomaly associated with BICs.**

***Keywords*— bound state in the continuum, scattering anomaly, periodic structure.**

I. Introduction

In a lossless periodic structure sandwiched between two homogeneous media, a bound state in the continuum (BIC) is a special eigenmode with a frequency in the radiation continuum [1]. If the structure, with a real relative permittivity $\epsilon_*(y,z)$, is periodic in y with period L, bounded in z, and surrounded by air ($|z| > d$), a TE or TM polarized BIC is a Bloch mode $u_*(y,z) = \phi_*(y,z)e^{i\beta_* y}$ with a real Bloch wavenumber β_* satisfying $|\beta_*| < k_* = \omega_*/c$, where ω_* is the real angular frequency, ϕ_* is periodic in y and tends to 0 as $z \to \pm\infty$. For a given real pair (β,ω), there is a unitary matrix (the scattering matrix) $\boldsymbol{S}(\beta,\omega)$ satisfying $\boldsymbol{S}\boldsymbol{a} = \boldsymbol{b}$, where $\boldsymbol{a}$ and $\boldsymbol{b}$ are column vectors for the coefficients of the incoming and outgoing propagating plane waves (from and to $z = \pm\infty$, respectively). The scattering matrix is well-defined even at the BIC point (β_*,ω_*).

It is known that for β near β_*, incident waves with a special frequency ω near ω_* may give zero reflection or zero transmission [2,3]. Such scattering anomalies are interesting and useful for practical applications, but they require the structure to have some symmetry, and usually do not occur if the structure has no symmetry.

II. Results

We describe a universal scattering anomaly that does not require any symmetry. It is about special relations between $\boldsymbol{a}$ and $\boldsymbol{b}$. While they are always linearly related by the scattering matrix $\boldsymbol{S}(\beta,\omega)$, we show that it is possible to have $\boldsymbol{b} = \boldsymbol{M}\boldsymbol{a}$ for a particular nonzero $\boldsymbol{a}$, where $\boldsymbol{M}$ is *any* unitary matrix satisfying

$$\det[\boldsymbol{S}(\beta_*,\omega_*) - \boldsymbol{M}] \neq 0. \tag{1}$$

Specifically, if $e^{i\theta}$ is *not* an eigenvalue of $\boldsymbol{S}(\beta_*,\omega_*)$, then there is a particular $\boldsymbol{a}$, such that $\boldsymbol{b} = e^{i\theta}\boldsymbol{a}$. It should be emphasized that the result holds for any β sufficiently close to β_*, but only for a particular ω near ω_*.

The precise statement of our result is as follows. *For any unitary matrix $\boldsymbol{M}$ satisfying (1) and any real β near β_*, there is a real frequency $\omega_\diamond$ and a nonzero vector $\boldsymbol{a}$, such that*

$$\boldsymbol{b} = \boldsymbol{S}(\beta,\omega_\diamond)\boldsymbol{a} = \boldsymbol{M}\boldsymbol{a}. \tag{2}$$

In other words, for any β near β_*, we are able to force outgoing waves to have a special relationship with the incident waves, but only for a particular set of incident waves and only at a particular frequency. We note that $\omega_\diamond$ depends on β continuously and also depends on $\boldsymbol{M}$. For each $\boldsymbol{M}$, $\omega_\diamond(\beta;\boldsymbol{M})$ is a curve passing through (β_*,ω_*) in the β-ω plane. In addition, we can show that the curves for different $\boldsymbol{M}$ are tangential to each other at (β_*,ω_*). Since the special scattering solution satisfying (2) exists near any nondegenerate BIC, without requiring additional conditions on the structure and the BIC, we say the scattering anomaly is universal.

If (β_*,ω_*) satisfies $|\beta_*| < \omega_*/c < 2\pi/L - |\beta_*|$, then $\boldsymbol{S}$ is a 2×2 matrix. Furthermore, if $\epsilon_*(y,z)$ is even in z, the BIC is either even or odd in z, and we can also focus on scattering solutions that are even or odd in z, namely, we can choose $\boldsymbol{a} = [1;1]$ or $[1;-1]$, respectively. In that case, if $e^{i\theta}$ is not an eigenvalue of $\boldsymbol{S}(\beta_*,\omega_*)$, then for any β near β_*, there is a real $\omega_\diamond$ near ω_*, such that $\boldsymbol{b} = e^{i\theta}\boldsymbol{a}$.

III. Conclusion

We describe a special scattering anomaly near non-degenerate BICs in periodic structures. It is about the universal existence of scattering solutions with $\boldsymbol{b} = \boldsymbol{M}\boldsymbol{a}$, where $\boldsymbol{M}$ is any unitary matrix such that $\boldsymbol{S}(\beta_*,\omega_*) - \boldsymbol{M}$ is nonsingular. Applications of this anomalous wave phenomena will be explored in future works.

Separating partially coherent light

Charles Roques-Carmes[1, 2]

[1] Stanford University, USA
[2] Institute of Science and Technology, Austria
*Corresponding author: crc@ista.ac.at

***Abstract*— We demonstrate the automatic separation of partially coherent light into its mutually orthogonal and incoherent components by variational processing in a silicon photonic circuit. This process formally finds and measures the eigenvectors and eigenvalues of the coherency matrix, hence also completely measuring the partially coherent state, while leaving it intact after optimization.**

***Keywords*— partial coherence, photonic integrated circuits.**

Modern photonics increasingly operates with high-dimensional optical fields with partial coherence. In such settings, the relevant information is carried not only by intensity but also by statistical correlations between field components, captured by the coherency matrix. While partial coherence has often been treated as a limitation, recent work has shown that it can be engineered as a resource for imaging, sensing, communication, and optical information processing. Exploiting it at scale, however, requires practical hardware that can measure and manipulate coherence in many modes without the quadratic overhead of conventional tomographic approaches.

Here, I will present a foundry-fabricated silicon photonic platform that performs coherence tomography and coherence processing directly on chip, with a method designed to scale efficiently in dimensionality. The central result is the automatic separation of an unknown partially coherent field into its mutually orthogonal and mutually incoherent components. Operationally, the chip implements a programmable unitary transformation that is tuned *in situ* so that the output ports directly carry the principal coherence modes of the input. At convergence, the device provides the eigenvalues and eigenvectors of the input coherency matrix, and it does so in a way that physically routes the corresponding components to distinct waveguide outputs. Importantly, this separation is achieved through unitary interferometric processing prior to detection, enabling the coherence structure to be accessed without relying on destructive, basis-by-basis measurements.

Our approach casts coherence tomography as a variational optimization problem [1-4]. A self-configuring interferometric network is trained layer-by-layer to maximize measured output power, which is equivalent to learning the dominant coherence modes sequentially. To make this feasible in integrated hardware, the experiment introduces a scalable gradient readout scheme: the phases of many interferometric elements are simultaneously dithered at distinct electronic frequencies, and the photodetected signal is demodulated to recover, in parallel, the gradient of the objective with respect to every tunable parameter in a layer. These gradients drive a standard gradient-based optimizer that converges rapidly and reproducibly. Because many practical partially coherent fields are low rank, the overall procedure scales linearly with the number of supported modes up to the rank of the coherency matrix, offering an efficiency advantage over conventional techniques that require a number of measurements growing quadratically with dimension.

Our work establishes a practical route to programmable coherence analysis and control in integrated photonics. It shows that coherence-mode decomposition can be implemented physically in a compact silicon platform using scalable, gradient-driven self-configuration. Such devices could enable real-time, information-optimal optical front ends for imaging and sensing, coherence-aware receivers for communication in challenging propagation environments, and integrated photonic processors that treat partial coherence as a controllable degree of freedom alongside mode, wavelength, and polarization.

***Abstract*— We demonstrate efficient simulation and optimization of millimeter-scale metasurfaces using GPU-accelerated finite-difference time-domain (FDTD) methods. Additionally, we show how optimized metasurfaces can be seamlessly integrated into system-level simulations through machine learning-based surrogate models, enabling rapid evaluation without repeated full-wave analysis.**

***Keywords*— metalenses, metasurfaces, FDTD, optimization.**

I. Introduction

Metasurfaces consist of meticulously arranged sub-wavelength structures (meta-atoms) that enable precise control over the phase, amplitude, and polarization of electromagnetic waves. While these devices have demonstrated remarkable capabilities in applications ranging from beam steering to optical computation [1], their practical deployment faces significant computational challenges. The design and optimization of large-scale metasurfaces—particularly those spanning millimeter dimensions with thousands of individual elements—requires computationally intensive full-wave electromagnetic simulations, and subsequent system-level integration demands repeated evaluations that multiply this burden. In this work, we address both challenges by demonstrating that GPU-accelerated finite-difference time-domain (FDTD) methods enable efficient gradient-based optimization of mm-scale metasurfaces, while machine learning-based surrogate models provide fast, differentiable representations suitable for system-level design workflows. Together, these techniques provide a complete pathway from component optimization to system integration for large-scale metasurface devices.

II. Multi-node Multi-GPU Simulations and Discussion

The primary challenge in simulating metasurfaces stems from their multi-scale nature: while individual sub-wavelength scatterers must be accurately resolved, the overall device often extends thousands of wavelengths in each lateral dimension. Since the FDTD method typically requires at least 10 grid cells per wavelength in the material, a millimeter-scale metasurface operating in the visible range necessitates over 10,000 cells along both x- and y-directions, with approximately 100 cells in the propagation (z) direction. This corresponds to approximately 10^{11} total grid cells, with material and field data alone requiring several terabytes of memory—far exceeding the capacity of single-GPU systems.

To overcome this limitation, we employ multi-GPU distributed computing across multiple nodes. As demonstrated in Fig. 1, the FDTD method exhibits nearly ideal scaling with the number of compute nodes, maintaining high parallel efficiency even when distributed across 32 to 64 GPUs. This scalability enables routine simulation and optimization of millimeter-scale metasurfaces that would otherwise be computationally intractable.

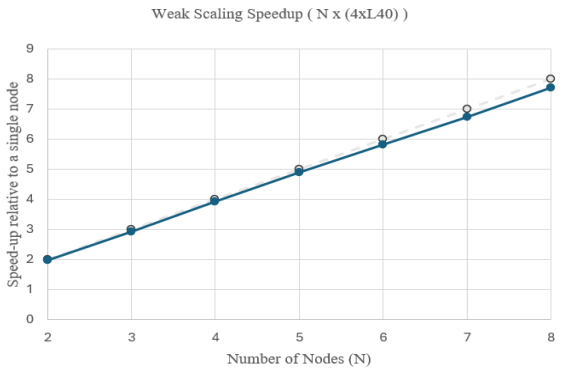

Fig. 1 Performance scaling of GPU-FDTD simulations with the number of GPU compute nodes. Each node consists of four Nvidia L40 GPUs. The dashed line shows perfect linear scaling while the solid line shows the measured speedup compared to a single node.

Since metasurfaces are typically thin (1–2 μm in the propagation direction), simulations require only approximately 10^4 time steps and complete in under 20 minutes per run. This computational efficiency not only enables millimeter-scale metasurface simulations but also makes iterative design workflows practical, including fine-grained parameter sweeps and gradient-based optimization with hundreds of iterations. Using this approach, it has been possible to design novel optical

sensors [2].

Once individual metasurface designs are finalized and verified, they must be integrated into system-level simulations that typically include combinations of traditional optical elements and metasurfaces. Ray tracing is the preferred method for such system simulations; however, accurately incorporating metasurfaces into ray-tracing frameworks without sacrificing computational efficiency remains challenging. The recently developed Windowed Fourier Transform (WFT) method [3] addresses this by maintaining ray-tracing performance while providing more accurate metasurface representation than previous approaches. However, machine learning-based surrogate models offer even greater flexibility and accuracy. By training neural networks on full-wave FDTD simulation data or on WFT results, we can create fast, differentiable representations of metasurface behavior that seamlessly integrate into ray-tracing workflows [4].

III. Conclusion

We have demonstrated that GPU-accelerated FDTD enables practical simulation and optimization of millimeter-scale metasurfaces containing thousands of sub-wavelength elements. By leveraging multi-GPU distributed computing with near-ideal parallel scaling, we achieve simulation times under 20 minutes despite handling approximately 10^{11} grid cells and terabytes of field data. This computational efficiency makes iterative design workflows feasible, including gradient-based optimization with hundreds of evaluations. Furthermore, we have shown that machine learning-based surrogate models trained on full-wave FDTD data provide accurate, efficient representations of metasurface behavior for system-level ray-tracing simulations, outperforming analytical approaches like the Windowed Fourier Transform method. Together, these advances establish a complete computational framework—from component-level optimization to system integration—that removes the computational barriers previously limiting large-scale metasurface development. This opens new opportunities for designing high-performance optical devices with unprecedented complexity and functionality.

Photo-Excited Silicon-Based Quarter-Wave Plate for Terahertz Applications

Shohei Tsuzuki[1], Jun Shibayama[1,*]

[1]Faculty of Science and Engineering, Hosei University, Japan
*Corresponding author: shiba@hosei.ac.jp

***Abstract*—This article investigates a photo-excited silicon quarter-wave plate in the terahertz region. Using the finite-difference time-domain method, the performance of the quarter-wave plate is calculated with a focus on light emission intensity. Depending on the intensity, this device acts as either a quarter-wave plate or a blocking filter.**

***Keywords*— FDTD, photo-excited silicon, quarter-wave plate, terahertz.**

I. Introduction

Quarter-wave plates play a crucial role in communication systems. In the terahertz (THz) region, quarter-wave plates have been investigated using metal plates [1]. Meanwhile, photo-excited silicon exhibits intriguing properties in the THz range, with its dielectric properties varying according to the light emission intensity [2]. In this article, we analyze photo-excited silicon quarter-wave plates using the finite-difference time-domain (FDTD) method [3]. It is shown that the device acts as either a quarter-wave plate or a blocking filter, depending on the given light intensity.

II. Discussion

Fig. 1 shows the configuration of the quarter-wave plate made of photo-excited silicon. The configuration parameters are as follows: the period $\Lambda = 840$ μm, the thickness $t = 560$ μm, and the size of the aperture $r_x = 560$ μm and $r_y = 730$ μm. The electrical property of the silicon is represented by the simple conductivity model [2] and the conductivity is varied to simulate the carrier generation change from the light emission. A linearly polarized E_x wave is tilted $\phi_{\text{in}} = 45°$ from the x axis and excited toward the z direction. The periodic FDTD method is used to calculate one period of the quarter-wave plate.

The calculated transmittance is shown in Fig. 2, in which the results for $\sigma = 1.0 \times 10^2$ S/m as the dashed lines and those for $\sigma = 1.0 \times 10^5$ S/m as the solid lines are presented. It is shown that the transmittance for $\sigma = 1.0 \times 10^2$ S/m remains low for both E_x and E_y waves, indicating a blocking filter. This occurs because silicon acts as a dielectric, causing the electric field to be absorbed within the silicon. On the other hand, the transmittance for $\sigma = 1.0 \times 10^5$ S/m exceeds 80% for both polarizations. This is because silicon behaves as a metal, preventing the absorption of the electric field. Although not shown in the figure, the axial ratio is calculated to be less than -3 dB in the range of 0.28 to 0.34 THz, demonstrating the functionality of the quarter-wave plate in the THz band.

III. Conclusion

We have investigated a terahertz quarter-wave plate consisting of an optically excited silicon material in the terahertz region. Only one period is calculated using the periodic FDTD method. The results showed that this plate functions either as a quarter-wave plate or as a blocking filter depending on the intensity of the emitted light. This plate converts linearly polarized light into circularly polarized light in the 0.28 to 0.34 THz range.

Near-field focusing and amplification of tip-substrate radiative heat transfer

M. Vescovo[1], P. Ben-Abdallah[1], R. Messina[1,*]

[1]Laboratoire Charles Fabry, UMR 8501, Institut d'Optique, CNRS

***Abstract*—By studying the spatially resolved near-field radiative heat transfer between a nanoscale probe and a substrate, we show that introducing a thin polar film atop a non-dispersive substrate leads to enhancement and lateral focusing of the heat exchange, offering a route toward the control of heat transfer at the nanoscale.**

***Keywords*— near-field radiative heat transfer, Poynting vector, heat-assisted magnetic recording.**

I. Introduction

When two bodies at different temperatures are separated by a vacuum gap, heat can be exchanged between them via the emission and absorption of thermal photons. In the far-field regime, where the separation exceeds the thermal wavelength $\lambda_{\rm th} = \hbar c/k_B T$ (on the order of a few microns at room temperature), this exchange is bounded by the Stefan–Boltzmann law. However, as first demonstrated by Rytov and later formalized by Polder and van Hove [1], [2], this limit breaks down in the near-field regime, where the separation falls below $\lambda_{\rm th}$. These pioneer works were followed by a plethora of theoretical and experimental developments (see e.g. Ref. [3] and references therein). In the near field, the radiative heat flux can be dramatically enhanced due to the tunneling of evanescent photons. This enhancement becomes especially pronounced when the interacting bodies support surface resonances such as phonon-polaritons in polar dielectrics or surface plasmons in metals [4]. These phenomena have opened promising avenues for nanoscale thermal management, solid-state cooling, infrared sensing and spectroscopy, energy conversion, and the emerging field of thermotronics.

An additional application domain is heat-assisted magnetic recording (HAMR) [5], [6], [7], where localized heating is used to transiently lower the coercivity of a magnetic substrate, enabling data writing with an external magnetic field. Achieving high information densities requires the confinement of heat to nanoscale regions, ideally approaching the superparamagnetic limit of tens of nanometers. In this context, we study the spatially resolved near-field radiative heat transfer between a nanoparticle and a substrate in the fluctuational-electrodynamics framework. Inspired by HAMR-like configurations, we address two key aspects, enhanced heat transfer and spatial localization, by investigating near-field radiative heat exchange between a nanoparticle–serving as a localized heat source–and a multilayer substrate composed of different materials. It is shown that the introduction of a thin polar film atop a non-dispersive substrate can lead to a substantial enhancement and spatial focusing of the radiative heat flux.

II. Methods

The theoretical framework employed falls within the well-established domain of dipolar near-field heat transfer, which has garnered significant interest over the past decade (see Ref. [8] and references therein). The system we consider is made of a spherical nanoparticle of radius R simulating a tip, made of silicon carbide (SiC). The nanosphere is placed at a distance d from a substrate covered by a film of thickness δ made of SiC, both assumed to be infinite along the transverse directions. The optical properties of SiC will be described by a Drude-Lorentz model [8]

$$\varepsilon(\omega) = \varepsilon_\infty \frac{\omega_L^2 - \omega^2 - i\Gamma\omega}{\omega_T^2 - \omega^2 - i\Gamma\omega}, \tag{1}$$

Concerning the underlying substrate, we explore a variety of non-dispersive materials having permittivities $\varepsilon_{\rm sub} = 2, 4, 8, 16$ and a very small imaginary part included for numerical reasons. The reason for this choice of permittivites is twofold. On one hand, sweeping over a range of possible permittivites allows us to investigate on the robustness of the effect associated with the thin film. On the other hand, the optical properties of the magnetic materials typically employed in HAMR are currently scarcely available in the far-infrared region of the spectrum, the most relevant one for radiative heat transfer close to ambient temperature. One result in this sense is the measurement of the refractive index of FePt thin films [9], resulting in a value of $n \simeq 4$ at $\lambda = 1.7\,\mu$m, motivating our choice of maximum $\varepsilon_{\rm sub}$ of 16.

III. Results and Discussion

In order to analyze the spatial distribution of the energy transferred between the nanosphere and the underlying substrate we focus on the z component S_z of the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, to be evaluated at the interface $z = 0$ between vacuum and substrate. This quantity can be calculated within a N-body fluctuational-electrodynamics approach complemented with the dipolar approximation [8]. In our scenario, we are going to focus on a single nanoparticle having radius

$R = 100\,\text{nm}$, temperature $T = 400\,\text{K}$, placed at distance $d = 300\,\text{nm}$ from the substrate, and assume that both the thermal bath and the substrate are at zero temperature. This allows us to focus purely on the contribution to the energy on the substrate coming from the nanoparticle thermal emission.

Our objective is to analyze the impact of the film and more specifically of its thickness on the amplification and focusing of energy transfer with respect to the reference configuration corresponding to the absence of film (substrate only). For each value of δ, the former will be quantitavely done by studying the ratio $S_z(0,0,0)/S_{\text{ref}}$ between the z component of the Poynting vector right below the particle and the reference value corresponding to the scenario in the absence of film, i.e. $\delta = 0$. As far as the focusing is concerned, it will be described by the half width at half maximum (HWHM) of the profile of $S_z(x,y,0)$, i.e. the x coordinate (in virtue of the rotational symmetry of the system) at which $S_z(x,0,0) = S_z(0,0,0)/2$.

Our main results are shown in Fig. 1, presenting these two quantites as a function of the film thickness δ for four different values of the substrate permittivity $\varepsilon_{\text{sub}} = 2, 4, 8, 16$. In Fig. 1(a), we see that for any chosen substrate permittivity, the curve starts at 1 as expected and shows a non-monotonic behavior with respect to δ, with a pronounced peak varying between 92 (for $\varepsilon_{\text{sub}} = 16$) and 183 (for $\varepsilon_{\text{sub}} = 2$). This first result already shows how a thin film having a thickness of hundreds of nanometers can induce a two-order-of-magnitude increase of the energy transferred between a nanoparticle and a substrate. Figure 1(b) shows that the presence of the thin film also has a strong impact on the width of the Poynting vector profile. These curves are also non-monotonic, with a FWHM going from the values $340, 340, 304, 260\,\text{nm}$ for $\varepsilon_{\text{sub}} = 2, 4, 8$ and 16, respectively, in the absence of film to 113, 128, 128, 128 nm in the best scenario in the presence of a film. By analyzing in detail the influence of the probe–substrate separation, film thickness and substrate permittivity, we reveal that the effect originates from near-field interactions governed by the interplay between film-induced modifications of electromagnetic mode dispersion and the distance-dependent coupling strength.

Fig. 1. (a) Ratio of the Poynting vector $S_z(0,0,0)$ below the nanoparticle and the one S_{ref} in the absence of film ($\delta = 0$) as a function of the film thickness δ. The 4 curves correspond to different values of the substrate permittivity (see legend). (b) Corresponding values of the HWHM.

IV. Conclusion

We demonstrate that the spatially resolved near-field radiative heat transfer between a polar nanoparticle and a non-dispersive substrate can be significantly controlled by introducing a thin polar film atop the substrate. By analyzing the magnitude and spatial distribution of the Poynting vector, we show that specific film thicknesses can lead to a pronounced enhancement and focusing of the local energy flux. This results from the interplay between the dispersion relations of resonant electromagnetic modes supported by the vacuum–film–substrate configuration and the nanoparticle–substrate separation. Our findings provide insights into the control of spatially resolved thermal radiation and point toward new strategies for nanoscale thermal management and may be extended to more complex scenarios, including multi-tip geometries and self-consistent treatment of heat diffusion within multilayer substrates.

***Abstract*— We develop a theory to study how a fast periodic modulation of a generic control variable affecting the near-field radiative heat coupling between two bodies produces a correction on the slow thermal dynamics.**

***Keywords*— radiative heat transfer**

The past two decades have established the foundations and experimental reality of near-field radiative heat transfer (NFRHT), where thermally excited evanescent fields enable photon tunneling across subwavelength gaps, yielding heat fluxes far exceeding the blackbody limit. Quantitative measurements down to nanometric separations have confirmed the predictions of fluctuational electrodynamics across diverse materials and geometries. These advances now allow dynamic control through electromechanical gap actuation or dispersion engineering.

In [1], we introduce a new mechanism for temperature control based on the fast modulation of parameters affecting radiative heat transfer. We analyze how rapid periodic modulation of a near-field coupling parameter influences the slow thermal dynamics of a lumped body.

***Abstract*— Simulating radiative heat transfer between nanostructures can be very demanding in terms of computational resources even with Fourier methods which are known to be very efficient for handling such structures, especially lamellar ones. For that case, we propose a method that leads to a further reduction of the computational load.**

***Keywords*— Fourier Modal Method, Radiative heat transfer, Computational electromagnetics.**

I. Introduction

Radiative heat transfer is a key phenomenon entering in many applications such as radiative heating-cooling or thermo-photovoltaic systems. Modelling such an effect requires efficient electromagnetic computational methods. Among these, the FMM (Fourier Modal Method) aka the RCWA (Rigorous Coupled Wave Analysis) is one of the most versatile and efficient approaches. This method can be made even more efficient when the nanostructures under study are subwavelength in height. This is possible because in such a situation, one can avoid solving the, computationally demanding, eigenvalue problem that is the heart of the FMM. Since the computation of the heat exchange is done over the entire electromagnetic spectrum, the subwavelength condition will be fulfilled over a non-negligible range of frequencies for which the computation will be greatly simplified. In this presentation, I will show how this applies, in detail, to radiative heat transfer computations. Finally, it is important to notice that such an approach can be applied in context of Casimir-Lifshitz force computations especially out of thermal equilibrium where computations over the entire electromagnetic spectrum are unavoidable.

II. Methods

The Fourier Modal Method [1] as applied to radiative heat transfer. The fields as well as the dielectric properties of the nanostructures are expanded in generalized Fourier series. When inserted into Maxwell equations this leads to an eigenvalue problem that must be solved in each periodic slice. This latter can be avoided when the height of the slice id subwavelength.

III. Conclusion

We have demonstrated a THz metamaterial with superior wavefront control and broadband absorption. Future work will extend the design to polarization-independent and reconfigurable THz devices.

***Abstract*— This work uses terahertz near-field microscopy to reveal how quasi–bound states in the continuum enhance the partial local density of optical states in finite metasurfaces. Experiments and simulations show strong, spatially confined PLDOS enhancement that saturates with array size, establishing practical limits and design rules for THz quasi-BIC engineering.**

***Keywords*— metasurface, bound states in the continuum, LDOS.**

I. Introduction

Near-field terahertz (THz) microscopy is used to directly probe how bound states in the continuum (BICs) enhance the partial local density of optical states (PLDOS) in nonlocal metasurfaces, revealing fundamental limits to BIC-enabled light–matter interaction. Symmetry-protected BICs supported by an infinite array of gold rod dimers remain decoupled from far-field radiation [1], but in finite arrays they manifest as quasi-BICs with finite radiative linewidths whose collective nature governs the PLDOS enhancement.

II. Methods

Here, a dual-probe THz near-field time-domain setup, enables direct excitation and detection of quasi-BIC modes and, thus, a direct experimental determination of the PLDOS at the position of the source dipole for defined dipole orientations. This technique has been previously exploited to unveil the symmetry protection of such collective modes in the near field [2], along with the strong confinement perpendicular to the metasurface plane. By comparing measurements on large-area metasurfaces to SCUFF-EM boundary-element calculations [4], a strong PLDOS enhancement is observed at the quasi-BIC frequency, highly localized at the rod edges and confined within a subwavelength mode volume [5].

III. Results and Discussion

Systematic variation of the array size from a single dimer to multi-dimer arrays shows that the quasi-BIC originates from collective modes whose number and spectral sharpness increase with metasurface size, leading to a diverging quality factor while the PLDOS enhancement saturates at moderate array sizes [5]. This saturation arises from the competition between Q-factor and mode volume, preventing an unbounded increase of PLDOS despite ever-higher Q. Spatially resolved PLDOS maps in the plane and along the out-of-plane direction demonstrate extreme confinement of the enhanced density of states to nanometric regions at the edges of the rods and an evanescent decay away from the metasurface, confirming that quasi-BICs provide both high-Q and deep subwavelength confinement. These results establish an experimental upper limits for BIC-induced LDOS enhancement in realistic finite metasurfaces and define design rules for maximizing on-chip light–matter interaction, with direct implications for THz quasi-BIC engineering.

IV. Conclusion

These results establish experimental upper limits for BIC-induced LDOS enhancement in realistic finite metasurfaces and define design rules for maximizing on-chip light–matter interaction, with direct implications for THz quasi-BIC engineering.

***Abstract*—We present time-frequency structured light for analog processing of ultrafast broadband waveforms. Using bounded Talbot array illuminator phase modulation with dispersion, phase-only optical systems redistribute coherent energy for denoising and user-defined filtering, and joint time-frequency analysis and processing of time-domain waveforms with bandwidths into the multi-THz range.**

***Keywords*— structured light, time-frequency processing, Talbot array illuminator, optical signal processing.**

Broadband waveforms encountered in microwave photonics, optical communications, sensing, spectroscopy, and ultrafast optics create a practical signal-processing problem. The relevant features may occur on picosecond or sub-picosecond time scales, while the optical or optically up-converted spectra can span hundreds of gigahertz to several terahertz. For such signals, full electronic capture followed by digital processing is often limited by the available real-time bandwidth, and in ultrafast optical measurements it may not be a realistic first step. This motivates photonic analog processing, in which selected operations are carried out directly in the optical domain before detection or lower-bandwidth electronic processing. In this work, dispersion and phase-only temporal modulation are used as the basic processing tools. The target functions include denoising, waveform reshaping, time-frequency filtering, and single-shot measurements that resolve how the spectral content of an ultrafast waveform evolves in time.

The central idea is to extend structured-light concepts from transverse spatial coordinates to the temporal and spectral coordinates of an optical waveform. In conventional structured light, one tailors the spatial amplitude, phase, polarization, or modal content of an optical beam [1]. Here, the corresponding control is applied through phase-only operations in time and optical frequency, namely temporal phase modulation and spectral phase filtering. Broadband waveform processing can therefore be formulated within a Fourier-optics framework in which the roles usually played by spatial propagation, lenses, and focusing are implemented in the time-frequency domain using dispersion and time-dependent phase modulation. The physical basis for this connection is space-time duality, where paraxial diffraction in space is mathematically analogous to dispersive pulse propagation in time, and a spatial lens is analogous to a temporal phase modulation or time lens [2], [3]. This analogy has enabled temporal imaging and temporal Fourier transformation, and more recently has supported optical wave-energy redistribution methods for analog photonic signal processing, including denoising through passive amplification and real-time, time-mapped spectrogram reconstruction, where the spectrogram is obtained through an optical implementation of the short-time Fourier transform (STFT) [4].

A practical challenge appears when the temporal-lens analogy is implemented over a large processing aperture. The ideal time lens requires a parabolic temporal phase, whose phase excursion grows with the duration of the waveform being processed. For long temporal windows or large time-bandwidth products, this can require a large and continuously varying phase swing that is poorly matched to practical electro-optic phase modulators. Talbot array illuminator (TAI) phase modulation provides a more implementable alternative. Instead of applying an unbounded parabolic phase, a TAI uses a periodic, phase-only temporal pattern designed under fractional Talbot conditions [5]. Since the phase is wrapped modulo 2π, the modulation remains bounded while still enabling controlled time-frequency energy redistribution when combined with a dispersive element.

The denoising operation provides an intuitive example of this redistribution. In a TAI followed by dispersion, coherent signal components satisfying the designed phase relation can recombine into selected temporal regions, whereas incoherent noise remains broadly distributed. The result is a passive intensity enhancement of the signal relative to the noise, which has been used for temporal passive amplification and optical signal denoising [6]. Recent theory further shows that the passive-amplification regime and the STFT regime of temporal TAIs are connected through the same underlying time-frequency mapping, analogous to the relationship between focusing and Fourier transformation in a spatial lens system [7].

The same dispersive and TAI phase elements can be configured for time-frequency analysis of broadband ultrafast optical waveforms. In this regime, dispersion and temporal phase modulation implement a time-to-frequency mapping, so that temporal features of the input waveform are transferred to resolvable positions in the output optical spectrum (see Fig. 1). The measured spectrum encodes the waveform's short-frequency Fourier transform (SFFT), allowing a time-frequency representation to be obtained from a single optical spectral acquisition. This approach has recently been demonstrated for complex optical waveforms spanning up to 11 THz over nanosecond durations, corresponding to time-bandwidth

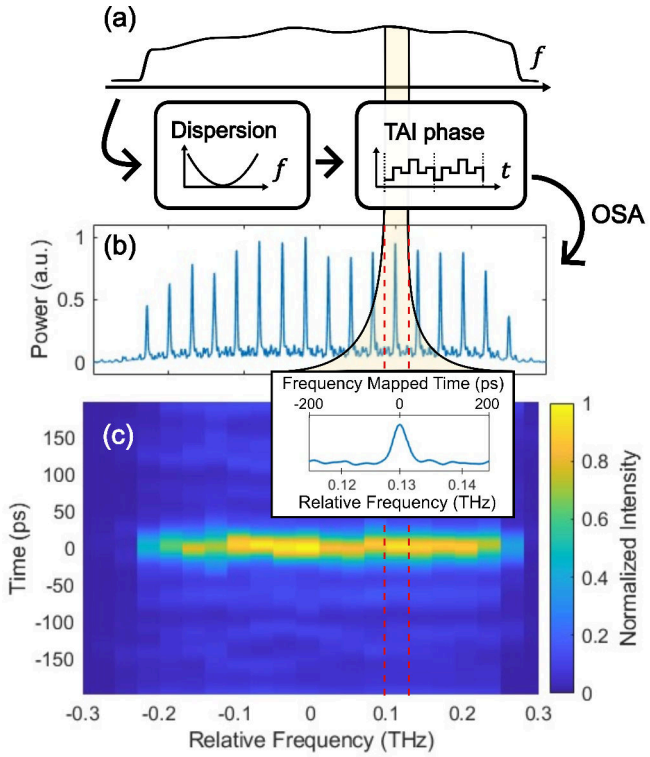

Fig. 1. Concept of the TAI-based linear optical short-frequency Fourier transform (SFFT) measurement. (a) A broadband transform-limited pulse is dispersed and then modulated with a temporal TAI phase profile. The output spectrum is measured by an optical spectrum analyzer (OSA). (b) Measured output optical spectrum after the proposed system. The selected spectral window, marked by the red dashed lines, provides the frequency-mapped temporal response shown in the inset. (c) Reconstructed time-frequency representation of the transform-limited input pulse, showing a temporally localized response across the measured bandwidth.

products above 16,000 [8]. The key point is that the optical system performs the time-frequency mapping, converting ultrafast temporal structure into a processed spectral waveform that can be measured with standard optical instrumentation.

Taken together, these results present TAI-based time-frequency structuring as a general phase-only methodology for analog photonic processing of broadband waveforms. The same physical ingredients, dispersive propagation and bounded temporal phase modulation, can support passive amplification, denoising, filtering, and single-shot time-frequency analysis, depending on the designed mapping. The approach is attractive because it does not require active optical gain or nonlinear conversion, and because its main components are compatible with practical photonic platforms. Near-term implementations can use dispersive fiber, chirped fiber Bragg gratings, electro-optic phase modulators, and optical spectrum analyzers, while integrated versions can build on dispersive waveguides, on-chip modulators, sources, and detectors [9]. More broadly, this work shows how concepts from structured light and Fourier optics can be translated from transverse beam shaping to the time-frequency processing of ultrafast waveforms.

***Abstract*— We demonstrate simultaneous generation of more than ten terahertz (THz) wavelengths using parametric generation and detection. Spectroscopic information is acquired in real time as camera images, enabling instantaneous sample identification via image recognition. The system allows rapid chemical sensing with strong potential for practical THz applications.**

***Keywords*—terahertz, machine learning, parametric generation.**

I. Introduction

One of the promising applications of terahertz (THz) waves is nondestructive inspection through opaque materials. For practical implementation, a real-time spectroscopic system capable of operating in the 1–2 THz region is required, since this frequency range offers material transparency and many chemicals exhibit characteristic fingerprint spectra.

To address this need, we have been investigating simultaneous multi-wavelength THz generation and detection by optically injecting multiple near-infrared (NIR) seed beam into an injection-seeded terahertz parametric generator (is-TPG)[1-3]. However, conventional approaches required the same number of injection light sources as the number of THz wavelengths, leading to issues such as high cost, limited controllability, and increased system complexity and size.

In this study, we employed cascaded multi-wavelength Stokes beams generated under high-intensity pumping in a nonlinear optical crystal ($LiTaO_3$) as multi-wavelength injection sources[4, 5]. Using only two seed laser with pump laser, we achieved simultaneous generation and detection of more than ten wavelengths in the 1–2 THz region.

II. Results and Discussion

The experimental setup is shown in Fig. 1. Laser beam emitted from an external-cavity semiconductor laser was pulse-amplified in a $LiTaO_3$ crystal under high intensity and then injected into a second crystal ($LiNbO_3$) to generate first- to fourth-order Stokes beams. Two such high-order Stokes beam sources (each generating different wavelength groups) were prepared. After passing through relay optics composed of lenses, they were combined using a half mirror and injected into a third $LiNbO_3$ crystal.

Through parametric wavelength conversion, multi-wavelength THz waves corresponding to the difference frequencies between each pair of injected wavelengths were generated. The generated multi-wavelength THz waves were upconverted to near-infrared detection Stokes beams via terahertz parametric detection and captured with a near-infrared

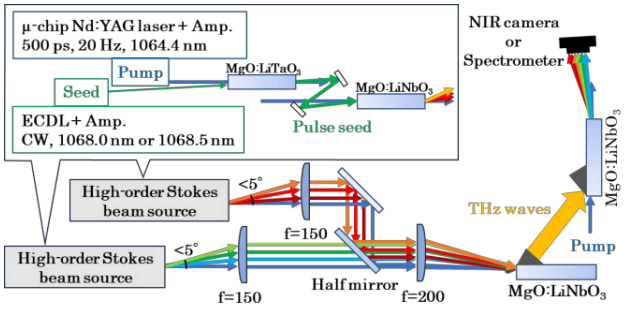

Fig. 1 Schematic diagram of multi-wavelength THz wave generation based on injection-seeded terahertz parametric generation (is-TPG) using high-order Stokes beams.

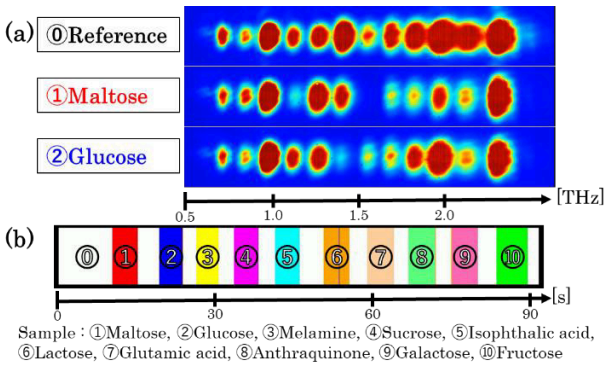

Fig. 2 Real-time identification of chemical reagents. (a) Representative detection Stokes images with and without sample insertion. (b) Time-series classification results obtained by machine learning.

camera. As shown in Reference in Fig. 2(a), simultaneous generation of 12 wavelengths was confirmed[6].

By combining this system with machine-learning-based classification[7], real-time reagent identification was demonstrated. Ten different reagents were sequentially inserted into the THz optical path, and the instantaneous changes in the detection Stokes beams were identified through image recognition. Examples of observed detection Stokes images without a sample, with maltose, and with glucose are shown in Fig. 2(a), clearly indicating differences depending on the sample.

The time-series results of machine-learning-based classification are shown in Fig. 2(b). Each color represents a different reagent. The system successfully achieved accurate real-time identification of all ten reagents.

III. Conclusion

We demonstrated simultaneous multi-wavelength terahertz generation and detection in the 1–2 THz region by using cascaded high-order Stokes beams in $LiNbO_3$ as multi-wavelength injection sources. More than ten THz wavelengths were generated and detected simultaneously with only two injection lasers.

By combining this system with machine-learning-based image recognition, real-time identification of ten different chemical reagents was achieved. The results indicate that the proposed method is effective for high-speed THz spectroscopic sensing and has strong potential for practical applications in chemical identification and nondestructive inspection.

***Abstract*—GaN waveguide polariton lasers are very promising for applications. We discuss recent experimental results and their theoretical description, including cw and pulsed mode-locked polariton lasing, the formation of single and multiple solitons in ridge waveguides, and also bound states in the continuum (BIC) and associated solitons in modulated waveguides.**

***Keywords*— polariton lasers, mode locking, solitons, bound states in the continuum.**

Polariton lasers are based on strong light-matter coupling of excitons and photons. They can exhibit a reduced lasing threshold thanks to the absence of the population inversion condition for Bose-Einstein condensation. GaN is one of the best materials for room-temperature polariton lasing [1] thanks to its robust excitons. Waveguide structures were suggested as best candidates for practical implementation of wide-bandgap polariton lasers, in particular in the UV, given that they provide longer photon lifetimes than planar microcavities and are much simpler to fabricate, opening the door to electrically-injected polariton lasers. Polariton amplification and lasing at room temperature have already been observed in polaritonic planar slab waveguides [2]. Here, we report several recent experiments with GaN ridge waveguides and modulated slab waveguides, focusing on the methods used for the theoretical description of these experiments.

First, *cw* monomode lasing has been observed from a ridge waveguide polariton laser under optical pumping [3]. A key feature of the polariton laser is that it does not require population inversion (or saturation of absorption), which allows lasing while pumping just a small fraction of the laser ridge. It is noteworthy that this configuration would preclude lasing in the standard electron-hole plasma regime. We used semi-classical Boltzmann equations coupled with propagation equations to describe this system and study the threshold dependence on the pumping fraction.

Next, by modifying the pumping conditions, multimode lasing was observed, with the intensity envelope exhibiting a shape characteristic for a soliton. Moreover, the modification of the free spectral range indicated the presence of mode locking [4]. We developed a model describing strong coupling of a guided photonic mode and an excitonic resonance, including spatial propagation, exciton-exciton interactions, losses, and gain due to exciton-exciton scattering from the reservoir. The model reproduces the formation of a spatiotemporal soliton, the change of the shape of the spectrum, and the mode locking due to polariton interactions. Further experiments and simulations have demonstrated the possible simultaneous presence of multiple coexisting solitons depending on the position of the pump (Fig. 1).

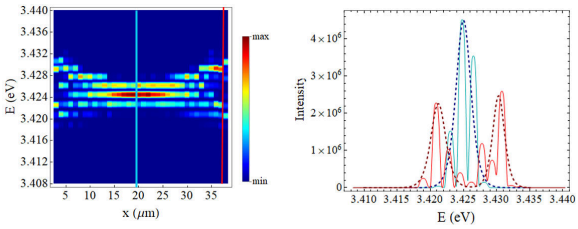

Fig. 1. Left: calculated spectrum of mode-locked polariton lasing as a function of the position of the pump along the ridge length, exhibiting a transition between a single soliton and two solitons. Right: two particular spectra for the pump positions indicated by red and blue vertical lines in the left panel.

Finally, we also studied polariton lasing in slab waveguides with a periodic modulation leading to the formation of bound states in the continuum (BICs) [5], characterized by a quenched emission rate. Computing the eigenstates with COMSOL, we demonstrate the topologically protected nature of the BIC, confirmed by polarization and momentum-resolved

experiments. Simulations of polariton condensation using a 1D time-dependent Schrödinger equation with gain, loss and interactions, demonstrate the formation of a spatial soliton at the BIC, also confirmed by experiments. The formation of this soliton is important because it affects the angular properties of emission of BIC polariton lasers, as well as their emission rate.

To conclude, we have successfully developed several theoretical models to describe different aspects of polariton condensation in GaN waveguides that reproduce qualitatively and quantitavely the experiments performed on such GaN structures.

***Abstract*— Inverse design of flat optics typically requires the simulation and optimization of systems described by over millions of parameters, which is computationally challenging. Addressing this, we introduce an open source inverse design framework and investigate its suitability in handling large parameter spaces and its most suitable optimization algorithm approaches.**

***Keywords*— inverse design, flat optics, meta-optics**

I. Introduction

Inverse design enables optimized optical elements/ optical systems reaching outstanding performance and optical functionalities beyond human intuition. Particularly, inverse design of complex shaped, i.e. freeform, flat optics has evidenced the possibilities in optimizing achromatic performance of focusing lenses [1], holograms [2], or image recognition [3], both in diffractive [4] and metasurface forms.

These advancements were enabled by the remarkable progress in computational capabilities, especially regarding gradient-based optimization strategies. In these, the calculation of the gradient is the crucial step, which has historically been performed via the Adjoint method [5]. Recently, the advent of machine learning frameworks and efficient software packages enabled the possibility to accurately calculate the gradient via automatic differentiation [6], which strongly increases design possibilities [7]. Automatic differentiation (AD) is a powerful method ultimately based on a chain rule differentiation, efficiently implemented in machine learning packages such as JAX [8]. Recent implementations show that AD is a feasible tool for inverse design of flat optics, both when employing Rigorously-Coupled Wave Analysis (RCWA) [9] or Finite-Difference Time-Domain (FDTD) [10] approaches for individual meta-element design, or when employing the thin-element approximation (TEA) with numerical diffraction propagators for amplitude and phase element design of the optical element [11]. In this line, Ref. [11] also demonstrates the appropriateness of the TEA and the local periodic approximation in design of metalenses through AD gradient-based optimization.

While AD and Adjoint method might be equivalent [12], their implementation in gradient-based optimization frameworks might differ and lead to different optimization performance (e.g. convergence, optimization time and memory usage). For large number of optimization parameters, such as the ones required in inverse design of flat optics typically with over millions of parameters, the optimization performance depends on the gradient calculation strategy, and its implementation as part of the optimization algorithm on a particular application use case [13,14]. From these, beam shaping applications are important use cases for which inverse design has demonstrated great success, both with AD [15] and Adjoint methods [16]. Yet, despite the recent success of AD approaches [15] and the historical robustness of Adjoint methods [17], their impact on the optimization performance remains unclear in the inverse design of freeform beam shaping elements within the thin element approximation.

II. Methods

Here, we introduce an optimization framework implemented into the open source package pyMOE [18] as a tool to perform inverse design of flat optics within the TEA, applied to beam shaping applications. The optimization framework flowchart is represented in Figure 1.

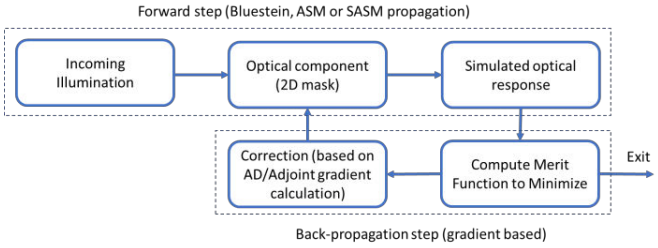

Fig. 1 Inverse design framework.

The optimization is performed such that a realistic target figure of merit is calculated for the output optical field of the element or optical system under design. The target figure of merit is a function of the system parameters, such as the number of pixels representing the optical system, which imparts a modulation of amplitude and phase to a traversing optical field. Forward simulation is employed to calculate the output field. For this purpose, efficient Bluestein [19] and (Scalable) Angular Spectrum Method (ASM) propagators [20] were implemented in Python and JAX. A loss function is constructed regarding the figure of merit quantity of the output propagated field against the desired target. The loss is iteratively minimized in a gradient-based optimizer algorithm until a convergence is reached. As such, the optimization performance depends on the gradient quality and gradient calculation efficiency.

III. Results and Discussion

To test its impact on the optimization performance, we present different inverse design runs with gradient calculations via either AD and the Adjoint method. Different optimization algorithms, such as Adam and algorithms available within SciPy optimize package, were evaluated for each of these gradient calculation methods and systematically compared. The optimization performance in terms of the figure of merit value, optimization convergence, and computation performance metrics are reported.

IV. Conclusion

This work demonstrates the merits of AD and Adjoint methods as gradient calculation strategies in gradient-based inverse design problems applied to beam shaping. The results demonstrate the suitability of the open source package pyMOE as a tool for optimization and design of realistic freeform flat optics described by a large number of parameters. The benchmarking results provide a guide for the development of appropriate inverse design numerical architectures for beam shaping applications, in terms of gradient calculation strategy and optimizer choice, as function of the number of optimized parameters. These numerical inverse design approaches generated optical elements susceptible of being physically validated in Spatial Light Modulator test setups [21], grayscale lithography [22], and/or metasurface implementations.

Nonreciprocal Surface Plasmons in a Metasurface Formed by Magnetically Biased Plasmonic Cylinders

***Abstract*— We study a metasurface formed by magnetically biased plasmonic cylinders supporting nonreciprocal magnetoplasmonic modes. Using a magnetized Drude model and cylindrical wave analysis, the electromagnetic response of the structure is investigated. The metasurface exhibits asymmetric dispersion and directional surface plasmon propagation, enabling tunable nonreciprocal behavior.**

***Keywords*— Magnetoplasmonics, Metasurfaces, Nonreciprocal wave propagation, Computational electromagnetics**

I. Introduction

Metasurfaces composed of subwavelength scatterers have emerged as powerful platforms for manipulating electromagnetic waves with unprecedented flexibility. By carefully engineering the geometry and material properties of their constituent elements, metasurfaces can control the amplitude, phase, and direction of scattered radiation, enabling applications such as beam steering, anomalous reflection, and wavefront shaping. In recent years, particular interest has been directed toward nonreciprocal metasurfaces, which break time-reversal symmetry and enable asymmetric propagation of electromagnetic waves. Nonreciprocity can be achieved through the use of magneto-optical or gyrotropic media, where the application of an external magnetic bias modifies the motion of charge carriers and introduces anisotropic electromagnetic properties. In plasmonic materials, the presence of a magnetic field affects the dynamics of free electrons through the Lorentz force, resulting in a tensorial permittivity with off-diagonal components responsible for nonreciprocal behavior. Such magnetoplasmonic systems have been shown to exhibit enhanced nonreciprocity when properly engineered [1]. Beyond conventional magneto-optical devices, nonreciprocal electromagnetic responses have also been explored in photonic topological systems, where breaking time-reversal symmetry can give rise to chiral surface states with robust propagation characteristics [2]. These developments highlight the importance of designing structured media capable of supporting asymmetric electromagnetic interactions

II. Methods

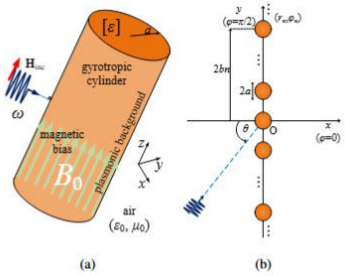

Figure 1: The building block of the considered setup. An infinitely long plasmonic cylinder biased by an axial magnetic field to inherit it with gyrotropic properties. TEz fields are assumed, able to "feel" the developed anisotropy. (b) Infinite core-shell cylinders positioned along vertical y axis to form a metasurface that gets obliquely excited by a plane TEz wave whose direction of propagation forms an angle θ with the horizontal x axis

The system under consideration consists of infinitely long plasmonic cylinders subjected to a static magnetic field applied along their axis. Under the influence of the magnetic bias, the conduction electrons within the plasmonic medium follow the magnetized Drude model, which leads to a gyrotropic permittivity tensor. The resulting medium is characterized by anisotropic electromagnetic properties, including off-diagonal permittivity components responsible for coupling orthogonal electric field components. The electromagnetic response of the structure is analyzed under transverse electric excitation, where the magnetic field is oriented parallel to the cylinder axis. The wave equation in the gyrotropic medium is solved analytically using cylindrical coordinate transformations and partial wave expansions. When the cylinder radius is significantly smaller than the operational wavelength, a dipolar approximation can be applied, allowing the scattering response to be expressed using only the lowest-order azimuthal harmonics. The metasurface configuration is formed by arranging the cylinders periodically along one spatial direction with a constant separation between adjacent rods. Each cylinder acts as a meta-atom, and the collective response of the array determines the electromagnetic behavior of the metasurface. The scattered

field from the entire structure is derived using cylindrical wave addition theorems and periodic summation techniques commonly used in the analysis of cylindrical metamaterial systems [4,5]. By applying appropriate boundary conditions at the surface of the cylinders, the scattering coefficients associated with the dominant azimuthal modes are determined. These coefficients are then used to evaluate the near-field and far-field scattering properties of both individual cylinders and the metasurface array.

III. Results and Discussion

Magnetically biased plasmonic cylinders exhibit strongly asymmetric scattering due to the difference between azimuthal modes +1 and -1. To quantify this behavior, a nonreciprocity metric is introduced based on the difference between the scattering coefficients of the two dipolar modes. In the absence of magnetic bias, the system remains reciprocal and the two modes possess identical amplitudes. However, when the cyclotron frequency associated with the magnetic field becomes nonzero, the degeneracy between these modes is lifted, producing strongly asymmetric scattering patterns. By exploring the parameter space defined by the operational frequency, cyclotron frequency, and cylinder size, operating regimes corresponding to maximally nonreciprocal scattering can be identified. In these regimes, one of the dipolar modes dominates the scattering response while the opposite mode becomes strongly suppressed. As a result, the scattered radiation exhibits highly asymmetric angular distributions. Multipolar analysis [6,7] shows that the enhanced nonreciprocity arises from the interaction between electric and magnetic dipole contributions to the scattering response. The interference between these modes produces strong directional radiation patterns and modifies the energy distribution in the near and far field. When the optimized cylinders are arranged into periodic arrays, the resulting structure behaves as a diffractive metasurface. The metasurface exhibits pronounced direction-dependent transmission and reflection properties when illuminated from opposite oblique directions. In particular, the distribution of diffracted power among the available diffraction orders changes significantly depending on the direction of incidence. This behavior demonstrates how the intrinsic nonreciprocal properties of the gyrotropic cylinders can be translated into collective metasurface responses.

IV. Conclusion

We investigated the electromagnetic response of magnetically biased plasmonic cylinders and demonstrated their use as meta-atoms for nonreciprocal metasurfaces. Analytical modeling based on cylindrical wave expansions revealed regimes where the asymmetry between azimuthal dipolar modes leads to maximally nonreciprocal scattering. Periodic arrays of these cylinders form metasurfaces exhibiting direction-dependent diffraction and asymmetric electromagnetic responses. These results highlight the potential of gyrotropic plasmonic structures for wavefront control and the development of nonreciprocal photonic devices.

Nonlocal metasurfaces for Quantitative Phase Microscopy

Ann Roberts[1,*]

[1]ARC Centre of Excellence for Transformative Meta-Optical Systems, School of Physics, The University of Melbourne, Victoria, Australia[2]

*Corresponding author: ann.roberts@unimelb.edu.au

***Abstract*— Metasurfaces offer significant promise in imaging applications where operations are performed on an optical field carrying information about a sample. In particular, they can facilitate phase contrast imaging of transparent objects in a compact platform. Here we discuss the application of nonlocal metasurfaces to the quantification of phase.**

***Keywords*— metasurfaces, phase contrast imaging, quantitative phase microscopy, image processing**

I. Introduction

The visualisation of transparent samples such as biological cells remains an ongoing challenge. Stains and exogenous labels are widely used in biomedical applications and medical diagnostics, but these fundamentally change the sample. Furthermore, this is not an option for imaging of non-biological materials. When light propagates through a sample, variations in thickness and refractive index within it change both the amplitude and the phase of the transmitted field. Although the amplitude can be sensed directly with a camera or by eye, in many cases significantly more information is encoded in the phase. This has motivated the development of a wide range of methods to not only enhance the contrast of an image by converting phase information to detectable intensity, but also to quantifying the phase itself. The latter provides detailed information about cell morphology, refractive index, and/or other relevant sample parameters. Qualitative imaging methods include Zernike phase contrast [1] and widely-used Differential Interference Contrast (DIC) Microscopy. Avenues to quantification, on the other hand, include interferometric approaches such as holographic microscopy as well as non-interferometric methods that can be further subdivided into deterministic and iterative approaches [2]. The latter are potentially time-consuming and resource-intensive, counter to the drive for sensor-level processing whereas currently available deterministic methods tend to involve the complex systems typically required to acquire multiple images. Metasurfaces, however, are attracting increasing interest as potential components in next-generation, compact, phase contrast imaging systems [3]. Here we discuss the use of nonlocal metasurfaces, multiplexing wavelength and polarisation, to Quantitative Phase Microscopy (QPM).

II. Methods

Here we demonstrate the application of nonlocal metasurfaces to converting phase gradients within an optical field to intensity [4,5] and then using this information to quantitatively extract the phase. Such devices have a characteristic dependence of the plane wave transmission through the metasurface on angle of incidence which, when considering the angular spectrum decomposition of an optical field, means that the device performs direct, in plane, filtering its spatial frequency content. This modifies the field and its intensity and is the basis of object plane Fourier filtering [6].

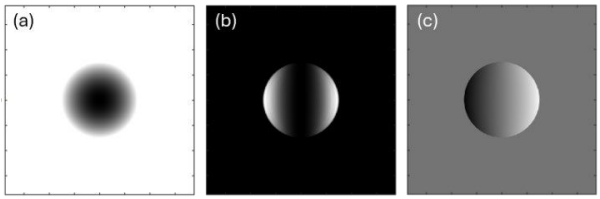

Fig. 1 (a) Phase map introduced by a spherical phase object into an optical field with zero intensity contrast; (b) resulting intensity after the field has passed through a metasurface with transfer function directly proportional to k_x; (c) intensity after the field has passed through a metasurface with transfer function of the form $H(k_x) \propto a + bk_x$.

In contrast to local metasurfaces, these Fourier processing devices are characterised in terms of their transfer function $H(k_x, k_y)$. Consider a metasurface where the transfer function is approximately linear in a component of the spatial frequency, e.g., $H(k_x) \propto k_x$. Light that has passed through a pure phase object (e.g., Fig. 1(a)) and then filtered by this metasurface results in a field that is proportional to the derivative of the phase with respect to the corresponding spatial coordinate, converting phase gradients to intensity (e.g., Fig. 1(b)). Information about the sign of the phase gradient, however, is lost. On the other hand, an offset can be introduced into the transfer function via off-normal illumination [5] or design [7,8], to produce an effective transfer function of the form $H(k_x) \propto a + bk_x$ where a and b are constants. This transfer function, asymmetric about normal incidence, generates a pseudo-3D

phase contrast image when used to image transparent objects (e.g., Fig. 1(c)) providing more information about the sample.

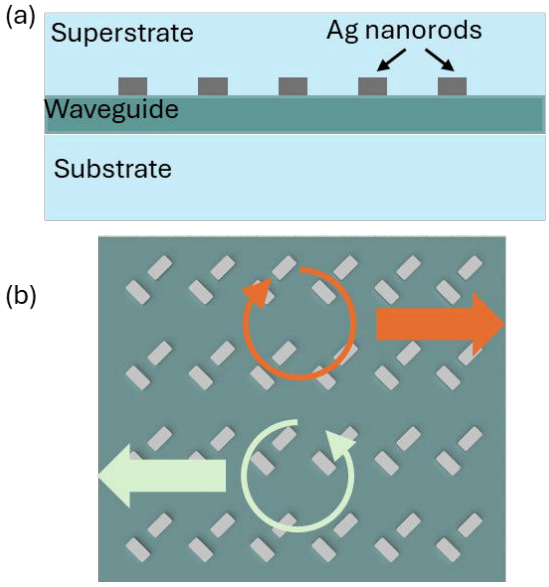

Fig. 2 Schematic showing the optical routing metasurface with (a) a side view and (b) a top view of the device highlighting the optical routing effect.

Here we generate this transfer function via the optical routing effect (Fig. 1) [7,8]. The metasurface consists of a 2D resonant waveguide grating with the waveguiding layer consisting of Si_3N_4 on a glass superstrate with a PMMA coating. Each unit cell consists of two orthogonally oriented Ag nanorods. Linearly polarised light at wavelength λ_1 illuminates a sample of interest. The transmitted field then passes through the metasurface and is then imaged with a polarisation-sensitive camera after passing through a quarter waveplate permitting discrimination of RCP and LCP images. Each of these images is formed with an asymmetric transfer function about $k_x = 0$ where changing the handedness of detection reverses the contrast of the image. This permits construction of a Differential Phase Contrast (DPC) image

$$I_{DPC} = \frac{I_{RCP} - I_{LCP}}{I_{RCP} + I_{LCP}} \quad (1)$$

highlighting horizontal phase gradients. Furthermore, the device is designed so that at a shorter wavelength λ_2, where $\lambda_1 - \lambda_2 \approx 40\,nm$, it has an asymmetric transfer function about $k_y = 0$ producing a DPC exhibiting vertical phase gradients. The DPC images generated at both wavelengths are sufficient to reconstruct the phase introduced into the field.

III. Conclusion

In this presentation the application of nonlocal metasurfaces exhibiting the optical routing effect to QPM will be discussed. The results of investigations into synthetic and biological samples will be presented.

Realization of Photonic Parallel Spaces and Overlapping Optical Devices

Yun Lai[1,*]

[1]School of Physics, Nanjing University, China
*Corresponding author: laiyun@nju.edu.cn

***Abstract*— We demonstrate the realization of photonic parallel spaces, i.e. meta-structures that behave as distinct effective media—with different refractive indices, impedances, or anisotropy—within the same physical space. This mechanism enables physically overlapping optical devices that operate independently, as if they exist in different dimensions.**

***Keywords*— metamaterials, parallel spaces, machine learning, photonic crystals.**

I. Introduction

Miniaturization and high-density integration are one of the central issues in modern science and technology. In classical physics, this is hindered by the one-to-one correspondence between a material and its unique effective parameters, making functional multiplicity inherently incompatible. Metamaterials have expanded parameter spaces beyond natural materials, yet still largely assume a one-to-one mapping between structures and their effective parameters. Here, we demonstrate a general class of meta-structures that can support multiple groups of eigenstates within the same frequency band, which are localized at distinct positions away from the Brillouin zone center in the momentum space. Each group of eigenstates correspond to a single effective medium. Depending on the boundary of excitation, different groups of eigenstates are selectively activated, causing the same structure to behave as distinct effective media—with different refractive indices, impedances, or anisotropy—within the same physical space. This phenomenon thus resembles the concept of parallel spaces existing in different dimensions, enabling functional multiplexing in space and opening a pathway toward ultra-compact, multi-functional optical systems composed of overlapping optical devices.

II. Methods

The phenomena of photonic parallel spaces and overlapping optical devices have been verified both numerically and experimentally through a series of designs.

The effective parameters of the meta-structure have been retrieved through both the transmission/reflection coefficients or the eigenfields. Both methods lead to the same results. Such parameters describe the bulk wave propagation in the meta-structure as well as the refraction/reflection behavior upon the selected boundary, but differ distinctly on different boundaries.

III. Results and Discussion

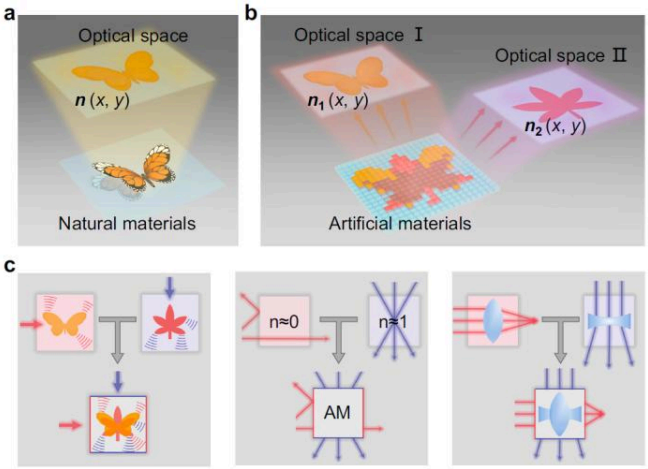

Fig. 1 The concept of photonic parallel spaces and overlapping optical devices.

Figure 1 shows the concept of photonic parallel spaces and overlapping optical devices. Unlike natural materials, meta-structures can exhibit two different distributions of refractive indices, impedances or anisotropy. For instance, such meta-structures can behave as the coexistence of a butterfly and a maple leaf, a n=0 material and a n=1 material, or a concave lens and a convex lens. They function independently for incident waves upon different boundaries. Numerical and experiments proofs will be shown in the talk.

IV. Conclusion

We have demonstrated the exciting possibility of creating photonic parallel spaces with metamaterials. This finding breaks the one-to-one correspondence between a material and its unique effective parameters for the first time.

***Abstract*— Waveguide-based dielectric laser accelerators are an emerging platform for the realization of miniaturized particle sources. In this work, we introduce a general time-domain adaptive approach that guarantees continuous synchronization between the pulsed accelerating field and particle motion in a tapered waveguide accelerator. Flexibility and accuracy of the methodology are illustrated through numerical examples with long and short pulses, as well as pulse trains.**

***Keywords*— Dielectric laser accelerators, guided-wave structures, tapered waveguides, dispersion engineering, time-domain electromagnetic modeling, optical pulse propagation.**

I. ADAPTIVE TAPERING STRATEGY

The optimal taper profile required to maintain continuous matching between the particle and phase velocity of a guided mode can be determined from the particle dynamics in the actual electromagnetic field. The taper also affects pulse propagation by modifying the envelope group velocity, higher-order dispersion coefficients and modal profile.

In this framework, it is necessary to evaluate, point by point, the relative position of the particle with respect to the pulse envelope to determine the change in particle velocity and, in turn, establish the taper. The idea behind the developed approach is to co-propagate the particle and the pulse and progressively determine the optimal waveguide profile.

Considering that the initial conditions of the problem are the velocity of the particle and the envelope of the input pulse, the optimal taper can be determined from calibration curves evaluated through mode solving. It follows that the particle time at each position, and therefore the field experienced by the particle, are calculated by applying an iterative process which continues until the particle reaches the end of the waveguide.

II. NUMERICAL EXAMPLE

The reported numerical examples focus on the longitudinal dynamics of a single electron along the axis of slot waveguides, where the transverse field components are negligible. This simplification allows for a clear treatment of the problem, while the approach can be extended to include transverse dynamics.

A relevant example of application of the algorithm is the taper for a slot waveguide driven by a pulse train. This configuration enables substantial increases in particle speed by applying short pulses in cascade. For the design example, a train of 5 pulses with $E_0 = 0.33$ GV/m and FWHM = 0.2 ps, spaced $\Delta t_0 = 0.6$ ps apart, has been considered, as illustrated in Fig. 1.

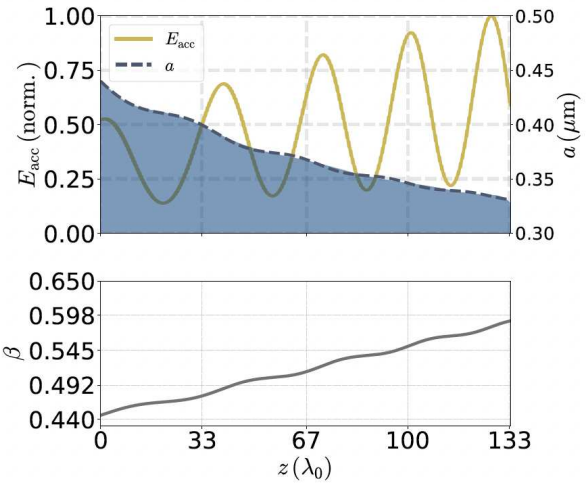

Fig. 1 Accelerating field and taper parameter a ensuring particle–field synchronization (top), and particle velocity β (bottom) along the accelerating path, induced by a train of Gaussian pulses.

***Abstract*—We develop a general method to bound the ordered singular values (channel amplitudes) of the electromagnetic Green function or W-operator for arbitrarily structured linear photonic systems. The approach yields computable, quantitatively predictive, upper bounds on the n^{th} singular value that capture the complexity of multi-channel tradeoffs and competing scattering effects.**

***Keywords* limits, inverse design, photonic design, optimization.**

I. Introduction

Motivations for wanting optical devices capable of controlling as many distinct inputs as possible are simple and compelling: e.g., (1) we would like to process more information, more efficiently [1]; (2) many electromagnetic devices are essentially communication systems, and communication performance is essentially the capacity of a system to transform distinguishable inputs [2]; (3) advances realized in machine learning over the past decade have opened previously unimaginable possibilities in signal processing and inference [3], removing many former operational constraints for electromagnetic information transfer.

From this vantage, the abstraction of channels and singular value decomposition (SVD) provides as a natural language for linear system design. Conceptually, SVD expresses the action of a linear operator as completely decoupled transformations, which tends to simplify both mental and phenomenological descriptions. For example, many electromagnetic processes are (relatively) simply described in terms of the Green operator [1], re-framing phenomenological understanding as questions of why the Green operator possess certain characteristics. Via SVD, the Green function is broken down into orthogonal "channels"—mappings between input currents in some sender to output fields in some receiver—that can be analysed independently, and are quantitatively ordered in terms of relative importance by their singular values or "channel amplitudes" (top Fig. 1). Practically, the first n transformation pairs of SVD sum to give the most accurate n-rank approximation that can be made to a linear operator under the nuclear or Frobenius (Hilbert-Schmidt, or trace) norm. Due to the effective equivalence between these norms and common engineering objectives like loss functions, power transfer and energy density, SVD is innately suggested in a variety of application areas [4].

Granting the utility of SVD in design, several questions are brought forward. Principally, how can the singular values of a device be analyzed and controlled [5], [6], [7]? And the complement, how many channels can a device (of some given size, composed of some given materials) possibly support above a specified cut-off value [8], [9], [10]? Our results continue ongoing efforts to understand the (fundamental) limitations of electromagnetic devices along this second line. Specifically we will showcase the first method to generally answer the following question that beings captures the tradeoffs imposed by multiple inputs and antagonistic scattering phenomena. *Given some volumes of space that may contain arbitrarily structured materials, how large can the n^{th} singular value of an electromagnetic transfer function (Green function or W-operator) be?*

Beyond its direct implications for multi-functionality, this metric is intertwined with a number of physical quantities of interest. For example, under an additive noise model (detector dominated noise), the number of singular values above a threshold strongly dictates achievable Shannon capacity [11], and is also closely related to mutual information [12] and Fisher information. Consequently, there are a range of scenarios related to communication, imaging and classification wherein the number of singular values that can be engineered above some cut-off is of paramount importance to performance. Moreover, nearly any trace formulation can be restated as a functional sum over the singular values of some transfer function, and in this way channel counts above a cut-off value provide an interesting point of comparison for a diverse collection of physics, such as emission phenomena like fluorescence, thermal radiation, heat transfer, and Casimir forces, as well as scattering phenomena like cloaking, extinction, absorption

Building through four illustrative examples pertaining to meta-optic design, laser awareness, and near-field heat transfer, our findings indicate that by combining the Courant-Fischer-Weyl min-max principle with a "rank-removal" corollary and

[1]Defined here as the inverse of the Maxwell operator—i.e. the linear mapping between currents and fields of an electromagnetic system.

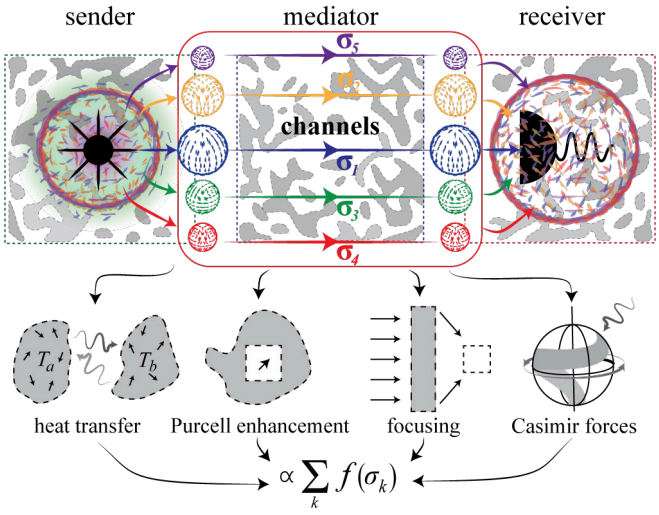

Fig. 1. **SVD, channels and channel amplitudes.** The figure illustrates the meaning of an electromagnetic channel in the sender-mediator-receiver convention. Each channel consists of a pair of connected input-output fields (one in the sender and one in the receiver) that are orthogonal to the fields of every other channel, along with a channel amplitude (the singular value σ_k) that dictates the strength of the mapping. Working in terms of channels leads to a completely decomposed description of communication. The lower part of the figure shows four physical phenomena, among many, that are described by functional sums over singular values: heat transfer, Purcell enhancement, lensing, and Casimir torques.

convex relaxation bounds [13] quantitatively accurate limits on the maximum (or minimum) of the n^{th} singular value of typical electromagnetic transfer functions are computable for moderately sized devices (up to $64\ \lambda^3$).

The photonic gearbox: ultra-high local density of states via cylindrical-symmetry breaking

Alessio Amaolo[1,*]

[1]Department of Chemistry, Princeton University, Princeton, NJ, USA
*Corresponding author: alessioamaolo@princeton.edu

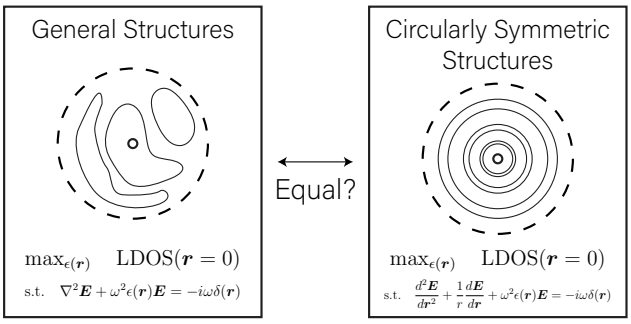

Fig. 1. Symmetry breaking in LDOS maximization. Comparison of the optimization domain for general, arbitrary dielectric structures (left) versus strictly cylindrically symmetric profiles (right). While intuition suggests that symmetric "Bragg onions" are optimal, we investigate whether the additional degrees of freedom in non-symmetric geometries can yield super-exponential scaling by coupling to higher angular momentum modes.

***Abstract*—We introduce the "Photonic Gearbox," a cavity design leveraging discrete rotational symmetry for potential super-exponential LDOS scaling. By computing fundamental limits for cylindrically symmetric structures, we empirically demonstrate the gearbox exceeds these bounds. This rigorously proves that symmetry breaking unlocks performance regimes strictly inaccessible to conventional cavity geometries.**

***Keywords*— metamaterials, inverse design, fundamental limits**

I. Summary

While traditional photonic engineering relied on assembling known physical building blocks like waveguides and resonators [1], [2], [3], the field is currently undergoing a paradigm shift toward computational inverse design. By treating the design process as a massive optimization problem, we can now discover complex, non-intuitive geometries that vastly outperform conventional devices [4], [5], [6]. However, a critical barrier remains: the "black box" nature of these gradient-based algorithms creates a fundamental ambiguity. When an optimization stalls, it is difficult to distinguish between a failure of the algorithm (trapped in a local minimum) and a failure of physics (hitting a fundamental limit). Resolving this ambiguity is essential for the next generation of optical device design. Complementing these numerical search methods is a parallel effort to quantify the ultimate physical limits of light-matter interaction. The key insight rests on a reformulation of the structural design problem to an optimization over fields (instead of geometry) subject to power conservation constraints [7], [8]. This framework has been applied to a vast array of problems, identifying scaling laws and certifying the optimality of known designs [9], [10], [11], [8], [12], [13].

In this talk, we first summarize important results in the area of photonic limits, illustrating how they can be used not only as performance metrics but useful figures for fundamental scaling behavior. We then discuss how fundamental limits are beginning to yield new paradigms of photonic design, whereupon information from fundamental limit relaxations can be leveraged to initialize inverse design problems near their global optima. We focus on one particular case study: the maximization of the Local Density of States (LDOS) in the case of a dipole surrounded by a structured cavity, a metric critical for spontaneous emission, heat transfer, and photovoltaics. In this case, standard physical intuition suggests that optimal structures resemble "Bragg onions", cylindrically symmetric quarter-wave stacks that yield exponential scaling with size via bandgap confinement. Rough arguments can be made to say that this must be optimal; for example, breaking the cylindrical symmetry could destroy the bandgap, reducing mode quality. Alternatively, we may argue that the symmetry of the problem itself requires cylindrically symmetric global optima. These structures also exhibit very favorable scaling; intuitively, each layer of the onion adds a constant factor reflectance, leading to an exponential scaling with size that is only capped by losses or by finite source bandwidth. Inverse design initialized with these structures can improve performance slightly; e.g., finite-size effects can be accounted for, yielding roughly a constant factor improvement. Yet the *scaling* remains: no structures have been found with super-exponential LDOS scaling.

Two fundamental questions arise. First, can the additional degrees of freedom available by breaking cylindrical symmetry be leveraged to exceed the performance of circularly symmetric structures? Second, can the exponential scaling of cylindrically symmetric structures be exceeded? Inspired by limits-based-design, we show an example where we answer these questions in the affirmative. These structures have discrete rotational symmetry and appear to work by coupling $m = 0$ to higher angular-momentum modes (hence the "gearbox" name). In the case of lossy structures, we demonstrate examples where gearboxes exceed the fundamental *limits* of performance

of cylindrically symmetric structures, constituting a proof of the necessity of symmetry breaking for optimal LDOS enhancement. Empirically, these structures also exhibit *super-exponential* scaling of LDOS enhancement with size up to a Q-factor of a billion, where the numerics of topology optimization begin to hinder convergence. These results suggest that improved scaling can be achieved via symmetry breaking even for a cylindrically symmetric problem, a surprising result with a multitude of potential applications.

Multiscale simulations of electronic excitations of molecules coupled to plasmonic nanostructures

Stefano Corni[1,2*]

[1]Department of Chemical Sciences, University of Padua, Italy
[2]CNR Institute of Nanoscience, Modena, Italy
*Corresponding author: stefano.corni@unipd.it

***Abstract*— Multiscale models for coupling electronic excitations and localized surface plasmon excitations have been developed, based on boundary element methods approach for the plasmonic nanostructures. Here such approaches will be presented and the latest development discussed, particularly in relation to quantization of the nanoparticle response.**

***Keywords*— boundary element methods, localized surface plasmons, molecular electronic excitations.**

Localized surface plasmon excitations, supported by, e.g., metallic nanostructures allow very high electromagnetic coupling with nearby molecules. Accurate modeling of these effects requires using a classical electromagnetic for the nanostructures, which should be coupled to an electronic structure description of the molecules whenever its spatial extension and chemical nature are relevant.

Through the year we have developed the theoretical framework and software implementation to address such coupling, using a boundary element method approach to the electromagnetic problem.[1] We have in particular focused on the quantized description of the nanostructures,[2,3] needed to investigate the strong coupling regime between the molecular and the plasmonic excitations.[4] In this talk I will present the recent developments of such modeling approach, and examples of applications.

***Abstract*— We exploit metamaterials to control wave propagation in multiple dimensions. Studies include the calculation of mathematical operations such as partial differential equations in space as well as the emulation of time refracted waves using metamaterials that are time dependent.**

***Keywords*— metamaterials, 4D metamaterials, time interfaces, Time-Varying media.**

I. Discussion

Metamaterials enable careful engineering of waves by modifying the space (geometries and materials) along which they propagate. Since their advent, they have opened new avenues for the development of improved devices (as well as the proposal and demonstration of new structures) in applications within science and engineering [1–4].

A relevant application in the field of metamaterials is the calculation of mathematical operations [5], with examples involving vector matrix multiplication, temporal derivates as well as integration and convolution (among others) [6–10]. In addition to manipulating waves in space (x,y,z), time t can also be introduced as a new variable, giving rise to four-dimensional metamaterials (4D, x,y,z,t) [11]. Among different temporal and spacetime modulations currently being explored, time interfaces are particularly interesting as they represent the *equivalent* of spatial interfaces between two materials [12]. Time interfaces have been explored in multiple scenarios [13–22], with experimental demonstrations starting to be reported [23–25].

Inspired by the importance of metamaterials to sculpt waves, here we present our latest efforts in the field by exploring wave propagation in spatial and spacetime media. We will show how metamaterials can be used to calculate the solution of partial differential equations (PDEs) in space by carefully engineering arrays of waveguides (from microwaves up to the optical regime) [26]. Moreover, applications in time varying media will include the emulation of time refraction using slow temporal changes of the optical properties of the medium as well as mimicking photonics *temporal aiming* using isotropic spacetime effective media[27–31].

***Abstract*— We demonstrate Miexciton enhanced fluorescence in monolayer WS_2 coupled with Silicon Huygens metasurface. We observed 18-fold enhancement of photoluminescence from A-exciton in monolayer WS_2 in intermediate coupling regime.**

***Keywords*— Miexciton, photoluminescence, WS_2, Huygens metasurface, intermediate coupling regime**

I. INTRODUCTION

Two-dimensional (2D) nanomaterials hold promise for many photonics applications [1]. Thanks to strong confinement energy of 2D exciton within atomic layer thickness, monolayer transition metal dichalcogenides (TMDCs) are expected to be applied in nanophotonic semiconductor devices operating at room temperature. A coherent coupled system between surface plasmon and 2D exciton in TMDCs, which is named "plexiton," has been attracted much interests over the past ten years [2-4].

In recent years, coherent coupling between multipole/anapole mode in single Mie resonator and exciton in TMDCs has been achieved and the enhancement of photoluminescence (PL) has been demonstrated [5,6]. These coupled modes are so called "Miexciton". We proposed in theory Si Huygens metasurface boosts absorptivity of monolayer WS_2 further using degenerated electric dipole (ED) and magnetic dipole (MD) [7].

In this talk, we report the recent progress of our experimental study about Miexciton and enhanced fluorescence of A-exciton in monolayer WS_2 placed on Si metasurface. We obtained Rabi splitting energy of Ω =81meV and observed 18-fold enhancement of PL in intermediate coupling regime [8].

II. METHODS

We fabricated single crystalline Si (c-Si) metasurface on quartz substrate. Then, we transferred a commercially obtained monolayer WS_2 grown on a sapphire substrate to the metasurface using a surface-energy-assisted transferring process.

III. RESULTS AND DISCUSSION

We observed the total absorptivity of the Miexciton reaches ~0.84 with Rabi splitting energy of Ω =81meV. In addition, the PL intensity increased exceeding 18-fold compared to a quartz film. From absorptivity spectra, we obtained energy damping rates of Miexciton γ_1=82meV and γ_2=124.6meV (exciton and Mie mode). We confirmed that this system is in intermediate coupling regime, i.e. $|\gamma_1 - \gamma_2|/2 < \Omega < (\gamma_1 + \gamma_2)/2$.

These results suggest that Miexciton in intermediate coupling regime enables substantial enhancement of PL processes, providing a powerful strategy for boosting light–matter interactions in 2D nanomaterials.

***Abstract*—We present measurements of small-scale radiative heat transfer of a glass microsphere immersed in a thermal bath facing three different planar substrates (SiO_2, SiC, and Au), or another glass microsphere, under vacuum, with different temperatures imposed within the system. We reveal many-body contributions and a subtle competition between near-field and far-field heat transfer.**

***Keywords*— thermal radiation, micro/nano scales, multi-probe measurements.**

INTRODUCTION

Several experimental demonstrations of near-field enhancement of radiative heat transfer between two bodies have been reported when a microsphere is positioned at a distance smaller than the thermal wavelength ($\lambda_{Wien} \approx 10$ µm at 25°C) from a planar substrate [1], [2]. Here, we focus on the transition regime from the far field to the near field, examining what occurs as a microsphere approaches a planar substrate [3] or as two microspheres are brought close to each other [4].

I. METHODS

We characterize the flux variations from the microscopheres in vacuum using a thermoresistive probe of platinum on a cantilever combined with a metrological Wheatstone bridge. A platform involving two such thermoresistive cantilevers has been designed for the experiments involving two microspheres, in such a way that they can be separately manipulated with nanometer precision over distances of tens of micrometers.

II. RESULTS AND DISCUSSION

The use of two independent thermal probes in our setup enables one to find where exactly radiative heat flows between the various bodies involved in the system, which also includes the bath at room temperature.

In the experiments, a non-monotonic behavior of the heat flux $\Delta Q = Q(\infty)-Q(d)$ is observed at the hottest microspheres under certain conditions. This effect results from the competition between far-field heat transfer with the environment due to the exchange of propagative waves and near-field heat transfer associated to the tunnelling of electromagnetic energy through the gap separation between the bodies when surface polaritons are thermally excited. An example of this behavior is presented in Fig. 1 in the two-microsphere configuration. Numerical simulations support our observations.

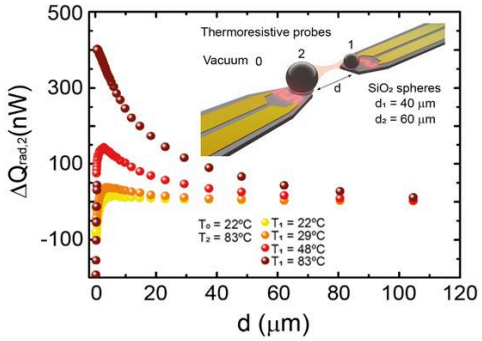

Fig. 1 Heat flux variation measured in sphere-sphere geometry with various temperatures within the system.

Scattering Symmetries in Metagratings

Karim Achouri[1,*]

[1]Institute of Electrical and Microengineering, École Polytechnique Fédérale de Lausanne (EPFL), Laboratory for Advanced Electromagnetics and Photonics, Lausanne, Switzerland

***Abstract*—We develop a simple formalism to connect the spatial symmetries of a metagrating unit cell and lattice to the shape of its scattering matrix. We use it to explain the emergence of extrinsic chirality in metagratings. And also to design metagratings exhibiting a step function response in momentum space.**

***Keywords*— metamaterials, metagratings, symmetries, scattering, electromagnetic theory.**

I. Introduction

Metagratings are diffraction gratings whose scattering elements are engineered to provide desired electromagnetic transformations. Note that, in this work, we are specifically interested in structures made of a single unit cell repeated periodically. In this case, metagratings are fundamentally similar to conventional metamaterials with the only difference being that they produce diffraction orders whereas metamaterials that are made of a single unit cell repeated periodically do not produced diffraction orders besides the zeroth ones in reflection and transmission [1], [2]. We therefore do not consider spatially varying metamaterials that often produce diffraction orders.

Due to the complexity of such structures and the lack of proper framework to analyze its scattering response, we have developed a formalism to connect the spatial symmetries of a metagrating to the symmetries of its angular scattering response.

II. Method and Results

The proposed methodology is based on our previous work in which we applied symmetry concepts, initially developed in [3], [4], to metasurfaces [5]. The method consists in finding representation matrices that describe how the metagrating scattering matrix transforms under a given symmetry operation, such as a reflection or a rotation. Once these representation matrices are found, it becomes trivial to compute its angular scattering properties under spatial transformations.

By using this approach, we demonstrate how achieving angular transmission asymmetry is impossible with a conventional reciprocal and lossless metasurface but possible with a metagrating [6]. This is the case because by breaking the spatial symmetries of a metagrating, we can asymmetrically direct the incident energy into a desired diffraction order, which is impossible with a conventional metasurface. At the conference, we will show the theory and experimental demonstration of this effect.

Another interesting effect is the concept of extrinsic chirality, where rotation of polarization effects akin to chiral responses are obtained with a non-chiral structure. We have already shown in [5] that such effects are impossible at normal incidence using a metasurface. However, the diffractive channels of a metagrating may be exploited to generate such extrinsic chiral responses.

III. Conclusion

The fact that metagratings exhibit open diffractive channels is an important advantage for controlling the flow of electromagnetic waves compared to conventional spatially uniform metasurfaces. These diffractive channels allow us to achieve responses that would otherwise be impossible to realize with non-diffractive reciprocal, passive and lossless structures.

***Abstract*—We utilise mathematical group theory and symmetry analysis to develop a quasicrystal design method, which is used to realise lasing from bound states in the continuum with high topological charges. Additionally, we show how these tools can be used for generating momentum space Hamiltonians with interesting topological characteristics.**

***Keywords*— plasmonics, bound states in the continuum, lasing, group theory.**

I. Introduction

Spatial symmetries act as a connecting thread across a wide variety of models and domains. In plasmonic lattices, bound states in the continuum (BICs) have been used for lasing, with the topological charge of the beam being inherently related to the rotational symmetry of the structure. By focusing on this symmetry, we develop a method for the design of quasicrystals that lase with very high topological charges. Furthermore, we show how group theoretical methods based on symmetries can be used for constructing momentum space Hamiltonians with fully controllable band-gaps and varying topological properties.

II. Methods

Our quasicrystal design method uses the symmetry properties of the desired beam to construct an approximation of the electromagnetic near-field. By targeting the nanoparticles to the nodes of this field, we can minimize ohmic losses in the desired mode, making it the most likely to lase. To build a working sample, two additional optimisation steps are required. The samples are fabricated and a produced laser beams are measured.

The momentum-space Hamiltonians consist of two components: a momentum-dependent component with degeneracies at the high-symmetry points, and a constant coupling Hamiltonian built from the symmetry-representations of the lattice.

III. Results and Discussion

We design and fabricate quasicrystals with C_8, C_{10} and C_{12} rotational symmetries and measure lasing with $q = -3, -4$ and -5 respectively. Additionally, the C_{12} lasing emission displays a rich tapestry of polarisation vortices and transitions between them, as is shown in Fig. 1.

By constructing varying momentum space Hamiltonians, we build bands carrying Chern numbers up to ± 3 and non-trivial Zak phases. Further, as the Hamiltonian is inherently built on real-space couplings, we model systems with finite sizes and directly observe topological edge states.

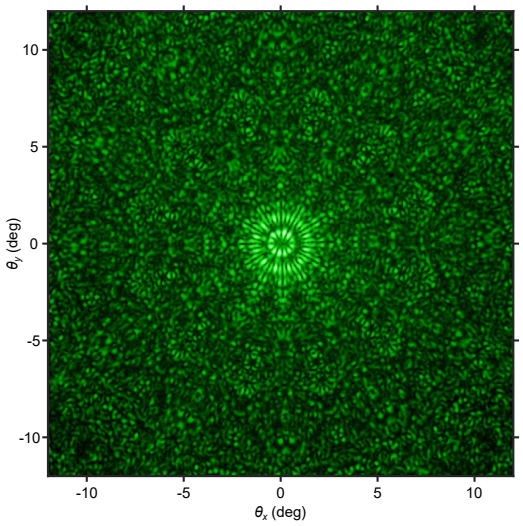

Fig. 1. Lasing emission from a C_{12v}-symmetric quasicrystal carrying high topological charges.

IV. Conclusion

We applied group theory for the design of plasmonic quasicrystals and momentum space Hamiltonians. This allowed us to reach lasing with BIC:s with high topological charges and design Hamiltonians with varying topological charactersitics.

***Abstract*— Meta-surfaces, made of subwavelength nanostructures, enable ultra-thin optical components but are challenging to design at millimeter scale using conventional FDTD. Moreover, periodic-local methods can fail to capture complex electromagnetic interactions between meta-atoms and may lead to inaccurate designs. We propose an AI-driven framework based on convolutional neural network emulators that support gradient-descent and generative design, improving efficiency, accuracy, and scalability for large-scale meta-surface optics.**

***Keywords*— Meta-materials, Meta-surface, CNN, Diffusion models.**

I. Introduction

A meta-surface is made of subwavelength nanostructures that enable ultra-thin optical devices [1-3]. Using electron beam lithography, research labs have shown that lenses, spectral filters, polarization band-pass filters, and beam shapers (hereafter called meta-diffusers) can be effectively implemented with flat meta-surface optics. As the technologies mature toward large-scale production, semiconductor companies are preparing for significant growth in this field. Supporting this transition requires accurate meta-surface simulations and innovative design methods. Due to the relatively large dimensions (in mm) of these optical systems and the sub-wavelength nature of the diffraction patterns, traditional electromagnetic simulation techniques based on the Finite Difference Time Domain (FDTD) [4] method can sometimes be challenging to apply. For this reason, alternative approaches are often used by optical designers. The commonly used phase-atom mapping technique in meta-surface design relies on a local periodic approximation, where each meta-atom is assumed to reside in an effectively infinite periodic array, and its geometrical parameter (e.g. the width of a pillar) is tuned to generate the desired local phase response based on a precomputed phase–width relation obtained from a single periodic meta-atom simulation. However, this periodic-local approaches for designing meta-surfaces [5-7] face significant limitations, mainly due to the difficulty of accurately modeling the complex inter-meta-atoms interactions that are critical for achieving optimal performance.

These constraints often create bottlenecks in the design workflow and lead to a high rejection rate during verification, when many designs fail to meet optical specifications (e.g., suppression of unwanted zeroth orders in beam shapers). To overcome these challenges, we introduced a new framework for the design of large-scale meta-surfaces. The key innovation is the integration of AI-driven capabilities, in particular convolutional neural network (CNN)-based emulators. This enables AI-based designs using a gradient descent approach but also opens new design methodologies based on generative modeling.

II. CNN-Based Meta-surface Designs

A more accurate way to handle this complexity than the previously mentioned heuristic local model is to use convolutional neural networks (CNNs) [8]. We build a database of over 10,000 realistic 20×20 meta-lens and meta-diffuser patches, storing 2D electric-field images 50 nm after the meta-surface. The meta-atoms are semiconductor pillars spaced at half-wavelength intervals embedded in a surrounding oxide buffer. The simulated FDTD near field is low-pass filtered and down-sampled, reducing the network output size by over a factor 1000 and enabling smaller CNN kernels for the same physical receptive field. A resolution of one pixel per pillar is sufficient to calculate the entire far field according to the Nyquist criterion for propagating waves. Among tested architectures, CNN learns the meta-surface near-field patterns efficiently achieving R^2 (R-squared) of nearly 0.99 (the R^2 is averaged over the far field). Such high R^2 indicates that the CNN model's predictions match very well the true values obtained from the FDTD far field simulations. However, other important quantities (such as the zeroth orders and

transmission) are also accurately emulated with CNN (see later).

This AI emulation of the near fields offers two main design benefits. First, it accelerates design verification: CNN-based emulators enable fast simulation of large-scale structures, drastically shortening the design loop compared to traditional methods. The simulation time of a CNN is significantly smaller than for FDTD: typically, a 128x128 design takes only a few seconds on a single-core machine, while it requires about 10 hours on a recent 15 cores CPU system. It ought to be mentioned that FDTD simulation of larger meta-surface can be very challenging and may require state of the art GPU-based calculations or domain decomposition techniques [4].

A typical comparison between the predictions of a heuristic local model and the CNN model is shown in Figure 1. As can be seen the differences are significant. A clear zeroth order is visible in the CNN-model (leading to an undesired axial intensity peak in the far field). These results can be compared to the FDTD rigorous simulation shown in Figure 2 (top) that also exhibits a large zeroth order.

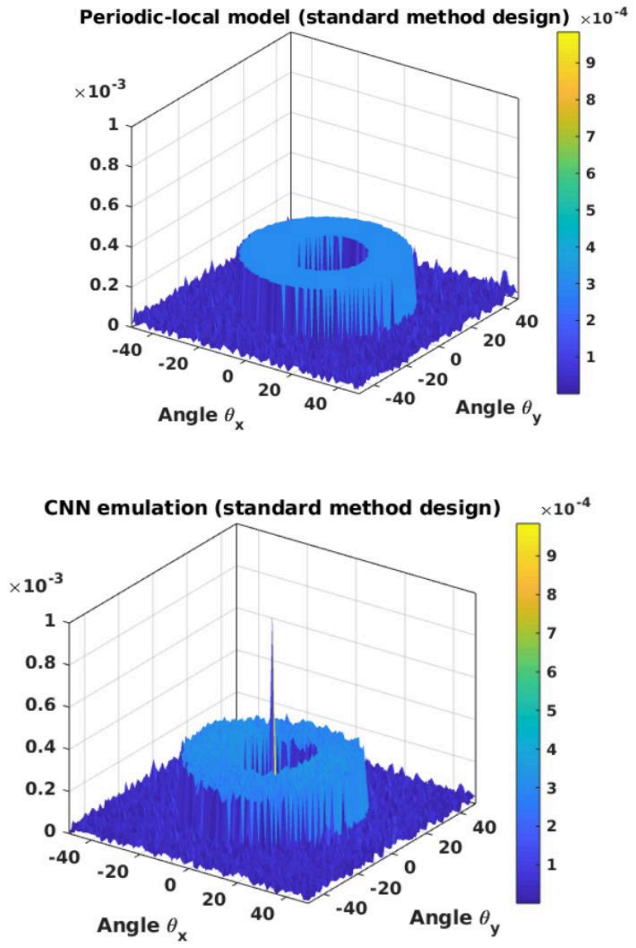

Fig. 1 Model prediction of the amplitude of the far field of a 98*98 pillars meta-surface with a heuristic local model (top) and using CNN-model (bottom).

Additionally, AI emulation of the near fields enables gradient-based performance optimization: thanks to the use of automatic differentiation, the CNN emulators can accurately compute the sensitivity of the optical response (for example, beam shape) to each structural parameter of the meta-atoms (such as pillar width). Instead of relying on brute-force verification, the framework can directly backpropagate the error between the simulated and desired performance allowing accurate optimizations based on gradient descent.

Figure 2 compares the FDTD-simulated far-field patterns of two meta-surfaces: one designed with a standard approach (relying on a periodic-local phase-pillar-width model), and one obtained using an AI-assisted gradient-descent optimization. In the case of the standard design method, a strong undesired zeroth diffraction order is clearly visible (at zero-diffracted angle), indicating poor suppression of on-axis transmission. In contrast, the AI-optimized meta-surface effectively suppresses this zeroth order, resulting in a cleaner far-field pattern that better matches the target beam profile and demonstrates the improved performance enabled by the gradient-based AI design framework. This is further emphasized in Figure 3, showing axial cuts of the previous far fields. All gradient descent-based simulation shown in this paper are obtained starting from the design obtained with a standard method (initial condition). For large meta-surfaces, composed of million pillars, we found out that such heuristic initial condition is key to achieving better results.

III. Diffusion-Based Meta-surface Designs

Beyond gradient-based optimization, recent advances in generative modeling have opened new possibilities for inverse design of complex photonic and meta-surface structures. State-of-the-art approaches such as diffusion models and Schrödinger bridges [9] offer powerful frameworks that can generate complex designs that do not depend on the relevance of the initial conditions such as with the gradient-based approaches. These methods can also generate families of high-performance candidates rather than a single locally optimized solution. They enable sampling directly from the distribution of designs conditioned on a target optical response, thereby complementing deterministic gradient-based methods and improving robustness, diversity, and exploration of the design landscape.

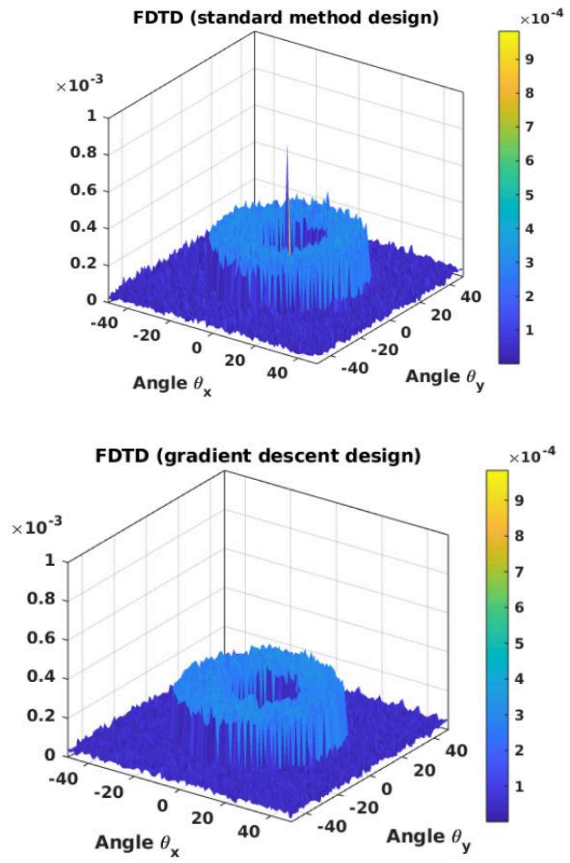

Fig. 2 FDTD simulation of the far field of a 98*98 pillars meta-surface designed with a standard method (top) and with AI-assisted design using a gradient descent (bottom).

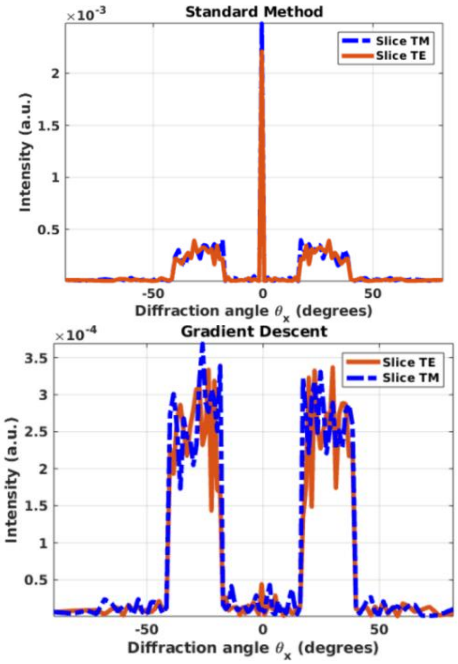

Fig. 3 Horizontal and vertical cuts of the far fields of figure 2. TE and TM refer to the two light polarization states.

We compared designs obtained with the standard method to those produced by a CNN-based gradient-descent approach, as well as by the diffusion-based method. All designs were verified using rigorous FDTD simulations. The corresponding far-field intensity patterns are shown in Figure 4 for 98×98 pillars metasurface designs obtained with the standard method, the CNN-based gradient-descent approach, and the diffusion-based method, all validated by rigorous FDTD simulations with their corresponding far-field patterns. For reference, the target design is also shown, whose far field is computed using the periodic-local-phase approximation. In that later case, the Far field exhibits a nearly perfect structure, very close to the desired far field shape.

Figure 5 report similar simulations across various design sizes. For each case, we also report the R^2 values computed with respect to the desired target far field, providing a quantitative measure of how well each design reproduces the specified optical response.

Figure 6 summarizes these results by plotting the R^2 values as a function of the meta-surface size. A clear and systematic improvement over the standard design method (based on the periodic-local approximation) is observed for both AI-based approaches. The diffusion-based generative design consistently pushes the performance closer to the target, while the CNN-driven gradient-descent method achieves slightly superior R^2 by fine-tunning the final design solution accurately. These trends highlight the scalability and effectiveness of AI-assisted design strategies for large-area meta-surfaces, especially in regimes where traditional local models fail to capture complex inter-meta-atom interactions.

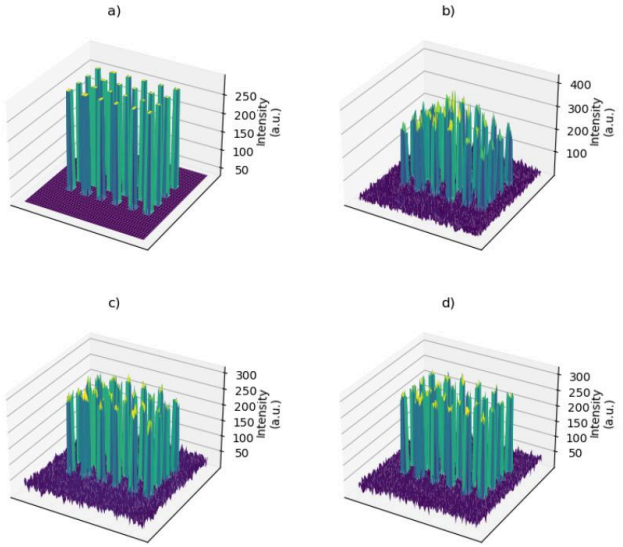

Fig. 4 Comparison of 98*98 pillars meta-surface designs obtained with the standard method (b), a CNN-based gradient descent approach (c), and the diffusion-based method (d). All designs validated using rigorous FDTD simulations, and the corresponding far-field patterns are shown. For comparison the target is also shown (a) and in that case, the far field is calculated using the periodic-local-phase approximation.

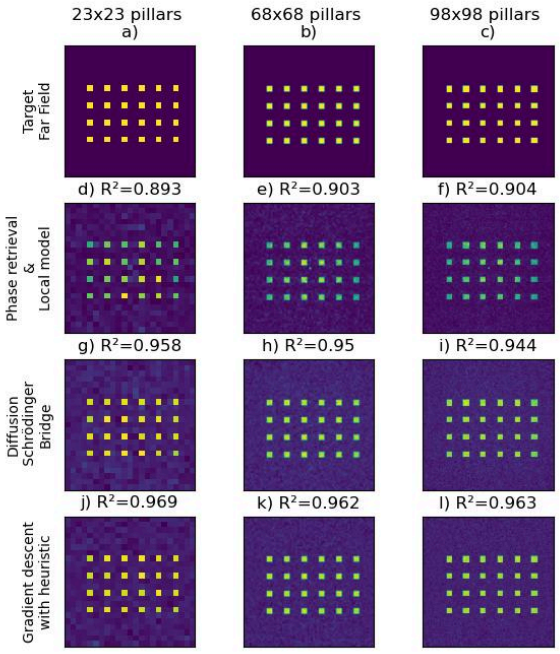

Fig. 5 Comparison of designs obtained with the standard method, a CNN-based gradient descent approach, and the diffusion-based method across various design sizes. All designs validated using rigorous FDTD simulations, and the corresponding far-field patterns are shown. The R^2 values are calculated using the target as a reference.

IV. Conclusion

We presented an AI-driven framework for large-scale meta-surface design that overcomes key limitations of both FDTD-only and periodic-local approaches. CNN-based emulators accurately reproduce FDTD responses (with averaged R^2 ≈0.99) while reducing simulation times from hours to seconds, enabling fast verification of millimeter-scale devices. Their differentiability supports gradient-based inverse design, yielding meta-surfaces with significantly improved performance—such as enhanced suppression of undesired zeroth diffraction orders—compared to standard heuristic designs.

In addition, diffusion-based generative models extend the framework to produce diverse families of high-quality designs conditioned on target optical responses, alleviating reliance on specific initial conditions. Overall, this AI-assisted methodology provides an efficient, accurate, and scalable path toward industrial-grade meta-surface optics design.

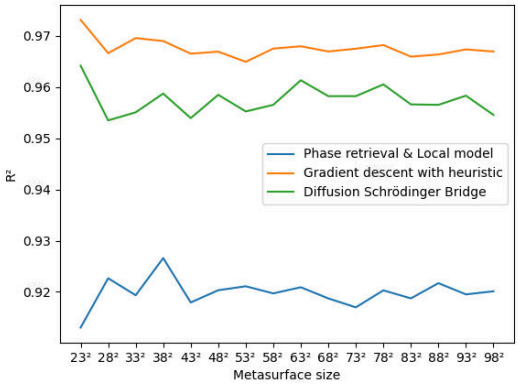

Fig. 6 Extracted R^2 as a function of the design size (see text and Figures 4-5 for details).

***Abstract*— We present three machine-learning-assisted design strategies for tunable metasurfaces. We use a neural network to optimize a metasurface for dual-frequency beam steering, employ transfer learning for reduction of simulation costs for composite unit cells and use a physics-informed model to design a metasurface for independent amplitude and phase control.**

***Keywords*— metamaterials, terahertz, machine learning.**

I. Introduction

Industrial applications demand increasingly advanced designs of functional metasurfaces that meet stringent industry standards.

II. Results and Discussion

First, we optimize the bias voltages of a tunable metasurface to simultaneously steer beams at 27 GHz and 31 GHz. Ideal phase profiles from Kirchhoff diffraction theory are mapped via a neural network to feasible voltage distributions, which enables dynamic, frequency-dependent beam steering over angles from 10° to 45°.

Second, we address the computational cost of designing composite unit-cell structures. By applying transfer learning from basic to complex unit-cell configurations, we reduce simulation requirements dramatically. We show that, for the example of a dipole–dipole structure, only 29 combined simulations are needed to reach a mean squared error of 0.05, compared to 583 when training from scratch.

Third, we employ a physics-informed machine-learning framework to achieve independent amplitude and phase control in a metasurface. Using a Temporal Coupled Mode (TCM) model, the dynamic tuning behavior is captured with just four simulations per design iteration. Machine learning predicts the TCM parameters from the metasurface geometry, which enables a rapid and efficient optimization.

III. Conclusion

These studies demonstrate that integrating electromagnetic theory, physics-informed modeling, and machine learning can accelerate the design of metasurfaces and metamaterials while meeting practical performance and hardware constraints. Such an approach can pave the way for industrially viable, dynamically tunable metasurfaces that are specifically designed for demanding tasks in the industrial environment.

Cooperative absorption in random particulate media: achieving spectral selectivity

Cédric Blanchard[1,*], Cristina Gila[1,2], Timothée Guerra [1,3], Olivier Rozenbaum [1],

[1*]Université d'Orléans, CNRS, CEMHTI UPR 3079, Orléans, France.

***Abstract*—We present a predictive framework for engineering optical functionalities in disordered systems using a T-matrix multiple-scattering approach. Cooperative many-body interactions enable near-perfect absorption at a target frequency with suppressed off-resonant absorption, turning disorder into a controllable design parameter. *Keywords*— Complex media, numerical modeling, optical properties design.**

I. Introduction

Accurately modeling electromagnetic interactions in large many-particle systems remains a major challenge in computational electromagnetics, especially when particles are randomly distributed and strongly coupled through multiple scattering. In contrast to ordered nanophotonic architectures, where periodicity and symmetry simplify numerical treatments, disordered particulate media resist predictive design due to the intrinsic complexity of many-body electromagnetic interactions. Yet, these systems are highly attractive for applications requiring scalable, robust, and low-cost optical materials, including large-area absorbers, thermal emitters, and infrared photonic components. In this contribution, we establish a predictive design framework for engineering optical functionalities in disordered many-particle systems, effectively turning disorder into a controllable design parameter. We further provide an experimental realization based on this strategy, establishing a departure from conventional trial-and-error approaches to disordered nanophotonics.

II. Methods

Our approach relies on a rigorous multiple-scattering framework based on the T-matrix formalism (see for instance Mishchenko [1]), which provides an efficient and accurate description of collective scattering and absorption in ensembles of randomly distributed particles.

Rather than enforcing order or engineered correlations, we exploit the intrinsic collective interactions that naturally arise in random particulate systems. These cooperative many-body effects open new regimes for light manipulation and enable optical functionalities that are both computationally tractable and experimentally realizable.

This computational framework is illustrated through the design and fabrication of novel materials showing spectral selectivity.

III. Results and Discussion

1. Numerical design of near-perfect absorption in disordered many-particle media. We introduce a bidispersed ensemble of randomly distributed nanoparticles, where one population provides resonant absorption and the other enhances multiple scattering [2]. By tuning the electromagnetic coupling within this many-particle system, we numerically demonstrate near perfect absorption levels, achieved without periodicity, resonant cavities, or fine structural control.

2. Experimental demonstration of cooperative absorption in disordered many-particle systems. We fabricate thin, large-area layers composed of resonant and lossless particles and characterize their optical response using infrared spectroscopy. The measurements reveal a strong and spectrally selective absorption peak arising from cooperative many-body interactions, in excellent agreement with numerical predictions.

IV. Conclusion

Beyond a proof of concept, our results establish a methodological and technological rupture, demonstrating that fully disordered many-particle systems can be engineered with a level of control comparable to ordered platforms, while inherently satisfying scalability and fabrication-tolerance constraints.

Deep Learning-Enhanced Dual-Comb Ghost Imaging with Minimally Invasive Probes

Myoung-Gyun Suh[1,*]

[1]NTT Research, Inc., 940 Stewart Drive, Sunnyvale, California, USA

***Abstract*—We present a dual-comb ghost imaging framework enabling video-rate, high-fidelity reconstruction without spatial or spectral scanning. By combining parallel comb-generated speckle patterns via a single-core fiber with a transformer-based deep learning model, we overcome conventional speed bottlenecks, offering a minimally invasive solution for compact fiber-based endomicroscopy.**

***Keywords*— ghost imaging, single-pixel imaging, optical frequency combs, deep learning, endoscopy.**

Ghost imaging (GI) reconstructs scenes by correlating structured illumination with single-pixel detector measurements [1], circumventing the need for multi-pixel arrays. While highly advantageous for scattering media, low-light conditions, or hardware-constrained environments like endoscopy, conventional GI is bottlenecked by the sequential generation of illumination patterns via spatial light modulators or mechanical scanning. This serial acquisition severely limits imaging speed, hindering the real-time observation of dynamic scenes even when compressive sensing techniques are applied.

To overcome this limitation, we introduce ghost imaging [2], [3]. This approach leverages the intrinsic parallelism of optical frequency combs (OFCs) and dual-comb interferometry, completely eliminating the need for slow spatial modulation or wavelength tuning. Broadband dual combs propagate through a single-core fiber to generate wavelength-multiplexed hyperspectral dual-comb speckle patterns. By mapping individual spectral lines to statistically independent spatial patterns, 3D optical information (2D spatial $\times$ 1D spectral) is compressed into a single time-domain signal. This allows hyperspectral speckle measurements to be acquired in a single shot using spatially non-resolved hardware.

Notably, unlike spectral correlation–based ghost imaging that relies on swept-frequency lasers [4], [5], our dual-comb approach enables fundamentally parallel pattern generation. This parallelism is crucial for imaging moving targets, as sequential pattern projection often introduces motion artifacts. Furthermore, the inherent frequency precision and stability of OFCs ensure highly repeatable speckle patterns at each comb line. This unique combination of parallel and stable pattern generation is essential for practical, video-rate ghost imaging.

To invert this highly compressed data, we use an application-specific, transformer-based neural network [2]. This deep-learning reconstruction, paired with spectral multiplexing, accurately recovers intensity measurement data using pre-recorded speckle patterns to achieve video-rate performance. The architecture drastically simplifies the optical front end while maintaining the core benefits of GI, enabling practical deployment in space-constrained platforms.

In conclusion, we experimentally demonstrate that dual-comb ghost imaging enables video-rate imaging using only a minimal optical front end: a single-core fiber and a single-pixel photodetector. Furthermore, our transformer-based model significantly enhances image quality by minimizing information loss during compression. While challenges remain for practical deployment—such as improving compact speckle-pattern generators [4], [6], optimizing light collection, and realizing gray-scale imaging [7]—this proof-of-concept validates high-fidelity GI using minimally invasive hardware. Combining comb-based parallel processing with deep-learning reconstruction holds strong promise for next-generation biomedical and sensing applications.

***Abstract*— Maintaining comfort with photonic thermal-management textiles can reduce energy use for heating and cooling in residential and office buildings. Here we outline the design cycle of a passive dual-mode thermoregulation fabric based on dynamic emissivity modulation, highlighting key photonic architectures, their limitations, and the strategies used to achieve a dimensionally stable design.**

***Keywords*— metamaterials, emissivity, thermoregulation**

More than half of the energy consumed globally is used for heating and cooling of largely empty buildings, both residential and commercial. Therefore, more localized heating and cooling efforts are essential.

Research on radiative thermal textiles enabled by nanophotonic and metamaterial concepts has advanced rapidly over the last decade. A key goal is a passive, power-free textile that autonomously switches between heating and cooling (dynamic dual-mode thermoregulation), improving comfort while reducing energy demand and mitigating risks during heat waves and cold spells.

Here we summarize the design evolution of a recently introduced dynamic emissivity-modulating textile (DEST), from early architectures and numerical modeling to the final device concept (Fig. 1). Emissivity modulation is based on the Stefan–Boltzmann law, in which radiative power scales with surface emissivity and temperature to the fourth power; controlling emissivity therefore controls radiative heat exchange with the environment. An early passive dual-mode concept is a static multilayer Janus fabric with asymmetric emissivity (high/low on opposite faces) [1]. Large emissivity contrast is obtained by engineering a metal–dielectric cylindrical-fiber photonic crystal. The design provides heating or cooling, but switching requires manual flipping, motivating autonomous alternatives.

A subsequent approach uses a highly emissive carbon-fiber base paired with metal-coated, low-emissive shape-memory nanofiber islands whose apparent area changes with temperature. In cold conditions the islands expand to cover more of the high-emissivity base, reducing the effective emissivity and suppressing radiative heat loss. In hot conditions the islands retract, exposing the high-emissivity base and increasing radiative cooling. A central challenge is mechanical and dimensional stability: the islands must remain registered to their original positions during cycling while the overall textile maintains constant dimensions.

The final design, DEST addresses this by incorporating a mechanically engineered metamaterial architecture that produces reversible macropore actuation while preventing out-of-plane distortion through a tailored cut pattern. The resulting textile responds to temperature and ambient humidity, passively switching between emissive and reflective states without external energy input, and delivers an approximately 6 °C reversible thermal comfort window [2].

***Abstract*— The ability of surface plasmon polaritons (SPPs) to decay into energetic (non-equilibrium) carriers in metals, and the subsequent harvesting of energetic carriers at metal surfaces leads to new device applications and enhanced or new reaction pathways in photoelectrochemical or photochemical processes occurring on the surface. Here we discuss consistent, repeatable, bright and visible luminescence from pyrolytic carbon dots (CDs) on Ag gratings formed and pumped by SPPs excited at 532 nm (2.33 eV). We emphasize computational modelling aspects that capture the principal observed phenomena.**

***Keywords*— surface plasmons, metamaterials, carbon dots, Purcell factors.**

I. Introduction

Metallic metasurfaces and nanostructures such as nanoantennas, gratings and nano-resonators can be designed to couple efficiently to an incident optical beam such that surface plasmon polaritons (SPPs) are excited thereon. The fields of SPPs can be enhanced by factors of 10 to 100× with respect to the incident field due to their confinement to sub-diffraction volumes, resulting in enhanced light-matter interactions at the nanoscale. These properties are fundamental and break some of the trade-offs that apply to interactions in bulk materials.

Moreover, SPPs decay into energetic (non-equilibrium) carriers in metals through absorption. The harvesting of energetic carriers at metal surfaces leads to new device applications, and to new or enhanced reaction pathways in photoelectrochemical or photochemical processes occurring on the surface. We recently reported bright visible luminescence from carbon dots (CDs) formed photochemically from a carbonaceous seed layer on Ag gratings by SPPs excited thereon at 532 nm (2.33 eV) [1,2]. In addition to inducing their photochemical formation, SPPs also pump optically the CDs, and receive Stokes-shifted radiation therefrom, which is then outcoupled by the grating into free-space visible light [3]. Here we review recent progress on such photoluminescent gratings, bearing CDs dots formed in situ directly thereon.

II. Results

Ag gratings on a thick Ag film on a Si substrate were formed by lithography, evaporation and lift-off [4]. A Ag grating on a semiconductor substrate also operates effectively as a heat sink to minimize thermal effects. Upon illumination such gratings support Bloch SPPs. An associated periodic distribution of non-equilibrium charge carriers is created over the illuminated area by absorption of SPPs therein. CDs are created by transformation of a carbonaceous seed layer under SPP excitation in an O_2 depleted environment [2]. The seed layer consists of partially pyrolyzed carbon originating from polymethylmethacrylate (PMMA) left behind from lithographic processing of the gratings [4]. The seed layer, the formation of CDs and the growth of fluorescence were monitored in real-time in-situ using Raman spectroscopy. The structure under test was placed in a gas chamber filled with an O_2 depleted gas, such as CO_2. Measured Raman spectra reveal the growth of D and G peaks indicating the formation of sp^2 bonded carbon, suggesting that graphitized CDs have formed from the seed layer. **Error! Bookmark not defined.**

The role of SPPs in our system is fourfold, as illustrated in Fig. 1: Firstly, pump SPPs catalyse the seed layer into graphitic CDs; secondly, pump SPPs excite the CDs; thirdly, SPPs receive Stokes-shifted quanta of energy emitted by the decay of excited CDs; and fourthly, SPPs scatter from the grating into specific free-space radiation channels [3].

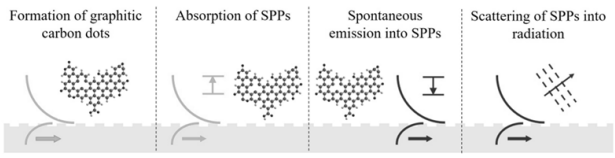

Fig. 1 The role of SPPs on photoluminescent gratings is fourfold: catalysis of carbonaceous seed layout into CDs; optical pumping of CDs; reception of Stokes-shifted emission from CDs; scattering off grating into visible free-space light.

Several aspects of the process illustrated in Fig. 1 were modelled using full-wave electromagnetic numerical techniques: i) The excitation of SPPs on Ag gratings was modelled at the pump wavelength assuming normally incident plane waves to validate the design space and arrive at theoretical enhancement factors on the surface; ii) the computed field distributions, and enhancement factors averaged over the grating surface, were then used to pump the carbon dots; iii) the Stokes-shifted emission due to the decay of the carbon dots into SPPs on the grating was then modelled to compute Purcell factors; iv) the diffraction of the SPPs from the grating into observable far field radiation was then computed. Theoretical results were compared with experiments to strong agreement.

III. Conclusion

CDs created *in situ* on a silver grating bearing a carbonaceous seed layer are shown to produce polarised photoluminescence in prescribed directions and at specific wavelengths. Photoluminescence emerges preferentially along the grating normal and in the ±1 diffraction directions, at wavelengths in the range of 560 to 700 nm when pumped at 532 nm, and with a *p*-polarisation. Photoluminescence lifetime measurements of CDs on gratings reveal a Purcell factor of about 80. These properties emerge because the CDs preferentially decay onto SPPs supported by the grating. Salient aspects of the experiments were successfully modelled via computational electromagnetics to very strong agreement. The ability to localise and form carbon dots *in situ* on nanostructured surfaces, and then control their emission characteristics, opens new possibilities for biosensing, inexpensive light sources, and quantum optics.

***Abstract*—Machine learning provides a unifying framework for high-dimensional forecasting of quantum coherence and photonic design. We use anticipatory modelling to mitigate spectral diffusion in solid-state emitters, significantly reducing spectral shifts. Combined with advancements in surrogate-based inverse design for the rapid co-optimization of emitter-circuit interfaces, we pave the way for robust, multiplexed quantum networks.**

***Keywords*— deep learning; quantum sensing; nanophotonics; inverse design**

I. Methods

To mitigate environmental dephasing in quantum emitters and ensure joint optimization of emitters and circuitry under realistic fabrication constraints, we use statistical machine learning to map slowly varying environmental noise. By analyzing sparse spectral measurements, our framework finds hidden temporal correlations within decoherence channels, enabling the internal prediction of unseen spectral diffusion trajectories across diverse solid-state systems, including nitrogen vacancy centers and quantum-dot spin qubits. This rapid cooptimization effectively bypasses the high-dimensional bottlenecks of traditional full-wave simulations. This can be further corroborated with the use of surrogate-based inverse design techniques to more efficiently traverse the high-dimensional landscape associated with this problem.

II. Results and Conclusion

This feed-forward stabilization mitigates environmental decoherence, reducing spectral shifts by average factors of 2.32 to 20.19 depending on emitter stability. Ultimately, this predictive framework provides a robust, scalable pathway for multi-node synchronization in quantum communication, computation, and sensing networks.

***Abstract*— The study tackles making q-BIC metasurfaces reliably manufacturable, focusing on EBL and silicon ICP-RIE constraints. It compares continuous and pseudo-Bosch etching by etch rate, sidewall angle, and roughness. It also models allowable fabrication tolerances, linking geometric deviations to Q, efficiency, and uniformity, and provides practical guidelines to improve design robustness and process stability.**

***Keywords*— metamaterials, EBL, pseudo-Bosch etching, fabrication tolerance.**

I. Introduction

Planar optics is enabling a rapid miniaturization and functional integration of optical systems, with metasurfaces emerging as a key platform to replace or augment conventional bulk components. Metasurfaces exploit arrays of subwavelength nanostructures ("meta-atoms") patterned on a surface to tailor optical wavefronts and diffraction with high design freedom, offering compact and lightweight solutions for advanced beam shaping and polarization control. In particular, the ability to engineer wavelength- and polarization-selective responses within deeply subwavelength thicknesses makes dielectric metasurfaces attractive for applications ranging from high-efficiency imaging and metalenses to sensing and nonlinear and quantum nanophotonics [1,2]. Among the most compelling metasurface concepts, symmetry-protected bound states in the continuum (BICs) provide optical modes with theoretically infinite quality (Q) factors. These states are "dark" because symmetry forbids coupling to external radiation channels. By introducing a controlled, small symmetry breaking, a BIC can evolve into a quasi-BIC (q-BIC) with a finite Q factor, allowing external excitation while preserving strong field confinement. Importantly, when a broken-symmetry structure is pumped at the q-BIC wavelength, the electromagnetic energy stored in the resonator can increase dramatically, enabling significant enhancement of resonant light–matter interaction and nonlinear optical processes. Achieving and reproducing the targeted q-BIC response, however, requires tight control of the nanoscale geometry, since the Q factor and the radiative coupling strength are highly sensitive to the exact magnitude and uniformity of the asymmetry [3].

II. Results and Discussion

This work addresses the practical challenge of translating q-BIC metasurface designs into reliable nanofabrication processes. We present a fabrication-oriented study focused on the constraints introduced by electron-beam lithography (EBL) and silicon dry etching, with emphasis on process-induced deviations that directly impact metasurface performance [4]. In many dielectric metasurfaces, the local optical response (phase and often amplitude/polarization) is mapped to geometry through propagation, geometric, or resonant mechanisms. Consequently, even small departures from the nominal meta-atom cross-section (such as sidewall taper, corner rounding, or critical-dimension bias) can produce systematic phase errors and non-uniform transmission. For resonant designs (including q-BIC metasurfaces), such deviations may shift the resonance conditions, reduce Q, and degrade contrast and efficiency. Furthermore, aspect-ratio dependent etching can introduce spatially varying depth non-uniformities across dense patterns, degrading the designed optical functionality. Finally, sidewall and surface roughness contributes to parasitic scattering and loss, lowering efficiency and broadening the point-spread function in imaging applications, while also reducing reproducibility.

Within silicon nanofabrication, fluorine-based inductively coupled plasma reactive-ion etching (ICP-RIE) chemistries are widely adopted due to their high etch rates and compatibility with standard process flows. Two distinct strategies are commonly used. In continuous mixed-gas processes (e.g., SF_6/CHF_3), etching and passivation occur simultaneously: fluorine radicals promote silicon removal while fluorocarbon fragments form an inhibiting layer, and anisotropy arises from balancing chemical etching with ion-assisted inhibitor removal at the feature bottom. In Bosch-type processes, etching and passivation are time-multiplexed through alternating steps, typically an SF_6 etch step followed by fluorocarbon deposition (e.g., C_4F_8). Bosch-like approaches can enhance sidewall protection and anisotropy, especially for high aspect ratios, but may introduce cyclic artifacts and roughness (scalloping) and increased sensitivity to timing and transport effects. Despite the widespread adoption of both methods, direct benchmarking under closely matched ICP-RIE conditions remains limited for dense nanoscale patterns with pitches and lateral dimensions on the order of a few hundred nanometres—precisely the regime most relevant for state-of-the-art metasurfaces. At these scales, radical transport limitations, local depletion, and polymer build-up/removal dynamics become strongly geometry-dependent, and recipes optimized for microscale features may not translate reliably to nanostructured layouts.

Here we report a comparative study of continuous and pseudo-Bosch ICP-RIE processes for etching EBL-defined silicon nanostructures. Specifically, we compare a continuous SF_6/fluorocarbon-based strategy with a pseudo-Bosch SF_6/C_4F_8 approach. To isolate the influence of etch strategy and passivation chemistry, we keep key operating parameters comparable across the two processes, including substrate temperature and chamber pressure. We evaluate etch rate, sidewall angle, and surface/sidewall roughness as primary performance metrics, as these quantities directly determine the effective optical response and the achievable Q factor in q-BIC metasurfaces (figure 1). In addition to benchmarking process, we model the admissible fabrication tolerances required to preserve q-BIC functionality. The optical response of non-ideal metasurfaces is simulated as a function of geometrical parameters affected by fabrication errors, enabling a quantitative link between process outcomes and resonant performance. By correlating fabrication-induced deviations with changes in the resonant response, we provide practical guidelines for improving both design robustness and process stability.

***Abstract*— Heavily doped semiconductors and polar dielectrics enable strong mid-infrared nonlocal and nonlinear light–matter interactions. Hydrodynamic carriers and bulk plasmons enhance Kerr nonlinearities and optical bistability in tunable nanoantennas and hybrid waveguides. In polar dielectrics, anharmonic phonons generate intrinsically nonlinear phonon–polariton responses that can be strongly amplified in nanostructures.**

***Keywords*— third harmonic generation, Kerr, hydrodynamic theory, heavily doped semiconductors, phonon polaritons.**

Material platforms that support strong nonlocal and nonlinear light–matter interactions are central to the development of mid-infrared (mid-IR) photonic technologies. Among these, heavily doped semiconductors and polar dielectrics are particularly promising systems. They offer high electromagnetic confinement, relatively low optical losses, and tunability of their collective excitations, positioning them as attractive alternatives to noble metals and traditional semiconductors for nonlinear and active photonic applications. In both material classes, collective electronic or ionic excitations give rise to pronounced nonlocal and nonlinear optical responses. In heavily doped semiconductors, the high density of free carriers leads to strong spatial dispersion and nonlinearities that can be accurately described using hydrodynamic theory (HT), which extends the classical Drude model by incorporating quantum pressure, carrier convection, and carrier-density gradient effects. Within this framework, doped semiconductors are predicted to exhibit free-electron nonlinearities exceeding those typically observed in metals and conventional dielectrics [1]. These predictions have been validated by experiments on third-harmonic generation (THG) in InGaAs nanoantennas, which demonstrated that free-carrier nonlinearities can dominate over lattice-related $\chi^{(3)}$ contributions [2]. A key manifestation of nonlocality in doped semiconductors is the existence of longitudinal bulk plasmons—charge-density oscillations that propagate through the bulk and exhibit intrinsic nonlinear behavior. These modes can strongly couple to localized electromagnetic resonances. For instance, coupling longitudinal bulk plasmons to metallic gap plasmons in nanopatch antennas enables strong enhancement of Kerr nonlinearities and ultralow-threshold optical bistability (≈1 mW/μm) [3]. Integration into metal–oxide–semiconductor architectures allows dynamic control of the free-carrier density, enabling large plasma-frequency shifts (0.89 μm/V) and reducing bistability thresholds down to 10 μW [4]. Beyond resonant nanoantennas, nonlocal nonlinearities also provide opportunities for integrated photonics. In all-semiconductor platforms, hybrid waveguides incorporating doped plasmonic layers support long-range hybrid modes with record-high Kerr nonlinearities [5]. When embedded in interferometric architectures, these waveguides enable large power-dependent modulation depths, relevant for all-optical modulation. In polar dielectrics, nonlocal nonlinearities arise from the anharmonic dynamics of optical phonons, where lattice vibrations coupled through long-range Coulomb interactions produce dispersive and intrinsically nonlinear phonon–polariton responses. In nanostructures made from such polar dielectrics, phonon–polariton resonances can similarly amplify nonlinear optical effects through extreme field confinement.

Useful and detrimental thermal radiation in near-field energy-conversion devices such as thermophotovoltaics

***Abstract*— We report on three different types of near-field energy-conversion devices, namely thermophotovoltaics, thermophotonics and thermal rectennae. All of them involve partial conversion of thermal radiation into electrical power above a certain energy threshold, namely the bandgap for the two first types of devices, and detrimental thermal-radiation exchange below this threshold. We discuss how to optimize the conversion and reduce the parasitic transfer by selecting an appropriate geometry and structuring the surfaces.**

***Keywords* — Thermophotovoltaics, LED, thermophotonics, thermal rectennae, phonon-polariton, multilayers, grating.**

I. Introduction

Energy-conversion devices based on light, such as photovoltaics or rectennae (see Fig. 1), can benefit from an increase of the radiative power transfer when emitter and converting device are approached at a distance below the wavelength in the photon tunneling regime. In particular, thermal-radiation based devices are not anymore bound by Planck's law and the blackbody limit in this regime. While this distance decrease provides a strong gain in potential power output, an issue is that the flux which is not converted into electrical power can lead to strong heating of the converting device and therefore to a decrease of the efficiency. We analyze the evolution of the useful and detrimental flux transfer as a function of distance for structures involving multilayers and grating-based surfaces.

II. Methods And Results

We consider first thermophotovoltaic devices, which involve a hot radiating emitter and a cold photovoltaic cell designed for conversion of mid-infrared radiation. Low-energy bandgap is required for optimum conversion [1]. Phonon-polariton have been long proposed for increased radiative exchange above bandgap, but their experimental realization seems more complex than initially thought [2]. In addition, optimizing the geometries is required in order to observe significant conversion. We then consider thermophotonic devices [3-4], which in addition to the cell include an active emitter, namely a light-emitting diode (LED) which is externally biased in order to emit light by electroluminescence in a narrow energy band just above bandgap. Very large efficiency is predicted in optimum conditions, i.e. with quantum efficiency close to unity. However, detrimental transfer below bandgap is also a severe issue, mostly due to the fact that III-V materials possess phonon-polaritons at low frequencies. Thermophotonic devices can be used as waste-heat harvesters but also as refrigerating devices [5]. Finally, we discuss thermal rectennae [6-7], the mechanism of which is based on photon-assisted electron tunneling across thin oxide layers. Whether the emitter radiative properties should be matched to the oxide layer or not is still an open question, especially in near field.

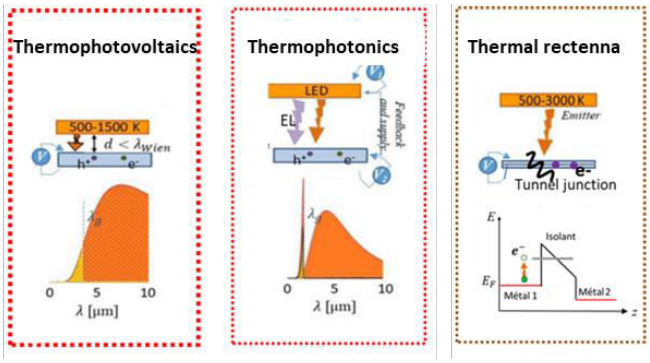

Fig. 1 Three types of radiative energy converters that can be used in near field

Fluctuational electrodynamics by means of Green's tensor and Rigourous Coupled Wave analysis (RCWA) [8] are used for the electromagnetic computations. Electrical simulations are made either in 0D (detailed balance) [4-5], by 1D analytical expressions or by using a 1D solver of the drift-diffusion equations including high carrier injection and thermionic-field emission in heterostructures [9].

III. Conclusion

We have addressed three types of near-field radiative energy converters by coupling electromagnetic and charge-carrier simulations. This allowed to study the impact of the configurations on the optical properties in the infrared and therefore their impact on power output and efficiency.

***Abstract*—The crystal configuration, symmetry, and the on-chip orientation affect the modal properties of anisotropic waveguides based on TFLN / LNOI technology. Beyond the direct numerical analysis, the hybridization of guided modes and the related conversion of polarization can be understood, also fully quantitatively, in terms of coupled mode theory.**

***Keywords*—thin-film lithium niobate, lithium niobate on insulator, anisotropic waveguides, mode hybridization, numerical analysis, perturbational modelling.**

I. TFLN / LNOI PHOTONIC CIRCUITRY

Advantageous nonlinear and electrooptic properties recommend thin-film lithium niobate (TFLN, [1], [2]) or lithium niobate on insulator (LNOI, [3], [4]) as a platform for integrated optical components. Rib- or strip waveguides are prepared from TFLN slabs of standard thicknesses, often with slanted sidewalls, as illustrated in Fig. 1.

Fig. 1. X-cut TFLN strip waveguide, schematic (a) and cross section (b), crystal and channel coordinates $\{X, Y, Z\}$ and $\{x, y, z\}$; the on-chip orientation of the channel is given by the angle θ between the channel axis z and the crystal Y-axis. Parameters: core thickness $t = 0.6\,\mu$m, cover thickness $c = 1\,\mu$m, channel top width w, sidewall angle $\phi = 30°$, material parameters [5], [6] for SiO_2 (n_s, n_c) and TFLN media ($\hat{\epsilon}_f$), with air cover (n_a), at a wavelength of $1.55\,\mu$m.

In this invited contribution, we review some of our recent results on the rigorous and perturbative computational modelling of the guidance properties of TFLN waveguides [7], as well as certain analytical results [8], [9] that are instrumental for their understanding. The core anisotropy affects the waveguide properties for all crystal configurations, where the channel orientation only plays a role for X-cut samples. Hence, also with a view to the effects of mode hybridization and polarization conversion, here we pick examples of X-cut strip waveguides at a typical telecommunication wavelength, for realistic cross section shapes and material parameters [5], [6].

II. NUMERICAL ANALYSIS

In the first place, we compute effective index levels and mode profiles by rigorous numerical means on the basis of the JCMwave finite element solvers [10], for the full tensor permittivity of the LN medium. Respective reference results [7] will be briefly discussed. As an example, Figs. 2 and 3 show the dependence of modal effective indices N on the channel orientation angle θ, and on the channel width w. Largely analytical results for 1-D TFLN slab modes [8], [9] establish rigorous effective index intervals for the numerical 2-D mode analysis of the channel waveguides. For the present structures with $y \leftrightarrow -y$ mirror symmetry, the guided modes can be (roughly) sorted into one of *three* symmetry classes ("even", "odd", or "complex", [7]); these classes are distinguished by different marker symbols in Figs. 2, 3. Modal polarization is characterized through a polarization ratio Π, given by the relative TE-related contribution to the modal power [7], and indicated in the figures through the marker color.

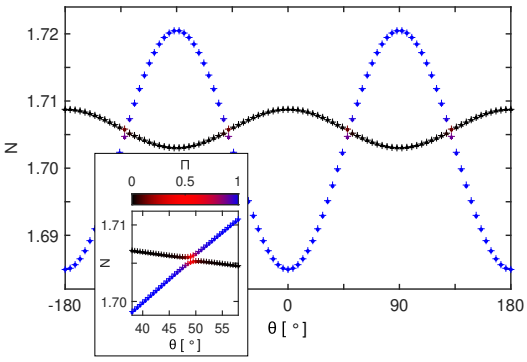

Fig. 2. Effective indices N of guided modes as a function of channel angle θ, for waveguides with a top width $w = 0.2\,\mu$m. Markers (overlapping), $+$: direct computations; other symbols: CMT approximation; marker colors indicate the polarization ratio Π, blue: TE-like, black: TM-like, red: intermediate.

III. PERTURBATIONAL MODELLING

Alternatively, the effects of the core anisotropy can be adequately modeled in terms of coupled mode theory (CMT, [11], [12], [7]). Numerical solutions for simpler channels with closeby scalar permittivity couple through the anisotropic parts of the full permittivity tensor. Fig. 2 compares respective results

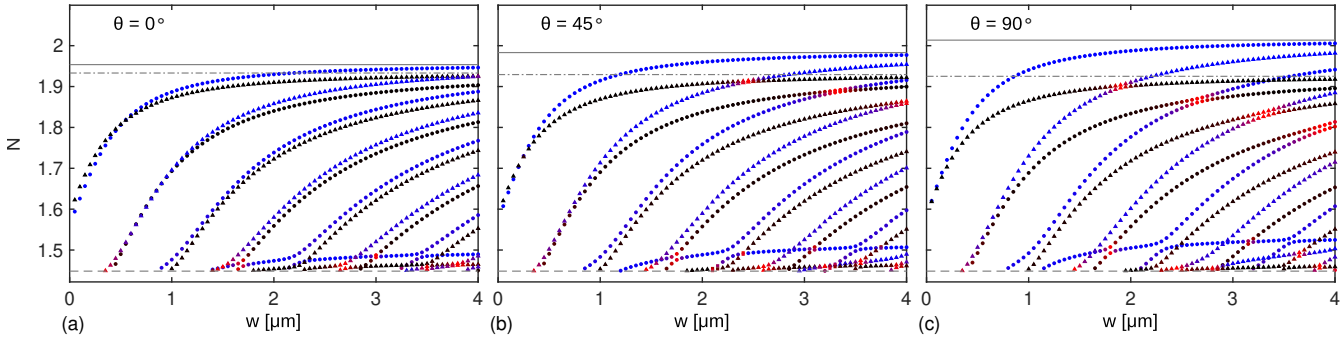

Fig. 3. Effective indices N of guided modes, as a function of channel top width w, for X-cut strip waveguides as in Fig. 1, oriented at angles $\theta = 0°$ (a), $\theta = 45°$ (b), and $\theta = 90°$ (c). Marker symbols distinguish types of $y \leftrightarrow -y$ mirror symmetry; marker colors relate to mode polarization (cf. Fig. 2, inset). Thin gray lines indicate intervals for effective indices, and their limits at large w, determined through 1-D mode analysis of related TFLN slabs.

for a scan over the waveguide orientation, for a narrow TFLN strip waveguide. Curves for effective index levels predicted by direct numerical computation, and through the CMT approximation, are in excellent agreement.

Further, good approximations of the true vectorial mode profiles are obtained in the form of CMT supermodes. Fields can become pronouncedly hybrid around avoided crossings of dispersion curves. As an example, we select parameters from the inset of Fig. 2. At $\theta = 49.25°$, the channel supports a pair of near degenerate, strongly hybrid modes with the essentially complex profiles shown in Fig. 4. Superimposing both fields with amplitudes of equal magnitude and sign leads to a TM-like field with a dominant E_x-component, while a superposition with amplitudes of opposite signs results in a TE-like profile with major E_y component. Upon balanced excitation, these modes cause full periodic TE-to-TM conversion of polarization with a half-beat length of about 1 mm.

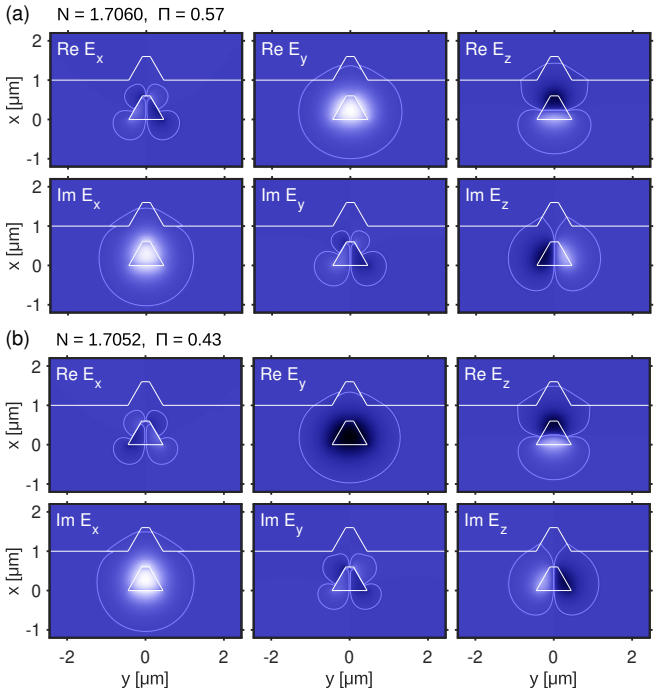

Fig. 4. Complex electric profile components of the two hybrid fundamental guided modes supported by a channel as in Fig. 1, for $w = 0.2\,\mu$m and $\theta = 49.25°$; colormap: black-negative, blue-zero, white-positive.

Unconventional Geometric Phases in Optics

Shubo Wang[1,*]

[1]Department of Physics, City University of Hong Kong, Hong Kong, China
*Corresponding author: shubwang@cityu.edu.hk

***Abstract*—We present two advances expanding the geometric phase paradigm. We show that the Pancharatnam-Berry phase can arise from the transverse spin of surface waves and enable on-chip wavefront manipulation. Furthermore, we report a new type of geometric phase—the Riemann-Silberstein phase—induced by SU(4) evolution in 4D polarization space.**

***Keywords*— geometric phase, Berry phase, metasurfaces**

The Pancharatnam-Berry (PB) phase arises from polarization evolution on the Poincaré sphere and has transformed nanophotonics through optical metasurfaces. However, the standard narrative of the PB phase is far from complete, as the conventional framework addresses only the 2D polarization space of free-space propagating waves. In this talk, I will introduce our recent works that push the boundaries of geometric phase optics. We begin by extending the conventional PB phase to the domain of surface/guided waves carrying a transverse spin, and then proceed to fundamentally generalize the concept into a 4D polarization framework.

I will first introduce our work about on-chip optical wavefront shaping by transverse-spin-induced PB phase [1]. The conventional PB phase relies on the longitudinal spin of free-space waves. However, in the realm of integrated photonics, we deal with surface plasmon polaritons and guided waves. These waves carry an intrinsic transverse spin that is locked to their propagation direction (known as spin-momentum locking). We ask a fundamental question: Can this intrinsic transverse spin induce a geometric phase similar to the longitudinal spin? By utilizing a metasurface composed of periodic metallic nano-bars on a metal substrate, we show that rotation of these meta-atoms can give rise to a geometric phase covering the full 2π range. The physical origin is attributed to the transverse spin of the evanescent field and its SU(2) polarization evolution mediated by the meta-atoms. This transverse-spin-induced PB phase enables us to design on-chip metasurfaces that steer and focus surface plasmons with high efficiency. This work bridges the gap between free-space geometric phase and surface/guided waves, offering a new mechanism for compact light manipulation and facilitating the exploration of near-field topological phenomena [2]. The mechanism can be generalized to other classical wave systems, enabling the observation of the PB phase in acoustic waves [3] and water waves [4].

In the second part of the talk, I will introduce our work on the Riemann-Silberstein (RS) geometric phase in 4D polarization space [5]. In the conventional 2D framework, the PB phase emerges from SU(2) evolution of electric field polarization. However, electromagnetic waves comprise both electric and magnetic fields, and the complete polarization state spans a 4D space encompassing electric, magnetic, and hybrid electric-magnetic polarizations. Thus, the conventional 2D framework cannot capture all degrees of freedom in the complete electromagnetic polarization. We reveal that SU(4) polarization evolution within the 4D polarization space can give rise to a new type of geometric phase, termed the RS phase, independent of the PB phase. The RS phase is governed by the hybrid electric-magnetic polarization and can emerge in arbitrarily polarized light. We show that the complementary PB and RS phases enable a high-dimensional geometric framework for understanding and controlling phase shifts across interfaces. Leveraging this framework, we design and realize a new class of geometric-phase metasurfaces that can achieve high-dimensional wavefront manipulation.

In summary, we introduce in this talk our recent efforts in expanding the horizon of geometric phase optics, which include generalizing the PB phase to surface/guided waves carrying an intrinsic transverse spin and exploring new geometric phases in the 4D electromagnetic polarization space. These results uncover a deeper, unified geometric framework for light-matter interactions in broad physical systems.

***Abstract*—In this contribution, we review our recent works aiming at the development of high-fidelity fullwave solvers and reduced-order models for studying nanoscale light-matter interactions. Additionally, we also discuss ML-based inverse design strategies for shaping these interactions through optimization of geometrical features of nanostructures.**

***Keywords*— Discontinuous Galerkin, Proper Orthogonal Decomposition, Machine Learning, nanophotonics, plasmonics, high performance computing.**

I. Introduction

Modeling and simulation of nanoscale light-matter interactions is an important part of photonic device design. Moreover, harvesting and tailoring these interactions with the help of inverse design approaches is an increasingly considered objective of computational nanophotonics. An inverse design methodology is generally based on two ingredients: on the one hand, a numerical method for characterizing the optical performance of a given design of the photonic device at hand, which will be referred in the sequel as the numerical characterization method; on the other hand, a numerical optimization algorithm, which has to be compatible with the required number of design parameters and the computational cost of the evaluation of a single design with the numerical characterization method. In this contribution, we address this dual objective by first combining two main numerical ingredients: (1) a high-fidelity fullwave solver based on a high order Discontinuous Galerkin (DG) method for solving the system of time-domain or frequency-domain Maxwell equations in 3D coupled to appropriate differential models of physical dispersion in photonic materials and, (2) a machine learning-based (ML-based) global optimization techniques that belongs to the class of Bayesian optimization. This combined numerical methodology has been successfully applied to various problems relevant to nanophotonics and plasmonics. Yet, for the most challenging problems, the simulation cost of a high-fidelity DG-based fullwave solver can be a major drawback. Thus, in order to reduce the computational overhead when dealing with finite size structures, or when an inverse design study involves a macro-cell structures taking into account near-field coupling between nanostructures, we also explore the development of data-driven reduced-order models for time-domain electromagnetics and nanophotonics.

II. High-fidelity fullwave solvers

For the numerical modeling of nanoscale light-matter interactions with fullwave methods, popular numerical modeling approaches are either working in the time-domain regime in the framework of the FDTD (Finite Difference Time-Domain) method, or in the frequency-domain regime in the setting of the RCWA (Rigorous Coupled-Wave Analysis) or FE (Finite Element) methods. In order to deal with problems involving irregularly-shaped geometrical structures, and multiple scales in space and time (or frequency), we have extensively investigated during the last ten years the Discontinus Galerkin discretization framework [1] for developing both time-domain and frequency-domain fullwave methods tailored to differential models of nanophotonics and plasmonics. These methods, which are respectively referred as the Discontinuous Galerkin Time-Domain (DGTD) [2] and the Hybridized Discontinuous Galerkin Frency-Domain (HDGFD) [3] methods, are geometry-conforming as they are formulated on an unstructured locally refined mesh for the discretization of the computational domain, and high-order accurate by relying on a polynomial interpolation method for the approximation of the electromagnetic field components within each cell of the mesh. Moreover, our implementation of these fullwave methods for three-dimensional problems can leverage high performance computing systems, including hardware platforms with multiple GPUs.

III. Data-driver reduced-order models

A variety of physical systems occurring in nature and in engineering are usually described by partial differential equations (PDEs) whose numerical solution requires considerable computational effort, especially in the case of parameterized PDEs, which often need to be solved for a range of parameter values. Such a situation is for instance encountered when studying electromagnetic wave propagation problems in complex geometries for different input parameters including frequency, direction of the incident wave, geometric dimensions, as well as material properties, which are described by the system of time-domain Maxwell's equations. In this context, reduced-order modeling allows to construct simplifications of a high-fidelity model of a complex physical problem. The resulting lower fidelity (also referred as surrogate) model can

capture the salient features of the source model so that one can quickly study a system's dominant effects using minimal computational resources. The reduced basis (RB) method [4] is a widely used family of reduced-order modeling techniques. The Proper Orthogonal decomposition (POD) method is a poular example of RB method. The POD method begins with a set of snapshot vectors extracted from high-fidelity numerical simulations or experiments; the POD basis vectors are then obtained by an eigensystem of a correlation matrix generated by the snapshot matrix whose columns are the snapshot vectors. In the classical POD method, a ROM is created by projecting (Galerkin projection) the semi-discrete numerical scheme used for obtaining the snapshots onto a low-dimensional space spanned by the POD basis. This approach is often referred as an *intrusive* ROM technique since it requires having access to the formulatiom of the original numerical scheme. The alternative approach that avoids this constraint consists in defining an appropriate decoupling of the construction of the POD basis and the prediction of the solution in a purely data-driven workflow. As a result, one obtains a *non-intrusive* ROM technique with decoupled offline (training) and online (inference) phases. In a non-intrusive ROM, the reduced-order coefficients for a new time (and parameter) value are obtained via an approximate mapping. The high-fidelity solver is only used to generate the snapshots, i.e., the training dataset, and there is a complete decoupling between the online evaluation and the offline training. In the recent years, we haev proposed such a non-intrusive ROM for the solution of parameterized electromagnetic scattering problems [5]. In this approach, in addition to the time parameter, the dielectric permittivity is also considered as a reduction parameter.

IV. Numerical optimization algorithms

Inverse design allows to shape nanosclae lightmatter interactions driven by a performance figure of merit. Several numerical optimization methodologies including both local (gradient-based) and global search methods can be considered for this objective. In our work, we consider using a numerical optimization algorithm for tailoring the geometrical characteristics of material nanostructuring or the shape of nanostructures. In other words, we place ourselves in the setting of geometrical optimization as opposed to topology optimization. For this purpose, we investigate an optimization framework that belongs to the class of Bayesian optimization methods, and which is known as Efficient Global Optimization (EGO) [6]. Contrary to the classical common global optimization strategies like Genetic Algorithms (GAs), the EGO method is not based on an adaptive sampling, but on a surrogate model, which is built on the basis of available objective function evaluations. This surrogate model uses a statistical learning criterion related to the optimization goal (usually called merit function) in order to identify which design (set of parameters) should be tested in the next optimization iteration that would provide better results close to the stated performance target. For the evaluation of a given design, we can use of one of the two high-fidely fullwave methods, i.e., the DGTD and HDGFD methods, or a data-driver reduced-order model.

A. Applications

In the context of the Atlantis research group at the Inria center of Université Côte d'Azur, we are developing an innovative software suite dedicated to computational nanophotonics, which hosts time-domain and frequency-domain variants of the DG method specifically designed for differential systems of nanoscale light-matter interactions, data-driven reduced-order models for time-domain nanophotonics, and EGO-based inverse design workflows for mono-objective [7], multi-objective [8] and robust optimization [9] scenarios. This software suite, which is named DIOGENeS, is currently exploited in several projects in collaboration with physicists, and the involve various photonic devices such as those illustrated in figure 1. In this contribution, we will present some concrete applications for illustrating the capabilities of the proposed numerical tools.

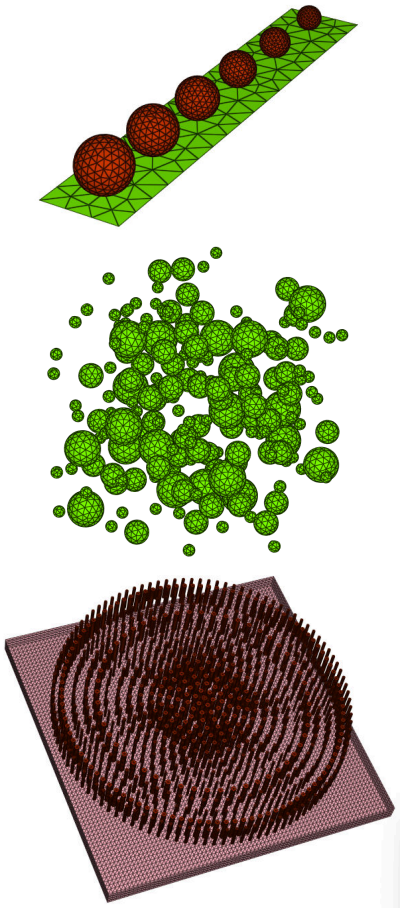

Fig. 1. Sample of photonic devices that are studied with the numerical tools of the DIOGENeS software suite. Top: a a metasurface with nanospheres. Middle: an random medium made of nanospheres with varying size. Bottom: a speherical metalens.

ACKNOWLEDGMENTS

The present work has benefited from different computational resources. On one hand, multi-CPU numerical experiments have been carried out using the Azzurra and PlaFRIM HPC clusters. As such, this work was supported by the French government through the France 2030 investment plan managed by the National Research Agency (ANR), as part of the Initiative of Excellence Université Côte d'Azur under reference number ANR-15-IDEX-01. The authors are grateful to the Université Côte d'Azur's Center for High-Performance Computing (OPAL infrastructure) for providing resources and support. PlaFRIM testbed is developed under the Inria PlaFRIM development action with support from Bordeaux INP, LABRI and IMB and other entities: Conseil Régional d'Aquitaine, Université de Bordeaux and CNRS (and ANR in accordance to the programme d'investissements d'Avenir. On the other hand, for multi-GPU numerical experiments, this work was provided with computing HPC and storage resources by GENCI at IDRIS thanks to the grant 2025-A0190616899 on the supercomputer Jean Zay's V100/A100/H100 partitions.

I. Introduction

Advances in computational capabilities and inverse design methodologies have enabled the discovery and engineering of novel and unconventional nanophotonic devices. In particular, topology-optimization-based inverse design can uncover fully three-dimensional, free-form nanophotonic structures that go beyond human intuition and achieve optical functionalities unattainable with conventional design approaches. By efficiently exploring vast design spaces using algorithms tailored for high-performance computing platforms, it becomes possible to identify new device concepts that can subsequently inform more conventional, physics-driven design strategies. Gradient-based topology optimization provides a robust and computationally efficient framework for navigating such large parameter spaces, enabled by efficient gradient evaluation techniques such as the adjoint method. This talk presents recent advances from my research group in computational nanophotonics and inverse design via topology optimization, with applications in meta-photonics and integrated optics, including:

- the inverse design of nanostructures made of arbitrary dispersive optical materials thanks to a formulation of the adjoint method in the time domain [1],
- the optimization of metallic and dielectric nanostructures and metasurfaces to achieve broadband absorption [2], [3],
- anapole effects in plasmonic meta-atoms that can be exploited as building blocks for transparent metasurfaces and metamaterials [4],
- integrated beam splitters designed via topology optimization to achieve arbitrary phases at the output ports [5],
- 3D free-form integrated optical circuits compatible with two-photon polymerization that outperform their 2D counterpart [6], and
- the topology optimization of nanostructures where the aim is to achieve a desired multipolar response in order to engineer the nanoantenna's scattering properties [7].

***Abstract*—High-efficiency compact GRIN metalenses, tailored for fabrication by SCRIBE, are designed using density-based topology optimization. Superior performance is demonstrated experimentally compared to traditional diffractive lenses of (near) identical dimensions, revealing the potential of combining SCRIBE with inverse design to realize improved optical devices fabricated using low-index contrast materials.**

***Keywords*— metalenses, visible light, topology optimization, inverse design, SCRIBE, GRIN.**

I. Introduction

Metalenses are maturing into powerful platforms for compact, lightweight, and highly functional optical components capable of replacing or augmenting traditional refractive elements across a wide range of applications. Here we explore the integration of large-scale inverse design via topology optimization with the high-resolution, freeform fabrication capabilities of SCRIBE to engineer next-generation GRIN metalenses. This combined approach leverages unprecedented control over spatially varying refractive index profiles for increased design freedom, pushing beyond the limitations of traditional design and fabrication methods.

II. Methods

Our method integrates full-wave electromagnetic simulation and density-based topology optimization (DBTO) with the subsurface controllable refractive index via beam exposure (SCRIBE) technique [1]. Informed by fabrication constraints and an experimentally measured dispersive refractive index we extend a DBTO method [2] to the design of compact, gradient index axisymmetric metalenses for use in the visible spectrum.

The topology-optimized lenses are fabricated by SCRIBE, where two-photon direct laser writing is performed within highly transparent porous silica ($PSiO_2$). SCRIBE allows for simultaneous definition of geometry and refractive index with sub-micron accuracy in 3D.

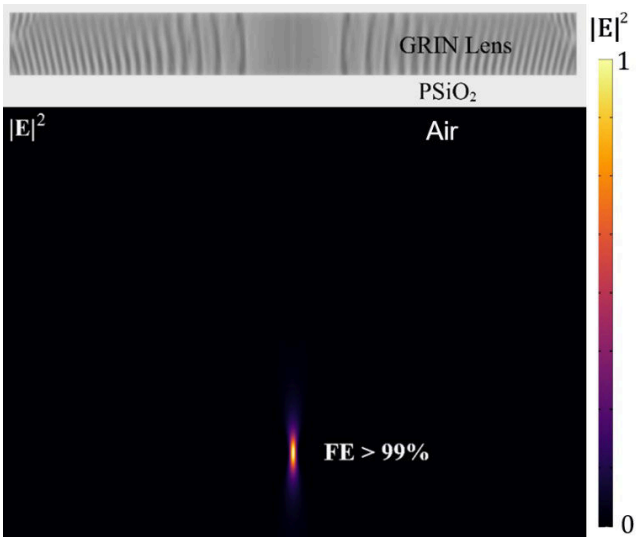

Fig. 1 Simulation data: Topology optimized GRIN metalens embedded in $PSiO_2$ (grayscale) and electromagnetic field intensity (inferno).

III. Results and Discussion

Numerically we demonstrate (near) unity focusing efficiency (FE) for all monochrome lenses (Fig 1), while above 70% focusing efficiency is demonstrated for an RGB triplet.

Experimentally, the refractive index profile and focusing efficiency of the print lens are characterized by multi-photon confocal fluorescence microscopy and custom-built setup. Monochromatic lenses with NAs of 0.3, 0.45 and 0.6 at 488nm, 542nm and 633nm respectively, are experimentally realized revealing significantly improved FE compared to traditional diffractive lenses, e.g. from FE~23% to FE~60% for 633nm light at NA=0.6. Our design and fabrication methods are extended to the design and realize a singlet achromatic lens with less than 5% chromatic focal length error. (For more details on the experimental methods see [3]).

IV. Conclusion

Leveraging density-based topology optimization, we inversely design and realize axisymmetric microlenses with NAs up to 0.6 that exhibit focusing efficiencies above 60% in the visible. We demonstrate, both numerically and experimentally, that the performance of our GRIN lenses significantly outpaces that of traditional diffractive lenses, particularly at high NAs, without compromising imaging quality. For broadband optimization across the visible spectrum, we numerically demonstrate a singlet achromatic microlens with high focusing efficiency and experimentally show a dramatic reduction in chromatic focal length error from 24.5% (for a standard diffractive lens) to 4.2%. Note that the design method may be leveraged for thin GRIN lenses with diameters in the mm-range on modern high-end desktop systems, thus our demonstrations are mainly size-limited by experimental constraints. To our knowledge, this is the first realization of singlet achromatic lens using one single lithography step and low refractive index materials.

Radiative decay of surface plasmon propagating in thin metal film

Arkadii Krokhin*, Andrey Bozhko

Department of Physics, University of North Texas, USA
*Corresponding author: arkadii.krokhin@unt.edu

***Abstract*—A narrow transition layer between metal and dielectric contains epsilon-near-zero surface (ENZ) formed by spill-out electrons and surface roughness. Electromagnetic field of surface plasmon leaks through the ENZ point leading to radiative attenuation. Here the radiative losses of surface plasmon are calculated for a thin metal film.**

***Keywords*— epsilon-near-zero, collisionless damping.**

I. Introduction

The decay of a surface plasmon propagating along a metal–dielectric interface is usually attributed to Joule losses in the metal and to wave scattering from random surface roughness. The evanescent nature of plasmonic fields in both the metal and the dielectric is a necessary condition for the existence of the surface mode and is typically assumed to arise from an ideally sharp metal–dielectric interface. However, even for atomically flat surfaces, the dielectric properties do not change discontinuously. The macroscopic dielectric function must therefore pass through zero when transitioning from its negative value in the metal to its positive value in the dielectric.

Spill-out electrons form a transition region a few angstroms thick above an atomically flat metal surface [1]. Near a rough surface, this region may become orders of magnitude thicker, depending on the mean height of the surface roughness. In any case, the thickness of the transition layer is much smaller than the optical wavelength and can therefore be safely neglected in conventional optical laws, such as Snell's law.

However, a surface plasmon carries energy distributed within the near-field zone, where the presence of even an atomically thin transition layer containing an ENZ region may strongly affect the evanescent character of the plasmonic field. At the point where the dielectric function approaches zero, plasmon energy leaks into the dielectric (or vacuum), giving rise to a radiative loss channel [2]. An analytical method for calculating radiative losses of a surface plasmon in a semi-infinite metal was proposed in Ref. [3]. It has also been demonstrated experimentally that a strong electric field applied normal to the interface shifts the ENZ point toward or away from the interface, thereby affecting the resonant conditions for surface-plasmon excitation.

Here, we analyze the effects of the transition layer on propagation of surface plasmon in a symmetric thin metallic layer and demonstrate that its energy leaks to dielectrics through the ENZ regions.

II. Dispersion and decay of surface plasmon in a metal film with two transition layers

We consider a metal slab of thickness $2d$ and dielectric function $\epsilon(\omega) < 0$ clad between two equal dielectrics with permittivities $\epsilon_d > 0$. Two metal-dielectric transition layers are formed at the both interfaces. If an external electric field is applied normal to the slab, it breaks the symmetry by decreasing the electron concentration at one interface and increasing it at the other.

A continuous dielectric function $\epsilon(z)$ approaches ϵ_d at $|z| > d$ and $\epsilon(\omega)$ for $|z| < d$. Assuming exponentially narrow transition layers, the function $\epsilon(z)$ can be written as:

$$\epsilon(z) = \epsilon_d + \frac{\epsilon(\omega) - \epsilon_d}{2}\left(\tanh\frac{z+d+l_2}{2\delta_2} - \tanh\frac{z-d+l_1}{2\delta_1}\right), \tag{1}$$

where $\delta_{1,2}$ are the widths of the transition layers on the upper and lower metal-dielectric interfaces. The parameters $l_{1,2}$ describe the asymmetry of the transition layers induced by the applied electric field. Electrical neutrality in the presence of the electric field is satisfied if $l_1 = l_2 = l$, regardless of the relation between δ_1 and δ_2. For any reasonable field strength, $l, \delta_{1,2} \ll d$. In the absence of an external field, $l_1 = l_2 = 0$ and $\delta_1 = \delta_2$. The dielectric function $\epsilon(z)$ vanishes at two points $z = z_{1,2}$ located near the metal–dielectric interfaces.

For p-polarized surface wave propagating along the x-axis, the dependence of the H_y component on the coordinate z is obtained from

$$\frac{d}{dz}\left(\frac{1}{\epsilon(z)}\frac{dH_y}{dz}\right) + \left(\frac{\omega^2}{c^2} - \frac{k^2}{\epsilon(z)}\right)H_y(z). \tag{2}$$

The differential term here exhibits a strong singularity at $z = z_{1,2}$. An analytical solution for $H_y(z)$ and the dispersion relation $\omega(k)$ can be obtained by applying a Fourier transformation over the coordinate z [3]. The Fourier transform of Eq. (1) leads to the integral eigenvalue problem for $h(p) = (2\pi)^{-1}\int_0^\infty H_y(z)e^{-ipz}dz$

$$\frac{\omega^2}{c^2}h(p) = \int_0^\infty (k^2 + pp')\eta(p-p')h(p')dp'. \tag{3}$$

In the sharp-boundary model, where $\epsilon(z)$ is a non-vanishing piecewise function, the kernel of Eq. (2) is Hermitian since $\eta(-p) = \eta^\star(p)$. The eigenvalue is then real and positive, yielding a real eigenfrequency $\omega(k)$. However, the transition layer

contains two ENZ points along the integration path. Shifting the integration contour to the lower half-plane (corresponding to $\mathrm{Im}\epsilon(z) > 0$) the function $\eta(p)$ acquires an imaginary part,

$$\eta(p) = \frac{1}{2\pi}\int_0^\infty \frac{1}{\epsilon(z)} e^{-ipz} dz - \frac{i}{2} \operatorname*{Res}_{z=z_1,z_2} \frac{e^{-ipz}}{\epsilon(z)} \tag{4}$$

which breaks the Hermiticity of the integral kernel. As a result, the dispersion relation of surface plasmon becomes complex, $\omega(k) = \omega_0(k) + \omega'(k) - i\omega''(k)$, where $\omega_0(k)$ is the surface-plasmon frequency without the transition layer. The frequency shift $\omega'(k)$ and radiative decay rate $\omega''(k)$ can be calculated from Eq. (2) using perturbation theory in a small parameter $\delta_{1,2}k$. These corrections are expressed in terms of the unperturbed magnetic-field distribution $H_0(z)$, which is an even (odd) function for the long (short)-range surface plasmon.

$$\frac{\omega'}{\omega_0} = \frac{c^2}{2\omega_0^2} \frac{\int_{-\infty}^{\infty} \left(\frac{1}{\epsilon(z)} - \frac{1}{\epsilon_0(z)}\right) \left(|kH_0|^2 + |H_0'|^2\right) dz}{\int_{-\infty}^{\infty} |H_0(z)|^2 dz} \tag{5}$$

$$\frac{\omega''}{\omega_0} = \frac{\pi c^2}{2\omega_0^2} \frac{\sum_{z=z_1,z_2} \frac{1}{|\epsilon'(z)|} \left(|kH_0(z)|^2 + |H_0'(z)|^2\right)}{\int_{-\infty}^{\infty} |H_0(z)|^2 dz} \tag{6}$$

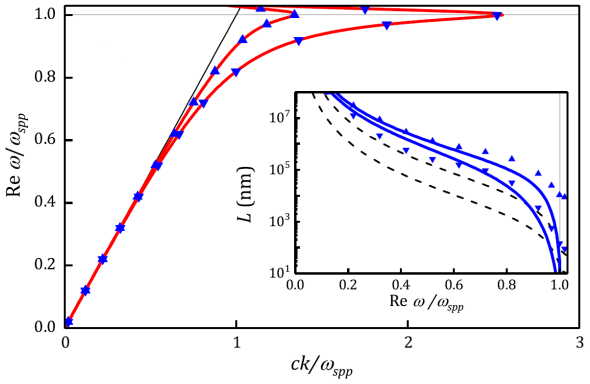

Fig. 1. Dispersion of surface plasmon for 50nm-thick silver slabs in air. The red curves and blue data points show the dispersion for the cases of sharp boundary ($\delta = 0$) and interfaces with transition layers (with $l_1 = l_2 = 0$ and $\delta_1 = \delta_2 = 2$ Å. The insets compare theoretical (blue lines) and numerical (blue data points) results for the collisionless damping rates, expressed in terms of propagation length. The rate of Joule losses is shown with dashed black lines. Dispersion with higher frequency (longer $L(\omega)$) corresponds to the long-range plasmon.

These equations were used to plot the dispersion and decay of a surface plasmon propagating in silver film of thickness 50 nm.The transition-layer widths were chosen as $\delta_1 = \delta_2 = 2$ Å and no external DC field was applied ($l_1 = l_2 = 0$). The continuous red and blue curves show the perturbative results obtained from Eqs. (5) and (6), while the blue triangles represent the numerical solution of Eq. (2).

The dispersion curves are only weakly perturbed by the presence of the transition layer. However, the radiative losses associated with the transition layer make a significant contribution to the decay length $L(\omega)$. For the short-range plasmon, radiative losses become comparable to Joule losses (dashed line) near the plasmonic resonance $0.8 < \omega/\omega_{spp} < 1$. For the long-range plasmon, radiative losses remain smaller than Joule losses. The radiative decay mechanism of the surface plasmon is, in some sense, similar to Landau collisionless damping, since neither originates from electron collisions in the metal.

These estimates were obtained for an atomically flat surface with a very narrow transition layer. Surface roughness increases the effective thickness of the transition layer by at least an order of magnitude. In this case, radiative losses can exceed Joule losses even for the long-range plasmon. Very close to resonance, the perturbation theory fails because the parameter δk is no longer small as $k \to \infty$.

Many applications of surface-plasmon resonance rely on the strength and localization of the electromagnetic fields near the metal surface. The singular behavior of the first term in Eq. (2) shifts the field maxima toward the ENZ point and enhances the discontinuities. The asymptotic solution of Eq. (2) near a point where the dielectric function vanishes yields $H_y(\xi) \sim 1 + \frac{1}{2}(k\xi)^2 \ln(k\xi)$ where $\xi = |z - z_{1,2}|$. While the magnetic field remains continuous, the electric-field components become singular: $E_x(\xi) = H_y'(\xi)/\epsilon(\xi) \sim \ln(k|\xi|)$, $E_z(\xi) = H_y(\xi)/\epsilon(\xi)$. Stronger than the sharp-boundary model predicts singularity can be considered as a "compensation" of the negative effect of radiative decay.

III. Conclusion

It is shown that due to the presence of the ENZ point within the transition layer between metal and dielectric, a surface plasmon inevitably loses energy even if the metal is lossless. The very existence of the ENZ point results in the delocalization of the plasmon energy, which therefore gradually radiates away from the interface and depletes the plasmon. The rate of radiative collisionless decay has been analytically and numerically calculated for a thin metal film sandwiched between two identical dielectrics. Even for an atomically thin transition layer a few angstroms thick, the radiative attenuation channel significantly reduces the propagation length of the short-range plasmon. A wider transition layer associated with surface roughness, with a mean height of several tens of nanometers, strongly reduces the propagation length of the long-range plasmon.

***Abstract*—We provide the overview of the state of art on development of magnetic wires with high Giant Magnetoimpedance (GMI) effect. Excellent soft magnetic properties and GMI ratio up to 750% have been observed in as-prepared low magnetostrictive amorphous Co-rich microwires. Appropriate processing, such as annealing, allows to increase further the GMI ratio value in both Co-rich and Fe-rich microwires. In both Fe and Co-rich microwires the maximum GMI ratio is observed for frequencies above 100 MHz.**

***Keywords*—Giant Magnetoimpedance, Magnetoelastic anisotropy, Magnetostriction, Amorphous microwires.**

I. Introduction

Studies of Giant magnetoimpedance, GMI, effect have attracted considerable attention in the last few years owing to its suitability for technological applications [1,2]. The main features of the GMI effect have been successfully explained in terms of classical electrodynamics that consider the influence of a magnetic field on the penetration depth of AC current (MHz-GHz frequency range) flowing through the magnetically soft conductor.

The most common quantity for the characterization of the GMI effect is the GMI ratio, ΔZ/Z, defined as:

$$\Delta Z/Z = [Z(H) - Z(H_{max})] / Z(H_{max}), \quad (1)$$

where H_{max} is the axial DC-field with maximum value up to few kA/m.

Extremely high sensitivity of the GMI effect to even low magnetic field attracted great interest in the field of applied magnetism, basically for applications in magnetic sensors and smart composites. Cylindrical shape and high circumferential permeability observed in amorphous wires are quite favorable for achievement of high GMI effect [1-4].

One of the tendencies in modern GMI sensors is the size reduction [3-5]. Recently developed magnetic sensors using the GMI effect allow achieving nT and pT magnetic field sensitivity with low noise [1,3,4]

The aim of this report is to provide recent results on the optimization of soft magnetic properties and the GMI effect in magnetic microwires.

II. Methods

We measured magnetic field dependences of impedance, Z, and GMI ratio, $\Delta Z/Z$, of magnetic microwires using a specially designed micro-strip sample holder. The sample holder was placed inside a sufficiently long solenoid that creates a homogeneous magnetic field, H. The sample impedance Z was measured using vector network analyzer from reflection coefficient S_{11}, reported elsewhere [3,6].

III. Results and Discussion

As discussed elsewhere [1-4], for amorphous materials characterized by the absence of magneto-crystalline anisotropy the main sources of magnetic anisotropy are the shape and magnetoelastic anisotropy, K_{me}. The latter is determined by the magnetostriction coefficient, λ_s, and the internal stresses, σ_i, by the relation [3]:

$$K_{me} = 3/2\, \lambda_s \sigma_i, \quad (2)$$

Nearly-zero λ_s –values can be achieved in $Co_{1-x}Fe_x$ alloys at x about 0,03 – 0,08 [3]. Accordingly, Co-rich microwires can present high GMI ratio. $\Delta Z/Z(H)$ dependencies measured at different frequencies in $Co_{67}Fe_{3.9}Ni_{1.4}B_{11.5}Si_{14.5}Mo_{1.6}$ (d=10.8 μm, D= 13.8 μm) microwire are shown in Fig. 1a. This microwire presents high maximum GMI ratio, $\Delta Z/Z_m$, (~530%) at optimal frequency of about 700 MHz (see Fig. 1b).

However, from $\Delta Z/Z_m(f)$ dependence for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ microwires with d=10.8 μm

and

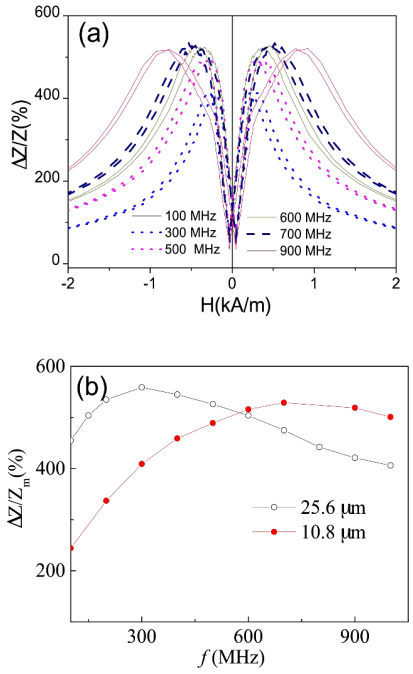

Fig. 1. *ΔZ/Z(H)* dependencies measured in $Co_{67}Fe_{3.9}Ni_{1.4}B_{11.5}Si_{14.5}Mo_{1.6}$ (d=25.6 μm, D= 26.6 μm) microwires (a) and $\Delta Z/Z_m(f)$ dependence for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ with d=10.8μm, D=13.8μm and d=25.6 μm, D= 26.6 μm microwires.

d=25.6 μm we can appreciate that for $Co_{67.7}Fe_{4.3}Ni_{1.6}Si_{11.2}B_{12.4}C_{1.5}Mo_{1.3}$ microwires with d=25.6 μm the optimal frequency is about 300 MHz at which $\Delta Z/Z_m \approx 560\%$ can be

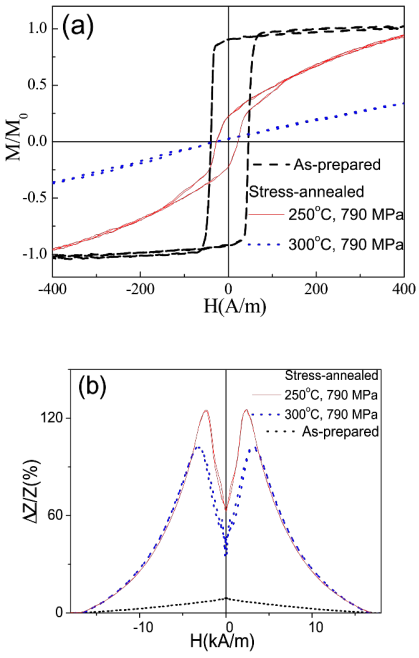

Fig. 2. Hysteresis loops (a) and *ΔZ/Z(H)* dependences measured at 300 MHz (b) of as-prepared and stress-annealed $Fe_{75}B_9Si_{12}C_4$ microwires.

achieved. The observed behaviour reflects the relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required [5]. The diameter reduction must be associated with the increasing of the optimal GMI frequency range [3,5].

Usually, highly magnetostrictive Fe-rich microwires present poor GMI effect. However, from the viewpoint of the cost Fe-rich microwires are preferable. Recently, we identified that the magnetic softness and GMI effect of Fe-rich microwires can be substantially improved by stress-annealing (see Fig. 2): an order of magnitude $\Delta Z/Z_m$ improvement (see Fig. 2b) is explained by transverse character of induced by stress-annealing magnetic anisotropy (see Fig .2a).

It is worth noting that annealing can also improve the GMI effect of Co-rich microwires. Thus, recently we reported $\Delta Z/Z_m$ up to 900% in annealed Co-rich microwires [6].

IV. Conclusion

We studied the factors allowing optimization of GMI effect of magnetic microwires. Generally, low coercivity and high GMI effect have been observed in as-prepared Co-rich microwires. We identified a relationship between the optimal frequency for the GMI performance and the wire diameter: to achieve the maximum GMI effect a trade-off between wire dimensions and frequency is required. GMI ratio of Fe-rich microwires can be substantially improved by the adequate postprocessing.

***Abstract*— ZEISS electron microscopy is indispensable method in the discovery of materials with enhanced or novel properties, metamaterials, nanophotonic, quantum photonics, facilitating high-resolution imaging, detailed characterization, and nanofabrication. The ZEISS electron microscopy contributes significantly to the understanding and advancement of this exciting field, enabling the development of novel applications in optics, sensing, telecommunications, and beyond.**

***Keywords*—metamaterials, electron microscopy, nanofabrication, focus-ion beam, Crossbeam.**

I. Introduction

Electron microscopy plays a pivotal role in metamaterials research, providing essential capabilities for both the fabrication and characterization of these advanced materials [1]. This talk presents the contribution of the latest developments in electron microscopy for nanofabrication, characterization, and analysis of metamaterials.

II. Methods

ZEISS focused ion beam scanning electron microscopes (FIB-SEM) of Crossbeam family provide solutions for nanofabrication with high precision and high spatial resolution. They combine the powerful imaging and analytical performance of a field emission scanning electron microscope (FE-SEM) with superior next-generation focused ion beam (FIB) processing capabilities for nanofabrication of new advanced materials and devices. This talk presents the advantages of nanofabrication using a ZEISS FIB-SEM microscope and simultaneous high-resolution imaging, structural analysis, morphology examination and characterization of material properties, that define the unique properties of advanced materials, such as metamaterials, photonic crystals, and plasmonic [2].

III. Discussion

ZEISS Crossbeam FIB-SEM provides not only detailed surface morphology images, but also 3D information enabling the assessment of the shape, size, and arrangement of the metamaterial structures, which are vital for their optical and electromagnetic behavior. ZEISS Crossbeam FIB-SEM allows obtaining structural, elemental, and compositional information with integrated energy dispersive x-ray spectroscopy (EDX) and electron backscatter diffraction (EBSD) and provides an understanding of the properties of metamaterials for specific applications.

The authors show the advantages of ZEISS Crossbeam's modular platform concept with the possibility to upgrade the microscope with growing needs, e.g. with the fs-laser for massive material ablation and high throughput of sample preparation [3].

IV. Conclusion

The combination of high-resolution ZEISS Gemini optics for imaging and super stable integrated FIB-column of ZEISS FIB-SEM for nanofabrication is an ingenious solution that advances fabrication approaches in metamaterials, nanophotonic, sustainable materials, quantum photonics, and new materials for nano-optics research.

The interaction of hot carriers with adsorbates

Johannes Lischner[1,*]

[1]Department of Materials, Imperial College London, United Kingdom
*Corresponding author: j.lischner@imperial.ac.uk

***Abstract*— Highly energetic or "hot" electrons and holes generated from the decay of localized surface plasmons can be harnessed for applications in photocatalysis, photovoltaics and sensing. I will discuss the interaction of these hot carriers with adsorbed molecules and connect this to experimental observations of chemical interface damping of plasmons.**

***Keywords*— hot carriers, chemical interface damping, photocatalysis.**

I. Introduction

Localized surface plasmons in metallic nanoparticles give rise to very strong light absorption. The decay of these excitations results in the generation of energetic or “hot” electrons and holes which can be harvested and harnessed for applications in photovoltaics, photocatalysis and sensing. To optimize hot carrier production in devices, a detailed theoretical understanding of the relevant microscopic processes, including light-matter interactions, plasmon decay and hot electron thermalization, is needed. In my talk, I will describe a material-specific theory of hot-carrier generation and relaxation in metallic nanoparticles which combines a classical description of the electromagnetic radiation with large-scale atomistic quantum-mechanical simulations. I will present results for hot carrier distributions in spherical nanoparticles of gold, silver and copper and discuss the relative importance of interband and intraband transitions as function of nanoparticle size. Next, I will describe how CO2 reduction performance of gold nanoparticles can be enhanced by changing the nanoparticle shape. Finally, I will present results the interaction of hot carriers with adsorbed molecules on nanoparticles surface and use this to explain recent observations of chemical interface damping.

II. Methods

Density-functional theory calculations of molecules on metallic surfaces are performed. The results of these calculations are combined with Fermi’s golden rule to evaluate the rate of chemical interface damping.

III. Results and Discussion

We calculate the contribution to the plasmon linewidth for different molecules on spherical gold nanoparticles. We are able to correlate these results with the adsorbate density of states obtained from ab initio calculations. Our results are in good qualitative agreement with recent measurements of plasmon propagation lengths in gold waveguides which are coated with different molecules.

IV. Conclusion

We have demonstrated that calculation of chemical interface damping can reliably reproduce experimental measurements.

Nanostructured GLAD optical coatings for reflectance and birefringence control

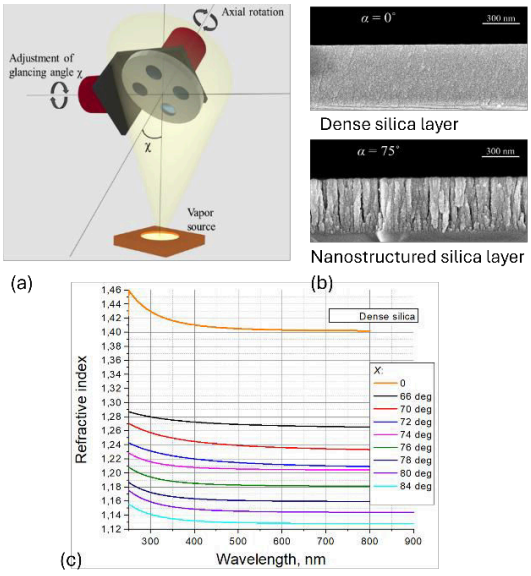
***Abstract* — In this work the possibilities to engineer the inner nanostructures of individual layer and applications for the formation of coating-based AR-, HR-coatings, polarizers and phase retarders were proposed.**

***Keywords* — all dielectric polarizer, waveplates, PVD technologies, high power lasers, optical elements.**

I. Introduction

During conventional physical vapor deposition (PVD), substrates are typically placed in continuously rotating holders to average the deposition angle and vapor flux intensity, resulting in homogeneous isotropic multilayer coatings. In such coatings, optical interference structures are formed by combining materials with high and low refractive indices to achieve the required variation of optical constants. In contrast, during glancing angle deposition (GLAD), the substrate is kept tilted relative to the vapor flux, allowing the formation of nanostructured anisotropic layers (Fig. 1a). This technique enables the growth of columnar thin films (Fig. 1b) with advanced optical constants and anisotropic properties (Fig. 1c).



Fig, 1. a) Schematic of the GLAD deposition principle. b) Dense and nanostructured coatings. c) Effective refractive index dispersions.

II. Methods and Results

Investigations of silica-based GLAD antireflection coatings have demonstrated higher resistance to laser radiation and broader spectral performance compared with conventional two-material coatings produced by the Ion Beam Sputtering (IBS) technique. These coatings consist of porous thin films with low intrinsic stress. High-reflection all-silica mirrors have also shown improved laser resistance compared with standard dielectric mirrors [1]. However, due to the highly porous structure of GLAD films, silica-based anisotropic coatings can be sensitive to environmental conditions, as water adsorption in the pores may alter the effective refractive index and birefringence. Recent studies have therefore explored alternative materials for anisotropic coatings. In particular, GLAD-deposited LaF_3 coatings have demonstrated suitable birefringence, low optical losses, and improved environmental stability for UV polarization optics, with retardance variations below 1% under changing humidity conditions for waveplates operating at 266 nm wavelength [2,3].

In the present work, the optical and structural properties of anisotropic single-layer coatings were investigated to determine optimal deposition conditions for low-loss birefringent coatings. Transmission and phase delay (retardance) between two orthogonal polarizations - along the shadowing plane (fast axis) and perpendicular to it (slow axis) - were measured using spectrophotometry and spectroscopic ellipsometry and later analyzed to determine optical constants.

Fresnel reflections at interfaces between materials with different refractive indices are unavoidable in optical systems. Conventional antireflection or high-reflection coatings are typically formed by alternating layers of high- and low-refractive-index materials with optical thicknesses equal to a quarter or half wavelength. For a wavelength of 355 nm, the refractive index of a dense SiO_2 layer is approximately 1.41, while anisotropic porous layers exhibit refractive indices of about 1.211 and 1.231 along the fast and slow axes, respectively. Therefore, within the coating design, dense and porous anisotropic films can effectively serve as high- and low-index materials.

The waveplate design aims to minimize the number of layers while maintaining high transmission and controlled birefringence. To reduce scattering originating from the nanostructured columnar morphology, the thickness of individual anisotropic layers was kept below 400 nm. In this way, high transmittance can be achieved while the required phase delay is obtained by adjusting the total thickness of anisotropic layers. Based on these principles, a waveplate for a wavelength of 355 nm was modeled and experimentally fabricated. The resulting coating demonstrates low optical losses and high transparency ($T \approx 99\%$), while indicating the potential to withstand high laser fluence (~40 J/cm²) in the nanosecond regime.

III. Conclusion

Nanostructured optical coatings fabricated by the GLAD technique were investigated as a versatile approach for controlling both reflectance and birefringence. The optical and structural properties of anisotropic layers were analyzed to determine deposition conditions suitable for low-loss birefringent coatings. The results show that nanostructured films exhibit different effective refractive indices along the fast and slow axes, enabling controlled birefringence, while dense and porous layers of the same material can function as high- and low-refractive-index components for reflectance control.

Based on these principles, waveplate structures for the ultraviolet spectral range were modeled and experimentally fabricated. The coatings demonstrate high transparency, low optical losses, and the ability to achieve the required phase delay through controlled anisotropic layer thickness. These results highlight the potential of nanostructured GLAD coatings for multifunctional optical elements, where both reflectance and polarization properties can be tailored for high-power laser and photonic applications.

***Abstract*— Two-dimensional, bipartite arrays of nanostructures offer great potential for photonic technologies. By tuning the relative position of the two nanoparticles within the unit cell, we theoretically anticipate and experimentally verify lattice resonances with diverse optical properties, including super- and subradiant modes, noninteracting ones, and out-of-plane polarized resonances.**

***Keywords*— Lattice resonances, periodic arrays, bipartite arrays of nanostructures.**

I. Introduction

Periodic nanoparticle arrays sustain collective lattice resonances arising from far-field interactions [1, 2, 3, 4]. Monopartite arrays provide the simplest platform for attaining these modes but offer limited tunability, typically requiring significant changes in particle size or array period to alter their optical behavior. Bipartite arrays, however, open new possibilities for variations in the optical response due to the interactions between the lattice resonances of its two sublattices. In particular, tuning the relative positions of the two particles within the unit cell enables control of these interactions and access to a broader range of optical responses without modifying the nanostructures themselves.

II. Methods

We combine theoretical calculations, based on the coupled dipole model [2, 5] and the finite-element method, with experimental measurements of bipartite arrays of nanodisks.

III. Results and Discussion

We theoretically and experimentally show that tuning the relative positions of nanostructures within the unit cell enables:

- Excitation of lattice resonances with super- and subradiant character.
- Realization of a bipartite configuration supporting noninteracting modes.
- Access to lattice resonances with out-of-plane character under normal incidence excitation [6].

IV. Conclusion

We have demonstrated that bipartite arrays of nanodisks are versatile platforms for achieving tailored optical responses.

***Abstract*—Two techniques for estimating the natural frequencies of tensegrity-inspired cellular metamaterials are presented and discussed. The first employs a standard frame/truss geometrically nonlinear finite element model implemented in ABAQUS™. The second uses single-degree-of-freedom modelling based on experimental results for quasi-static compression. Examples focus on a four-strut simplex tensegrity-inspired lattice.**

***Keywords*— cellular metamaterials, tensegrity, additive manufacturing, MJP, finite elements.**

I. Introduction

The final goal of the present project is to experimentally evaluate the natural frequencies of cellular metamaterials [1], [2] with uniform or graded mechanical properties [3]. Cells (or supercells) are inspired by tensegrity modules [4], [5] and lattices are printed with MultiJet Printing (MJP) additive manufacturing technology. Conducting experimental studies on a specific scale requires the selection and calibration of appropriate measuring devices. To do this, one must first estimate the order of magnitude of the measured frequencies. The goal of this paper is to determine the frequency range that can be measured. Such preliminary studies constitute a prelude to the efficient implementation of a more general task, which is to determine the effect of varying degrees of mechanical properties of the lattices on their dynamic response. Two estimation techniques are proposed, which are based on finite element (FE) formulations (frame and lattice models) [6], [7] and semi-experimental estimation based on quasi-static compression tests using a lattice continuum tensegrity model [8], [9]. A mesh consisting of 216 cells (grouped in 27 supercells) based on a four-strut simplex tensegrity module (Figure 1) was chosen as an illustrative task.

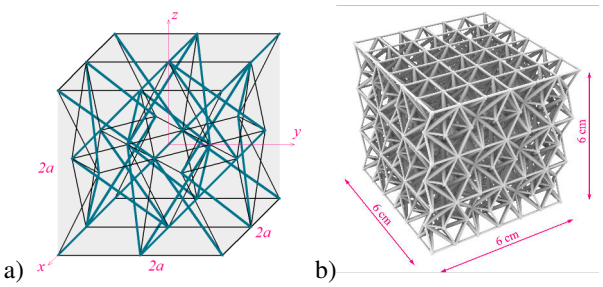

Fig. 1. Simplex-based lattice: a) Supercell; b) Metamaterial.

II. Techniques for Natural Frequency Estimation

The most widely used tool for computational modelling of structures is the FE method [6]. The first approach for estimating natural frequencies is based on the frame and truss models available in ABAQUS™ software, in the geometrically nonlinear range [7]. The FEM enables determination of the natural frequencies and corresponding eigenmodes of free vibrations. The computational data are assumed to be ideal in geometric and physical terms, consistent with the manufacturer's specifications of the printing resin. In the truss model, T3D2 finite elements are used, whereas in the frame model, B32 beam elements are applied, with three elements per each lattice member to ensure convergence.

The second approach for estimating natural frequencies is semi-experimental. Here, the effective stiffness of the lattice K is determined from the force-displacement curve obtained in a quasi-static compression test performed on additively manufactured specimens, whose mass is measured prior to testing. The system is reduced to a single-degree-of-freedom model with stiffness K and mass M, allowing the estimation of the frequency of the assumed vibration mode. Unlike the FEM-based approach, this method relies on experimentally measured properties of the printed metamaterial at the considered scale. This estimation method is motivated by the authors' observation of the uncertainty of the computational data regarding the material properties, which sometimes differ significantly from those declared by the manufacturer and depend on factors such as the time between printing and testing, humidity, and additive manufacturing technology.

Based on the continuum model of tensegrity [8], [9], the properties of the supercell can be expressed in terms of the linear theory of elasticity. In the present study, a truss model is used, which takes into account self-equilibrated normal force systems, leading to the Voight constitutive matrix $\mathbf{E}$ [10]. The effective mechanical properties of the entire structure (Figure 1b) are equivalent to those of the supercell (Figure 1a) [9]. Knowledge of the matrix $\mathbf{E}$ allows estimation of the vibration frequencies corresponding to deformation modes other than those imposed experimentally, such as shear modes.

A reliable theoretical estimation of natural frequencies at the selected scale is essential for the proper design of the experimental campaign for tensegrity-inspired metamaterials.

III. Results and Discussion

The proposed techniques are illustrated using an MJP-printed four-strut simplex lattice (Figure 1b). Each cell has dimensions of $a \times a \times a$, with $a = 1$ cm. The struts and cables have circular cross-sections with diameters of 1.46 mm and 0.65 mm, respectively. The parent material has a Young's modulus of 1612 N/mm^2 and a mass density of 0.001169 g/mm^3.

The first and second natural frequencies in the frame model are 382 Hz and correspond to shear-type vibration in vertical planes. A representative mode (XZ plane) is shown in Figure 2a. The colour scale represents the magnitude of the total displacement. The third natural frequency is 570 Hz and corresponds to a vertical (Z direction) extensional mode (Figure 2b). The natural frequencies obtained from the truss model are about 20% lower, reflecting the increased flexibility of the lattice compared to the beam-based representation.

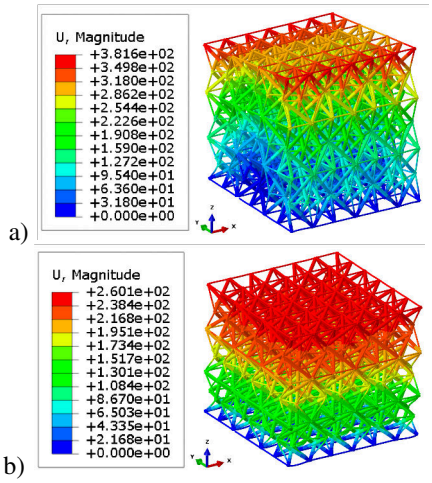

Fig. 2. Eigenmodes: a) Shear; b) Volumetric.

The semi-experimental estimation is based on a quasi-static compression test performed on the Instron 5567 testing machine (Figure 3a). The resulting force-displacement curve averaged for five specimens (with standard deviation marked) is shown in Figure 3b. The experimentally determined tangential stiffness is approximately 200 N/mm, and the average mass of the specimen is 32.84 g.

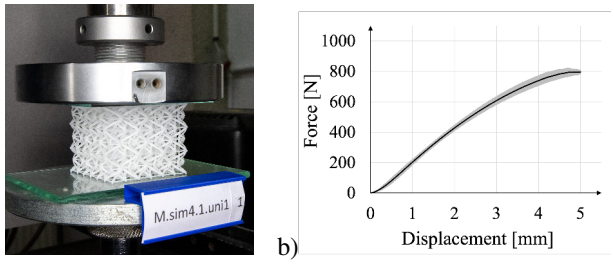

Fig. 3. Experiment: a) Compression test; b) Force-displacement graph.

The natural frequency of the single-degree-of-freedom system is estimated as 367 Hz, which is lower than the value of 570 Hz obtained from the FEM, but remains within the same order of magnitude. The quantitative discrepancy may result from uncertainty in the Young's modulus used in the FEM and the physical linearity of the computational model.

An estimate of the shear-type eigenfrequency can be obtained from the square root of the ratio of the coefficients e_{55} and e_{33} in the elasticity matrix $\mathbf{E}$ derived from the continuum model [9] for the supercell (Figure 1a):

$$e_{33} = \frac{EA}{a^2}\left(1.1851 + 2.1466k - 0.3449\sigma\right), \tag{1}$$

$$e_{55} = \frac{EA}{a^2}\left(0.7407 + 0.2683k + 0.1724\sigma\right), \tag{2}$$

where: EA— stiffness of the strut, k—cable-to-strut stiffness ratio, σ—level of self-equilibrated normal forces.

Neglecting the small influence of σ, the shear-mode vibration frequency for the single-degree-of-freedom quasi-experimental model can be estimated as $0.7 \times 367 \approx 257$ Hz.

IV. Conclusion

The two techniques presented for estimating the natural frequencies of cellular tensegrity-inspired metamaterials allow the determination of the order of magnitude of their dynamic response. The semi-experimental single-degree-of-freedom formulation leads to values slightly lower than those obtained from the FE analysis, but of the same order. The discrepancy can be attributed to uncertainties in the computational input data. For the structure fabricated using the MJP technique and inscribed in a 6 cm cube with four-strut simplex cells, the lowest natural frequency was estimated to be approximately 257 Hz.

***Abstract*— Metasurfaces and diffractive optics integrated onto fibre tips can extend the capabilities of ultrathin imaging probes, but scalable fabrication remains a key challenge. We present transfer-fabricated metafibres and show how their combination with transmission-matrix wavefront shaping enables improved focusing, depth control, and advanced fibre-based imaging.**

Keywords—metafibres, metasurfaces, multimode fibre imaging, wavefront shaping

I. Introduction

Optical fibre endoscopes with diameters comparable to a human hair are attractive for minimally invasive imaging because they can access confined environments while supporting modalities including confocal, fluorescence, polarization-sensitive, and optical coherence tomography (OCT) imaging [1-4]. Their utility can be further expanded by incorporating on-tip optical functionality that shapes the emitted field, for example to improve lateral resolution, extend depth of field, or tailor contrast for a specific modality [3]. However, many established routes for producing fibre-tip micro-optics—including focused-ion-beam milling, direct laser writing, nanoimprinting, and serial lithographic patterning—remain difficult to scale to large numbers of low-cost devices. Transfer-based manufacturing offers a more practical path that can exploit wafer-level processing, but many existing demonstrations have been restricted to relatively simple or single-layer geometries [5,6]. Here we build on scalable transfer methods to realise single- and multi-layer metasurface devices on fibre probes, with architectures relevant to advanced imaging [8].

Multimode fibres (MMFs) are particularly compelling imaging platforms because they provide thousands of spatial degrees of freedom within an exceptionally small form factor. When the propagation through the fibre is measured through its transmission matrix (TM), wavefront shaping can be used to synthesize focused spots at the distal end and scan them to form images. TM-based approaches have already enabled high-resolution reflectance and fluorescence imaging as well as volumetric refocusing through a single MMF [1,2,7]. A key limitation, however, is that the resolution of a bare MMF is bounded by its numerical aperture (NA), which is set by the refractive-index contrast of the waveguide. For typical fibres this constrains the minimum focal width to around the micron scale at visible wavelengths, even under ideal calibration conditions. As a result, bare-fibre systems cannot fully exploit the available wavefront control to exceed the intrinsic focusing capability of the guide.

A powerful strategy is therefore to combine calibrated wavefront shaping with distal optical structures that add new spatial-frequency content or modify the phase response at the output facet. Plasmonic metasurfaces have been explored for this purpose, but scalable fabrication and system-level calibration remain significant challenges [10]. In this work we focus on transferred metasurface and diffractive elements—including Fresnel zone plates (FZPs) and axicons—that can be integrated onto fibre facets using a manufacturable process. These structures increase the effective optical functionality of the probe by supporting tighter focusing or extended-depth-of-field beams at a designed working distance from the facet. When combined with TM measurement, the fibre and on-tip element can be treated as a single composite optical system, allowing the engineered field to be scanned and exploited for imaging rather than acting as a fixed passive optic.

We therefore present a unified framework in which scalable metafibre fabrication and advanced wavefront shaping are developed together for imaging. We describe the transfer-based fabrication of single- and multi-layer devices on fibre end facets, and we discuss representative imaging behaviour from composite MMF-meta-optic systems. In particular, we show that FZP-based metafibres can produce focal spots that are smaller than those obtained with the corresponding bare fibres, while axicon-based metafibres can generate needle-like beams with substantially extended depth of field. These capabilities are directly relevant to raster-scanned MMF imaging and to hybrid modalities such as polarization-resolved imaging, where tailored distal wavefronts can improve either resolution, depth tolerance, or modality-specific contrast [11].

II. Methods

Metafibres were fabricated by defining planar diffractive and metasurface patterns on a donor substrate using wafer-compatible lithographic processing, followed by transfer of the patterned structures onto cleaved optical fibre facets (Fig. 1). The process supports both single-layer and stacked devices, enabling not only simple lenses but also more advanced multi-layer optical functions [8]. In parallel, the optical response of

selected multimode-fibre devices was characterised using transmission-matrix measurement so that the proximal input field could be optimized to generate controlled distal foci or extended beams after propagation through the combined fibre-meta-optic system [7].

To assess imaging relevance, we considered transferred Fresnel zone plates and axicons as exemplar devices. The FZP designs were chosen to provide a finite working distance and enhanced focusing strength, while the axicon designs were used to generate Bessel-like beams with extended axial invariance. Device performance was evaluated through distal beam profiling and resolution-target imaging, and preliminary compatibility with OCT instrumentation was assessed to examine the suitability of the metafibre approach for depth-resolved biomedical imaging [8].

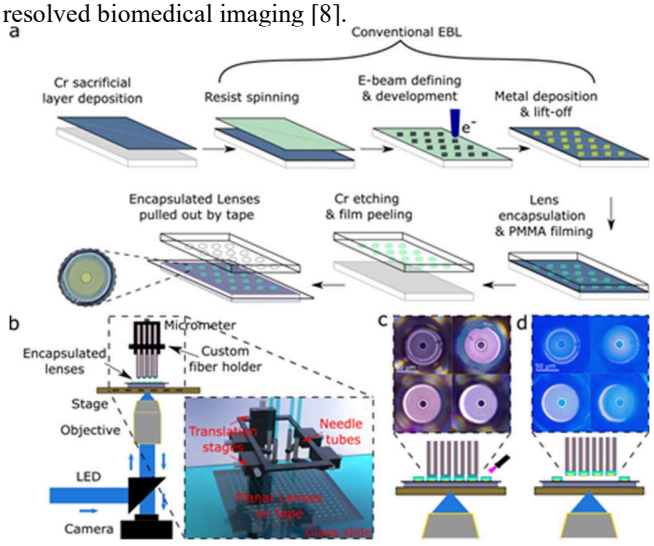

Fig. 1. Scalable fabrication process for transferring single- and multi-layer metasurface devices onto fibre facets [8].

III. Results and Discussion

The transferred devices demonstrate that wafer-scale fabrication and fibre-tip optical engineering can be combined without sacrificing imaging function. Fresnel zone plate metafibres produced compact focal spots at working distances of a few hundred micrometres from the fibre facet, allowing imaging to be performed beyond the near-contact regime of a bare fibre. In representative measurements, the zone-plate devices generated a near-Gaussian focus around 235 um from the tip with an axial extent of roughly 100 um.

To demonstrate imaging performance, we fabricated and transferred Fresnel zone plates onto fibers. The zone plate produced a tight Gaussian focus at ~235 µm with a 100 µm depth of field (DOF), enabling high-fidelity imaging at distances inaccessible to bare fibers, though with some background speckle.

Spot-size measurements as a function of imposed input NA further support the benefit of combining on-fibre diffractive elements with wavefront shaping. For FZP on both 50 um and 110 um core diameter MMFs, the composite fibre-FZP system produces smaller focal spots than the corresponding bare fibre under the same illumination constraints, with the larger FZP giving the strongest improvement. In practice, the effective NAs inferred from the measured spot widths remain below the nominal fibre NA of 0.22. This likely reflects non-ideal TM calibration, finite detector sampling, uncertainty in identifying the exact focal plane, and imperfect field synthesis at the proximal modulator. These effects also explain the residual intensity variation between nominally identical scanned spots. Even so, because the same experimental limitations apply to both bare-fibre and metafibre measurements, the observed improvement provides a conservative estimate of the enhancement enabled by the FZP.

More broadly, these results underline the value of treating the metafibre not simply as a static micro-optic but as part of an actively controlled imaging system. Scalable transfer lithography enables high-performance optical structures to be placed at the distal tip, while TM-based wavefront shaping provides the adaptive control needed to exploit those structures across the field of view. This combination is particularly promising for advanced imaging, where one wishes to tailor beam shape, working distance, and resolution in a modality-specific manner. The same platform could support future probes for OCT, multiphoton excitation, polarization-sensitive imaging, or structured illumination endoscopy.

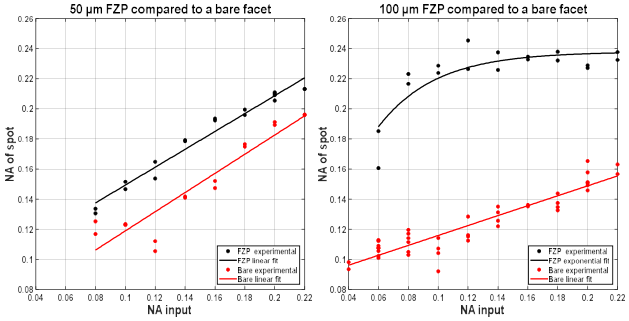

Fig. 2. Comparison of focal-spot full width at half maximum (FWHM) obtained when restricting the proximal input modes to different effective illumination NAs, for bare fibres and for fibres carrying transferred FZPs [9]

IV. Conclusion

Metafibres produced by scalable transfer lithography offer a practical route to advanced fibre-end probes that unite manufacturable nanophotonics with adaptive optical control. By integrating Fresnel zone plates, axicons, and potentially more complex multilayer metasurfaces onto fibre facets, it becomes possible to engineer the distal field for specific imaging tasks while preserving the compactness required for minimally invasive access. When these devices are combined with transmission-matrix characterisation and wavefront shaping, the resulting composite system can deliver tighter focusing, longer working distance, or extended depth of field compared with a bare fibre, all of which are highly relevant for practical endoscopic imaging.

The broader significance is that fabrication and control should be developed together: scalable metafabrication

provides the optical functionality, and wavefront shaping turns that functionality into a flexible imaging tool. This co-design perspective opens a path toward disposable or application-specific fibre probes for OCT and other advanced modalities, with scope for further gains through improved multilayer devices, better calibration fidelity, and modality-optimised meta-optic designs.

***Abstract*— This work characterizes nitride-based nanoparticle arrays and shows that stoichiometry can be used to adjust their plasmonic and photothermal responses. Measurements and simulations reveal narrow, tunable, and robust plasmonic network resonances that show promise for nitride-based devices and metasurfaces.**

***Keywords*— metamaterials, nitrides, TiN, ZrN, plasmonics.**

I. Introduction

Transition metal nitrides, and in particular titanium nitride (TiN) and zirconium nitride (ZrN), are emerging as robust alternatives to noble metals for plasmonics owing to their high thermal stability, CMOS compatibility, and tuneable optical response. In this work, we provide a combined experimental and numerical study of nitride thin films and lithographically defined nitride nanoparticle arrays, and we assess their potential for near-field enhancement, photothermal conversion, and surface lattice resonance engineering from the visible to the near-infrared.

II. Methods

TiN and ZrN films are grown by DC magnetron sputtering under mixed Ar/N_2 atmospheres, with the nitrogen flow systematically varied to tune stoichiometry. A comprehensive characterization of the structural properties was conducted on the various samples. From UV–visible transmission we determine indirect optical bandgaps in the 1.2–2.4 eV range, with values and trends that differ from many literature reports due to the nature of the electronic transitions and stoichiometry.

III. Results and Discussion

Using the measured optical constants, we quantify for each film the Faraday and Joule figures of merit, which separate near-field enhancement from heat generation [1]. ZrN exhibits a pronounced plasmonic resonance around 500–600 nm with strong near-field enhancement but limited broadband photothermal response, whereas TiN shows a broader response extending into the near-IR, with a Joule number that remains significant at long wavelengths, making it attractive for broadband heat generation.

We then fabricate square arrays of nitride nanoparticles (cones and truncated cones) on fused silica by electron-beam lithography and reactive ion etching, covering diameters from 120 to 200 nm, heights from 40 to 80 nm, and periods from 200 to 700 nm. Extinction spectra are measured in a quasi-symmetric dielectric environment by index-matching glycerol, and are compared to 3D FDTD simulations using the experimentally retrieved n and k. We observe good agreement between experiment and theory, including the emergence of narrow, Fano-like lattice resonances when the localized surface plasmon of individual particles hybridizes with Rayleigh anomalies of the array. Increasing the period produces red-shifts and linewidth narrowing consistent with plasmonic surface lattice resonances, while increasing particle size induces a strong red-shift and broadening in line with Mie-type behaviour.

IV. Conclusion

Our results demonstrate that both TiN and ZrN support strong, tuneable plasmonic and lattice-mode responses, with the nitride stoichiometry offering an additional handle to engineer linewidth, resonance position, and the balance between field enhancement and photothermal conversion. These properties make nitride nanoparticle arrays promising platforms for robust, high-temperature plasmonic devices, meta surfaces, and thermoplasmonic applications where conventional noble metals are limited.

***Abstract*— We reveal abnormal hot carrier thermalization in twisted bilayer graphene at van Hove singularities using time-resolved ultrafast photoluminescence autocorrelation spectroscopy. A prolonged relaxation lifetime of approximately 600 femtoseconds is observed due to phonon bottleneck and interlayer charge redistribution, unveiling nonequilibrium dynamics in moiré-engineered graphene.**

***Keywords*— Twisted bilayer graphene, van Hove singularity, ultrafast spectroscopy, hot carrier dynamics, moiré photonics**

I. Introduction

Moiré engineering provides a powerful route to tailor electronic and optical properties of two-dimensional materials. Twisted bilayer graphene (TBG) exhibits angle-dependent band reconstruction, leading to van Hove singularities with enhanced density of states and strong light–matter interaction. While ground-state properties of twisted graphene systems have been extensively explored, their nonequilibrium excited-state dynamics remain largely unexplored. Understanding hot carrier thermalization at van Hove singularities is essential for developing ultrafast optoelectronic and photonic devices based on moiré materials.

II. Methods

TBG samples with controlled twist angles were fabricated via dry transfer and encapsulated with hexagonal boron nitride. Ultrafast photoluminescence (PL) measurements were performed using femtosecond pulsed laser excitation. Time-resolved ultrafast PL autocorrelation spectroscopy was employed to directly probe hot carrier relaxation dynamics with sub-30 femtosecond temporal resolution. Ground-state electronic structures were calculated using density functional theory. Real-time time-dependent density functional theory simulations were conducted to model carrier thermalization and electron–phonon coupling processes.

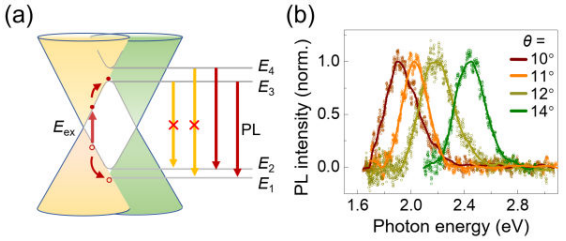

Fig. 1 Ultrafast PL of TBG. a. Schematic of optical selection rules of ultrafast PL in TBG. b. Twist angle dependent PL peaks.

III. Results and Discussion

Ultrafast PL spectra of twisted bilayer graphene exhibit distinct emission peaks associated with van Hove singularities, absent in monolayer graphene. The emission peak energy depends strongly on twist angle, confirming its moiré origin.

Time-resolved ultrafast PL autocorrelation measurements reveal two distinct relaxation channels. Carriers on linear Dirac bands relax within approximately 150 femtoseconds, comparable to monolayer graphene. In contrast, carriers associated with van Hove singularities exhibit a significantly prolonged lifetime of approximately 600 femtoseconds.

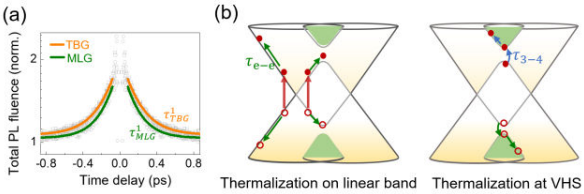

Fig. 2 Abnormal hot carrier thermalization. a. Prolonged hot carrier lifetime of TBG. b. Abnormal thermalization at VHS.

Time-dependent density functional theory simulations show that this abnormal thermalization arises from Mini-gap bottleneck effects near van Hove singularities that suppress rapid intraband scattering and interlayer charge redistribution processes that slow carrier relaxation in real space.

These findings demonstrate that moiré band engineering not only modifies static density of states but fundamentally reshapes nonequilibrium carrier dynamics.

IV. Conclusion

We experimentally and theoretically demonstrate abnormal hot carrier thermalization at van Hove singularities in twisted bilayer graphene. The prolonged relaxation lifetime originates from phonon bottlenecks and interlayer charge redistribution enabled by moiré band reconstruction. This work establishes twisted bilayer graphene as a platform for engineering ultrafast carrier dynamics and moiré-enabled photonic functionalities.

Abstract— We present a physics-based computational framework for wide-beam electromagnetic scattering in large-scale, aperiodic, and anisotropic media. The approach combines wavelet decomposition with the Aperiodic Fourier Modal Method (AFMM), enabling scalable full-wave simulations over extended domains. A wide incident beam is represented as a superposition of localized beamlets propagated through overlapping subdomains, ensuring efficient computation and smooth field reconstruction in strongly heterogeneous and anisotropic structures. The method provides physically interpretable near-field observables, including spatial variance, kurtosis, and anisotropy indices, with applications to terahertz biophotonic imaging and, also an the efficient design of photonic metasurfaces.

Abstract: Two-dimensional (2D) materials show potential for compact, low-profile on-chip quantum computing and quantum communications applications. In particular, the second-order nonlinear polarizability $\chi^{(2)}$, an important materials parameter for the generation of entangled photon pairs via parametric downconversion, can be notably enhanced in monolayer 2D materials. The relationship between this nonlinear susceptibility and multi-layer stacking, orientation and material defects can be revealed by spectroscopic, polarization-resolved imaging. A spectrally-resolved multi-photon luminescence (MPL) and second harmonic generation (SHG) imaging microscope is used to examine the nonlinear optical properties of 2D materials and their heterostructures. We visualize the spectrally-resolved MPL and SHG in multi-layer two-dimensional (2D) materials WSe_2, In_2Se_3 and their heterostructures. In WSe_2, we observe the correlation between the symmetry-induced suppression of SHG for even-numbered layers, where inversion symmetry is established, and the presence of edge and localized defect states on the finite-sized 2D flakes, revealed by variations in MPL. The polarization-resolved SHG in the single and multi-layer 2D material identifies the symmetry and orientation of the layers. The application of the methods to determine $\chi^{(2)}$ in multi-layer heterostructures is also described.

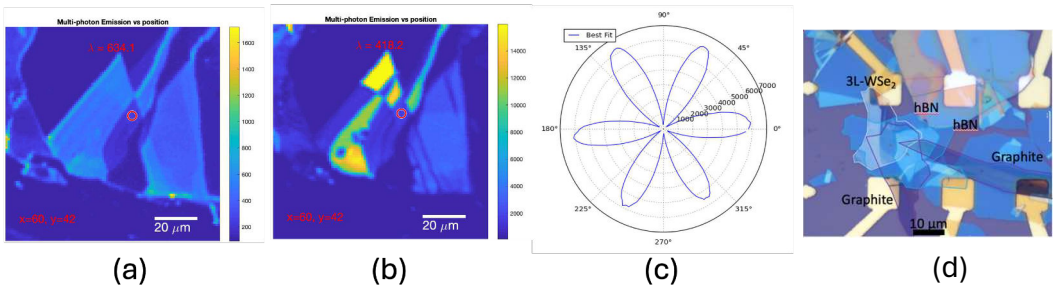

Figure: (a) Multiphoton luminescence from few-layer WSe_2 flakes; (b) second harmonic image formed at λ=418nm of sample shown in (a); (c) polarization resolved second harmonic from few-layer WSe_2 flakes; (d) heterostructure of hBN/few-layer-WSe_2.

Laser-induced formation of plasmonic nanostructures

Rodrigas Liudvinavičius, Kernius Vilkevičius, Evaldas Stankevičius*

Department of Laser Technologies, Center for Physical Sciences and Technology, Lithuania
*Corresponding author: evaldas.stankevicius@ftmc.lt

***Abstract* — Plasmonic nanostructures enable strong light matter interactions and advanced optical functionalities but are commonly fabricated using costly and low throughput lithographic techniques. We demonstrate laser induced formation of plasmonic nanostructures using direct laser writing enabling single step chemical free large area fabrication suitable for scalable and cost-effective photonic applications.**

***Keywords* — metasurfaces, plasmonic nanostructures, femtosecond laser, direct laser writing.**

Plasmonic structures are engineered systems capable of manipulating and controlling the behavior of surface plasmons, enabling strong light–matter interactions, enhanced optical absorption, and efficient light emission. These properties make plasmonic nanostructures highly attractive for applications in sensing, photonics, energy harvesting, and optical security. Conventionally, such structures are fabricated using high-resolution nanolithography techniques[1, 2], including electron-beam lithography and focused ion beam milling. While these methods provide excellent precision, they are inherently time-consuming, costly, and limited in scalability, which restricts their applicability for large-area and commercially viable production.

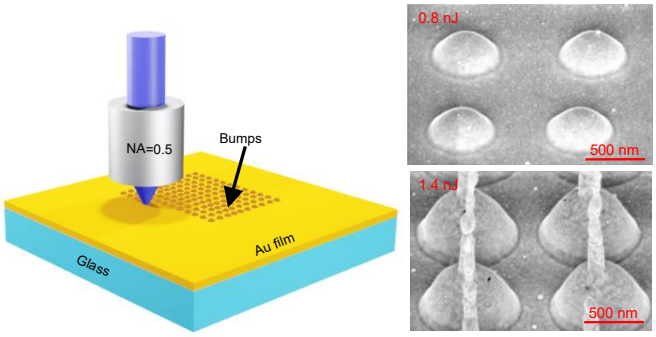

Fig. 1. Laser-induced nanostructuring on a thin Au film (left) and SEM images of structures morphologies formed at different pulse energies (right). Scale bars : 500 nm.

Laser-based fabrication techniques [3-9] have emerged as a promising alternative for the formation of plasmonic nanostructures. In contrast to conventional lithographic approaches, laser processing enables single-step, maskless patterning over large areas without the need for chemical processing or vacuum-based equipment. This significantly reduces fabrication complexity, processing time, and overall production costs. Moreover, laser-induced nanostructuring offers high flexibility in tailoring surface morphology (Fig. 1) and optical response by adjusting laser parameters such as fluence, pulse duration, and scanning strategy.

Here, the formation of plasmonic nanostructures using the direct laser writing technique will be explored. The laser–matter interaction mechanisms responsible for nanoscale structure formation, along with the resulting plasmonic properties of the fabricated surfaces, will be discussed. The demonstrated approach enables scalable fabrication of functional plasmonic structures over areas up to tens of square millimeters, making it particularly attractive for practical and industrial applications. The presented results highlight the potential of laser-based nanofabrication as a cost-effective and versatile route toward next-generation plasmonic devices.

***Abstract*— This study shows metamaterial phase-shifting integrated circuits with continuous 2π phase controllability operating at 300 GHz. To cope with the demand for high-density packaging in future beamforming devices, chips were mounted in hollow waveguide modules fabricated using a high-resolution 3D printer (RECILS). The phase-shifting characteristics were evaluated.**

***Keywords*— metamaterials, integrated circuits, phase shifter, terahertz, wireless communication, 3D printing.**

I. Introduction

In recent years, rapid advancements in semiconductor technology have opened many opportunities for new applications. One of these new applications that gained a lot of attention is related to terahertz waves, in particular from 100 to 500 GHz, which is a promising candidate for the development of high-capacity and high-speed wireless communication networks [1]. In wireless communication, the gradually increasing sophistication and data usage demand require larger bandwidths, higher data rates, and high-capacity systems that can support a large number of users simultaneously.

Metamaterials have revolutionized electromagnetic wave control. The growing demand for advanced terahertz technologies necessitates innovative material design approaches. However, despite very promising characteristics of terahertz waves, problems with non-line-of-sight propagation, atmospheric attenuation, or low wave wraparound are still challenging to overcome [2]. To address these issues, high-gain and highly directive antennas that can configure their radiation pattern to avoid obstacles and guide the wave in free space are necessary. In terahertz bands, the use of conventional phase arrays brings many challenges [3], including complex feed networks, large chip size compared to the wavelength, small antenna size, and resulting small gain, etc.

In this work, to tackle these issues, a metamaterial phase-shifting integrated circuit (IC) is designed to control the transmission phase of the electromagnetic (EM) wave propagating through the hollow waveguide. The design and fabrication of the chip were based on an indium phosphide (InP) semiconductor process. To cope with future development and the necessity for multichannel beamforming devices that are easy to handle and provide beam control in azimuth and elevation, a high-resolution 3D printing technology is used. 3D printing is a simple and cheap fabrication method of complex beamforming structures that can host multiple chips with various functions, providing more design freedom and flexibility than commercially used technology.

II. Methods

Fig. 1(a) shows an image of the split block module package that was designed to host metamaterial IC chips, and was fabricated using RECILS, utilizing photosensitive acrylic resin [4]. The package module includes a WR3.4 rectangular waveguide (300 GHz band) and chip mounting area in the center. To allow for guided transmission of the EM waves through the structure, the inner walls of the package were electroless plated with Cu film, as shown in the figure. The package was divided along the ***H*** plane of the waveguide, allowing for the placement of the chip along the ***E*** plane.

The inset shows a magnification of the surface of the 3D printed package with Cu plating. As can be seen, the individual passes of the printer are visible, and although, in this work, the *z*-axis (additive layer thickness) resolution of RECILS was about 20 μm (50 times smaller than the wavelength at 300 GHz), the device easily achieves the fabrication of palm-sized objects.

Fig. 1(b) shows images of fabricated metasurface IC chips [5]. An active metamaterial unit cell based on Jerusalem cross geometry was used with integrated indium phosphide high-electron mobility transistors (InP-HEMT). Transistors are used as variable capacitors and can dynamically adjust the capacitance in the gap of metamaterials, in response to negative bias voltage applied to the gate. The chip placement in 3D printed packages aligns the electric field along gaps with incorporated HEMTs, so the excited resonance can be tuned by the change of the total capacitance (C_{GS}, C_{GD}, C_{DS}) of the transistors. In this work, two types of chips were designed and fabricated, one with 39 cells (3×13 cells – 3 cell chip (3C)) and one with 72 cells (4×18 cells – 4 cell chip (4C)). The size of

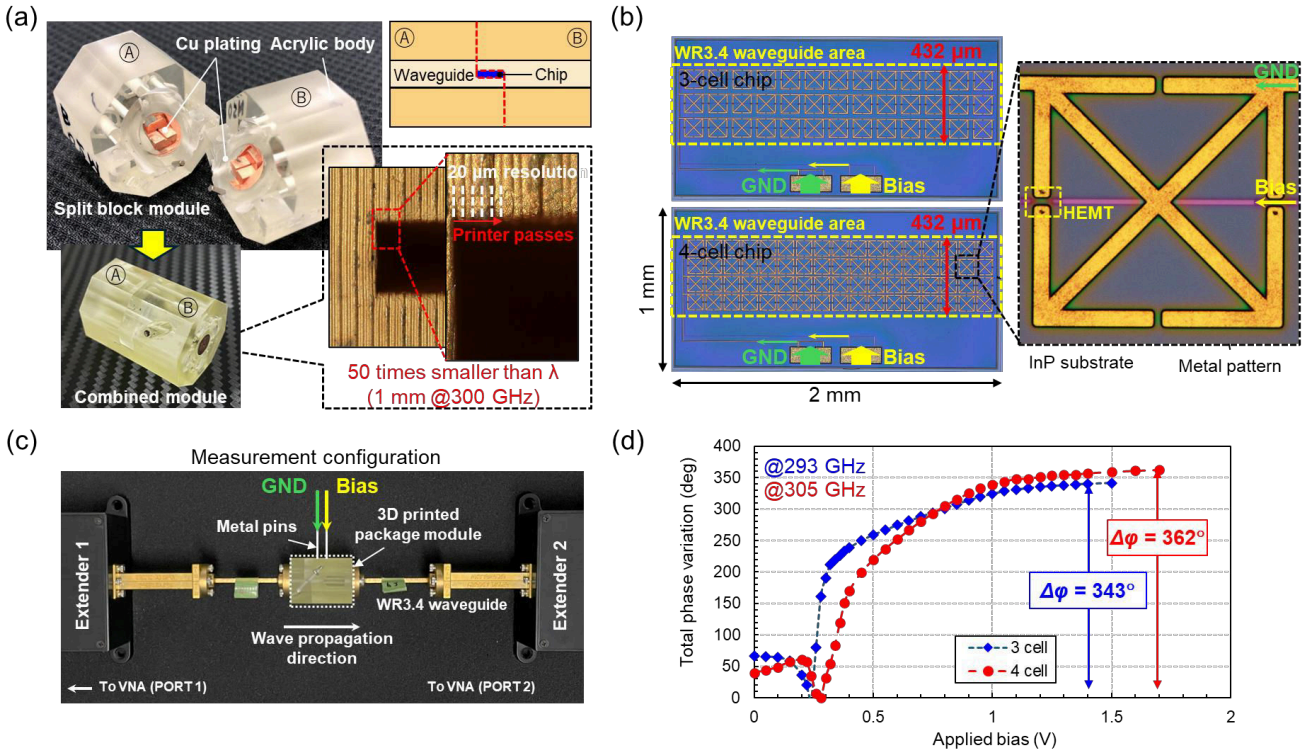

Figure 1. (a) Acrylic 3D-printed split block module for 300 GHz band fabricated with 20 µm step resolution. (b) Images of fabricated metamaterial chips and the magnification of a single cell. (c) Measurement setup and results of the total phase variation evaluation.

both chips was 1×2 mm.

III. Results and Discussion

Fig. 1(c) presents the measurement setup used in this work. The RF signal from the vector network analyzer (VNA) was applied through J-band (220-3 GHz) extenders to the device. The negative bias from an external DC power supply was applied to the metamaterial IC chips through pins and internal wiring. Fig. 1(d) shows changes of the total phase transmitted through the 3D printed package with phase phase-shifting chip. For the 3-cell metamaterial chip, the total phase variation $\Delta\varphi$ = 343° was successfully obtained for the bias change in the range from 0 V to -1.5 V. Similarly, the change of the total phase in the 4-cell chip of $\Delta\varphi$ = 362° was achieved for the bias voltage range from 0 V to -1.7 V. The differences in operation of the two chips were associated with the change of the metasurface design and associated with different numbers of cells and HEMTs.

IV. Conclusion

In this work, InP-HEMT-based metamaterial chips were implemented into a 3D printed split block module package, operating at the 300-GHz band. The controllable phase variation of over 2π (360°) was achieved, showing prospects for the replacement of conventional phase array antenna technology in higher frequency bands. The realization of a 3D-printed module package verifies the capabilities of printing technology for the fabrication of complex structures for communication in terahertz frequencies.

In the next step of this work, multiple phase shifter metamaterial IC chips will be implemented in a single 3D printed package to demonstrate the beamforming abilities of the devices in the 300 GHz band.

Super□Resolution Interferometric Lithography Beyond the Diffraction Limit Enabled by a Tuneable Metasurface

Mohammad Mahdi Jafarizadeh[1,*], Leila Yousefi[1,*]

[1]School of Engineering and Informatics, University of Sussex, Falmer, England, UK

Abstract— **To overcome the diffraction limit in optical lithography and achieve resolutions beyond this fundamental barrier, we propose a multi-mask interferometric lithography technique. In this approach, a tunable metasurface is employed to engineer the light passing through the masks, enabling the formation of the desired pattern on the photoresist.**

***Keywords*— diffraction limit, interferometric lithography, metasurfaces, subwavelength patterning.**

I. Introduction

One of the major bottlenecks in nanoscale semiconductor fabrication arises from the diffraction limit, which restricts resolution to $\lambda/(2\,NA)$, where λ is the working wavelength and NA is the numerical aperture of the imaging system [1, 2]. To overcome this limitation, various methods such as interferometric lithography [3, 4] and immersion interference lithography have been developed. These techniques enable subwavelength patterning; however, their application is limited to producing only periodic structures and cannot be used to create non□periodic patterns with arbitrary shapes. Direct□write approaches, including scanning probe, dip□pen, and electron□beam lithography [5-7] eliminate the need for masks and offer super□resolution fabrication capabilities. However, they suffer from low throughput and practical fabrication constraints, which limit their suitability for mass production in the semiconductor industry.

In this work, we propose a novel interferometric lithography framework that overcomes the diffraction limit by using multiple masks with feature sizes larger than the diffraction limit and converting these features into diffraction□limited dimensions with the aid of a tuneable metasurface. Unlike conventional interference□based techniques, which are restricted to generating periodic patterns, the proposed approach enables the fabrication of non□periodic, arbitrary patterns with resolutions well beyond the diffraction limit.

II. Methods

The proposed procedure, along with the optical setup required for its implementation, is illustrated in Fig. 1. As shown in this figure, the spectrum of the desired pattern—obtained through a Fourier transform—is decomposed into spectral bands of width $2k_0$, where $k_0$denotes the propagation constant in the air. Each spectral band is then used to generate a corresponding mask following a mathematical processing step. The details of this mathematical procedure are explained in the following sections.

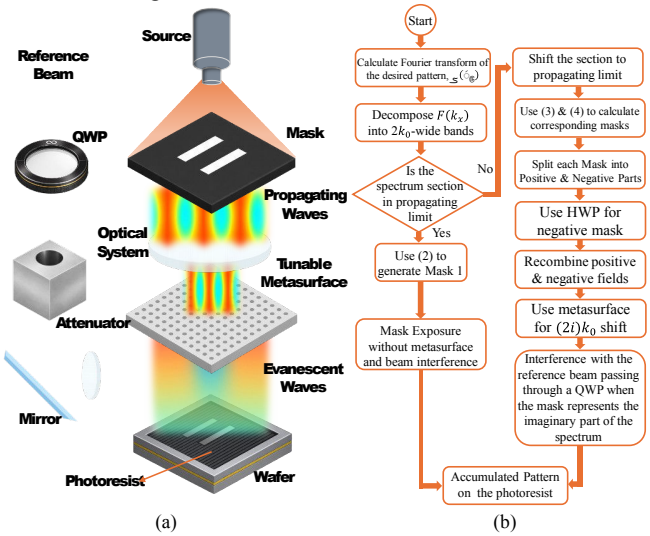

Fig. 1. (a) Workflow illustrating the mask□generation process. (b) Optical setup required to implement the proposed technique.

The intensity of the target pattern, $I(x)$ can be expressed analytically as:

$$I(x)=f_1(x)+\frac{1}{\pi}\sum_{i=2}^{m}\left[f_i^R(x)\cos(k_{sh}x)-f_i^I(x)\sin(k_{sh}x\right. \quad (1)$$

where $k_{sh}=(2i-1)k_0$, $k_0=2\pi/\lambda$, and m represents the number of sections. Here, f_1, f_i^R, and f_i^I denote the mask functions defined over the $|k|<k_0$ region and the i-th shifted spectral band, respectively. Each mask function is derived by mapping the associated spectral band $k\in[-k_0,k_0]$, yielding:

$$f_1(x)=\int_{-k_0}^{k_0}F_{\mathrm{re}}(k)\cos(kx)\,dk \quad (2)$$

$$f_i^R(x)=\int_{-k_0}^{k_0}\left[F_{\mathrm{re}}(k+k_{sh})\cos(kx)-F_{\mathrm{im}}(k+k_{sh})\sin(kx)\right]c(3)$$

$$f_i^I(x)=\int_{-k_0}^{k_0}\left[F_{\mathrm{re}}(k+k_{sh})\sin(kx)+F_{\mathrm{im}}(k+k_{sh})\cos(kx)\right]\varsigma \quad (4)$$

The mask functions shown above may contain negative values, which cannot be physically realized in transmission. To address this limitation, we propose a technique in which each pattern is decomposed into two masks representing the positive and negative components of the function. To implement the negative components optically, a half-wave plate (HWP) is incorporated into the setup (see Fig. 1b). The tunable metasurface applies a $(2i)k_0$ spectral shift to transmitted fields corresponding to each mask, thereby repositioning the spectrum to its intended location. To retrieve phase information at the photoresist, the modulated field is interfered with a coherent reference beam whose phase is set to 0 or $\pi/2$, depending on whether the real or imaginary mask set is under exposure. The accumulated intensity recorded on the photoresist can be expressed as:

$$I'(x)=\alpha_1^2 f_1^R(x)+\sum_{i=2}^{m}\left|\alpha_i e^{-jk_0x}+\alpha_{ref,i} f_i^R(x) e^{-j(2i)k_0x}\right|^2 \quad (5)$$

where $I'(x)$ denotes the reconstructed intensity pattern. The first term corresponds to the baseband contribution, while the remaining terms represent the intensity resulting from the real and imaginary masks interfering with respective reference beams. The coefficients α_i and $\alpha_{ref,i}$ determine the contribution of each mask exposure and its corresponding reference beam. These coefficients are optimized based on Rayleigh and FWHM-separation criterion to suppress the residual terms and ensure appropriate peak-to-valley contrast within the dynamic range of the photoresist.

III. Results and Discussion

To evaluate the performance of the proposed framework, we use it to reconstruct the pattern shown in Fig. 2(a). As illustrated, the pattern has an arbitrary shape with feature sizes as small as $\lambda/10$. Achieving this resolution requires a spatial spectrum extending to $|k|\le 5k_0$, which corresponds to five spectral bands, as shown in Fig. 2(b).

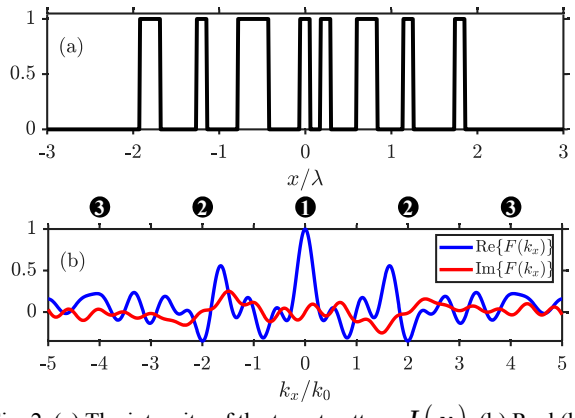

Fig. 2. (a) The intensity of the target pattern, $I(x)$. (b) Real (blue) and imaginary (red) parts of the spatial spectrum $F(k_x)$ obtained through a Fourier transform.

Using expressions (2) – (4), the real and imaginary mask patterns are computed and shown in Fig. 3. The accumulated intensity resulting from metasurface modulation and controlled interference is presented in Fig. 4. As illustrated, the reconstructed intensity closely matches the target pattern and satisfies the Rayleigh resolvability criterion for all adjacent peaks, thereby validating the accuracy and effectiveness of the proposed technique.

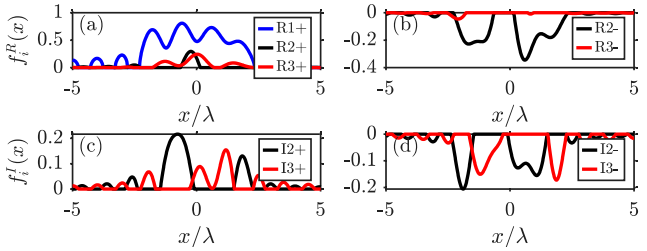

Fig. 3. Generated masks for the pattern shown in Fig. 2 representing different parts of spectrum: (a) positive real (b) negative real (c) positive imaginary (d) negative imaginary

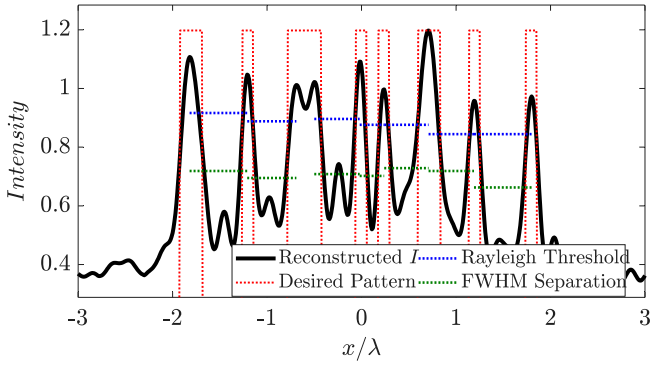

Fig 4. Reconstructed pattern (black) is compared with the desired pattern (red). Blue and green dashed lines represent the Rayleigh and FWHM criteria, respectively. The exposure coefficients obtained by optimization are $(\alpha_1,\ \alpha_{ref,1})=(0.26,0)$, $(\alpha_2,\alpha_{ref,2})=(1.2,\ 0.3)$, and $(\alpha_3,\ \alpha_{ref,3})=(1.35,0.27)$

IV. Conclusion

A super-resolution multi-mask interferometric lithography technique is proposed that overcomes the diffraction limit and achieves enhanced resolution. Unlike approaches restricted to periodic patterns, this method can generate arbitrary-shaped features. The technique leverages multiple exposures, a tuneable metasurface, and interference-based enhancement to further improve resolution. Numerical results demonstrated reconstruction of arbitrary patterns with feature sizes as small as $\lambda/10$, satisfying Rayleigh and FWHM resolvability criteria within the photoresist dynamic range.

Constructive homogenization of dispersed random composites

Vladimir Mityushev

Faculty of Computer Science and Mathematics, Cracow University of Technology, Krakow, Poland

***Abstract*—The asymptotic analysis is applied to derive an analytical approximate formula for the macroscopic permittivity of 2D dispersed random composites. This formula extends the lower order Maxwell-Garnett approximation, revealing that many other popular formulas for dispersed media derived from effective medium approximations are asymptotically equivalent.**

***Keywords*— dispersed random composites, RVE, structural sums, macroscopic property tensor.**

I. Introduction

Consider a multi-phase composite with non-overlapping inclusions embedded in the 2D matrix. The composite is supposed to be represented by a periodicity cell Q introduced as follows. The plane coordinates $\mathbf{x} = (x_1, x_2)$ will be identified with the complex variable $z = x_1 + \mathrm{i}x_2$. Let $\boldsymbol{\omega_1} = 1, \quad \boldsymbol{\omega_2} = \mathrm{i}$ be the fundamental periods on the complex plane $\mathbb{C}$. Let Re and Im stand for the real and imaginary parts of values.

Consider N non-overlapping simply connected domains G_k in the unit periodicity cell Q with piece-wise Lyapunov's boundaries L_k and the multiply connected domain $G = Q \backslash \cup_{k=1}^{N} (G_k \cup L_k)$, the complement of all the closures of G_k to Q. Let the permittivity of the host is normalized to unity, and the permittivity of kth inclusion be a complex number ε_k.

Let complex functions u and u_k satisfy Laplace's equation. The perfect contact between the components is expressed by equations on L_k $(k = 1, 2, \dots, N)$

$$u(t) = u_k(t), \quad \frac{\partial u}{\partial \mathbf{n}}(t) = \varepsilon_k \frac{\partial u_k}{\partial \mathbf{n}}(t), \tag{1}$$

where the normal derivative $\frac{\partial}{\partial \mathbf{n}}$ on L_k is used.

II. Main formula

Introduce the contrast parameters $\varrho_k = \frac{\varepsilon_k - 1}{\varepsilon_k + 1}$ and the averaged contrast parameter over inclusions $\langle \varrho \rangle = \sum_{k=1}^{N} \varrho_k |G_k|$. Let $s_{jk}^{(0)}$ denote the normalized complex static moments of the domains G_k. Let a_k be the complex coordinate of the gravity center of G_k; $E_p(z)$ the Eisenstein functions of order p; $E_{p,mk} := E_p(a_m - a_k)$ for $m \neq k$.

Introduce the multiple structural sums

$$\mathcal{L} = \frac{1}{\pi} \sum_{k,m=1}^{N} \varrho_k \varrho_m |G_k||G_m| E_{2,mk}, \tag{2}$$

$$\begin{aligned} &\mathcal{V}_1 = \tfrac{2}{\pi} \textstyle\sum_{k,m=1}^{N} \varrho_k \varrho_m |G_k||G_m| E_{3,mk} (s_{1k}^{(0)} |G_k|^{\frac{1}{2}} \\ &- s_{1m}^{(0)} |G_m|^{\frac{1}{2}}), \end{aligned} \tag{3}$$

$$\begin{aligned} &\mathcal{V}_2 = \tfrac{3}{\pi} \textstyle\sum_{k,m=1}^{N} \varrho_k \varrho_m |G_k||G_m| E_{4,mk} \times \\ &\left(|G_k| s_{2k}^{(0)} + |G_m| s_{2m}^{(0)} - 2 \left(|G_k||G_m| \right)^{\frac{1}{2}} s_{1m}^{(0)} s_{1k}^{(0)} \right), \end{aligned} \tag{4}$$

$$\begin{aligned} &\mathcal{V}_3 = \tfrac{4}{\pi} \textstyle\sum_{k,m=1}^{N} \varrho_k \varrho_m |G_k||G_m| E_{5,mk} \times \\ &\Big[|G_k|^{\frac{3}{2}} s_{3k}^{(0)} - |G_m|^{\frac{3}{2}} s_{3m}^{(0)} \\ &+ 3 \left(|G_k|^{\frac{1}{2}} |G_m| s_{1k}^{(0)} s_{2m}^{(0)} - |G_m|^{\frac{1}{2}} |G_k| s_{2k}^{(0)} s_{1m}^{(0)} \right) \Big]. \end{aligned} \tag{5}$$

and the shape cumulative parameter

$$\mathcal{J} = \frac{1}{4\pi} \sum_{k=1}^{N} \varrho_k^2 \int_{L_k} \mathrm{d}\bar{t} \int_{L_k} \frac{\overline{\tau}}{\tau - t} \, \mathrm{d}\tau. \tag{6}$$

The above sums can be written in dimensionless form $\mathcal{J}_0 = f^{-1}\mathcal{J}$, $\mathcal{L}_0 = f^{-2}\mathcal{L}$, $\mathcal{V}_{0j} = f^{-\frac{j+4}{2}}\mathcal{V}_j$ using the total fraction f of inclusions.

The permittivity tensor can be calculated by the formula

$$\begin{aligned} \boldsymbol{\varepsilon}_\perp &= (1 + 2\langle \varrho \rangle) I + 2f \begin{pmatrix} \mathrm{Re}\, \mathcal{J}_0 & -\mathrm{Im}\, \mathcal{J}_0 \\ -\mathrm{Im}\, \mathcal{J}_0 & -\mathrm{Re}\, \mathcal{J}_0 \end{pmatrix} \\ &+ 2f^2 \begin{pmatrix} \mathrm{Re}\, \mathcal{L}_0 & -\mathrm{Im}\, \mathcal{L}_0 \\ -\mathrm{Im}\, \mathcal{L}_0 & 2 - \mathrm{Re}\, \mathcal{L}_0 \end{pmatrix} \\ &+ 2f^{5/2} \begin{pmatrix} \mathrm{Re}\, \mathcal{V}_{01} & -\mathrm{Im}\, \mathcal{V}_{01} \\ -\mathrm{Im}\, \mathcal{V}_{01} & -\mathrm{Re}\, \mathcal{V}_{01} \end{pmatrix} \\ &+ 2f^3 \begin{pmatrix} \mathrm{Re}\, \mathcal{V}_{02} & -\mathrm{Im}\, \mathcal{V}_{02} \\ -\mathrm{Im}\, \mathcal{V}_{02} & -\mathrm{Re}\, \mathcal{V}_{02} \end{pmatrix} \\ &+ 2f^{7/2} \begin{pmatrix} \mathrm{Re}\, \mathcal{V}_{03} & -\mathrm{Im}\, \mathcal{V}_{03} \\ -\mathrm{Im}\, \mathcal{V}_{03} & -\mathrm{Re}\, \mathcal{V}_{03} \end{pmatrix} + O(\varrho_0^3 f^4), \end{aligned} \tag{7}$$

III. Conclusion

The formula (7) was derived in [1]. It is the most general formula for the effective permittivity tensor for 2D dispersed random not densely packed composites. Computer simulations and applications can be found in [1] and [2].

***Abstract*–We demonstrate an Airy-beam-generating element designed for the 28 GHz band based on our original high-refractive-index, low-reflectance metasurface. The results indicate that this metasurface is broadly applicable to electromagnetic wave manipulation.**

***Keywords*— metasurface, millimeter wave, Airy beam.**

I. INTRODUCTION

Millimeter waves play an important role in current 5G and future 6G wireless communication systems and are expected to be further utilized [1]. However, high-frequency waves often fail to reach desired locations in obstructed environments due to reduced diffraction. In this study, we designed an element to generate Airy beams [2] based on our original metasurface with a high-refractive-index and low-reflectance [3] in the millimeter-wave band. An Airy beam is a type of non-diffracting wave characterized by self-accelerating and self-healing properties [4]. Demonstrating an Airy-beam-generating element can contribute to millimeter-wave communications in obstructed environments [5].

II. DESIGN

Fig. 1 (a) and (b) show the overall view of the designed Airy-beam-generating element and its unit-cell structure, respectively. The element converts an incident plane wave at 28 GHz into an Airy beam. The structure shown in Fig.1(a) consists of cut metal wires with varying lengths l and spacings g, designed to approximate the ideal transmission phase distribution. The ideal transmission phase distribution of the Airy-beam-generating element is defined as 0° when $\mathrm{Ai}(y) > 0$ and 180° when $\mathrm{Ai}(y) < 0$ [6,7], as shown in Fig. 2. Here, $\mathrm{Ai}(y)$ denotes the Airy function given in Eq. (1), where u is a scaling constant. The Airy-beam-generating element was constructed by arranging cut metal wires with the parameters shown in Table 1.

$$Ai(y) = \frac{1}{\pi}\int_0^{\infty} \cos\left(\frac{t^3}{3} + \frac{y}{u}t\right) dt \qquad (1)$$

III. SIMULATION

Fig. 3(a) and (b) show (a) the simulation model and (b) the simulated electric-field intensity at a distance of 100 mm after the element, respectively. We investigated the self-healing property of the Airy beam by placing a PEC obstacle along the propagation path of both Airy and Gaussian beams. As shown in Fig. 3(b), the electric-field intensity of the Airy beam after transmission through the element is higher than that of the Gaussian beam in the obstacle-affected direction as highlighted in yellow. These results indicate that the beam transmitted through the Airy-beam-generating element exhibits self-healing properties.

IV. CONCLUSION

We designed the Airy-beam-generating element designed for the 28 GHz band based on our original high-refractive-index, low-reflectance metasurface. These results indicate that our original high-refractive-index, low-reflectance metasurface is broadly applicable to electromagnetic wave manipulation.

Electron-Driven Photon Sources for Ramsey Interferometry with Electron Beams

Nahid Talebi[1]

[1]Institute for Experimental and Applied Physic, Kiel University, Germany
*Corresponding author: talebi@physik.uni-kiel.de

***Abstract*— Electron-driven photon sources provide compact platforms for probing decoherence dynamics of qubits in two-dimensional materials. Here, we demonstrate how both planar and 3D-printed architectures enable precise control over the properties of the emitted light.**

***Keywords*— electron-driven photon source, Ramsey interferometry, 2D materials.**

I. Introduction

Electron-driven photon sources (EDPHSs) are integrated radiation platforms inside electron microscopes that act as localized optical sources, enabling techniques such as Ramsey interferometry and pump–probe spectroscopy of material excitations at the nanoscale [1–5]. When electron beams interact with materials, they can generate light through multiple radiation mechanisms, including transition radiation, polariton excitations, Cherenkov radiation, and Smith–Purcell radiation. Engineering the electromagnetic environment of the electron beam, particularly through structured materials and metamaterials, provides a powerful route to tailoring the properties of the emitted radiation [6]. In this work, we demonstrate how both planar geometries [7] and more complex three-dimensional (3D) architectures [8] can be used to control and shape light generation within the electron microscope.

II. Results and Discussion

Planar electron-driven photon sources operate based on the generation of surface plasmon polaritons (SPPs) excited by electron beams interacting with a thin metal film, such as gold, deposited on a Si_3N_4 membrane [7]. To enable the generation of far-field radiation from SPPs, an array of nanopinholes is fabricated in the thin film using focused ion beam milling. The positions and size distribution of the pinholes are designed such that the far-field radiation pattern, as well as the emission spectrum, exhibit desired properties, such as a collimated beam [2], a focused beam [5], or a vortex beam [4] (Fig. 1). These arrays provide a flexible platform for spectral and spatial control of the emission. Moreover, multiple sources can be integrated on a single Si_3N_4 membrane, allowing fast acquisition using different sources. To control the position of the EDPHS structures with respect to the samples under investigation, a three-axis piezo stage is used.

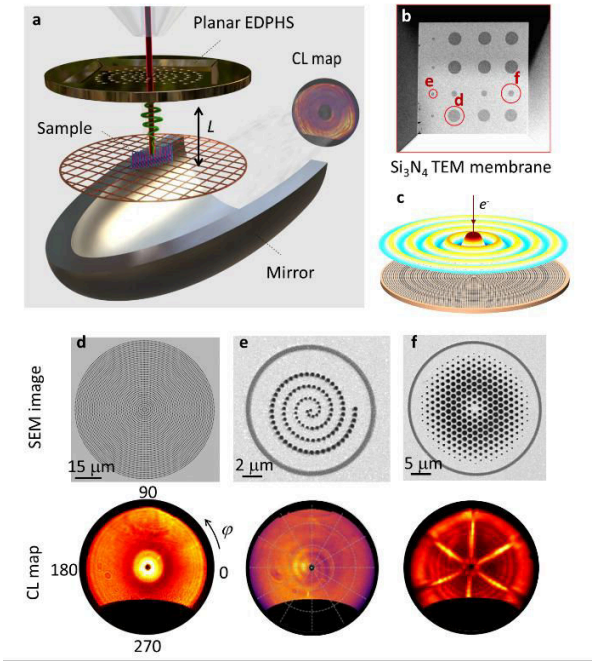

Fig. 1. (a) Ramsey interferometry setup comprising an EDPHS structure positioned above the sample and the apparatus used for collecting and analyzing the cathodoluminescence radiation. (b) SEM image of a Si_3N_4 membrane containing multiple planar EDPHS structures. (c) Radially propagating SPPs interact with the nanopinholes to generate light with tailored radiation properties. (d–e) SEM images of representative planar EDPHSs and their corresponding angle-resolved cathodoluminescence maps shown below each image, acquired at a wavelength of 800 nm.

The electron beam therefore interacts with the EDPHS, generating light with tailored radiation properties, and subsequently interacts with the sample. The radiation from the EDPHS induces a coherent polarization, such as exciting exciton polaritons [2] or creating a coherent superposition of qubit states [3]. The electron beam then interacts with the sample again after a free-evolution time, modifying the superposition. The resulting cathodoluminescence spectrum exhibits spectral and momentum-space interference fringes, whose visibility depends on the mutual coherence between the EDPHS field and the sample polarization. The visibility as a

function of time reveals quantum decoherence in the excitation scheme, such as phonon-mediated dephasing of defect excitations in hexagonal boron nitride [3].

For further enhancing the radiation intensity, we propose and realize a novel configuration for phase-matched generation of photons from electron beams, leveraging the phase-matching concept. An electron propagating parallel to a waveguide can generate light in a phase-matched configuration, when $k_g = \omega v_{el}^{-1}$, where k_g is the phase-constant of the optical modes of the waveguide, ω is the photon angular frequency and v_{el} is the electron velocity. However, in this configuration the excited optical waves remain inside the waveguide. Our principle here, utilizes a helically formed optical fiber that enables a sequential interaction of the electron beam with the waveguide in a phase-matched configuration, expressed by [8]

$$k_g = \left(\Lambda\omega/v_e - 2m\pi\right).\left(\left(2\pi r_h\right)^2 + \Lambda^2\right)^{-\frac{1}{2}}.$$

where m is an integer number specifying the diffraction modes, Λ is the helical pitch, and r_h is the radius of the helix (see Fig. 2a). In this way, the excited photons are partially guided within the waveguide and constructively interfere with the photons generated in subsequent interaction events. The cross section of the helical waveguide is designed in a way to enable the phase-matching concept by allowing optical modes with the phase

constants that satisfy equation (1). The radius of the polymer fiber is therefore 400 nm. The structure is fabricated using the Quantum X series of the NanoScribe Company (Fig. 2b). We further deposit a thin layer of gold on it with the thickness of 40 nm to permit for the excitation of coherent guided plasmon polaritons that substitute the major contribution in the interaction with electron beams. The radiation from this structure was characterised using cathodoluminescence spectroscopy. The generated photons from the source exhibit two orders of magnitude higher photon yield compared to planar waveguides and demonstrate a helically-polarized and collimated radiation pattern (Fig. 2c and d).

III. Conclusion

In a summary, the realized 3D electron-driven photon source transcends the state-of-the-art via an improved photon yield and an unprecedented control on the polarization and directionality of the emitted photons. It paves the way toward phase-locked and pump-probe spectroscopy at the 1-nm spatial resolution and few-femtoseconds spatial resolution inside an electron microscope.

Acknowledgments

We acknowledge collaborations with Dr. Jochen Zimmer, Mr. Fabian Rahn and Dr. Aaron Kobler for fabricating the structures (NanoScribe Company). Summary

Metamaterials provide a powerful design framework across mechanical, optical, and acoustic domains, enabling functionalities that are inaccessible with conventional materials. In soft electronics–based implantable devices, where mechanical compliance must coexist with high functional performance, meta-structural design offers a unique opportunity to decouple material softness from device capability. In this presentation, we examine how metamaterial concepts can be applied to implantable soft electronic systems to enhance sensing performance and to introduce new modes of control over device end-of-life behavior.

The primary focus of this work is on mechanical metamaterials for ultrasensitive strain sensing, a critical function in implantable electronics for monitoring subtle biomechanical signals. Crack-based strain sensors are widely recognized for their high sensitivity, which arises from resistance modulation induced by the opening and closing of microcracks in thin conductive films. However, despite their excellent performance at relatively large strains, these sensors exhibit a fundamental limitation in the low-strain regime. At infinitesimal deformations, Poisson-induced lateral contraction of conventional substrates promotes premature crack closure, leading to a sharp loss of sensitivity and limiting their applicability to intracorporeal environments.

To overcome this intrinsic constraint, we introduce an auxetic mechanical metamaterial architecture that reprograms the crack-opening mechanism itself.[1] By engineering a substrate with a strongly negative Poisson's ratio, uniaxial tensile loading induces biaxial expansion rather than lateral contraction. This deformation mode suppresses crack-edge reconnection and enables immediate and orientation-independent crack-gap opening, even at extremely small applied strains. Finite element analysis and microscopic observations confirm that the auxetic meta-architecture fundamentally alters local strain redistribution at crack sites, activating a crack-opening regime that is inaccessible in conventional soft substrates.[2]

As a result, the mechanically programmed crack sensor exhibits dramatically enhanced sensitivity in the initial deformation regime, achieving reliable detection of strains down to the 10^{-5} level. This hypersensitive response enables the resolution of subtle biomechanical dynamics that were previously difficult to access using soft electronic sensors. In particular, we demonstrate the ability to detect pulsatile deformations associated with cerebral vasculature, highlighting the relevance of mechanical metamaterial design for implantable biointerfaces requiring extreme sensitivity and conformal contact.

Beyond sensing performance, the mechanical metamaterial framework also provides a pathway to address broader system-level challenges in soft electronics. While this presentation primarily emphasizes mechanical metamaterials, we additionally introduce an emerging concept that integrates acoustic metamaterials with transient implantable electronics as a forward-looking extension. In this approach, externally applied ultrasound is used to mechanically fragment implanted devices and accelerate their degradation. Mechanically programmed meta-structures enable more efficient localization of acoustic energy, allowing faster and more spatially controlled disassembly compared to unstructured systems. Although still at an early stage, this concept illustrates how metamaterial design can extend beyond operational performance to actively shape device behavior at the end of life.

Together, these examples demonstrate that metamaterials can serve as an enabling framework for actively governing both sensing performance and degradation pathways in implantable soft electronic systems. By shifting the design paradigm from material-centric optimization to structural and mechanical programming, this work highlights the potential of metamaterials to support next-generation bio-integrated and transient electronics that combine high sensitivity, mechanical compliance, and programmable life cycles.

***Abstract*—We investigate harmonic generation in silicon-based membranes and metasurfaces operating in the visible and UV spectrum. Our combined experimental-theoretical study reveals second, third, and higher harmonic generation up to the seventh order. Resonant field confinement in corresponding metasurfaces enable enhaced efficient UV emission and predictive design of nonlinear nanophotonic devices.**

***Keywords*— nonlinear optics, silicon, silicon nitride, third-harmonic generation, ultrafast nonlinear optics, high-index dielectric metasurfaces, high harmonic generation.**

I. Introduction

Semiconductor and metallic nanostructures are now widely incorporated into photonic devices across numerous applications that harness light propagation and electromagnetic field localization at nanometer length scales. At these scales, both linear and nonlinear light–matter interactions display nonconventional behavior that cannot be adequately described by standard theoretical models. In bulk materials, harmonic generation is typically optimized in transparent, highly nonlinear media under phase-matching conditions to maximize conversion efficiency. In contrast, when dimensions are reduced to the nanoscale, phase matching loses relevance, absorption is not necessarily detrimental, and the electric-dipole approximation no longer dominates, enabling contributions from typically neglected higher-order and multipolar terms. Furthermore, the effective nonlinear susceptibilities, $\chi^{(2)}$ and $\chi^{(3)}$, can differ significantly from their bulk local values and may depend on pump depletion, pulse duration, and the underlying nonlinear mechanisms. Achieving a quantitative understanding of these nanoscale nonlinear sources is therefore crucial for the rational design and development of next-generation nonlinear nanophotonic devices.

Here, we report a series of experiments on harmonic generation in silicon(Si)-based membranes and metasurfaces. The generated harmonics are intentionally tuned to the visible and ultraviolet spectral regions, where Si-based materials are typically overlooked because of strong absorption. Despite this, our results clearly demonstrate that efficient light emission is achievable even when the harmonic wavelengths lie within the nominally opaque regime of these materials.

Beginning with simple freestanding membranes and a characterization of their intrinsic nonlinear optical response, we subsequently design and analyze resonant metasurfaces derived from the same materials. Under resonant excitation with ultrafast near-infrared pulses, these nanostructured metasurfaces strongly confine the electromagnetic field within their volume, thereby enhancing light–matter interaction and substantially increasing higher harmonics generated in the visible, UV or deep-UV wavelength ranges. Using specialized detection systems, we accurately measure THG conversion efficiencies ranging from 10^{-6} to 10^{-12}, achieving excellent agreement with theoretical predictions in terms of spectral shape, linewidth, and peak amplitude.

II. Results and Discussion

Initially we measure second harmonic generation (SHG) and third harmonic generation (THG) from Si and silicon nitride (Si_3N_4) resonant membranes. The comparison of these experimental results with the numerical predictions of our theoretical model allows the identification of the valence electrons effective mass, which determines SHG efficiency and oscillator parameters that control third order processes. With these results we can accurately predict the nonlinear optical properties of more complex structures, without artificially separating the effective $\chi^{(2)}$ into surface and volume contributions, and by simultaneously including effects of linear and nonlinear dispersions.[1] The Si sample is a single-crystal undoped $< 100 >$ Si membrane suspended over a frame(Fig.1(a). In Fig.1(b) we display linear pump transmittance vs. incident carrier wavelength for 200nm and 1340nm-thick membranes. The spectra consists of a series of Fabry-Perot resonances whose free spectral range depends on thickness. THG data are shown in Fig.1(c), where we report the spectral response for normal and oblique angles of incidence. A maximum THG efficiency of 2×10^{-9} is obtained at 466nm, with the pump tuned to 1400nm at normal incidence. Our results suggest that judicious exploitation of the nonlinear dispersion of ordinary semiconductors can provide reasonable nonlinear efficiencies well into the UV range.

We then design resonant 1D periodic gratings, etched into the abovementioned Si and Si_3N_4 membranes. Fig2 shows the Si_3N_4 membrane (Fig.2(a)) and the fully etched strips (Fig.2(d)) designed to sustain a characteristic Mie type resonance at or near 800nm (Fig.2(e)). Under TE illumination, the dip in the transmission spectra is a result of light localization in the bulk of the material (inset of 2(d)). This strong light localization corresponds to a resonant THG spectral variation

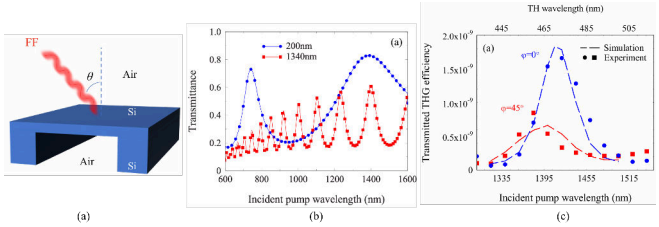

Fig. 1. (a) Si membrane Schematic diagram, (b) Transmittance vs incident pump wavelength for the 200nm- and 1340nm–thick Si membranes. Both samples display Fabry-Perot resonances according to their thicknesses. (c) Measured and simulated THG spectra for 1340nm-thick membrane. Markers exemplify the data obtained at 0° (filled blue circles) and 45° (filled red squares); corresponding simulations for 0° (dashed blue curve) and 45° (dashed red curve)[1].

as theoretically predicted, and shown in Fig.2(f), with a peak enhancement factor of $\sim$ 400 times, with respect to the THG from flat membrane(Fig.2(c). This planar architecture is fully transparent, operable at normal incidence and coan be integrated into planar Si on insulator (SOI) optical components, providing a flexible design toolbox for polarization-independent UV and deep-UV nano-light sources.

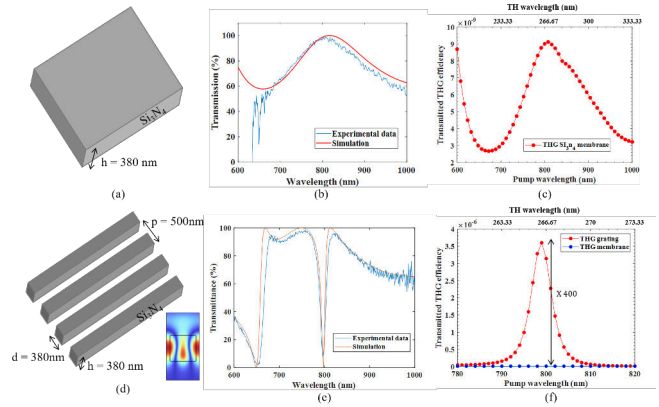

Fig. 2. Si_3N_4 membrane (a) Schematic diagram, (b) Linear transmission and (c) THG spectral response. Suspended grating in Si_3N_4 (d) Schematic diagram (e) Linear transmission and (f) Resonant THG spectral response and enhancement peak.

Finally, we report experimental observations of high harmonic generation, up to the 7th harmonic, generated from a suspended subwavelength Si film resonant in the UV range at 210 nm, the current limit of our detection system. In Fig.3 we show the measured and simulated spectra generated by a $\sim 3TW/cm^2$, 85fs pump pulse tuned to 1475 nm incident normal to the surface to temporarily suppress even harmonics. The measured conversion efficiencies are $4.2 \times 10^{-5}, 6.2 \times 10^{-7}$, and 4.57×10^{9} for 3rd, 5th, and 7th harmonic, with peak power densities of order $126MW/cm^2, 1.8MW/cm^2$ and $14kW/cm^2$, respectively, despite being tuned in the absorption and metallic ranges. We explain the experimental data with a time domain, hydrodynamic-Maxwell approach broadly applicable to most optical materials. Our approach accounts simultaneously for surface and magnetic nonlinearities that generate even optical harmonics, as well as linear and nonlinear material dispersions beyond the third order to account for odd optical harmonics, plasma formation, and a phase locking mechanism that makes the generation of high harmonics possible deep into the UV range, where semiconductors like Si start operating in a metallic regime.

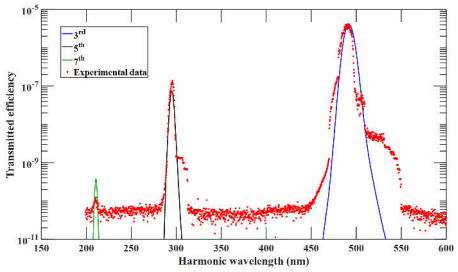

Fig. 3. Measured and simulated spectra of transmitted 3rd, 5th, and 7th harmonic conversion efficiencies for a single pulse 85 fs in duration, carrier wavelength tuned to 1475 nm, peak power density of $3TW/cm^2$, and normally incident on the Si film [3]

III. Conclusion

We demonstrate that Si and Si_3N_4 nanostructures enable efficient harmonic generation from the visible to the deep-UV, even within nominally absorbing or metallic spectral regions. Resonant metasurface engineering and strong field confinement yield orders-of-magnitude enhancement of nonlinear conversion efficiencies, including high harmonics up to the seventh order. The excellent agreement between experiments and our hydrodynamic-Maxwell model provides quantitative insight and predictive capability for designing CMOS-compatible nonlinear nanophotonic devices beyond bulk-material limitations.

***Abstract* - We demonstrate that periodic multilayer perfect-conductor dielectric structures with subwavelength slits support propagating multilayer gap plasmons with tunable wavenumber spectra and interlayer phase coherence. The number of supported modes increases with layer number, enabling controllable field localization and propagation for advanced photonic and metamaterial device applications.**

***Keywords* - gap plasmons, multilayer plasmonics, spoof plasmons, metamaterials, photonic devices**.

I. Introduction

Gap plasmons provide strong electromagnetic field confinement and enhanced propagation compared with conventional surface plasmon polaritons. While single gap plasmon modes have been extensively studied, multilayer gap plasmon systems remain largely unexplored. Theoretical and computational investigation of multilayer plasmonic systems is important because coupling between layers can enable additional control over propagation characteristics, dispersion behavior, and field localization.

This work introduces multilayer gap plasmons supported by alternating metallic and dielectric layers containing periodic subwavelength slits. The study demonstrates that collective plasmon modes can propagate through the entire multilayer stack, enabling new degrees of freedom for waveguiding, metasurface design, and metamaterial engineering.

II. Methods

The investigated structure consists of alternating perfectly conducting slabs and dielectric layers with periodic slit arrays in each conductor layer. The system is modeled using Maxwell's equations with Bloch periodic boundary conditions along the periodic direction and outgoing-wave boundary conditions normal to the multilayer stack.

Field expansions are applied separately within dielectric layers and slit regions, and boundary matching conditions are used to construct a matrix eigenvalue problem. Bound gap plasmon modes are identified by solving for wave numbers that produce near-zero eigenvalues. Numerical calculations were performed for multilayer systems ranging from three to more than fifty layers, as well as for the infinite-layer limit.

III. Results and Discussion

The results demonstrate that multilayer structures support multiple propagating gap plasmon modes across the full stack thickness. As the number of layers increases, the number of supported modes increases and approaches a continuous band structure in the infinite-layer limit.

The calculated wave number spectrum extends both below and above the free-space wave number. Modes below the free-space wave number correspond to leaky or weakly confined modes that become more confined as layer number increases, while higher wave number modes exhibit strong confinement and enhanced interlayer coherence.

Field profile analysis confirms that electromagnetic energy is localized primarily within dielectric gap regions, while metallic regions remain field-free except within slit openings. Higher-order spatial harmonics introduce only minor phase shifts without significantly distorting mode shape, confirming that the fundamental mode dominates propagation behavior.

IV. Conclusion

Multilayer periodic conductor–dielectric structures with subwavelength slits can support propagating multilayer gap plasmons with tunable spectral and coherence properties. Increasing layer number increases modal density and enables band formation. Interlayer phase behavior is governed by plasmon wave number, enabling engineering of coherent field propagation across multilayer systems. These findings provide a foundation for designing advanced plasmonic waveguides, multilayer metasurfaces, and photonic metamaterials. Future work will extend the model to real metals across the electromagnetic spectrum and explore geometry optimization for specific device applications.

Emergence of higher-order exceptional points in composite non-Hermitian quantum systems

Jan Wiersig[1,*], Weijian Chen[2]

[1]Otto-von-Guericke-Universität Magdeburg, Fakultät für Naturwissenschaften, Institut für Physik, Universitätsplatz 2, 39016 Magdeburg, Germany

[2]Department of Physics and Astronomy, North Carolina State University, Raleigh, North Carolina 27695, USA

Abstract—We investigate the emergence of higher-order exceptional points (EPs) in composite quantum systems formed by the tensor product of multiple subsystems, each exhibiting an EP. We determine the resulting spectral response strength, and show that the presence of the higher-order EP causes initially entangled states to disentangle during time evolution.

Keywords— non-Hermitian physics, exceptional points, composite quantum systems.

I. Introduction

Exceptional points (EPs) are spectral degeneracies in open quantum and wave systems that produce counter-intuitive effects with potential applications. At an EP of order n, precisely n eigenenergies and the associated eigenstates of the non-Hermitian Hamiltonian $\hat{H}_0$ merge into a single state. Under a small perturbation, $\hat{H}_0 + \varepsilon\hat{H}_1$ with perturbation strength $\varepsilon > 0$, the eigenenergies E_j show a strong spectral response bound by [1]

$$|E_j - E_{\mathrm{EP}}|^n \leq \varepsilon ||\hat{H}_1||_2 \, \xi, \tag{1}$$

with spectral norm $||\cdot||_2$ and spectral response strength ξ. Clearly, EP-enhanced sensing applications prefer large ξ.

Here, we study the emergence of higher-order EPs in quantum systems composed of non-interacting subsystems, each with a completely degenerate eigenenergy spectrum exhibiting at least one EP. For instance, for a bipartite system the Hamiltonian of the full system is

$$\hat{H} = \hat{H}_{\mathrm{A}} \oplus \hat{H}_{\mathrm{B}} = \hat{H}_{\mathrm{A}} \otimes \mathbb{1}_{\mathrm{B}} + \mathbb{1}_{\mathrm{A}} \otimes \hat{H}_{\mathrm{B}} \tag{2}$$

with Kronecker sum $\oplus$, identity operators $\mathbb{1}_{\mathrm{A}}$, $\mathbb{1}_{\mathrm{B}}$, and subsystem Hamiltonians $\hat{H}_{\mathrm{A}}$, $\hat{H}_{\mathrm{B}}$ each with an EP.

II. Results and Discussion

We show that a composite system of N subsystems, each with a leading-order EP of order n_α, possesses an EP of order [2]

$$n = 1 + \sum_{\alpha=1}^{N} (n_\alpha - 1). \tag{3}$$

Crucially, $n > n_\alpha$, i.e. the EP order is increased. Moreover, Eq. (3) differs from the naive expectation $n = \prod_{\alpha=1}^{N} n_\alpha$.

Next, we prove that the spectral response strength for the full system can be calculated as

$$\xi = (n-1)! \prod_{\alpha=1}^{N} \frac{\xi_\alpha}{(n_\alpha - 1)!} \tag{4}$$

with ξ_α being the subsystem's spectral response strength.

Any generic initial state $|\psi\rangle$ of the composite system is entangled. We reveal that, in the long-time limit, such a state approaches the leading-order EP eigenstate, which is a product state. This EP-induced disentanglement is illustrated in Fig. 1 by plotting the concurrence, $\mathcal{C} := 2|\alpha\delta - \beta\zeta|$, of a normalized state $|\psi\rangle = (\alpha, \zeta, \beta, \delta)^{\mathrm{T}}$ for a composite system made of two second-order EPs. For most initial Bell states, the concurrence decays monotonically from its maximum value to zero, indicating a loss of entanglement.

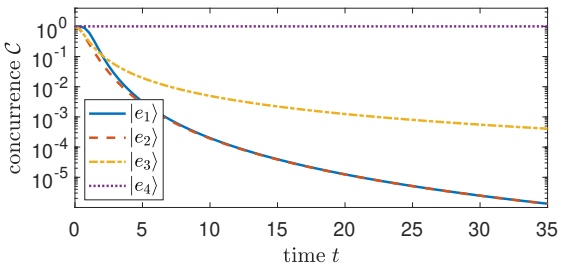

Fig. 1. Time evolution of concurrence $\mathcal{C}$ for four initial Bell states $|e_j\rangle$ in a system composed of two second-order EPs; t is dimensionless.

III. Conclusion

We have shown that composite quantum systems, each possessing an EP, can exhibit a higher-order EP whose order exceeds that of the individual components. We derived simple expressions for both the EP order and the spectral response strength, and revealed the intriguing phenomenon of EP-induced disentanglement.

***Abstract*—One of the exceptional features of non-Hermitian systems is the unidirectional wave interactions. At a particular (exceptional) point the situation can be achieved, that the external radiation is efficiently coupled into the system, but the internal radiation cannot escape backwards. We realize this idea in non-Hermitically modulated thin films, consisting of a Hermitian part - the periodic corrugation of the surfaces of a film, and a non-Hermitian part - the modulation of losses along the film. We prove numerically and demonstrate experimentally that the incident radiation, coupled with such a non-Hermitian thin film, is unidirectionally trapped into a planar mode of the film, does not escape from the film (or escape weakly due to experimental imperfections), and is efficiently absorbed there.**

***Keywords*— metamaterials, non-Hermitian systems.**

I. Introduction

One of the exceptional features of non-Hermitian systems is unidirectional wave interactions. Simultaneous modulation of the real and the imaginary part of the interaction potentials (of the refractive index and the gain/loss in the case of optical systems) can result in unequal coupling coefficients between the fields of different parts of the system. The unidirectional coupling can be arranged between internal fields and external radiation as well. At a particular (exceptional) point, the situation can be achieved, that the external radiation is coupled into the system, but the internal radiation cannot escape backwards. In this way, the incident radiation can be trapped inside the non-Hermitian system and, eventually, can be efficiently absorbed there.

II. Results and Discussion

We design the structure by analytic estimations and numerical simulations (Fig.1); we fabricate the structure by physical vapor deposition (titanium dioxide - TiO_2) on nanostructured substrates, and nonuniformly deposit the absorber by magnetron sputtering with the glancing angle method (nickel - Ni); we record the angular transmission/reflection profiles, and we reconstruct angle – asymmetric absorption map. Asymmetric absorption (asymmetry factor 2) is mediated by the left-/right-propagating waveguiding modes of the thin film, in good correspondence with the theoretical estimations [1].

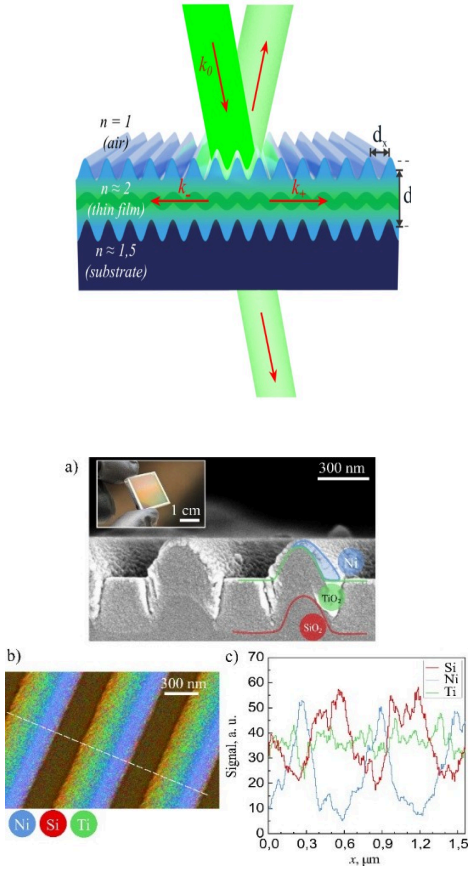

Fig. 1. Geometry, and realization.

Abstract—We propose a photonic neuromorphic computing architecture based on symmetry-protected robust zero modes. We experimentally demonstrate that even a small set of coupled nanolasers can implement non-convex boundaries, enabling the classification of highly compressed handwritten digits.

Keywords— photonic computation, zero modes, nanolaser array.

I. Introduction

Photonic neuromorphic computing has emerged as a promising approach toward energy-efficient artificial neural networks (ANNs). Nanolasers, in particular, are attractive candidates owing to their ultralow power consumption and intrinsic nonlinearities [1], [2], [3]. In this work, we propose a photonic neuromorphic computing architecture based on symmetry-protected non-Hermitian zero modes in coupled semiconductor photonic crystal nanolaser arrays. We experimentally demonstrate that even a small set of coupled nanolasers can realize non-convex tasks, enabled by their intrinsic nonlinearities and effective multilayer features.

II. Methods

The principle of our coupled nanolasers is illustrated in Fig. 1. An input image of a handwritten '1', represented as a matrix $\mathbf{I}$, is linearly mapped onto a pump distribution $\mathbf{P}$ via a encoding matrix $\mathbf{M}$, such that $\mathbf{P} = |\mathbf{MI}|$. The resulting pump pattern is then projected onto the nanolaser array using a spatial light modulator (SLM). The coefficients of $\mathbf{M}$ are adjusted such that the optical spectrum—serving as the output layer—exhibits a lasing zero mode (interpreted as a positive response) when the digit '1' is presented. Conversely, for any other handwritten digit, the zero mode remains off, indicating a negative response [4].

III. Results and Discussion

As a proof-of-principle, we fabricate a 2×2 photonic crystal coupled nanolaser array and evaluate its performance on a highly compressed handwritten digits dataset.

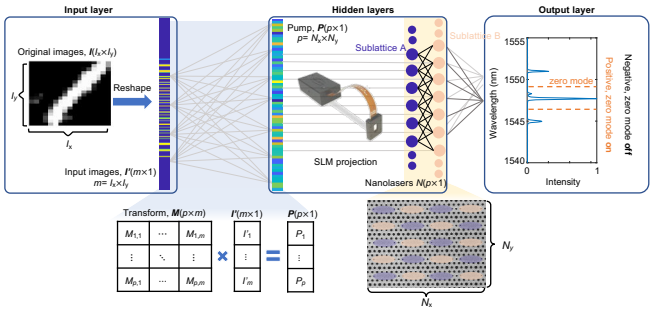

Fig. 1. Schematic of the optical computation architecture.

The dimensionality reduction induces severe information loss, resulting in substantial class overlap within the feature space (see the left panel of Fig. 2), thereby increasing the complexity of the decision boundary. We benchmark the nanolaser array against conventional nonlinear classifiers, the results are demonstrated on the right panel of Fig. 2.

At relatively high resolutions, all classifiers achieve nearly 100% accuracy as the data remain linearly separable in the high-dimensional feature space. However, as the input dimensionality decreases, classifier accuracy declines. At extremely low resolution—where the input is reduced to just 4 features—the boundaries between the two classes significantly overlap, causing single-layer linear classifiers, such as the perceptron, to fail in achieving reliable performance. In this regime, the presence of the nonlinear hidden layer with recurrent couplings becomes essential for maintaining classification accuracy. Notably, our nanolaser array performs comparably to nonlinear classifiers, particularly when the input information is highly compressed, thereby demonstrating its capability to process low-dimensional data efficiently using only four nonlinear neurons.

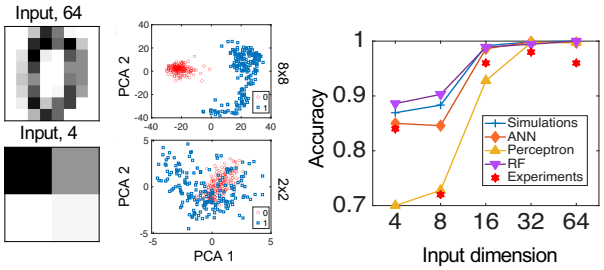

Fig. 2. Performance of different classifier as a function of the input data size.

IV. Conclusion

In this work, we propose and experimentally demonstrate a photonic neuromorphic computing architecture utilizing symmetry-protected zero modes in coupled nanolaser arrays. By engineering the optical materials to exploit exceptional point bifurcations, we could excite symmetry-protected zero modes, which serve as robust outputs for classification tasks. Moreover, the intrinsic nonlinear response—arising from gain saturation and the amplitude-phase coupling of the semiconductor nanolasers—combined with the recurrent couplings in the hidden layer, enable the array to efficiently handle nontrivial classification tasks using only a small number of neurons.

***Abstract*—The introduction of periodic non-Hermitian potentials in damped-driven and damped-active NonLinear Schrödinger Equation permits stabilization and accessibility of solitonic structures.**

***Keywords*— Non-Hermitian metastructures, solitons, stabilization.**

I. Introduction

Many optical systems are modeled by generalizations of the Nonlinear Schrödinger Equation (NLSE). Damped-Active optical systems, such as lasers, can be well described by the Complex Ginzburg-Landau Equation (CGLE), while Damped-Driven systems like Kerr micro-resonators are modeled by the Lugiato-Lefever Equation (LLE). In both cases turbulence can be tamed by stabilizing solitonic solutions through the introduction of non-Hermitian potentials (complex modulations of the refractive index and gain/loss). While both models are generalizations of the Nonlinear Schrödinger Equation (NLSE), their stabilization mechanisms and dynamics differ according to the nature of the medium.

Non-Hemitian modulations revealed strong capabilities for the stabilization of optical systems. Introducing non-Hermitian spatiotemporal modulations in extended systems induces new phenomena and new system solutions. It permits several applications by controlling the modulation, like turbulence reduction, stabilization of eigenstates, or the generation of new stable solutions.

Aside from homogeneous solutions, other non-homogeneous stationary solutions are found in both Damped-Active and Damped-Driven systems. The most well-known are simple stable periodic solutions but also localized states although frequently showing an unstable behaviour. This is the case of solitons in Damped-Active and Damped-Driven systems modeled by the CGLE and LLE respectively.

II. Stabilization of the CGLE

The unmodulated one dimensional CGLE easily shows instability and turbulent behaviours. particularly when the self-focusing coefficient increases and diffusion decreases, leading to amplitude or phase turbulence. The system supports various stationary periodic solutions, such as Turing rolls and trains of solitons, although these states are typically highly unstable and embedded within the turbulent regime [1,2].

In this case we introduce stationary non-Hermitian potentials, consisting of complex modulations of the refractive index and gain/loss. This modulation effectively reduces or supresses turbulence by creating stable attractors from pre-existing unstable bifurcations, even with modulation amplitudes as low as 5% of the gain for particular potential configurations.

This technique is robust across different parameters, including higher spatial dimensions (2D) and fractional extensions of the model. A particular example is the emission regularization in Vertical-Cavity Surface-Emitting Lasers (VCSELs).

III. Stabilization of the LLE

Aside, systems described by Damped-Driven Nonlinear Schrödinger Equations like the LLE describes passive systems with losses where external energy is injected, such as Kerr micro-resonators. This system naturally supports dark dissipative solitons in the normal group velocity dispersion regime. These structures emerge due to the bistability between two stable homogeneous solutions. Without modulation, while single solitons are stable, trains of equidistant solitons are typically unstable due to the lack of an effective potential to pin them together [3].

Introducing non-Hermitian potentials in normal dispersion regimes uncovers a novel and hybrid formation mechanism for solitons. This mechanism blends the physics of the two canonical formation scenarios: homogeneous bistability and pattern-homogeneous state bistability. The potential induces a dual behavior in the base states, allowing the system to use wavy quasi-homogeneous states as patterns to form localized

structures. This results in a scenario where many species of stable single solitons and soliton molecules can coexist.

A particular application of this approach is the stabilization of soliton trains and the real-time manipulation of frequency combs in Kerr micro-resonators, including deterministic and reversible switching between these different types of solutions.

IV. Conclusion

In conclusion, the application of non-Hermitian potentials provides a powerful and versatile framework for stabilizing nonlinear optical systems, effectively taming the inherent turbulence in Damped-Active systems (CGLE) and enabling the deterministic control of localized states in Damped-Driven systems (LLE). By introducing complex modulations of the refractive index and gain/loss, these potentials transform unstable periodic solutions and chaotic regimes into stable attractors, such as regularized emission in VCSELs or hybrid soliton molecules in Kerr micro-resonators, offering in the last a real-time manipulation of frequency combs and the generation of diverse, stable light structures [4].

I. Introduction

Time reversal symmetry is a fundamental concept that appears in many branches of wave physics and it is based on the underlying conservation of energy. Closely related to time reversal is the technique of phase conjugation (PC) [1], [2], [3], [4], [5]. Phase conjugation is an important method that can be experimentally realized by using four wave mixing technique of nonlinear optics or alternatively by combining digital holography with wavefront shaping by spatial light modulators. Most of the initial studies were based on applications of bulk homogeneous media, but recently phase conjugation was extended to complex media. More specifically, in a series of experiments, reverse propagation by phase conjugation was used to create tight focusing of light propagating in multimode optical fibers (MMFs).

In general the vast majority of these works on phase conjugation and reverse propagation concerns optical systems without gain or loss, in other words conservative structures. These ideas led to the area of non-Hermitian photonics [6], [7], which is the physical background of our study. Returning to our initial problem of phase conjugation, almost all studies are based on conservation of energy, in order to be able to exactly reverse the optical waves, which means that, in principle, phase conjugation works only in conservative (hermitian) systems. Once the medium contains gain or loss, problems arise. The conclusion was clearly stated in [8], where it was theoretically proven that the losses (or equivalently gain) spoil phase conjugation. More specifically, for purely lossy (or gainy) media exact reverse propagation is impossible [8]. The situation is different when we have a distributed gain and loss index spatial profile [9], [10], [11], [12].

More specifically, here we suggest two different strategies [13] in order to achieve a tight focused spot at the output of a non-Hermitian optical system. The first one [13] is based on the underlying rotational-time symmetry of the system and the second one [14] on the singular value decomposition of the propagator or the transmission matrix of the problem. Note that the second method does not require any symmetry, and can be generally applied in any non-Hermitian system.

II. Methods

Regarding the first problem of phase conjugation in complex media, we consider rotationally-time $\mathcal{RT}$-symmetric structures (where $\mathcal{R}$ stands for rotation and $\mathcal{T}$ for complex conjugation). In particular, we introduce the new concept of rotation phase conjugation ($\mathcal{R}PC$), where we apply the combination of phase conjugation and rotation-reflection symmetry operations to the wavefront in a medium that has $\mathcal{RT}$-symmetry. That way one can achieve perfect focusing via reverse propagation after the wavefront is properly rotated.

Regarding the second method, where no symmetry is required, we consider the propagator $\hat{G} \equiv e^{z\hat{M}}$ (where $\hat{M}$ is the evolution matrix of our paraxial equation of diffraction) or the transmission matrix $\hat{T}$ of the multimode system, that can be a slab waveguide or a photonic lattice or a multimode fiber. Once we have computed $\hat{G}$ or $\hat{T}$, we perform singular value decomposition (SVD) and determine the right/left singular eigenstates of the problem for a given propagation distance z. Proper superpositions of singular eigenstates result to the wavefront at $z = 0$ that will lead to a tight focused spot at the output of the system.

III. Results and Discussion

Our results are shown in Figs.1,2, where we illustrate the formation of a focused spot by the two alternative ways. First the concept of Rotation Phase conjugation ($\mathcal{R}PC$) for a multimode fiber is illustrated in Fig.1 and secondly the singular focusing for a slab waveguide in Fig. 2.

IV. Conclusion

We have examined the problem of phase conjugation-reverse propagation and focusing in media that contain gain and loss, following two different ways [13], [14] . Firstly, we showed that by properly combining gain and loss materials, we can achieve exact reverse propagation by relying on the concept of Rotation Phase conjugation ($\mathcal{R}PC$)[13] . We have

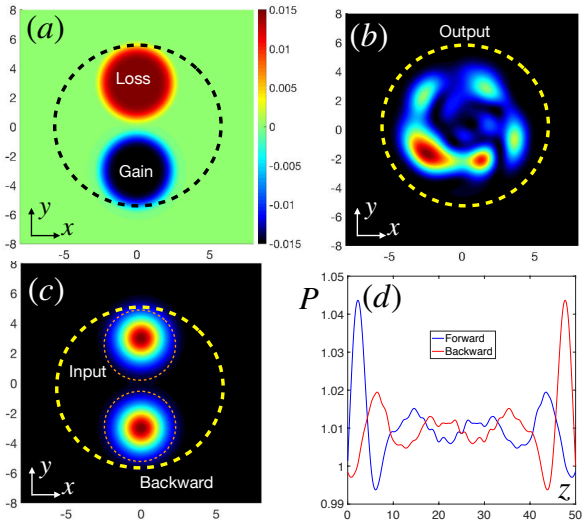

Fig. 1. Parity-phase conjugation in a multimode fiber with one core with gain and the other with loss. (a) The imaginary part of the optical potential in the transverse plane. The dotted circle is the real part of the index modulation profile. (b) Output intensity at $z = 50$ under a wide gaussian excitation localized at the lossy core. (c) Comparison of the input beam and the backward beam after $\mathcal{R}PC$ at the end facet of the fiber. (d) Power oscillations for the forward and backward evolution, in the same coordinate system.

identified the conditions under which perfect inversion of the forward propagation is possible in a single non-Hermitian $\mathcal{RT}$-symmetric complex medium. Secondly, we have performed SVD to the propagator/transmission matrix of the paraxial guided wave system, and through analytically derived formulas we identified the wavefronts at the input fact at $z = 0$ that will lead to a predetermined focused spot at the output of the system [14]. Our theoretical results may provide useful insights regarding imaging, wavefront shaping and focusing of waves in complex non-Hermitian media.

***Abstract*— We analyze the sensitivity of non-Hermitian Hamiltonian gratings mapped onto a spherical (anti-) parity-time (PT) symmetry state space. We focus on sensing along trajectories defined by the spherical axes (r, θ, φ) of the PT sphere from initial states selected thereon.**

***Keywords*— Complex modulated gratings, Active gratings, Sensors.**

I. Introduction

Parity-time (PT) symmetry and anti-PT symmetry are general properties of non-Hermitian Hamiltonian systems that have been widely studied and developed [1,2]. Unbroken PT symmetric systems satisfy the commutation operation $[\mathcal{H}, \mathcal{PT}] = 0$, and unbroken anti-PT symmetric systems satisfy the anticommutation operation $\{\mathcal{H}, \mathcal{PT}\} = 0$, where $\mathcal{P}$ is the parity operator and $\mathcal{T}$ is the time reversal operator. The complex relationship between the non-Hermitian Hamiltonian $\mathcal{H}$ and these operators can be written [3]:

$$\mathcal{PTH} = e^{j2\theta}\mathcal{HPT} \tag{1}$$

where θ is the phase of the complex eigenvalue of the non-Hermitian Hamiltonian $\mathcal{H}$.

We consider a grating having a longitudinal perturbation satisfying [4]:

$$n(z) = n_{\text{ave}} + \Delta n_r \sin\left(\frac{2\pi}{\Lambda} z\right) + \mathrm{j}\Delta n_\mathrm{i} \cos\left(\frac{2\pi}{\Lambda} z + \theta\right) \tag{2}$$

where $n(z)$ is the complex refractive index distribution of the Bragg grating along the z (propagation) axis, n_{ave} is the average complex refractive index, Δn_r and Δn_i are the strength of the real and imaginary index perturbations, Λ is the period of the grating, and θ is the phase difference between the real and imaginary index perturbations and is equivalent to θ in Eq. 1. The grating is PT symmetric when $\theta = q\pi$, anti-PT symmetric when $\theta = q\pi \pm \pi/2$ where $q \in \mathbb{Z}$, and anyonic PT symmetric for other values of θ. Also, the system is in a PT unbroken state for $\Delta n_r > \Delta n_i$, in a PT broken state for $\Delta n_r < \Delta n_i$, and at an exceptional point (EP) for $\Delta n_r = \Delta n_i$. In previous work [4], we represented the parameter space of Eq. 2 graphically in spherical coordinates as shown in Fig. 1. We now use this representation to explore sensing along specific directions on the PT sphere representing changes in PT state from initial states. This approach provides a different perspective on the design of sensors, leading to new insights and concepts [5].

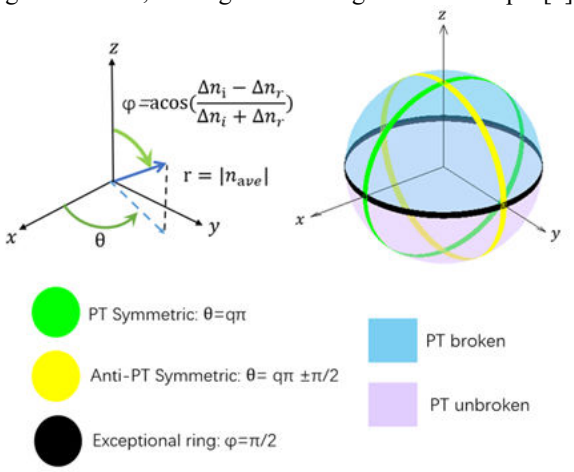

Fig. 1. Spherical representation of complex modulated Bragg gratings with the identification of special PT states.

II. Results

We analyze the sensitivity of complex-modulated gratings in specific PT states by inducing perturbations along the three spherical coordinates: Perturbation along the radius r which is directly related to average effective index n_{ave}, perturbation along the azimuthal coordinate θ which corresponds to the phase shift between the real and imaginary perturbations, and perturbation along the polar coordinate φ which is a function of the normalized differential strength between the imaginary and real perturbations (Δn_i and Δn_r).

Fig. 2 summarises example results for sensing along the anti-PT symmetry ring ($\theta = \pi/2$) about the north pole as sketched in Fig. 2(i). State evolution along the φ axis occurs by perturbing Δn_r by an additional real index perturbation Δn_c. Fig. 2(ii) shows that sensing along this ring leads to increasing

reflectance as the state evolves towards one of the EPs. The reflectance response shows slight shifts in peak wavelength around the Bragg wavelength with Δn_c. The transmittance response develops distinct extrema on either side of the Bragg wavelength, as shown in Fig. 2(iii), which can be monitored differentially (or as a ratio) as a measurand. The direction of the shifts in the reflectance response indicates the direction of state evolution with φ along the anti-PT symmetry ring, as does the side on which the transmittance maximum or minimum occurs near the Bragg wavelength. It is evident from Fig. 2 that extremely large transmittance sensitivities are possible in this scheme considering that perturbations in real index of the order of 10^{-4} can induce changes of about 0.3 in transmittance.

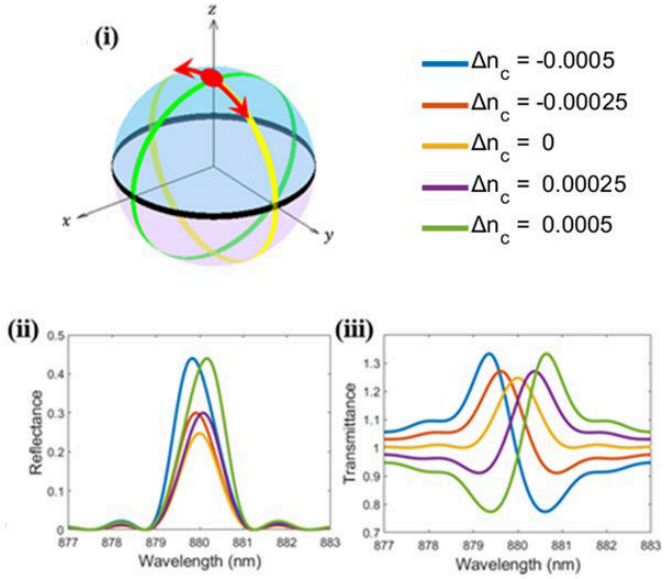

Fig. 2. Spherical representations of complex modulated Bragg gratings and sensing in the extreme PT broken state along the $\theta = \pi/2$ ring.

III. Conclusion

We introduce a PT-sphere trajectory framework for complex-modulated Bragg gratings that provides a new perspective for sensor design. By engineering evolution along the sphere's axes, the spectra exhibit controllable wavelength shifts and amplitude changes, enabling multiple practical measurands beyond conventional peak tracking. The evaluated scheme yields promising sensitivities, and the independence of the spherical axes also enables inference of responses for gratings in arbitrary (anyonic) PT states. This opens new prospects for compact, high-performance multi-parameter sensing based on PT-state engineering of Bragg gratings.

Topology in space, time, and space-time

Alexander Szameit[1,*]

[1] Instituti of Physics, University of Rostock, Germany
*Corresponding author: alexander.szameit@uni-rostock.de

***Abstract*— In this invited talk, I will present our most recent experiments on topological states residing at temporal interfaces.**

***Keywords*— Topological Photonics, Quantum Simulation**

In recent years, topological phenomena in photonic systems have attracted much attention, with their striking features arising from robust states in the energy gaps of spatially periodic media. However, light waves are entities that extend in space as well as time, such that one may ask whether topological effects can also occur in the temporal domain, or even space-time. Intuitively, systems that are periodic in time may be gapped in momentum, leading to topological states localized at time interfaces. However, time - in contrast to space - exhibits a unique unidirectionality often referred to as the “arrow of time”. Inspired by these features, I will present our most recent experiments on topological states residing at temporal interfaces. Moreover, I will discuss the formation of spacetime-topological events and demonstrate unique features such as their limited collapse under disorder and causality-suppressed coupling.

Mode-cleaning in multimode fibers via chiral non-Hermitian modulations

Muriel Botey[1,*], Ramon Herrero[1], Mingshu Chen[2], Almantas Galvanauskas[2], Kestutis Staliunas[1,3]

[1]Departament de Física, Universitat Politècnica de Catalunya (UPC), Barcelona, Catalonia
[2] University of Michigan- Ann Arbor, Michigan, USA

***Abstract*— We report on a spatial mode-cleaning mechanism via chiral gain/loss and index modulations in a multimode fiber. By exploiting non-Hermitian-symmetry breaking, a cascading power flow funnels energy from higher-order modes into the lowest-order mode, enabling robust, high-quality beams with fiber-standard-fabrication generation methods.**

***Keywords*— multimode fibers, non-Hermiticity, nanophotonics, exceptional point, exceptional ring**

I. Introduction

In non-Hermitian systems, exceptional points (EPs) are spectral singularities where two or more eigenvalues and their corresponding eigenvectors simultaneously coincide. Unlike degeneracies in conventional Hermitian systems—where eigenvalues are identical but eigenvectors remain orthogonal—an EP marks a collapse of the eigenbasis, rendering the underlying system matrix defective [1]. Distinctively, adiabatically encircling an EP in parameter space (e.g., in modulated non-Hermitian waveguides, photonic crystals, or nonlinear microcavities) exploits the underlying Riemann surface topology to induce a state exchange. This non-trivial evolution swaps the modes, transferring energy between them, while simultaneously accumulating a topological geometric phase.

On the other hand, light propagation in unperturbed multimode waveguides depends strictly on the core's refractive index profile; in particular, parabolic graded-index (GRIN) fibers exhibit equidistant propagation constants and periodic self-imaging, whereas arbitrary profiles yield quasi-periodic field evolution. Physical perturbations—such as bending or twisting—introduce mode coupling that triggers complex, turbulent dynamics. Crucially, conventional Hermitian perturbations (purely real refractive index modulations) always enforce symmetric, bidirectional mode coupling, manifesting as periodic Rabi oscillations governed by strictly real-valued eigenvalues.

In this paper, we propose a highly robust mode-management scheme for multimode fibers. Building upon recent demonstrations of non-Hermitian mode-cleaning in parabolic multimode waveguides [2-4].

II. Helical Waveguide

The proposed architecture implements simultaneous three-dimensional chiral modulations of both the refractive index and the gain/loss profile along the fiber, consisting of two pairs of satellite cores embedded within the main multimode fiber core, all twisted along the propagation axis, z, with a helical pitch, Λ. The trajectories tracking the centers of these modulation zones —one introducing a pure refractive-index (real, *re*) perturbation and the other an gain/loss (imaginary, *im*) perturbation —follow the helical paths in cylindrical coordinates: $(r,\phi)_{re} = (d, 2\pi z/\Lambda)$ and $(r,\phi)_{im} = (d, 2\pi z/\Lambda+\theta)$ respectively; where θ is the relative azimuthal shift. By establishing a three-dimensional non-Hermitian lattice, this helical structure represents a major advancement over earlier non-Hermitian self-cleaning methods [3,4], offering a practical and robust paradigm for regularizing modal dynamics and mitigating turbulence in high-power multimode fibers. Moreover, the proposal does not rely on high nonlinearities as other self-cleaning schemes previously reported [5]. The proposal may be realized within actual technological means, see Fig 1.

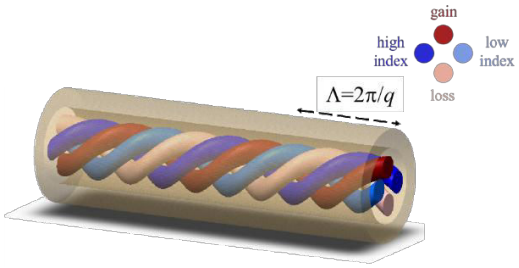

Fig. 1 Schematic representation of the proposed helical non-Hermitian fiber with four cores [6].

Numerical simulations confirm that the continuous modal cascade delivers Gaussian-shaped beams. It is important to note that, contrary to the initial proposal [2], the present modulation

scheme provides asymmetric coupling between helical modes with different orbital angular momentum.

Upon incidence of a mode with high orbital angular momentum (LG_{03}), we observe a significant energy cascading towards the lower-order mode (LG_{00}). The asymmetric mode-conversion process is shown in Fig.2.

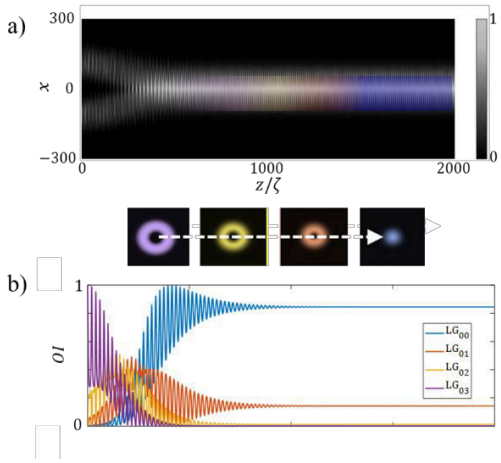

Fig. 2 a) Numerical propagation of an incident LG_{03} mode along the helical non-Hermitian fiber. b) Overlap Integral (OI) of the propagating beam on modes LG_{03}, LG_{02}, LG_{01}, and LG_{00}, showing the energy cascading.

III. Discussion

Interestingly, mapping the energy conversion in Ref. [4], we already observed that the energy transfer occurred close to resonance between the spatial modulation and propagation constant of the modes, being that the most efficient cascading does not occur exactly at the *PT*-symmetry breaking point, see Fig. 3a.

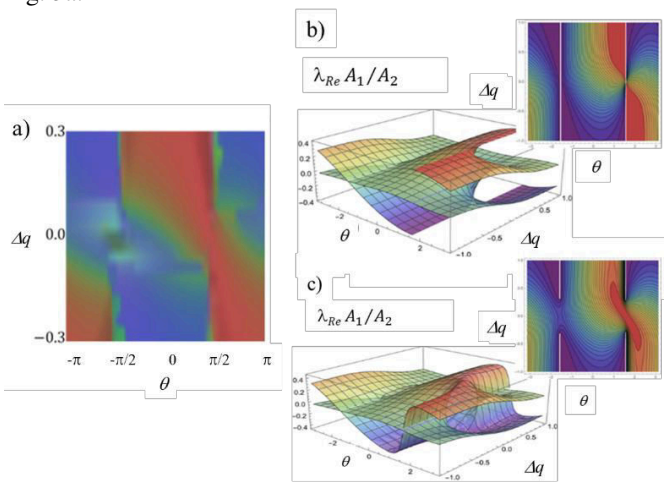

Fig. 3 a) Overlap integral, *OI,* where the lowest order mode intensity is depicted in red, the second in green, and the third in blue; depicted in the parameter space of the spatial frequency detuning, Δq, with respect to the propagation constant of the modes [4]. b)/c) Two coupled modes analysis. Ratio between the real part of the eigenvalues of both modes for an EP and an exceptional ring when the energy transfer is maximized [6].

A simplified two-mode coupled analysis—omitting non-interacting modes—fully accounts for this analytical result. In the case of balanced index/gain-loss modulation, we observe the existence of an EP. For slightly unbalanced values of the real and imaginary modulations, there exists an exception ring that efficiently funnels energy to the lower mode. In turn, a larger energy exchange area in parameter space corresponds to a more robust interaction, compare Figs. 3b and 3c.

IV. Conclusion

We propose and demonstrate a feasible non-Hermitian self-cleaning helical waveguide. The numeric simulations can be explained by a simplified two-coupled-mode analysis, which shows that the best scenario does not coincide with the PT-symmetry breaking point.

A quantum particle in a potential well with an absorbing barrier - non-Hermitian tunneling

Eva-Maria Graefe

Department of Mathematics, Imperial College London, UK

e.m.graefe@ic.ac.uk

***Abstract*—A 1D quantum box, with a central region with negative imaginary potential, modelling absorption, is considered. For strong absorption this acts as a Zeno barrier, forming an effective double well. The resulting near-degenerate eigenstates possess complex eigenvalues, fundamentally altering superposition dynamics compared to the periodic tunneling of the Hermitian counterpart.**

***Keywords*— non-Hermitian, tunneling, spectral properties**

I. Introduction

We consider a quantum particle in a one-dimensional box, with a central region with constant imaginary potential, modelling absorption. Specifically, the Hamiltonian is given by

$$\hat{K} = \frac{1}{2m}\hat{p}^2 + V(\hat{q}), \tag{1}$$

with the complex potential

$$V(x) = \begin{cases} \infty, & x \le -L \\ 0, & -L < x \le -a, \\ -\mathrm{i}\Gamma_0, & -a < x < a, \\ 0, & a \le x < L, \\ \infty, & L \le x, \end{cases} \tag{2}$$

where $0 < a < L$, and Γ_0 is a positive real absorption constant.

II. Methods and Results

A simple textbook procedure leads to quantisation conditions for complex eigenenergies, which we solve numerically to obtain eigenvalues and eigenfunctions of the system. An example of trajectories of energy eigenvalues in the complex plane, as Γ_0 is varied from zero to nine, where $L = 3$ and $a = 1$ is depicted in Figure 1. The blue dots are eigenvalues corresponding to symmetric eigenfunctions, and the red dots correspond to anti-symmetric eigenfunctions. The nine eigenvalues with the lowest real parts of the energy are shown. Here we observe how for small values of the absorption all eigenvalues pick up negative imaginary parts corresponding to decay of the probability amplitude in the corresponding eigenstates. With larger absorption some states become increasingly shorter lived, while other states become more stable, as is common in open systems. This phenomenon is often referred to as resonance trapping or a quantum Zeno effect. For strong absorption, the absorbing region acts like a physical barrier, and the eigenstates localise either in the absorbing (very short lived states) or the non-absorbing (very long lived states) regions.

The structure of the eigenvalue trajectories depends on the relative size of the absorbing region (i.e. the ratio of a and L). For the case $a = 1$ and $L = 3$ depicted in the figure, every third state localises in the absorbing region and becomes extremely short lived for large Γ_0, while the other states form a pair of symmetric and anti-symmetric states localised in the non-absorbing regions. For other ratios of a and L other scenarios appear, including cases with exceptional points, where two states of the same symmetry type degenerate for specific values of Γ_0.

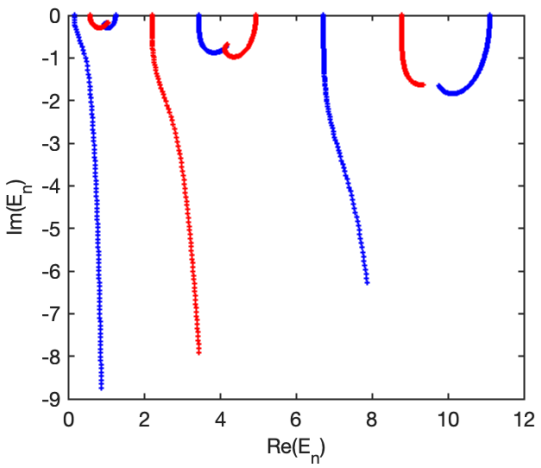

Fig. 1. Trajectories of the lowest nine complex energy eigenvalues in the complex plane in dependence of Γ_0 for 100 values of Γ_0 equidistant in the range [0 9], for $L = 3$ and $a = 1$. The eigenvalues corresponding to symmetric eigenfunctions are depicted in blue, those corresponding to anti-symmetric eigenfunctions in red.

In the case of a real potential barrier, the lowest energy pairs of symmetric and anti-symmetric states with near degenerate eigenvalues, with superpositions localised on either side of the barrier, lead to the periodic tunneling behaviour characteristic of symmetric double well potentials. In the non-Hermitian case, however, the near-degenerate energies of the symmetric and anti-symmetric pair also have (slightly different) imaginary parts. This leads to a very different phenomenon, where a superposition of the two states, initially localised on one side of the effective potential barrier, decays into the state with the longer lifetime (which is not always the symmetric state), with probability equally distributed between the two sides.

***Abstract*— We propose a geometric design methodology for architected microstructures achieving highly anisotropic stiffness without altering material composition. This enables decoupled control of axial and shear moduli, facilitating directional wave control, mode conversion, and energy confinement. An annular metastructure demonstrates superior azimuthal wave trapping compared to isotropic counterparts.**

***Keywords*— elastic anisotropy, wave mode conversion, directional bandgap, vibration isolation.**

I. Introduction

Metamaterials have revolutionized the control of elastic waves, enabling applications such as acoustic insulation[1], negative refraction[2], and waveguiding[3]. However, achieving these properties often requires complex resonant elements that compromise mechanical robustness or limit operational bandwidth[4]. Anisotropic materials offer a promising alternative by utilizing direction-dependent mechanical properties to manipulate wave motion[5,6].

Current design approaches for anisotropic materials, such as fiber-reinforced composites or standard honeycombs, often face challenges regarding interface bonding or coupled stiffness properties. To address these limitations, we propose a novel design methodology for architected microstructures that achieve strong, tunable anisotropy solely through geometric configuration. By systematically varying geometric parameters, we demonstrate stiffness anisotropy exceeding three orders of magnitude. We further investigate the dynamic characteristics, revealing phenomena such as directional bandgaps and wave mode conversion, which are utilized to design an annular metastructure for efficient vibration isolation and energy localization.

II. Design and Methodology

The proposed unit cell consists of horizontal, inclined, and vertical beams arranged in a periodic lattice. The design decouples the stiffness contributions: horizontal beams primarily sustain axial forces (high stiffness), while inclined beams deform via bending under vertical loads (low stiffness).

We derived the effective elastic moduli theoretically and validated them using Finite Element Method (FEM) simulations. The normalized effective Young's modulus in the x-direction $\bar{E}_1^*$ and y-direction $\bar{E}_2^*$ are governed by the geometric parameters: horizontal beam thickness h, inclined beam angle θ, thickness t, and height d. The effective stiffness in the x-direction is approximated as:

$$\bar{E}_1^* \approx \frac{h}{l} \tag{1}$$

where l is the cell size. Conversely, the y-direction stiffness is dominated by the bending of inclined beams, allowing independent tuning of the principal moduli.

We further optimized the structure by introducing an oblique lattice configuration to enhance mode conversion efficiency and broaden directional bandgaps.

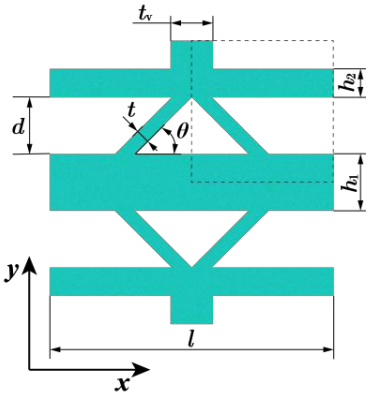

Fig. 1 Unit cell geometry of the proposed metamaterial.

III. Results and Discussion

A. Tunable Anisotropy

Systematic variation of geometric parameters reveals that the degree of anisotropy spans over three orders of magnitude. The axial stiffness ratio and shear-to-axial ratio can be tailored independently. This geometric decoupling allows for precise customization of the constitutive matrix for specific wave control requirements.

Specifically, by designing the horizontal beam thickness h to be much larger than that of the inclined beams t, we induce a transition in mechanical response. The structure behaves as a

rigid, stretching-dominated medium along the x-axis, while remaining compliant and bending-dominated along the y-axis. Consequently, the resulting anisotropy ratio can be precisely adjusted, facilitating extreme wave steering capabilities such as collimation.

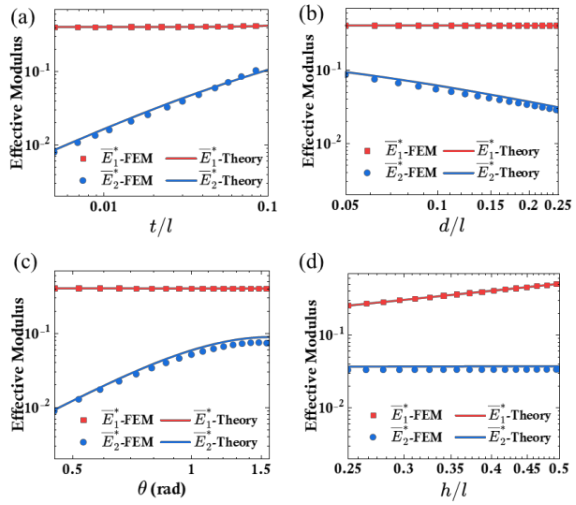

Fig. 2 Dependence of effective moduli on geometric parameters. (a-d) Variation of normalized effective Young's moduli E_1^* and E_2^* with respect to dimensionless geometric parameters.

B. Wave Propagation and Mode Conversion

Dynamic analysis reveals distinct behavior for quasi-longitudinal (Q_p) and quasi-transverse (Q_s) waves. The slowness curves indicate that energy propagation for Q_p waves is concentrated along the principal axes, while Q_s waves exhibit a butterfly-like distribution.

At high frequencies, we observed directional bandgaps where wave propagation is suppressed along the y-direction. Furthermore, a mode conversion mechanism was identified: wave vectors initially oriented in the y-direction are converted into bending waves of the horizontal beams, redirecting energy by 90 degrees into the x-direction.

C. Annular Metastructure Application

To demonstrate practical utility, we designed an annular metastructure based on the oblique lattice. The annular metastructure was constructed by mapping the Cartesian unit cells into a polar coordinate system. The radial stiffness corresponds to the soft axis, while the circumferential stiffness corresponds to the stiff axis.

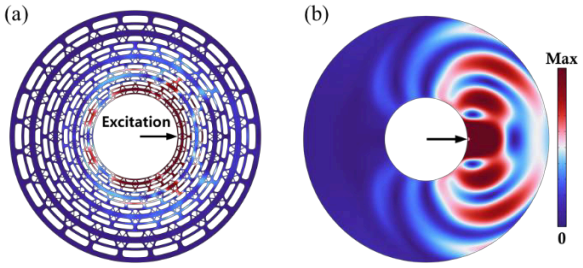

Fig. 3 Comparison of wave propagation behaviors. (a) Transient displacement field of the anisotropic annular metastructure, demonstrating effective azimuthal energy confinement under radial excitation. (b) Transient displacement field of the isotropic counterpart, showing significant outward radial energy leakage.

Under radial excitation, the structure exhibits efficient wave trapping and azimuthal energy confinement. As shown in the transient displacement fields, wave energy in the metastructure is guided circumferentially, protecting the outer boundary. In contrast, the isotropic counterpart allows energy to radiate outward. Frequency response measurements confirm that the anisotropic design suppresses radial leakage significantly compared to the isotropic case.

IV. Conclusion

This work establishes a framework for designing anisotropic architected materials with decoupled stiffness properties. We demonstrated that simple geometric tailoring can achieve pronounced anisotropy, enabling advanced wave control mechanisms such as directional bandgaps and mode conversion. The proposed annular metastructure verifies the potential for vibration isolation and acoustic steering in engineering applications.

Direct Tensor Processing with Coherent Light

Yufeng Zhang[1,*], Kaizhi Wang[2], Xuhan Guo[2], Zhipei Sun[1]

[1]Department of Electronics and Nanoengineering, Aalto University, Finland

***Abstract*— We propose a parallel optical matrix-matrix multiplication scheme implemented using a single propagation of coherent light and extend it to tensor-matrix multiplication via wavelength multiplexing. Building on this framework, we investigate its application in different optical neural network architectures and its potential deployment in metasurface devices.**

***Keywords*— optical computing, optical neural networks.**

I. Introduction

Artificial intelligence increasingly relies on tensor processing, especially matrix-matrix multiplication (MMM), which imposes heavy bandwidth and energy demands on GPUs. Optical computing offers high bandwidth, parallelism and low power, but existing optical neural networks often trade generality for parallelism, requiring repeated propagations, multiplexing or architecture-specific designs. Here, we introduce direct parallel optical matrix-matrix multiplication, which performs MMM in a single coherent light propagation by exploiting the bosonic nature of light and spatial-frequency duality[1]. And we extend it to parallel optical tensor-matrix multiplication by wavelengths multiplexing. Simulations and experiments validate GPU-consistent processing, enabling a GPU-compatible optical neural-network framework for convolution neural networks (CNN) and vision transformers (ViT), and establishing optical computing as a scalable platform for general tensor processing.

II. Methods

Conventionally, matrix-matrix multiplication is performed by computing the Hadamard product between each row of matrix A and each column of matrix B, followed by summation to obtain each output element. In optics, the Hadamard product can be implemented by spatial amplitude modulation, while summation can be approximated by Fourier-transform-based integration using quadratic phase modulation, such as a lens[2]. The main challenge is to compute all row-column dot products in parallel and map them to distinct output positions without interference.

Our method[1] addresses this challenge by exploiting the time-shifting and frequency-shifting properties of the Fourier transform (Fig. 1a). First, the elements of matrix $\boldsymbol{A}$ are encoded into the amplitude and position of a coherent optical field, while each row is assigned a distinct linear phase gradient. A column-wise Fourier transform is then applied by imaging along the row direction and focusing along the column direction. Owing to the time-shifting property, each row after this operation contains a superposition of all rows of $\boldsymbol{A}$. Matrix $\boldsymbol{B^T}$ is subsequently encoded through amplitude modulation, producing parallel Hadamard products between this hybrid optical field and $\boldsymbol{B^T}$. Finally, a row-wise Fourier transform performs the summation. Because different rows of $\boldsymbol{A}$ carry different phase gradients, the frequency-shifting property separates their contributions into distinct spatial-frequency positions, yielding the corresponding MMM outputs without mutual interference.

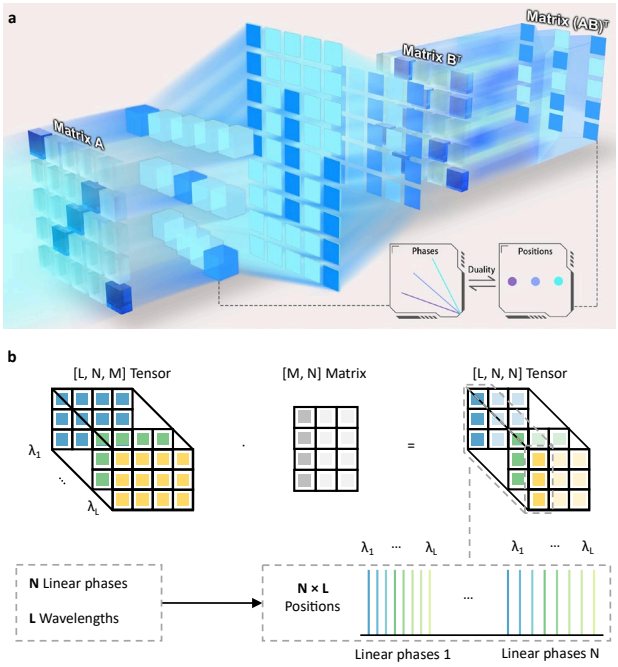

Fig. 1 Principle. a. Optical matrix-matrix multiplication with coherent light. b. Optical tensor-matrix multiplication by multiple wavelengths extension[1].

Since it relies only on coherent amplitude and phase modulation, it naturally supports wavelength multiplexing. An optical field containing L wavelengths and N phase gradients is mapped to L × N spatial-frequency positions, enabling tensor-matrix operations between an [*L, N, M*] tensor and an [*M, N*]

matrix within a single propagation process[1] (Fig. 1b).

III. Results and Discussion

To validate the reliability of our method[1], we designed an optical prototype and compared its experimental results with those obtained from GPU-based MMM across various scenarios[1]. We conducted a large sample quantitative analysis across multiple matrix sizes ([*10, 10*], [*20, 20*], [*30, 30*], [*40, 40*], [*50, 50*], with 50 random matrix pairs for each size) and evaluated the computational errors between our method[1] and GPU-based MMM (Fig. 2a). The results showed that both the mean absolute error (less than 0.15) and the normalized root-mean-square error (less than 0.1) remained low, confirming the accuracy and reliability of our method[1].

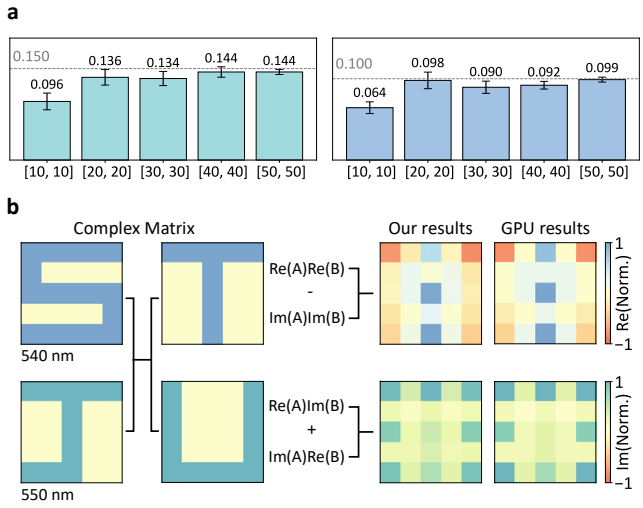

Fig. 2 Results of matrix and tensor multiplications[1]. a. Matrix-matrix multiplications. Left: average mean absolute error (MAE). Right: average normalized root-mean-square error (RMSE). The horizontal axis indicates different matrix sizes. Each bar shows the mean MAE or RMSE over 50 random samples of the corresponding size (black numbers denote the mean values; grey numbers are baselines), and the error bars represent ±1 standard deviation. b. Tensor-matrix multiplications.

In addition, we encoded the real and imaginary parts of a complex-valued matrix (with patterns 'S' and 'J') onto two distinct wavelengths and performed two rounds of two-wavelength MMM with another complex matrix (patterns 'T' and 'U') to realize full complex MMM. The results[1] show a high degree of consistency with those computed by GPU (Fig. 2b), and this process can be equivalent to the real-valued multiplication between a [*2, 5, 5*] tensor and two [*5, 5*] matrices.

Due to the high consistency between our method[1] and GPU tensor core-based MMM, this method theoretically enables the direct deployment of standard GPU-based neural network architectures. This eliminates the need to design custom network architectures tailored to the unique optical propagation constraints of conventional optical neural networks. To further validate this capability, we conducted direct inference experiments using both CNN and ViT networks on our simulation and prototype, utilizing MNIST and Fashion-MNIST (FMNIST) datasets. These architectures include three representative tensor processing steps common in modern neural networks: multi-channel convolution, multi-head self-attention and multi-sample fully connected layers. We first used four different models (CNN-MNIST, ViT-MNIST, CNN-FMNIST and ViT-FMNIST) trained on GPUs with non-negative weights and tested inference across GPU, simulation and prototype of our method[1]. Inference outputs were highly consistent across all platforms, demonstrating that our method[1] supports a wide range of tensor processing operations and enables the direct deployment of GPU-trained weights (Fig. 3a). Furthermore, we used two successive simulated optical MMM units to directly execute all linear operations with unconstrained GPU-trained weights, achieving inference accuracy highly consistent with GPU results (Fig. 3b).

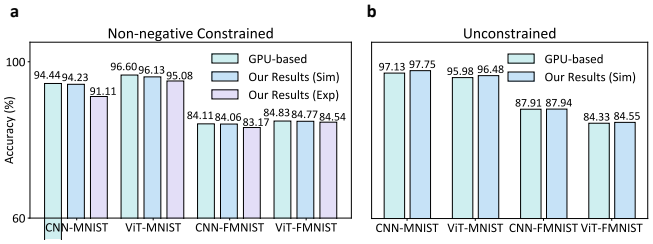

Fig. 3 Results of optical neural networks[1]. a. Tests of direct deployment of non-negative constrained GPU-trained weights across different networks and datasets on our simulation and prototype. Sim, simulation; Exp, experiment. b. Tests of direct deployment of all-step unconstrained GPU-trained weights across different datasets on our simulation.

Besides, our method[1] requires only passive phase modulation, excluding data input and output, making it broadly compatible with free-space optical computing platforms. Its high theoretical parallelism could substantially boost effective performance when combined with high-speed, large-scale photonic hardware[3]. Moreover, customized metasurfaces may replace bulky phase-modulation optics, enabling compact free-space optical accelerators compatible with advances in nanofabrication.

IV. Conclusion

In conclusion, this work[1] demonstrates that a single propagation of coherent light can realize parallel matrix-matrix multiplication and can be extended to tensor-matrix multiplication through wavelength multiplexing. We further show that this concept provides a foundation for implementing general optical neural networks.

***Abstract*— Plasmonics offers unique opportunities to enhance and engineer optical chirality at the nanoscale. In this talk we present an overview of our recent research in chiral plasmonics, starting with discussion of how plasmonic chirality can be defined, and then presenting how it can be used to engineer chiral optical scattering and emission.**

***Keywords*— chirality, plasmonics, helicoid .**

I. Introduction

Chiral light carrying a spin or/and orbital angular momentum is of fundamental importance for controlling light-matter interactions with chiral molecules and nano-objects, paving the way for advanced applications in nanophotonics and photochemistry. Chiral plasmonic nanostructures offer unique advantages for engineering and enhancement of chiral light-matter interactions, potentially providing strong chiral responses in scattering, absorption, extinction and emission.

In this talk, we will discuss the relation between chirality and optical activity of plasmonic nano-objects, with differentiating chiral responses in extinction, absorption, scattering, and emission [1]. We will also discuss how to engineer directional chiral scattering and emission from plasmonic helicoids [2] The results are important for the design of chiral plasmonic devices for sensing, displays, and quantum technologies.

II. Methods

The circular dichroism (CD) spectrometry, optical thermometry, Fourier-plane microscopy and chiral electric luminescence were employed to analyse the chiral effects predicted in chiral plasmonic nanostructures, such as gold helicoid nanoparticles. The simulations were performed by using the finite element method (COMSOL Multiphysics software). Gold helicoids were fabricated by a L-glutathione guided growth method [1-3].

III. Results and Discussion

Molecular meso-compounds possess multiple chiral centres but do not exhibit a chiral optical signature because they have an internal plane of symmetry, In contrast to molecules, in nanostructures in addition to absorption, scattering plays an important role. We introduce a novel concept of meso-chiralilty for nanoparticles when the substantial chirality in absorption and scattering can be hidden inside a completely achiral response in extinction due to the opposite sings of these components. In this case, the essentially chiral local response of the nanoparticle remains undetected or significantly underestimated using conventional circular dichroism (CD) measurements. At the same time, while the overall chiral response of meso-chiral nanoparticles is zero, the hidden chiral behaviour can significantly affect local enantio-sensitive light-matter interactions. Notably, this property is not so uncommon in chiral plasmonic nanoparticles, which was demonstrated on the examples of multi-wound particles, helixes, and helicoids, and is experimentally verified for the latter.

In order to achieve unidirectional chiral scattering, we introduced a concept of rotating chiral dipoles. Implementing this concept by engineering multipole excitations in helicoidal plasmonic nanoparticles, we experimentally demonstrate enantio-sensitive and highly-directional forward scattering of circularly polarised light. The intensity of this highly-directional scattering is defined by the mutual relation between the handedness of the incident light and the chirality of the structure.

The chiral light emission has been explored in the chiral tunnel junctions based on gold helicoid nanoparticles. The intrinsic chirality of chiral plasmonic structures incorporating tunnel junctions, defines the spin and orbital angular momenta in tunnelling-driven light emission.

IV. Conclusion

We have demonstrated plasmonically assisted light-matter interactions affecting absorption, scattering and emission of chiral light. The diverse phenomena emerging in chiral plasmonics provide a novel framework for further design of advanced chiral nanophotonic devices.

***Abstract*— We find enantiosensitive but non-dichroic signals in the 3D photoelectron angular distribution of chiral molecules upon multiphoton ionization with elliptically polarized light. The robustness of enantiosensitivity against ellipticity is an example of symmetry protection, opening unexplored opportunities for imaging ultrafast dynamics in chiral molecules with polarization-structured light.**

***Keywords*— chirality, multiphoton, symmetry, ellipticity, laser, photoelectron.**

The interaction of randomly oriented chiral molecules with circularly polarized light leads to effects that change sign upon reversal of either molecular chirality (enantiosensitivity) or light's polarization (circular dichroism). Among these effects, multiphoton ionization has provided privileged access to ultrafast electron dynamics in randomly oriented chiral molecules through the forward-backward asymmetry of photoelectron angular distributions (PADs) [1].

Here, we found that the combination of elliptical polarization, multiphoton ionization, and 3D detection reveals the presence of Non-Dichroic EnantioSensitive (NoDES) tensor observables in the PAD [2,3]. That is, upon expansion of the PAD into spherical harmonics, we found that certain expansion coefficients have opposite sign for opposite enantiomers but do not change sign upon reversal of the ellipticity, confirming recent theoretical suggestions [4]. Our experiments on camphor, fenchone, and alpha-pinene demonstrate that these NoDES contributions reach about 1% of the total ionization yield.

We found that NoDES contributions originate from the combination of two effects: (i) dichroic and enantiosensitive forward-backward asymmetry and (ii) dichroic and non-enantiosensitive angular streaking. The product of these two effects leads to a cancellation of dichroism without a cancellation of enantiosensitivity.

Our symmetry analysis reveals that the NoDES observables belong to the A_u irreducible representation of the PAD, which is antisymmetric with respect space inversion and hence enantiosensitive, but symmetric with respect to π rotations that reverse the ellipticity and hence non-dichroic. That is, the behavior of NoDES observables stems from the symmetry of a subset of (rank ≥ 3) tensors in the PAD.

Besides elliptical polarization, A_u also emerges, e.g., in bichromatic ω-2ω fields with linear polarizations perpendicular to each other. Indeed, our numerical simulations for the latter field also show NoDES contributions of the order of 1% in the two-photon, multiphoton, and strong-field regimes.

NoDES observables open new opportunities for imaging chirality when polarization is not constant throughout the interaction region, e.g., when using structured light.

***Abstract*—Conventional optical methods for detecting molecular chirality rely on weak magneto-electric effects and therefore offer limited sensitivity. Here we explore an alternative approach based on locally chiral light, whose electric field follows a chiral trajectory in time and can produce strong enantio-sensitive responses within the electric-dipole approximation. We propose implementing this concept in micro-fluidic platforms for rapid optical recognition of chiral molecules in solution.**

***Keywords*—nonlinear optics, ultrafast physics, molecular chirality, enantio-sensitive detection, micro-fluids.**

Not surprisingly, the term *chirality* is not particularly informative in isolation, as it simply denotes the absence of mirror symmetry. Yet it is precisely this seemingly broad notion that underlies its physical significance. Indeed, in static media, chirality manifests itself in several distinct ways. One familiar example is circular birefringence [1], which originates from magneto-electric coupling associated with the lack of mirror symmetry at the molecular scale, whereby right- and left-circularly polarised light experience different refractive indices. Another arises in structurally chiral media, wherein the helical stacking of birefringent layers causes the principal axes of the dielectric tensor to rotate periodically along the optical axis [2]. Despite their different microscopic origins, these manifestations share a common consequence: they enable optical discrimination of chiral matter, underpinning a wide range of detection techniques—see the review in [3].

Beyond its traditional role in spectroscopy and sensing, chirality has recently emerged as a powerful mechanism for engineering light-matter interactions in structured photonic media. For instance, the interplay between circular birefringence and structural chirality has been shown to give rise to unconventional Bragg-type phenomena, such as the so-called *reverse* circular Bragg resonance, which occurs in regimes of extreme optical activity where negative refraction leads to a 'reversal' of the medium's handedness [4]. It has further been demonstrated that sufficiently strong chirality can fundamentally alter modal dispersion in wave-guiding systems, whence enabling the emergence of exceptional points through contra-directional coupling between modes without the need for gain–loss modulation or indeed spatial periodicity [5]. Chirality has also been exploited as a design parameter for optical analog computing: indeed, by combining circular and linear birefringence in cascaded uniform slabs, it becomes possible to engineer spectral holes that enable broadband spatial differentiation and edge detection without relying on conventional Bragg gratings or resonant nano-structures [6].

The aforementioned applications of chirality, whether arising from molecular handedness or from the chiral meta-atoms of artificial meta-materials, rely on magneto-electric coupling. In practice, however, this coupling is intrinsically weak. Nature's optically active media, such as sugar solutions, produce only minute optical rotations (order of 10^{-5}), which ultimately limits any sensitivity capabilities. Recent advances in ultrafast photonics have opened new prospects for the detection of small chiral molecules, which are increasingly recognised as important biomarkers in diagnostics. Traditional chemical approaches, e.g. mass spectrometry, can offer greater sensitivity, yet they typically do so at the expense of speed and experimental simplicity.

In the nonlinear regime of light-matter interactions, chiral effects are symmetry allowed already within the electric-dipole approximation [7]. This creates an opportunity to circumvent the intrinsically weak magneto-electric coupling responsible for conventional optical activity. Indeed, locally chiral electromagnetic fields [8-10], whose electric field vector itself traces a chiral trajectory in time, can drive ultrafast electronic currents in molecules with a strongly enantio-sensitive response, whence enabling chiral discrimination that can approach unity [8-10].

Building on these recent proposals [8-10], we have developed analytical and numerical approaches to model the generation of locally chiral fields within *micro-fluidic* environments, wherein tailored optical waveforms interact with liquid-phase samples confined within micro-channels. In this talk, I will discuss how the high enantio-sensitivity demonstrated in free-space strong-field experiments can be transferred to such compact platforms, thereby opening the possibility of integrated photonic devices for efficient chiral sensing in biological media.

Twisted light generates robust many-body states for practical quantum computing

F. J. Rodríguez[1], L. Quiroga[1], N. F. Johnson[2,*]

[1]Departamento de Física, Universidad de Los Andes, Bogotá D.C., Colombia
[2]Physics Department, George Washington University, Washington, DC 20052, USA

***Abstract*—Twisted light carries orbital angular momentum and can drive interaction-enabled excitations of confined electrons that are dark to uniform dipolar probes. We show how this "beyond-Kohn" channel becomes a concrete control primitive for quantum computing: correlation sectors in few-electron quantum dots form a tunable ladder of robust many-body states (robust here in the limited sense of symmetry-protected selection rules and persistent chiral fingerprints; topological gap protection requires $N \geq 3$), and a twisted-light pulse provides fast optical write, read, and scalable addressing. The analytically solvable Calogero limit provides closed-form spectra and matrix elements that translate directly into gate parameters, while screened and Coulomb interactions preserve the same qualitative chiral fingerprints.**

***Index Terms*—twisted light, orbital angular momentum, chiral spectroscopy, quantum dots, correlations, fractional quantum Hall physics, Calogero model, quantum computing**

I. Introduction

Ultrafast chiral spectroscopy is often formulated through polarization and dipole selection rules. Twisted light adds chirality via orbital angular momentum (OAM) and can address internal (relative-motion) excitations that remain dark to spatially uniform dipolar driving. [1]–[3] In magnetized quantum dots, these internal excitations are precisely where strong correlations live: they organize the "magic-number" angular-momentum spectrum and (for larger particle number N) they connect continuously to fractional quantum Hall effect (FQHE) states. [7], [8], [11]

The motivation for quantum computing is twofold.

First, topological many-body states offer a route to hardware-level robustness: a gap and symmetry structure can suppress certain local error channels. [9], [10] Even before true topological order sets in (which requires $N \geq 3$), few-electron "Laughlin-like" correlation sectors provide sharply distinct wavefunctions with different correlation holes and different spatial structure.

Second, twisted light provides an *optical* control layer: the same OAM selection rules that make certain transitions visible also make them *addressable*. This suggests a "photonic control bus" concept in which a spatial light modulator (SLM) steers and sets the beam's OAM so that (i) beam position selects the dot, while (ii) vorticity selects the transition. This optical addressing can, in principle, scale without dense on-chip wiring.

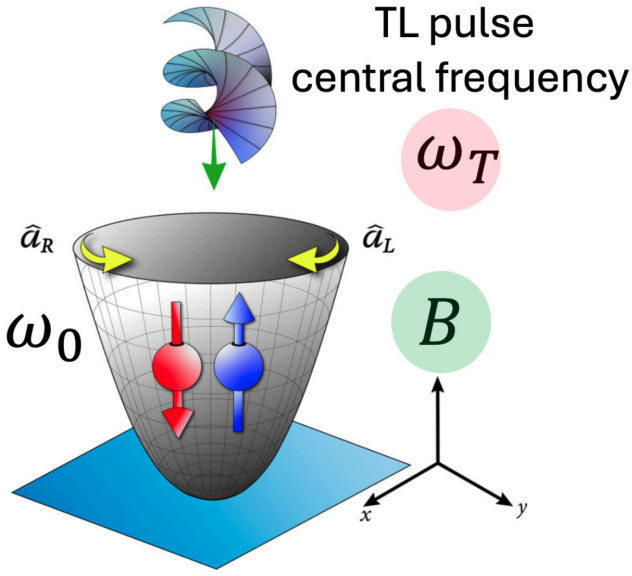

Fig. 1. Schematic representation of the system. A twisted-light (TL) pulse is incident on two interacting charged electrons confined in a two-dimensional harmonic quantum dot, under a perpendicular magnetic field B. The chiral operators $\hat{a}_R$ and $\hat{a}_L$ destroy right- and left-circular orbital quanta of the relative motion, respectively.

The underlying physics channel is established in our recent work on twisted-light chiral spectroscopy of interacting electrons in nanostructures under magnetic field. [4] In that setting, twisted light breaks the (generalized) Kohn theorem by coupling to the *relative* coordinate, opening interaction-enabled "dark" lines that are absent for uniform dipole probes. [4] Here we recast those exact selection rules and matrix elements in the language of quantum information: they define a natural qubit encoding, a universal single-qubit gate set, and a concrete path toward entangling two-qubit gates.

II. Two-electron quantum dot under magnetic field: why $N = 2$ matters

A. Center-of-mass vs. relative motion and Kohn Theorem protection

Two electrons of effective mass m^* in a 2D parabolic confinement (frequency ω_0) under perpendicular magnetic

field B are described by a Hamiltonian that separates exactly into center-of-mass (CM) and relative parts. Defining complex coordinates $z_j = x_j + iy_j$, and

$$Z = \frac{z_1 + z_2}{2}, \qquad z = z_1 - z_2, \tag{1}$$

the non-interacting problem becomes two independent Fock–Darwin oscillators with frequencies

$$\omega = \sqrt{\omega_0^2 + \omega_c^2/4}, \qquad \omega_c = \frac{eB}{m^*}, \tag{2}$$

and (in ladder-operator form) right/left circular modes with $\omega_R = \omega + \omega_c/2$ and $\omega_L = \omega - \omega_c/2$.

The **generalized Kohn theorem** states that a spatially uniform dipolar probe ($l = 0$) excites only the CM degree of freedom in a parabolic dot, independent of interactions. [11] Hence, dipole absorption cannot diagnose the internal correlated spectrum.

Twisted light changes this: because its field has spatial structure (nonzero OAM index l), it can carry multipole components that couple directly to the *relative* coordinate. The resulting absorption therefore fingerprints correlations rather than just the CM mode. [4]

B. Correlation sectors as "Laughlin-like" states at finite N

In the lowest Landau level (LLL) language, the two-electron antisymmetric polynomial is $(z_1 - z_2)$, and the Laughlin-like family is

$$\Psi_q^{(N=2)}(z_1, z_2) = (z_1 - z_2)^q \, e^{-(|z_1|^2 + |z_2|^2)/(4\ell_B^2)}, \qquad q \text{ odd}. \tag{3}$$

For $N = 2$, calling $q = 3$ a "$\nu = 1/3$ Laughlin state" is algebraically correct but physically thin: it has the correct correlation hole but not the topological features (anyon statistics, edge theory, degeneracy) that require $N \geq 3$. [8] Nevertheless, the *ladder* $q = 1 \to 3 \to 5 \to \cdots$ is a sharp, exactly defined set of correlation sectors. This is precisely the structure that twisted light can address selectively.

III. Twisted Light Coupling and Selection Rules

A twisted-light mode is characterized by OAM index l and helicity $\sigma = \pm 1$ (circular polarization). The *total* angular momentum transferred per absorbed photon is $s = l + \sigma$. For the parabolic-dot geometry, the internal (relative-motion) coupling takes a compact ladder-operator form. [4] For example, for the quadrupole-like case ($l = 1$ with $\sigma = +1$, hence $s = 2$) one obtains

$$\hat{H}_{2e}^{(l=1)} = \hbar\omega_R \hat{a}_R^\dagger \hat{a}_R + \hbar\omega_L \hat{a}_L^\dagger \hat{a}_L + V_{e-e}(|\hat{\vec{r}}|) + i\mathcal{E}_0 f(t) \left[e^{-i\omega_T t} \left(\hat{a}_R^\dagger + \hat{a}_L \right)^2 - e^{i\omega_T t} \left(\hat{a}_R + \hat{a}_L^\dagger \right)^2 \right], \tag{4}$$

with a coupling amplitude $\mathcal{E}_0$ (an energy scale) set by the beam amplitude and waist, and $f(t)$ the pulse envelope. This dimensionless light-matter coupling strength is $\mathcal{E}_0 = \frac{q_e A_0 k_r \ell_0^2 \omega_T}{2}$ using the notation of Ref. [4] to which we refer for definition of the parameters. The key point is the selection rule:

$$\Delta|m| = \pm s, \qquad s = l + \sigma, \tag{5}$$

so that, for $l = 1, \sigma = +1$, twisted light drives $\Delta|m| = \pm 2$ transitions between odd-$|m|$ correlation sectors. In the left-chiral convention appropriate to the LLL branch for $B > 0$, the physical states have $m \leq 0$ and we use $|m| = -m$ as a nonnegative sector label; then absorption that *increases* $|m|$ corresponds to $m \to m - s$.

IV. Exactly Solvable Calogero Limit: Closed-Form Spectrum and Matrix Elements

A. Why the Calogero interaction is useful

A generic screened interaction can be modeled as $V(r) \propto 1/r^\eta$ with $1 \leq \eta \leq 2$. [4] The inverse-square limit $\eta = 2$ is special: it yields the Calogero interaction

$$V_{\text{Cal}}(r) = \frac{\hbar^2}{2\mu} \frac{\alpha}{r^2}, \qquad \mu = m^*/2, \tag{6}$$

for which the relative-coordinate eigenstates are analytic. [6], [12] This solvable limit provides a symmetry "skeleton" for the spectroscopy, and the qualitative chiral fingerprints persist for Coulomb-like interactions. [4]

B. Exact eigenstates and energies

For the relative coordinate (r, ϕ), the Calogero ground state at fixed angular momentum m (radial quantum number $n = 0$) is [6], [12]

$$\psi_{0,m}^{(\alpha)}(r, \phi) = \frac{e^{im\phi}}{2\sqrt{\pi}\,\ell_0 \sqrt{\Gamma(\alpha_m + 1)}} \left(\frac{r}{2\ell_0} \right)^{\alpha_m} e^{-r^2/(8\ell_0^2)}, \qquad \alpha_m = \sqrt{m^2 + \alpha}. \tag{7}$$

Here ℓ_0 is the single-particle Fock–Darwin length, $\ell_0 = \sqrt{\hbar/(2m^*\omega)}$ with $\omega = \sqrt{\omega_0^2 + \omega_c^2/4}$, so that a product of single-particle Gaussians $e^{-\sum_i |z_i|^2/(4\ell_0^2)}$ produces the relative Gaussian $e^{-r^2/(8\ell_0^2)}$. The corresponding relative energy spectrum is

$$E_{n,m}^{\text{rel}} = \hbar\omega \, (2n + 1 + \alpha_m) + \frac{m\hbar\omega_c}{2}, \tag{8}$$

with $\omega = \sqrt{\omega_0^2 + \omega_c^2/4}$. For the physically relevant left-chiral branch at $B > 0$ we take $m \leq 0$ and label sectors by $|m| = -m$; since α_m depends on m^2, only the linear cyclotron term distinguishes the two chiralities.

These closed-form expressions are rare in correlated quantum systems. They imply that energy splittings between correlation sectors (e.g. $|m| = 3$ vs. $|m| = 5$) are analytic functions of the interaction parameter α.

C. Exact twisted-light matrix elements

For transitions between $n = 0$ Calogero states labelled by the nonnegative sector index $|m|$ (so we write $m \geq 0$ below) driven by twisted light carrying total angular momentum $s = l + \sigma$, the reduced matrix element takes the closed form [5]

$$\mathcal{M}_{m \to m+s}^{(\alpha)} = \frac{\Gamma\left(\frac{\alpha_m + \alpha_{m+s} + s + 2}{2} \right)}{\sqrt{\Gamma(\alpha_m + 1)\,\Gamma(\alpha_{m+s} + 1)}}. \tag{9}$$

This analytic dependence is not a mathematical luxury: it directly sets the Rabi frequency of a driven qubit and therefore the gate time and fidelity (Section V).

V. Quantum computing mapping: correlation-sector qubit and gates

A. Qubit encoding in correlation sectors

We define a computational basis from two odd-$|m|$ relative-motion sectors. A concrete choice is

$$\begin{aligned} |0\rangle &\equiv |m=-3\rangle \quad (\text{sector } |m|=3), \\ |1\rangle &\equiv |m=-5\rangle \quad (\text{sector } |m|=5). \end{aligned} \tag{10}$$

which are adjacent under the $s=2$ selection rule. Throughout, we make the reasonable assumption that the spin-polarized triplet manifold is selected by magnetic field and Zeeman splitting, so the qubit is encoded purely in the orbital correlation sector. Physically, $|1\rangle$ has a larger correlation hole than $|0\rangle$ and a larger typical relative separation.

This encoding is not (yet) topological: at $N=2$ there is no anyonic braiding, no edge conformal field theory, and no topological degeneracy. The value is instead that these are *interaction-defined* wavefunctions with distinct correlations, and twisted light addresses them selectively.

B. Single-qubit X rotations: twisted-light Rabi oscillations

Near resonance with the $|0\rangle \leftrightarrow |1\rangle$ transition and within the rotating-wave approximation, the driven two-level subspace has an effective Hamiltonian of the form

$$H_{\text{eff}} = \frac{\hbar\delta}{2}\sigma_z + \frac{\hbar\Omega_R}{2}\sigma_x, \tag{11}$$

where δ is the detuning and Ω_R is the Rabi frequency. Up to known geometric prefactors from the optical field, Ω_R is proportional to the Calogero matrix element in Eq. (9):

$$\Omega_R \propto \mathcal{E}_0 \left|\mathcal{M}^{(\alpha)}_{3\to 5}\right|. \tag{12}$$

A resonant pulse of duration t implements

$$R_x(\theta) = \exp\left(-i\frac{\theta}{2}\sigma_x\right), \qquad \theta = \Omega_R t, \tag{13}$$

i.e. an X rotation with angle set by pulse area.

C. Single-qubit Z rotations: phase accumulation

Free evolution for a time τ between pulses produces a Z rotation through the energy splitting between the two chosen sectors:

$$\hbar\omega_{\text{qubit}} = E^{\text{rel}}_{0,-5} - E^{\text{rel}}_{0,-3} = \hbar\omega\left(\alpha_5 - \alpha_3\right) - \hbar\omega_c, \tag{14}$$

i.e.

$$\omega_{\text{qubit}} = \omega\left(\sqrt{25+\alpha} - \sqrt{9+\alpha}\right) - \omega_c. \tag{15}$$

The corresponding phase gate is

$$R_z(\phi) = \exp\left(-i\frac{\phi}{2}\sigma_z\right), \qquad \phi = \omega_{\text{qubit}}\tau. \tag{16}$$

Because Eq. (8) is analytic in α, the qubit frequency is known in closed form.

D. Universality: compiling arbitrary single-qubit unitaries from Rx and Rz

In circuit-model language, a *universal* single-qubit gate set is one from which any unitary $U \in SU(2)$ can be synthesized to arbitrary accuracy. The pair $\{R_x(\theta), R_z(\phi)\}$ is universal: any single-qubit unitary admits an Euler-angle decomposition

$$U = R_z(\phi_3)\, R_x(\theta)\, R_z(\phi_1), \tag{17}$$

so in practice a pulse–wait–pulse sequence suffices to implement an arbitrary rotation. The significance of the $N=2$ TL–Calogero system is that both the pulse-driven angle $\theta = \Omega_R t$ and the free-evolution phase $\phi = \omega_{\text{qubit}}\tau$ are controlled by *analytic* functions of the interaction parameter α (Eqs. (12) and (8)).

E. Readout: twisted-light spectroscopy as a correlation diagnostic

A key conceptual point is that twisted light provides a natural *state-discrimination channel*: the same selection rules that enable writing excitations also yield correlation-sensitive absorption lines. [4] Spectroscopy is a route toward readout by resolving transitions that originate predominantly from $|0\rangle$ or from $|1\rangle$ (e.g. by driving to a higher $|m|$ sector with distinct resonance). A true projective, single-shot measurement still requires a device-specific detector architecture and signal-to-noise analysis. This gives the platform a useful write–diagnose symmetry: prepare with one pulse family, interrogate with the same optical channel.

F. Why the Calogero parameter matters for gate design

The interaction parameter α enters both the spectrum (Eq. (8)) and the matrix element (Eq. (9)). Hence, it acts as a continuous "knob" that tunes:

- the qubit frequency ω_{qubit} (phase gate rate),
- the Rabi frequency Ω_R (pulse time),
- leakage and selectivity, by controlling level spacings to nearby sectors.

In realistic dots, α is not literally an inverse-square coupling, but it can be viewed as an effective parameter capturing screening and confinement; the analytically solvable point provides guidance for robust operating regimes. [4]

G. Leakage and anharmonicity: why an interacting ladder can help gate fidelity

A practical qubit must behave approximately as a two-level system under the applied drive. Here the relevant leakage channels are transitions from $|0\rangle \equiv |m|=3$ and $|1\rangle \equiv |m|=5$ into neighboring sectors such as $|m|=1$ or $|m|=7$. A helpful feature of the Calogero spectrum is that it is *anharmonic* in m because $\alpha_m = \sqrt{m^2+\alpha}$. For a TL mode carrying s units of angular momentum, the transition frequency between $n=0$ sectors is

$$\begin{aligned} \omega_{|m|\to|m|+s} &= \frac{E^{\text{rel}}_{0,-(|m|+s)} - E^{\text{rel}}_{0,-|m|}}{\hbar} \\ &= \omega\left(\alpha_{|m|+s} - \alpha_{|m|}\right) - \frac{s\omega_c}{2}. \end{aligned} \tag{18}$$

TABLE I
TWISTED LIGHT AS A CONTROL LAYER FOR CORRELATION-SECTOR QUBITS.

Role	Physical action	Quantum-information meaning
WRITE	Resonant TL pulse (choose l, σ, pulse area)	Implements $R_x(\theta)$ between correlation sectors.
READ	TL spectroscopy of correlation-sensitive lines	Distinguishes correlation sectors; projects onto $\|0\rangle$ or $\|1\rangle$.
SCALE	SLM steering + vorticity selection	Optical addressing of many dots without dense wiring; mode selectivity sets $\Delta\|m\|$.

For the qubit choice in Eq. (10) with $s = 2$, the *anharmonicity* that controls off-resonant leakage to $|m| = 7$ is

$$\mathcal{A} \equiv \omega_{5\to7} - \omega_{3\to5} = \omega\left[(\alpha_7 - \alpha_5) - (\alpha_5 - \alpha_3)\right]. \quad (19)$$

Because $\mathcal{A}$ is an analytic function of α, the solvable limit provides a direct way to identify parameter regimes where $\mathcal{A}$ is large compared to the Rabi rate Ω_R, suppressing leakage. This is the same "anharmonicity engineering" logic used in transmons, but here it arises from *correlations* rather than Josephson physics.

VI. TOWARD A PHOTONIC CONTROL BUS AND MULTI-QUBIT OPERATIONS

A. Write, read, scale: a minimal control narrative

Table I summarizes the operational viewpoint suggested by the physics above.

B. Addressability: diffraction limit and near-field requirements at THz frequencies

The "SCALE" line in Table I intentionally highlights an attractive idea: a spatial light modulator (SLM) can steer a beam to select a dot, while the OAM/polarization choice selects $\Delta|m|$ and therefore the internal transition. However, for the intraband orbital transitions emphasized here, the natural frequencies are typically in the THz range (Sec. IX), corresponding to free-space wavelengths $\lambda \sim 0.3$–3 mm. A diffraction-limited far-field spot size is therefore orders of magnitude larger than typical lithographic dot spacings (tens to hundreds of nm, or $\sim \mu$m-scale pitches in larger arrays). This mismatch is the central scalability challenge for the "photonic control bus" vision and should be stated explicitly.

There are several physically plausible routes forward, all of which fit naturally into the META (metamaterials/photonics) scope: (i) *Proof-of-principle sparse arrays*: begin with isolated dots separated by tens–hundreds of μm so that a THz focus can address them individually. (ii) *On-chip near-field localization*: integrate each dot with a local THz antenna, resonator, or metasurface element that converts an incident beam into a tightly confined near field at the dot location (subwavelength confinement is routine in resonant near-field structures even when λ is macroscopic). (iii) *Waveguide delivery*: route THz/mid-IR power on chip to selected sites, using the optical beam mainly as a global clock or for frequency selectivity. (iv) *Frequency-upshifted designs*: use stronger confinement and/or different materials to push the relevant orbital splittings into the mid-IR, where λ is ~ 10 μm and far-field addressing becomes less extreme.

In short: mode selectivity via OAM is a genuine asset, but *spatial* selectivity at THz wavelengths will likely require near-field or structured-photonic engineering rather than simple far-field focusing.

C. A concrete two-qubit entangling gate mechanism

A scalable architecture requires at least one entangling two-qubit gate. For two nearby dots A and B, the inter-dot Coulomb interaction depends on the charge distribution in each dot. Because different correlation sectors have different spatial extent, the interaction energy is state dependent. A clean analytic diagnostic of this size difference is the exact Calogero expectation value [5]

$$\langle r^2\rangle_{m,\alpha} = 4\ell_0^2(\alpha_m + 1), \qquad \alpha_m = \sqrt{m^2 + \alpha}. \quad (20)$$

This motivates an effective ZZ coupling model:

$$H_{ZZ} = \frac{\hbar J}{4}\,\sigma_z^{(A)}\sigma_z^{(B)}, \qquad J \equiv \frac{U_{11} + U_{00} - U_{10} - U_{01}}{\hbar}, \quad (21)$$

where U_{ij} is the electrostatic energy when dot A is in $|i\rangle$ and dot B in $|j\rangle$.

1) Closed-form estimate of J from a long-distance multipole expansion: Equation (21) defines the entangling rate J, but it is useful to have an explicit estimate. Assume two *non-overlapping* dots whose centers are separated by an in-plane distance D (typically $D \sim 200$–500 nm in gated devices [15]). Let the electron positions in dot A be $\mathbf{r}_{A,1} = \mathbf{R}_A + \mathbf{r}_A/2$ and $\mathbf{r}_{A,2} = \mathbf{R}_A - \mathbf{r}_A/2$, where $\mathbf{r}_A$ is the internal (relative) coordinate; similarly for dot B. The inter-dot interaction is then

$$V_{AB} = \frac{e^2}{4\pi\varepsilon}\sum_{a=1}^{2}\sum_{b=1}^{2}\frac{1}{|\mathbf{D} + \mathbf{r}_{A,a} - \mathbf{r}_{B,b}|}, \qquad \mathbf{D} \equiv \mathbf{R}_B - \mathbf{R}_A. \quad (22)$$

For $D \gg \sqrt{\langle r^2\rangle}$ one may expand $1/|\mathbf{D} + \boldsymbol{\delta}|$ in powers of $\boldsymbol{\delta}/D$ and then average over the rotationally symmetric internal states (for which $\langle\mathbf{r}\rangle = \mathbf{0}$). A derivation can be obtained by Taylor expanding $1/|\mathbf{D} + \boldsymbol{\delta}|$ and using isotropic angular averages; equivalently, it is the leading quadrupole–quadrupole contribution for planar charge distributions. The result is:

$$U_{ij} \approx \frac{e^2}{4\pi\varepsilon}\left[\frac{4}{D} + \frac{\langle r^2\rangle_i + \langle r^2\rangle_j}{4D^3} + \frac{9}{64}\frac{\langle r^2\rangle_i\,\langle r^2\rangle_j}{D^5} + \cdots\right], \quad (23)$$

where $\langle r^2\rangle_i$ denotes the internal size in dot A when it is in $|i\rangle$, and $\langle r^2\rangle_j$ is the corresponding size in dot B. The D^{-3} term produces only *single-qubit* frequency shifts (it is additive in i and j and cancels in $U_{11} + U_{00} - U_{10} - U_{01}$). The leading *entangling* contribution is the D^{-5} cross-term, giving

$$J \approx \frac{1}{\hbar}\frac{e^2}{4\pi\varepsilon}\frac{9}{64}\frac{\left(\Delta\langle r^2\rangle\right)^2}{D^5}, \qquad \Delta\langle r^2\rangle \equiv \langle r^2\rangle_1 - \langle r^2\rangle_0. \quad (24)$$

Using the exact Calogero size formula in Eq. (20), $\Delta\langle r^2\rangle = 4\ell_0^2(\alpha_5 - \alpha_3)$, this becomes

$$J \approx \frac{1}{\hbar}\frac{e^2}{4\pi\varepsilon}\frac{9}{4}\frac{\ell_0^4(\alpha_5-\alpha_3)^2}{D^5}. \tag{25}$$

For representative GaAs parameters ($\varepsilon = \kappa\varepsilon_0$ with $\kappa \simeq 12.9$ and $\ell_0 \simeq 10$ nm; Sec. IX) and $\alpha_5 - \alpha_3 \simeq 2$ (noninteracting limit), Eq. (24) gives $J/(2\pi) \sim 0.08$–8 MHz for $D = 500$–200 nm, corresponding to a controlled-phase time $t_{\rm CZ} = \pi/J \sim 6$ μs–70 ns. The steep D^{-5} scaling makes this gate *highly tunable*: bringing dots closer or using a larger effective size difference (larger $\Delta\langle r^2\rangle$) rapidly enhances J.

Free evolution for time $t = \pi/J$ implements a controlled-phase (CZ-equivalent) gate up to single-qubit Z rotations.

This mechanism is not topological—it is analogous to capacitive ZZ coupling in other platforms—but it is concrete and testable, and its distinctive feature is that the basis states are *correlation sectors* written and read optically by twisted light.

D. Coupled $N = 2$ dots as a two-qubit module: analytic interdot entanglement and an XY gate channel

a) Connecting single-dot and coupled-dot "magic-number" transitions.: In an isolated, spin-polarized $N = 2$ parabolic dot, the low-energy branch is organized by odd relative angular momenta $|m| = 1, 3, 5, \ldots$; as the magnetic field is increased the ground state typically steps through this odd-$|m|$ ladder (the $N = 2$ analogue of the well-known $N = 3$ magic-number sequence $L = 3k$). For two dots, the uncoupled spectrum is the direct product $|m_A, m_B\rangle$ of the *same* single-dot ladders. Coulomb-range interdot interactions then reshape these inherited "magic" sectors by creating resonant anticrossings and entangled eigenstates when two product states become nearly degenerate. The Benjamin–Johnson selection rule makes this concrete: the dominant mixing occurs between $|m, m+2\rangle$ and $|m+2, m\rangle$, i.e. the same $\Delta|m| = 2$ step that twisted light addresses within a single dot. In this sense, coupled-dot "magic-number transitions" are not a separate phenomenon: they are the single-dot magic ladder *promoted* to a two-site module, where interdot interactions convert near-degeneracies into exchange-like (XY) entangling dynamics.

The capacitive ZZ mechanism in Sec. VI-C1 is the simplest entangling interaction to model, but it is not the only one available when two dots are brought into Coulomb range. In fact, a qualitatively different entangling channel—a resonant, exchange-like XY *coupling* between $|01\rangle$ and $|10\rangle$—appears already in early analytic work on coupled few-electron dots with $N = 2$ electrons *per dot*. This is directly relevant to the present proposal because our qubit basis states $|0\rangle \equiv ||m| = 3\rangle$ and $|1\rangle \equiv ||m| = 5\rangle$ differ by $\Delta|m| = 2$, exactly the "quantum" transferred between dots in those analytic coupled-dot solutions.

1) Benjamin–Johnson multiple-dot model: entanglement without tunneling: Benjamin and Johnson introduced an analytically solvable model of P colinear, two-dimensional quantum dots, each containing two electrons, arranged vertically with interdot separation s. [22] Interdot tunneling is neglected; adjacent dots are coupled purely by the two-body electron–electron interaction, an "optical wiring" channel that can exist even in the absence of any single-particle tunneling term. [22] They take an inverse-square interaction (Calogero form) both within each dot and between adjacent dots,

$$V_{\rm intra} = \sum_{a=1}^{P} \frac{\beta}{\left|\mathbf{r}_{a,1} - \mathbf{r}_{a,2}\right|^2}, \tag{26}$$

$$V_{\rm inter} = \sum_{a=2}^{P}\sum_{i,j=1}^{2} \frac{\beta}{\left|\mathbf{r}_{a,i} - \mathbf{r}_{a-1,j}\right|^2 + s^2}, \tag{27}$$

and then Taylor-expand $V_{\rm inter}$ under the physically transparent assumption that typical in-plane separations are smaller than s. [22] To order Pr^2/s^4 the coupled-dot problem remains exactly solvable; higher-order terms (schematically Pr^4/s^6) are then treated by analytic perturbation theory. [22]

For $P = 2$ identical dots, the low-lying eigenstates can be labeled as direct products $|m_1, m_2\rangle$, where m_a is the relative angular momentum quantum number of the two-electron state in dot a. [22] At the exactly solvable order ($\propto r^2/s^4$), the pair $|m, m+2\rangle$ is degenerate with $|m+2, m\rangle$. The next-order interdot perturbation then mixes these states *selectively*: in the nearly-degenerate subspace, the perturbation only connects $|m_a, m_b\rangle$ to $|m_c, m_d\rangle$ if $m_a - m_c = m_d - m_b = 0$ or ± 2. [22] As a result, the relevant eigenstates are entangled superpositions of the form

$$|\Psi_\pm\rangle = \frac{1}{\sqrt{2}}\Big(\,|m+2, m\rangle \pm |m, m+2\rangle\,\Big) \tag{28}$$

(identical dots, on resonance) and for unequal dot sizes (weakly nondegenerate case) they become $(p\,|m+2, m\rangle + q\,|m, m+2\rangle)$ with $p \neq q$ set by the detuning. [22] Benjamin and Johnson show that these entangled states can become *ground states* over finite B-field windows, and interpret their formation as a resonance phenomenon closely analogous to Förster energy transfer; in an array, the corresponding "Frenkel exciton" can propagate and form an exciton band. [22]

2) Mapping to the correlation-sector qubit: an iSWAP/$\sqrt{i\text{SWAP}}$ entangler: This structure maps almost one-to-one onto the present qubit encoding. Take two dots A, B with local basis $|0\rangle \equiv ||m| = 3\rangle$ and $|1\rangle \equiv ||m| = 5\rangle$. Then the two-qubit states

$$|01\rangle \equiv |3, 5\rangle\,, \qquad |10\rangle \equiv |5, 3\rangle \tag{29}$$

are precisely the $(m, m+2)$ and $(m+2, m)$ pair with $m = 3$ in Eq. (28). The coupled-dot perturbation therefore generates an effective *exchange* Hamiltonian in the $\{|01\rangle\,, |10\rangle\}$ subspace:

$$\begin{aligned} H_{XY} &= \hbar J_{\rm ex}\Big(\,|01\rangle\langle 10| + |10\rangle\langle 01|\,\Big) \\ &= \frac{\hbar J_{\rm ex}}{2}\Big(\sigma_x^{(A)}\sigma_x^{(B)} + \sigma_y^{(A)}\sigma_y^{(B)}\Big), \end{aligned} \tag{30}$$

with $J_{\rm ex}$ set by the relevant interdot matrix element (the same perturbative order that produces the entangled eigenstates). On exact resonance (identical dots), the eigenstates are the Bell

states $|\Psi_\pm\rangle = (|01\rangle \pm |10\rangle)/\sqrt{2}$ with splitting $2\hbar J_{\rm ex}$. Free evolution under H_{XY} implements an entangling gate:

$$U(t)\,|01\rangle = \cos(J_{\rm ex}t)\,|01\rangle - i\sin(J_{\rm ex}t)\,|10\rangle\,, \tag{31}$$
$$U(t)\,|10\rangle = \cos(J_{\rm ex}t)\,|10\rangle - i\sin(J_{\rm ex}t)\,|01\rangle\,. \tag{32}$$

Thus $t = \pi/(2J_{\rm ex})$ yields an iSWAP (up to single-qubit phases), and $t = \pi/(4J_{\rm ex})$ yields a $\sqrt{i\rm SWAP}$ which is maximally entangling. Crucially, the same coupled-dot analysis provides a *control knob*: detuning the dots (e.g. via slightly different confinement strengths) moves the $|01\rangle$ and $|10\rangle$ energies apart, suppressing the mixing (the "quadratic Stark" analog in Ref. [22]). In quantum-information language, this is an on/off switch for the XY entangler, complementary to the always-on but tunable ZZ coupling of Sec. VI-C1.

3) Johnson–Benjamin double-layer model: analytic four-electron precursor to bilayer FQHE: A closely related analytic benchmark is provided by Johnson and Benjamin's exactly solvable *double-layer* (vertical) model with two electrons per layer. [23] They consider electrons confined in each layer by a 2D parabolic potential in a perpendicular magnetic field, neglect inter-layer tunneling, and include both intra- and inter-layer inverse-square interactions. By introducing center-of-mass and relative coordinates within each layer and between the layer centers of mass, and then Taylor-expanding the inter-layer interaction under the assumption that the typical in-plane separation is less than the layer separation s, the Hamiltonian becomes exactly solvable once the expansion is truncated at quadratic order. [23] In particular, truncation at the second term yields an additive constant plus a sum of four decoupled solvable Hamiltonians,

$$\begin{aligned} H &= \frac{4\beta}{s^2} + \sum_{i=1}^{4} H_i(u_i, q_i), \\ \omega_1 &= \omega_0, \quad \omega_2 = \omega_3 = \left(\omega_0^2 - \frac{4\beta}{m^* s^4}\right)^{1/2}, \\ \omega_4 &= \left(\omega_0^2 - \frac{8\beta}{m^* s^4}\right)^{1/2}. \end{aligned} \tag{33}$$

where H_1 and H_4 are single-particle Fock–Darwin problems and H_2, H_3 are two-body (Calogero) problems for the intra-layer relative coordinates. [23] The resulting ground-state sequence in magnetic field is $|m_2, m_3\rangle = |1,1\rangle, |3,3\rangle, |5,5\rangle, \ldots$ with odd $m_{2,3}$ set by antisymmetry within each layer. [23] Johnson and Benjamin further define an effective small-N filling factor per layer $\nu_a \simeq 1/m_a$, giving a total sequence $\nu = \nu_1 + \nu_2 = 2, 2/3, 2/5, \ldots$ that is consistent with the observed bilayer fractions for sufficiently separated layers. [23] They also emphasize that the analytically obtained correlated wavefunctions differ fundamentally from the standard Jastrow/Greek–Roman (mmn) forms used in bilayer FQHE modeling. [23]

For the present proposal, Eq. (33) is useful in two ways. First, it provides a closed-form dependence of mode frequencies on the geometric separation s, making it an analytic "calibration model" for how vertical coupling renormalizes energy scales (and hence how interdot coupling shifts qubit splittings and detunings). Second, it highlights a genuinely multi-dot feature absent in the single-dot problem: an additional collective coordinate (the relative coordinate between layer centers of mass) with its own tunable frequency $\omega_4(s)$. In an engineered device, this degree of freedom can be viewed as a candidate mediator mode for coupling qubits beyond pure static ZZ shifts.

4) How this strengthens the twisted-light quantum-computing proposal: Taken together, these two analytic coupled-dot benchmarks strengthen and extend the QC narrative in three concrete ways:

(a) **They provide an explicit, symmetry-selective XY entangler for the same $\Delta|m| = 2$ qubit ladder.** The $|3,5\rangle \leftrightarrow |5,3\rangle$ mixing predicted for coupled $N = 2$ dots is precisely the exchange channel needed for iSWAP-type two-qubit gates, complementing the capacitive ZZ gate in Sec. VI-C1.

(b) **They suggest an "exciton transport" architecture for dot arrays.** In the Benjamin–Johnson picture, a localized change of m on one dot can resonantly propagate as a Frenkel exciton band in a chain. [22] In our language, this is propagation of a local correlation-sector excitation. Twisted light provides the natural way to *write* such an excitation on a selected dot and *read* it out spectroscopically at another location.

(c) **They supply analytic s-dependence and mode structure for vertically coupled modules.** The Johnson–Benjamin decomposition makes clear which collective coordinates are activated by vertical coupling and how their frequencies scale with s. [23] This is exactly the kind of analytic handle needed to design detuning-based on/off control of interdot exchange and to anticipate extra spectator modes that may need to be dynamically decoupled.

In short: the coupled-dot literature already contains an analytic demonstration that two $N = 2$ dots can generate strong, interaction-mediated *entangled* eigenstates without tunneling. Twisted light adds the missing ingredient for quantum information: a structured, sector-selective optical handle to coherently address the internal ladders and thereby turn those coupled-dot correlations into a programmable gate set.

E. Comparison with established qubit platforms

The correlation-sector qubit shares features with several established platforms while introducing genuinely new elements: (i) an interacting many-body basis, and (ii) structured-light control of internal motion. Table II provides a compact comparison.

VII. Noise channels and robustness considerations

Because the encoding in Eq. (10) uses different *charge-correlation* sectors, the dominant decoherence mechanisms are expected to resemble those of "charge-like" qubits rather than pure spin qubits. This does not invalidate the platform; it clarifies what must be engineered and what "robustness" realistically means at the $N = 2$ stage.

TABLE II
CONTEXT: CORRELATION-SECTOR QUBIT COMPARED TO COMMON PLATFORMS (QUALITATIVE).

Feature	$N = 2$ **correlation-sector qubit**	**Superconducting transmon**	**Trapped ion**
Basis states	Relative-motion sectors $\|m\| = 3, 5$ (correlations)	Weakly anharmonic oscillator levels	Hyperfine/optical atomic levels
Single-qubit drive	Twisted light pulse (l, σ)	Microwave pulse	Laser pulse
Native X gate	TL Rabi oscillation (Eq. (13))	Microwave Rabi	Raman/direct Rabi
Native Z gate	Free evolution (Eq. (16))	Detuning/flux bias	Free evolution
Anharmonicity	Correlation-induced $\alpha_m = \sqrt{m^2 + \alpha}$	Josephson nonlinearity	Atomic structure
Analytic gate parameters	**Exact** in Calogero limit (Eqs. (8), (9))	Typically calibrated numerically	Exact (atomic theory)
Two-qubit coupling idea	State-dependent Coulomb ZZ (Eq. (21))	Capacitive/inductive coupling	Shared motional modes
Topological upgrade path	$N \geq 3$ FQHE droplets and quasiholes	None intrinsic	None intrinsic

A. Control errors: pulse area, detuning, and mode purity

Twisted-light gates rely on resonant driving, so standard coherent-control considerations apply: (i) pulse area errors ($\theta \neq \Omega_R t$), (ii) detuning errors ($\delta \neq 0$ in Eq. (11)), and (iii) imperfect OAM/helicity mode purity (admixture of unwanted s values). The advantage of the analytic framework is that these errors can be propagated through closed-form expressions for the gate unitary and (in principle) optimized using composite pulses and robust control sequences, without relying purely on black-box calibration.

B. Environmental decoherence: phonons and electrostatic noise

In a semiconductor dot, coupling to acoustic phonons and to charge noise in nearby gates and impurities will induce relaxation and dephasing between correlation sectors. Since $|0\rangle$ and $|1\rangle$ differ in spatial extent, they couple differently to fluctuating electrostatic potentials, producing dephasing analogous to that of charge qubits. A practical strategy is therefore to operate in regimes where: (i) the energy splitting $\hbar\omega_{\text{qubit}}$ is large compared to $k_B T$ (suppressing thermal mixing), and (ii) the relevant transitions are well separated from leakage channels (large anharmonicity $\mathcal{A}$ in Eq. (19)).

C. What "robust" can mean in this context

At $N = 2$, "robust" should not be interpreted as topological fault tolerance. Instead, it refers to two experimentally useful features already demonstrated in the spectroscopy setting: (i) twisted light targets internal excitations that are symmetry forbidden to dipole probes (a clean signal channel), and (ii) the qualitative chiral fingerprints persist for a range of interaction forms from screened to Coulomb. [4] These properties motivate the $N = 2$ dot as a *calibration-grade* gate primitive and as a stepping stone to $N \geq 3$ droplets where true topological protection may be approached.

D. Decoherence: a quantitative dephasing estimate and the key engineering challenge

A realistic assessment must confront decoherence. Our encoding uses *orbital correlation sectors* ($|m| = 3$ and $|m| = 5$), so it is "charge-like" in the sense that the energy depends on the spatial distribution. However, a definite-m state in an ideal circular dot is *rotationally symmetric* and satisfies $\langle \mathbf{r} \rangle = \mathbf{0}$, so it carries *no permanent in-plane dipole moment*. As a result, spatially uniform electric-field noise couples primarily to the center-of-mass (Kohn) mode rather than directly dephasing the internal qubit. The leading internal sensitivity is instead *quadrupolar*: fluctuations of the confining curvature (or equivalently, field gradients) shift the two qubit levels differently because $\langle r^2 \rangle$ differs.

A simple analytic estimate follows from a "curvature-noise" model in which gate-voltage noise induces a small fluctuation $\delta\omega_0$ of the bare harmonic confinement. Since $\omega^2 = \omega_0^2 + \omega_c^2/4$, the relative Hamiltonian contains a term $(\mu\omega^2/2)\, r^2$ with $\partial H/\partial\omega_0 = \mu\omega_0 r^2$. By the Hellmann–Feynman theorem,

$$\frac{\partial E_m}{\partial \omega_0} = \mu\omega_0 \langle r^2 \rangle_{m,\alpha}, \qquad \Rightarrow \qquad \frac{\partial \omega_{\text{qubit}}}{\partial \omega_0} = \frac{\mu\omega_0}{\hbar} \Delta\langle r^2 \rangle, \tag{34}$$

with $\Delta\langle r^2 \rangle \equiv \langle r^2 \rangle_{|m|=5} - \langle r^2 \rangle_{|m|=3} = 4\ell_0^2(\alpha_5 - \alpha_3)$ from Eq. (20). For quasi-static Gaussian noise with rms amplitude σ_{ω_0}, the rms fluctuation of the qubit splitting is

$$\sigma_{\omega_{\text{qubit}}} = \left| \frac{\partial \omega_{\text{qubit}}}{\partial \omega_0} \right| \sigma_{\omega_0} = \frac{\mu\omega_0}{\hbar} \Delta\langle r^2 \rangle\, \sigma_{\omega_0}, \qquad T_2^* \sim \sigma_{\omega_{\text{qubit}}}^{-1}. \tag{35}$$

Equation (35) cleanly identifies the levers that improve dephasing: suppress curvature noise (σ_{ω_0}), reduce sensitivity via large magnetic field ($\omega_0/\omega \ll 1$ so gate voltages weakly perturb ω), or engineer a smaller $\Delta\langle r^2 \rangle$ (at the cost of reduced J in Sec. VI-C1).

To connect with experiment, charge qubits in semiconductor double quantum dots typically exhibit T_2^* in the ns range

when operated away from optimized "sweet spots" (e.g., a decoherence time $\sim$ 1 ns in early GaAs charge-qubit oscillations [19], and a maximum coherence time $\sim$ 7 ns at the charge-degeneracy point consistent with a $1/f$ noise model [20]). An important mitigating feature of our *single-dot, circular* encoding is that the internal qubit is not a dipole qubit; in an ideal harmonic dot the leading charge-noise coupling can be strongly suppressed [21]. Nevertheless, the message for feasibility is clear: unless the device is engineered to reduce effective curvature noise (material choice, screening, symmetric operation, and/or dynamical decoupling enabled by fast optical control), decoherence is likely to be the dominant constraint for gate fidelity.

Finally, it is useful to express a minimal "coherent-control" requirement in terms of the Rabi frequency. From Eqs. (11) and (12), a resonant pulse drives oscillations at $\Omega_R = 2\mathcal{E}_0|M^{(\alpha)}_{3\to5}|/\hbar$ (up to envelope factors). A necessary condition for high-contrast Rabi oscillations is therefore

$$\Omega_R T_2^* \gg 1, \tag{36}$$

while two-qubit gates require $J T_2^* \gg 1$. Equations (24)–(36) provide a compact quantitative checklist: *fast optical control is available in principle*, but turning the correlation-sector qubit into a high-fidelity quantum-computing primitive hinges on suppressing (or refocusing) the remaining quadrupolar charge-noise channels.

VIII. Roadmap: from N=2 gate primitives to topological FQHE control

The $N = 2$ system is simultaneously (i) a fully analytic gate primitive and (ii) a stepping stone toward genuinely topological FQHE degrees of freedom at $N \geq 3$.

A. What carries over robustly to larger N

Three qualitative features are expected to generalize:

1) **OAM selection rules are symmetry-protected.** The angular-momentum transfer $s = l + \sigma$ implies $\Delta L = \pm s$ for the many-body state, providing a tunable ladder between total-angular-momentum sectors.
2) **Kohn protection remains the baseline.** Spatially uniform dipole probes ($l = 0$) excite only CM motion, remaining blind to correlations in a parabolic dot. Twisted light is therefore the minimal optical route to correlation spectroscopy.
3) **Line strengths are correlation diagnostics.** The intensity of a TL-driven transition depends on interaction-defined eigenstates (pseudopotentials), so spectroscopy directly probes correlation content. [4]

B. Quantitative $N = 3$ Calogero scaffold: $1/N$ expansion and the magic-number ladder

For $N = 3$ the pairwise inverse-square interaction

$$V^{(N=3)}_{\rm Cal} = \frac{\hbar^2\beta^2}{m^*}\sum_{i<j}\frac{1}{r_{ij}^2}, \tag{37}$$

admits a semi-analytic spectrum in a magnetic field via the resummed $1/N$ expansion of Ref. [12] (see also Ref. [6]). The center-of-mass still decouples exactly in a parabolic dot, so the relevant spectrum organizes by the *internal* total angular momentum. To avoid confusion with the optical OAM index l, we denote the many-body angular-momentum sector by $L \geq 0$ (standard FQHE convention); for $B > 0$ this corresponds to the low-energy left-chiral branch of the dot spectrum.

In the notation of Ref. [12], the internal energies can be written in the compact form

$$E_{L;\,n_u,n_\triangle,m_\triangle} \approx \hbar\omega\Big[\sqrt{L^2+6\beta^2}+\delta(L;n_\triangle,m_\triangle) + 2n_u + 1\Big] - \frac{\hbar\omega_c}{2}L, \tag{38}$$

where $\omega = \sqrt{\omega_0^2+\omega_c^2/4}$, n_u counts the symmetric "breathing" mode, and $(n_\triangle, m_\triangle)$ label an effective 2D "shape" mode of the triangle. The shift $\delta(L; n_\triangle, m_\triangle)$ is an $\mathcal{O}(1)$ quantity fixed by a simple transcendental equation (given explicitly in Ref. [12]) and is easily obtained numerically. Ref. [12] also provides explicit approximate eigenfunctions in the normal-mode coordinates, so TL matrix elements reduce to standard oscillator integrals. Equation (38) is therefore a *design-level* scaffold for $N = 3$: it gives transition frequencies, anharmonicities, and parameter trends without full diagonalization.

a) Magic-number ladder and the $L = 3k$ sequence.: For three *spin-polarized* fermions, Ref. [12] finds that the ground state progresses through the "magic" angular momenta

$$L_{\rm gs}(B) \in \{3, 6, 9, 12, \dots\}, \tag{39}$$

as the magnetic field is increased, reproducing the well-known incompressible/magic-number phenomenology of three-electron dots and agreeing qualitatively with Coulomb calculations. [13] In particular, the $q = 3$ Laughlin precursor sits at $L = 9$, and the adjacent $L = 12$ manifold is precisely where the single-quasihole and the $\Delta L = 3$ edge excitations live.

b) Why an $s = 3$ twisted-light pulse is special at $N = 3$.: A quasihole at the origin is created by

$$\hat{Q}_{\rm qh} = \prod_{i=1}^{3} z_i \equiv e_3(z_1, z_2, z_3), \tag{40}$$

which raises total angular momentum by $\Delta L = +3$. A twisted-light mode with $s = l + \sigma = 3$ therefore targets the correct sector *directly* ($L = 9 \to 12$). In the LLL-projected language, the simplest $s = 3$ optical multipole is the power-sum symmetric polynomial

$$p_3(z) \equiv \sum_{i=1}^{3} z_i^3. \tag{41}$$

Newton's identity for three variables,

$$p_3 = e_1^3 - 3e_1e_2 + 3e_3, \tag{42}$$

makes the physics transparent: an $s = 3$ drive necessarily contains a *direct quasihole component* ($\propto e_3$) plus components

TABLE III
KEY GATE-LEVEL QUANTITIES AND HOW TO OBTAIN THEM IN THE ANALYTIC CALOGERO MODEL VS. A REALISTIC COULOMB/SCREENED DOT. THE POINT IS NOT THAT CALOGERO MUST BE QUANTITATIVELY EXACT, BUT THAT ALL REQUIRED PARAMETERS ARE EITHER CLOSED-FORM (CALOGERO) OR DIRECTLY CALIBRATABLE (DEVICE).

Quantity	Calogero ($1/r^2$)	Coulomb/screened ($1/r$)
ω_{qubit}	Eq. (14)	TL spectroscopy (line positions)
$\mathcal{A}$	Eq. (19)	ED / radial solve + spectroscopy
$M_{3\to5}$	Eq. (9)	ED / radial solve (wavefunctions)
Ω_R	Eqs. (11) and (12)	Rabi calibration (pulse area)
$\langle r^2\rangle_m$	Eq. (20)	ED / radial solve
J	Eq. (24)	multipole + ED / calibration

in the other $\Delta L = 3$ basis states (e_1^3 and e_1e_2). Interactions select the eigenbasis within the $L \to L+3$ manifold, so the experimentally relevant question becomes quantitative: what is the overlap of the TL-driven superposition with the quasihole eigenstate, and can it be enhanced by spectral selectivity and pulse shaping?

C. Realistic interactions vs. Calogero: what must be validated quantitatively

The Calogero model is powerful because it yields exact closed-form energies and matrix elements, but a quantum-computing proposal ultimately lives or dies on quantitative device-level parameters: the qubit splitting ω_{qubit}, the Rabi rates Ω_R and leakage rates set by the anharmonicity $\mathcal{A}$, and the two-qubit coupling J. For generic Coulomb or screened interactions, the *qualitative* chiral fingerprints and selection rules can persist [4], but high-fidelity pulses require that the key quantities be either (i) close enough to Calogero predictions, or (ii) experimentally calibratable.

A practical viewpoint is that the Calogero analytics should be used as an *initial design model* and as a way to identify which transitions are symmetry-allowed/forbidden and which sectors are targeted by a given (l,σ). Then, for a given device with a realistic interaction, one performs a short spectroscopic calibration using the same TL control channel: the transition frequencies directly determine ω_{qubit} and $\mathcal{A}$, while Rabi oscillations determine Ω_R for the chosen pulse shape. This is completely standard in other qubit modalities (superconducting circuits, trapped ions), and it reduces the burden on the Calogero-to-Coulomb *quantitative* match.

To make this explicit, Table III lists the minimal set of quantities that must be known (or measured) to run gates, together with the closed-form Calogero expressions already derived in this paper and the corresponding "how to obtain" route for a Coulomb/screened dot. For $N = 2$, the Coulomb/screened problem is still one-dimensional in the relative radius r for each m, so all entries can be produced numerically by straightforward radial diagonalization (or by exact diagonalization in a truncated Fock–Darwin basis) without the exponential complexity of many-body FQHE.

The remaining quantitative question is *fidelity transfer*: how close must the Calogero-designed pulse be to the Coulomb-optimized pulse to achieve high fidelity? Because our protocol is intrinsically spectroscopic, the most conservative answer is: it need not be close at all, provided the device is stable enough that ω_{qubit} and Ω_R can be calibrated and remain stationary over the experiment. The more optimistic possibility—to be tested numerically for representative device geometries—is that the relevant quantities (especially the selection-rule structure and relative strengths of the dominant matrix elements) vary smoothly across repulsive central interactions, so that Calogero provides not just qualitative guidance but a quantitatively good first guess.

D. How the Gambardella $\mathrm{SU}(1,1)$ machinery can be leveraged for this project

A central practical obstacle in scaling beyond the analytically solvable $N = 2$ case is to retain an operator-level understanding of *which* many-body sectors are bright/dark under twisted light and how the relevant transition frequencies and anharmonicities scale with interaction strength. A powerful (and underused in the quantum-dot literature) route is to exploit the fact that inverse-square interactions belong to a broad class of Hamiltonians whose *dynamical group* is $\mathrm{SU}(1,1)$.

Gambardella showed that for N interacting particles in any spatial dimension, after eliminating the center of mass, the internal Hamiltonian with a quadratic (harmonic) term plus an additional translation-invariant potential that is homogeneous of degree -2 has $\mathrm{SU}(1,1)$ as a spectrum-generating algebra: the Casimir eigenvalue fixes the ladder spectrum, and a family of eigenfunctions can be generated algebraically by raising operators acting on the ground state. [14] This includes (as special cases) Calogero–Sutherland-type inverse-square forces and also certain three-body and higher-body homogeneous interactions. [14]

a) Why this is directly relevant to parabolic quantum dots.: Even though quantum dots are defined by a *one-body* parabolic confinement $V_{\mathrm{dot}} = \frac{1}{2}m^*\omega_0^2\sum_i r_i^2$ rather than an explicit pair potential, the identity

$$\sum_{i=1}^{N} r_i^2 = NR^2 + \frac{1}{N}\sum_{i<j} r_{ij}^2, \qquad R \equiv \frac{1}{N}\sum_{i=1}^{N} r_i, \tag{43}$$

implies that *after* center-of-mass separation the internal confinement is proportional to $\sum_{i<j} r_{ij}^2$. Thus, the internal problem in a parabolic dot fits naturally into the "quadratic pair + homogeneous -2" class treated in Ref. [14] once the CM degree of freedom is removed. The magnetic field adds the standard Fock–Darwin L_z term; it lifts chiral degeneracies but does not eliminate the internal ladder structure (Sec. IV already illustrates this explicitly for $N = 2$).

b) $\mathrm{SU}(1,1)$ *generators and ladder structure.:* In Jacobi coordinates $\{X_a\}_{a=1}^{N-1}$ for the internal motion (with conjugate momenta $\{P_a\}$), define the quadratic "size" operator, dilation

operator, and scale-invariant Hamiltonian,

$$\hat{C} = \frac{m^*}{2}\sum_{a=1}^{N-1} X_a^2, \qquad \hat{D} = \frac{1}{2}\sum_{a=1}^{N-1}(X_a\cdot P_a + P_a\cdot X_a)\,, \\ \hat{H}_0 = \frac{1}{2m^*}\sum_{a=1}^{N-1} P_a^2 + V_{\rm hom}(\{X_a\}), \tag{44}$$

where $V_{\rm hom}$ is translation invariant and homogeneous of degree -2 (e.g. Calogero $1/r_{ij}^2$). Then (under the homogeneity condition) these operators close an $\mathfrak{su}(1,1) \cong \mathfrak{so}(2,1)$ Lie algebra, [14]

$$[\hat{C},\hat{D}] = 2i\hbar\hat{C}, \qquad [\hat{C},\hat{H}_0] = i\hbar\hat{D}, \\ [\hat{H}_0,\hat{D}] = -2i\hbar\hat{H}_0. \tag{45}$$

The trapped internal Hamiltonian is $\hat{H}_{\rm int} = \hat{H}_0 + \omega^2\hat{C}$ (with an appropriate effective ω set by ω_0 and B). Standard linear combinations of $(\hat{H}_0, \hat{C}, \hat{D})$ define $\mathrm{SU}(1,1)$ ladder operators $\hat{K}_\pm$ and a Cartan generator $\hat{K}_0$ such that $\hat{K}_+$ raises the "breathing" quantum number by one step. [14] Consequently, within each $\mathrm{SU}(1,1)$ tower the spectrum is a near-harmonic ladder with step $\simeq 2\hbar\omega$ (exact in the solvable class), while the tower label is set by the Casimir (equivalently, by the interaction-determined "angular" sector on the $(N-1)$-dimensional shape sphere).

c) How this helps twisted-light control design.: For the purposes of this proposal, the Gambardella viewpoint supplies three concrete project tools:

1) **State construction beyond brute force.** Ref. [14] gives a constructive scheme in which a family of excited states is generated by an energy-raising operator acting on the ground state. This mirrors our $N = 2$ Laguerre–tower structure (Sec. IV) and provides an analytic scaffold for $N \geq 3$ breathing-mode ladders.
2) **Selection-rule bookkeeping.** Twisted-light operators are low-order polynomials in the coordinates (LLL-projected multipoles). Decomposing them into irreducible pieces with respect to $\mathrm{U}(1)$ rotations ($\Delta L = \pm s$) and the $\mathrm{SU}(1,1)$ ladder structure predicts, *a priori*, which internal towers are addressable at given s and which matrix elements are symmetry-forbidden.
3) **A bridge to realistic Coulomb dots.** Even when the true Coulomb interaction breaks exact solvability, $\mathrm{SU}(1,1)$ remains a useful organizing principle for near-harmonic internal ladders. The program is then to (i) use the $\mathrm{SU}(1,1)$ scaffold to design pulses and expected spectral patterns, and (ii) calibrate the remaining interaction-specific mixing by exact diagonalization in the LLL basis.

d) Worked example: $N = 3$ and the $s = 3$ TL operator selects a finite set *of SU(1,1) towers.:* To make the "tower selectivity" concrete, consider the lowest-Landau-level polynomial language for $N = 3$. The Laughlin state at filling $\nu = 1/3$ has polynomial $\mathcal{V}^3 = \prod_{i<j}(z_i - z_j)^3$ and total angular momentum $L = 3N(N-1)/2 = 9$. A TL pulse with $s = l + \sigma = 3$ (e.g. $l = 2$, $\sigma = +1$) injects $\Delta L = +3$. In the LLL-projected long-wavelength limit, the corresponding internal driving operator reduces to the symmetric power-sum polynomial

$$\hat{O}^{\rm LLL}_{s=3} \propto \sum_{j=1}^{3} z_j^3 \equiv p_3(z_1, z_2, z_3), \tag{46}$$

which maps the $L = 9$ Laughlin state into the $L = 12$ manifold. For $N = 3$ this manifold is three-dimensional, and a natural basis is given by multiplying $\mathcal{V}^3$ by the degree-3 symmetric polynomials $\{e_3,\ e_1e_2,\ e_1^3\}$. Using Newton's identity (Eq. (42)),

$$p_3 = e_1^3 - 3e_1e_2 + 3e_3, \tag{47}$$

we immediately see that a *single* $s = 3$ TL pulse does not create a pure quasihole state $e_3\mathcal{V}^3$; rather, it creates a specific superposition across *three* candidate towers.

This is exactly where the SU(1,1) language earns its keep. After separating the center of mass, e_1 is proportional to the CM coordinate ($e_1 = 3Z_{\rm CM}$), so the e_1^3 and e_1e_2 pieces contain CM excitation content, while e_3 is the quasihole factor. In Gambardella's terms, each linearly independent homogeneous polynomial that solves the "angular" problem is a lowest-weight vector of some SU(1,1) representation; the internal breathing ladder is generated by K_+ acting on it. Equation above therefore *decomposes the TL drive into reduced matrix elements* connecting the Laughlin tower to a *finite, explicitly identified set* of target towers. All other towers in the same $L = 12$ sector (if present at larger N) are "dark" in the idealized limit because their lowest-weight vectors are orthogonal to the polynomial content of p_3. Interactions and non-idealities can mix these towers, but the polynomial decomposition provides a controlled starting point for which modes are expected to be bright/dark and why.

In short, Gambardella's dynamical-group framework turns "$N \geq 3$ is hard" into a structured workflow: identify the relevant $\mathrm{SU}(1,1)$ towers (breathing vs. shape), compute the twisted-light selection rules and dominant overlaps, and then layer Coulomb realism on top.

E. What becomes genuinely new at $N \geq 3$

At $N \geq 3$, Laughlin-like droplets support quasiholes with fractional charge and anyonic exchange phases. [8], [9] Optically addressing the $\Delta L = N$ quasihole sector is therefore the first step from "correlation spectroscopy" toward preparation of topological excitations. For $N = 3$, the preceding subsection makes this concrete: an $s = 3$ twisted-light drive targets the $L = 9 \to 12$ manifold where the single-quasihole and the $\Delta L = 3$ edge excitations reside.

To connect explicitly to standard FQHE wavefunction language, recall that a quasihole at the origin is created by multiplying the many-body polynomial by $\prod_{i=1}^{N} z_i$, which increases total angular momentum by N and inserts one quantum of vorticity (one unit of flux) through the droplet. Hence, for $N = 3$ the operator $\hat{Q}_{\rm qh} = \prod_{i=1}^{3} z_i$ raises L by $+3$, and a twisted-light mode with $s = 3$ (e.g. $l = 2, \sigma = +1$) is the minimal optical multipole that can populate that sector

in a single pulse. If the relevant matrix element is sizable *and* the $L = 12$ eigenbasis is spectroscopically resolvable, this becomes an optical "write" primitive for a quasihole *sector* (with selectivity set by interaction-defined overlaps, cf. Sec. VIII-B).

a) Abelian anyons as a phase resource.: Laughlin quasiholes are *Abelian* anyons: exchanging two quasiholes yields statistical angle $\theta = \pi/q$ (a full braid gives $2\theta = 2\pi/q$) but (on simply connected geometries with fixed quasihole positions) no fusion-space degeneracy, so braiding alone is not universal. [9], [10] Nevertheless, such phases can provide robust, geometry-insensitive conditional phases when combined with non-topological control. In this sense, Abelian anyons provide a *protected phase resource* even when they do not supply a universal gate set by braiding alone. [9]

b) How twisted light might participate in braiding protocols.: If twisted light can (i) create quasihole sectors and (ii) be spatially steered by a spatial light modulator, a natural speculative direction is to use structured light not only as a spectroscopy tool but as a way to *move* localized charge deficits (quasiholes) in time. In macroscopic FQHE samples, quasihole motion is typically controlled by electrostatic gates or local potentials; an optical route would be faster (pulse timescales) and potentially more flexible in geometry. A key open question for this program is whether sufficiently localized optical potentials can be engineered without heating the electronic system out of the LLL.

c) Long-term direction.: The "photonic control bus" viewpoint motivates extending the same TL-selective spectroscopy/state-preparation ideas to engineered dot states whose excitations are non-Abelian. [9], [10]

d) Non-Abelian targets.: Ultimately, universal topological quantum computation requires non-Abelian anyons. [9], [10] While the present work focuses on Laughlin-like correlations and their Calogero limits, the broader program is clear: identify correlated dot states (possibly in higher Landau levels or in engineered interactions) whose excitations support non-Abelian statistics, and test whether twisted light can selectively prepare and interrogate those sectors.

F. Proposed conference-scale research program

A concrete near-term experimental roadmap is:

1) **Spectroscopy in a single dot ($N = 2$).** Verify TL-only internal transitions and extract $\Delta m = \pm 2$ selection rules. [4]
2) **Coherent control.** Demonstrate Rabi oscillations between $|m| = 3$ and $|m| = 5$ sectors and Ramsey interferometry for phase control.
3) **Two-dot conditional phase.** Engineer state-dependent Coulomb coupling and test a ZZ-type entangling phase gate.
4) **Scale-up.** Extend to $N = 3$ dots and test $s = 3$ pumping into the quasihole sector as an optical state-preparation primitive.

Even if the long-term target is topological quantum computing, the $N = 2$ stage already yields a complete, analytically characterized, optically driven single-qubit gate module—a rare benchmark system for bridging correlated-electron physics and quantum information science.

TABLE IV
REPRESENTATIVE NUMBERS SUPPORTING TL CONTROL OF CORRELATED SECTORS IN FEW-ELECTRON QUANTUM DOTS.

Quantity	Typical value	Comment / source
Dot confinement energy	$\hbar\omega_0 \sim 3$ meV	Harmonic estimate used to model GaAs dots with $d_{\mathrm{eff}} \approx 100$ nm [15].
Charging energy	$E_c \sim 1$–4 meV	Screened vs. unscreened estimates for $d_{\mathrm{eff}} \approx 100$ nm (and a commonly used intermediate value $E_c \simeq 2$ meV in model spectra) [15].
Magnetic field	$B \lesssim 16$ T	Field range routinely applied in few-electron dot spectroscopy [15].
Cyclotron energy (GaAs)	$\hbar\omega_c \simeq (1.73\,\mathrm{meV/T})\,B$	Set by the effective mass $m^* = 0.067m_e$ [15].
Zeeman scale (GaAs)	$\lvert g\rvert\mu_B B \simeq (0.025\,\mathrm{meV/T})\,B$	With $g_{\mathrm{GaAs}} = -0.44$ [15].
Base temperature	$T \sim 100$–200 mK	Typical measurement temperatures in few-electron dot transport spectroscopy [15].
THz-TDS waveform	pulse $\lesssim 1$ ps, bandwidth around 1 THz	Single-cycle THz pulses used in time-domain spectroscopy (photoconductive or optical-rectification based) [16].
Strong-field THz example	$E_{\mathrm{pk}} = 236$–819 kV/cm	High-repetition-rate DSTMS optical-rectification source (1–10 kHz) [17].
THz vortex-beam components	0.3–0.45 THz ($\lvert L\rvert = 1, 2$); 0.62–1.3 THz ($\lvert L\rvert = 1$)	Survey of demonstrated THz vortex shapers and mode converters (including reports of $\lvert L\rvert \le 3$ at 1.8–2.8 THz) [18].

IX. REPRESENTATIVE EXPERIMENTAL NUMBERS AND FEASIBILITY

To make the proposal concrete, we collect representative parameter values from the few-electron quantum-dot and ultrafast/THz literature. The goal is not to lock in a single device design, but to show that the *energy scales, magnetic fields, temperatures, and pulse bandwidths* required to drive the twisted-light (TL) selection rules are already standard in nanostructure experiments.

A useful conversion is $1\ \mathrm{meV}/h \simeq 0.242$ THz, so a typical confinement $\hbar\omega_0 \sim 3$ meV corresponds to a natural scale $f_0 \sim 0.73$ THz. In the quantum Hall (Fock–Darwin) regime, the low-energy ladder spacing between successive lowest-Landau-level orbitals is

$$\hbar\omega_- = \hbar\sqrt{\omega_0^2 + \omega_c^2/4} - \frac{\hbar\omega_c}{2}, \tag{48}$$

so for $\hbar\omega_0 = 3$ meV and $B = 3$ T (i.e. $\hbar\omega_c \simeq 5.2$ meV) one finds $\hbar\omega_- \approx 1.36$ meV ($f_- \approx 0.33$ THz), while at $B = 5$ T one finds $\hbar\omega_- \approx 0.93$ meV ($f_- \approx 0.22$ THz), all within standard far-infrared/THz bandwidths [16], [17]. These are precisely the frequencies relevant for the $|m| \to |m| + s$ internal ladders that TL addresses.

For spatial scales, $\hbar\omega_0 = 3$ meV and $m^* \approx 0.067m_e$ imply a single-particle Fock–Darwin length $\ell_0 = \sqrt{\hbar/(2m^*\omega_0)} \approx 14$ nm at $B = 0$. In a magnetic field the relevant Gaussian length uses $\omega = \sqrt{\omega_0^2 + \omega_c^2/4}$, giving $\ell_0(B = 5\ \mathrm{T}) \approx 10$ nm,

comparable to the magnetic length $\ell_B = \sqrt{\hbar/(eB)} \approx 11.5$ nm at $B = 5$ T. Hence the relevant internal-coordinate matrix elements are set by tens-of-nanometre length scales, consistent with few-electron dots in the $d_{\text{eff}} \sim 100$ nm class [15].

Finally, the optics side is compatible with the selection rules: the protocol requires only modest OAM charges ($l = 1, 2$ in most of the worked examples), and THz vortex converters with $|L| = 1$ (and in some cases $|L| = 2$) have been demonstrated in the 0.3–1.3 THz range, with reports of $|L| \leq 3$ at a few THz [18].

A. How the González–Quiroga–Rodríguez $N = 3$ theory can scaffold the topological roadmap

A main bottleneck in moving from the fully analytic $N = 2$ case to genuinely topological droplets ($N \geq 3$) is that the correlated spectrum becomes multi-dimensional and brute-force exact diagonalization scales rapidly with Hilbert-space size. A particularly useful intermediate step already exists in the few-body literature: González, Quiroga, and Rodríguez developed a resummed $1/N$ expansion (with N essentially set by the internal angular momentum scale) for three particles in a 2D parabolic dot under magnetic field with a Calogero ($1/r^2$) repulsion. [12] For our purposes, the value is practical: their method yields a design-level semi-analytic spectrum *and* explicit normal-mode wavefunctions (breathing vs. shape) that reduce twisted-light matrix elements to oscillator integrals, while reproducing the correct "magic-number" ground-state ladder and its magnetic-field-driven transitions in good qualitative agreement with Coulomb benchmarks. [12], [13]

X. Conclusion

Twisted light provides an optical handle on correlation physics in magnetized quantum dots by accessing relative-motion excitations that are dark to uniform dipolar probes. In the analytically solvable Calogero limit, both the spectrum and the twisted-light matrix elements are closed-form functions of the interaction strength, allowing gate parameters to be written down explicitly. This makes the $N = 2$ system a concrete single-qubit gate primitive (with a plausible two-qubit extension via state-dependent Coulomb coupling) and a controlled stepping stone toward $N \geq 3$ FQHE droplets where quasiholes become genuinely topological excitations. The central message for quantum computing audiences is operational: twisted light enables *WRITE* (pulse-create a correlation sector), *READ* (spectroscopically diagnose correlations), and *SCALE* (optical addressing via SLM) in a unified photonic control layer.

***Abstract*—We demonstrate real-time macroscopic control of electromagnetic helicity and resonant frequency in a rectangular cross-section microwave cavity resonator by dynamically twisting its conducting boundaries. The resulting mirror asymmetry induces magnetoelectric coupling between near-degenerate transverse electric and magnetic modes, generating helical hybrid eigenmodes with resonant frequencies proportional to their electromagnetic helicity.**

***Keywords*— electromagnetic helicity, chirality, microwave cavity resonators, mode hybridisation.**

I. Introduction

Electromagnetic radiation that is chiral in nature is distinguished by its left- or right-handed polarization and underpins a broad range of phenomena in nanophotonics [1], [2], metamaterials [3], quantum information, and precision sensing [4], [5], [6]. A fundamental measure of this chirality is electromagnetic helicity [7], [8], which quantifies the spatial overlap of electric and magnetic fields.

It has traditionally been assumed that hollow metallic cavity resonators cannot sustain bulk electromagnetic helicity in free space [9]. However, recent work has demonstrated the existence of helical resonant eigenmodes in vacuo [5], [4]. Here, we extend this concept by experimentally demonstrating continuous, real-time modulation of electromagnetic helicity in a mechanically twisted rectangular microwave cavity resonator.

II. Methods

Electromagnetic helicity may be expressed by projecting the complex electromagnetic state vector's spin onto its linear momentum [10], [11], [12], [13], [14]. For a monochromatic resonant mode i, the global electromagnetic helicity is defined as

$$\mathscr{H}_i = \frac{2\,\mathrm{Im}\left[\int \vec{\mathbf{E}}_i(\vec{r}) \cdot \vec{\mathbf{H}}_i^*(\vec{r}) dV\right]}{\sqrt{\int \vec{\mathbf{E}}_i(\vec{r}) \cdot \vec{\mathbf{E}}_i^*(\vec{r}) dV \int \vec{\mathbf{H}}_i(\vec{r}) \cdot \vec{\mathbf{H}}_i^*(\vec{r}) dV}}, \quad (1)$$

where $\vec{\mathbf{E}}_i(\vec{r})$ and $\vec{\mathbf{H}}_i(\vec{r})$ denote the electric and magnetic field distributions of the mode.

Introducing a geometric twist angle ϕ breaks the mirror symmetry of the rectangular cavity boundaries. This perturbation induces magnetoelectric coupling between near-degenerate transverse electric (TE) and transverse magnetic (TM) modes of the untwisted resonator. Finite-element simulations of the transverse electric ($\vec{E}_\perp$) and magnetic ($\vec{H}_\perp$) fields for the $\mathrm{TM}_{2,1,0}$ and $\mathrm{TE}_{2,0,1}$ eigenmodes of a WR-137 cavity are shown in Fig. 1(a) and (b), respectively. The twist lifts the modal degeneracy, producing hybrid eigenstates $\psi^{\pm}_{2,1,0}$ corresponding to in-phase and out-of-phase TE-TM superpositions. The resulting hybrid modes are shown in Fig. 1(c,d). This behaviour can be understood through the dual symmetry of Maxwell's equations: the geometric twist effectively rotates the electric and magnetic fields together, generating helical resonant eigenmodes.

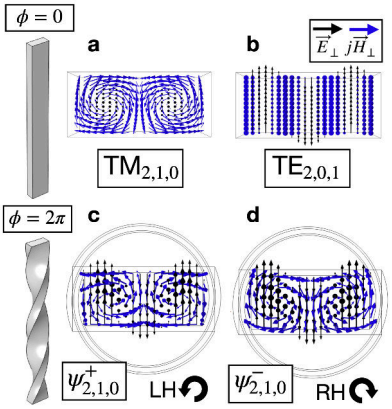

Fig. 1. The $\vec{E}_\perp$ (magenta) and $j\vec{H}_\perp$ (black) field distributions for FEM eigenmode simulations of the WR-137 rectangular cross-section cavity resonator are shown for $\phi = 0$ ((a) $\mathrm{TM}_{2,1,0}$ and (b) $\mathrm{TE}_{2,0,1}$ modes) and $\phi = 2\pi$ ((c) $\psi^+_{2,1,0}$ and (d) $\psi^-_{2,1,0}$ modes).

The hybrid states $\psi^{\pm}_{2,1,0}$ not only acquire non-zero $\mathscr{H}_i$ under twist but also exhibit symmetric frequency splitting relative to their untwisted counterparts, $\mathrm{TM}_{2,1,0}$ and $\mathrm{TE}_{2,0,1}$.

III. Results

Geometric twisting is analogous to filling the cavity with an isotropic chiral medium characterised by a chirality parameter κ. An empirical mapping between twist angle and effective chirality for the $\psi^{\pm}_{2,1,0}$ modes is given by

$$\kappa_{\mathrm{eff}} \approx -\frac{\phi}{88.55}. \quad (2)$$

The corresponding resonant frequency shift follows the perturbative relation

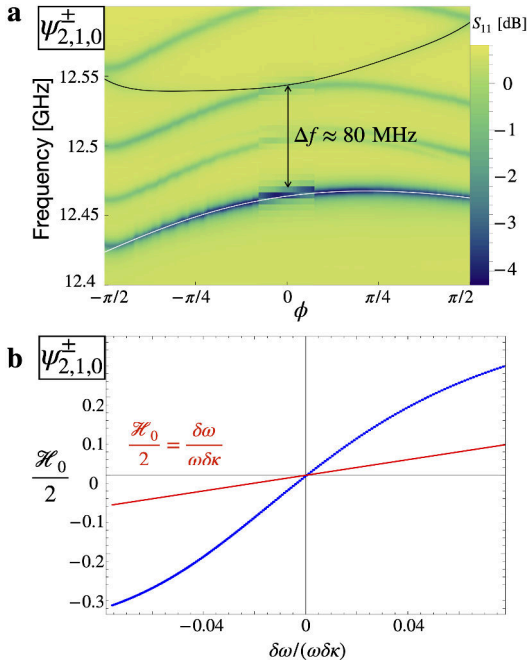

Fig. 2. (a) Measured reflection (S_{11}) response of the helically corrugated WR-137 rectangular cavity. The resonance of the hybrid mode $\psi^{\pm}_{2,1,0}$, arising from coupling between the $\mathrm{TE}_{2,0,1}$ and $\mathrm{TM}_{2,1,0}$ modes, is highlighted by cyan and black dashed markers. The experimentally extracted $\psi^{\pm}_{2,1,0}$ frequencies (black trace) are then used in (b) to compare the left-hand side of Eq. (3) with the right-hand side derived from finite-element eigenmode simulations of the untwisted cavity, where an effective chirality parameter κ_{eff} is introduced into the medium. The blue line denotes the theoretical prediction given by Eq. (3).

$$\left(\frac{\delta\omega}{\delta\kappa\,\omega_0}\right)_{\kappa_0 \ll 1} = \frac{\mathscr{H}_0}{2\mu_r\epsilon_r}, \tag{3}$$

where $\mathscr{H}_0$ denotes the helicity of the untwisted mode. Here $\delta\omega = \omega_1 - \omega_0$ corresponds to a small perturbation $\delta\kappa$. This proportionality establishes a direct link between helicity and resonant frequency tuning, enabling mechanical control of both quantities.

Experimentally, a commercially available helically corrugated WR-137 waveguide was enclosed with metallic endcaps to form a twistable resonator. One endcap was mounted on a motorised rotation stage, enabling continuous variation of ϕ while monitoring the reflection response.

The measured S_{11} spectra (Fig. 2) show clear twist-induced frequency shifts of the $\psi^{\pm}_{2,1,0}$ hybrid modes. The frequency maximum occurs at a small positive twist angle, attributed to intrinsic right-handed corrugation that introduces effective surface chirality.

The experimentally extracted frequency shifts exhibit an approximately linear dependence between $\frac{\delta\omega}{\omega_0\delta\kappa}$ and $\mathscr{H}_0$, consistent with the perturbative model of Eq. (3). The experimental gradient is steeper than the theoretical prediction, likely due to corrugation effects and geometric changes arising from waveguide buckling during twisting. Despite this, the rate of change of both $\mathscr{H}_0$ and $\frac{\delta\omega}{\delta\kappa\omega_0}$ is consistent.

IV. Conclusion

We experimentally demonstrate dynamically tunable electromagnetic helicity in twisted microwave cavity resonators. Geometric mirror asymmetry induces magnetoelectric mode coupling, generating bulk chiral eigenmodes in free space. The proportional relationship between helicity and resonant frequency enables real-time mechanical tuning, establishing a reconfigurable platform for chiral cavity engineering and helicity-based device applications.

***Abstract*— We show that two color phase-locked free-electron laser pulses induce interferometric and enantio-sensitive photoemission in propylene oxide. Our method isolates coherent chiral contributions, resolving individual multi-electron states. This provides direct access to chiral electronic currents on sub-femtosecond timescales.**

***Keywords*— chirality, free electron laser, attosecond science, interferometry**

Electron dynamics in chiral molecules unfold on attosecond timescales and often involve correlated multi-electron motions that are difficult to isolate from single-electron signals and rapid decoherence. A probe combining attosecond temporal resolution with inherent sensitivity to molecular handedness is required to access these fundamental many-body effects. Here we demonstrate such a probe using two-color phase-locked pulses from the free-electron laser (FEL) FERMI, which provides the necessary spectral resolution (<40 meV) and phase stability (<10 as) for addressing these dynamics [1,2].

We employ phase-locked, orthogonally polarized ω and 2ω pulses from the FERMI FEL to ionize propylene oxide. Photoelectrons are detected by VMI as function of two-color delay. The interference of ω+ω and 2ω quantum pathways to the same final ionic state is controlled by the phase between the two colors and produces an enantio-sensitive rotation of the photoelectron angular distribution that encodes a characteristic chiral molecular phase [3,4]. In our experiment, we identified in the photoelectron spectrum of propylene oxide a specific interference pathway. The 2ω *reference* pathway produces a 2h1p (2-holes 1-particle) ionic state via shake-up process. The ω+ω *signal* pathway involves the photoexcitation by the first ω photon to a state with an inner-valence hole, which then undergoes a prompt, laser-assisted Auger-Meitner decay, a multi-electron process stimulated by the absorption of a second ω photon. By performing the Fourier transform of the rotation of the photoelectron angular distribution with respect to two-color phase delay, we extracted the enantio-sensitive molecular phase associated to this interference, with a temporal resolution of ~40 as, across the photoelectron energy region of 2h1p final states. This phase exhibits a clear π-shift between opposite enantiomers, which confirms the enantiosensitivity of the measurement. Its complete characterization as a function of the energy provides a direct signature of the internal helical currents and sub-femtosecond charge redistribution of a chiral system.

With this experiment, we demonstrate attosecond enantio-sensitive interferometry of correlated multi-electron dynamics. The method is particularly sensitive to coherent pathways, providing a robust way to trace attosecond multi-electron correlations that precede rapid decoherence and fragmentation, and opening new avenues for observing ultrafast charge redistribution in chiral systems.

***Abstract*—Tailored laser fields are a powerful tool to investigate chirality. We show that the interaction of vector beams with chiral molecules results in topological chiral rings, where the handedness of the molecules is imprinted in the divergence of their light emission.**

***Keywords*— chirality, tailored laser fields, structured light, nonlinear optics, vector beams**

I. Introduction

Laser light can be tailored in a wide variety of ways. From standard temporal and spectral shaping, which led to the generation of ultrashort laser pulses, to harnessing light's polarization or creating beams with properties associated to their spatial structure. Interestingly, the capability of shaping light's symmetries and structure can be used to investigate matter's symmetries and structure. Chirality, a universal property of objects that are not superimposable to their mirror image, is especially relevant in this context. Tailored fields allow us to probe chiral matter and ultrafast chiral dynamics in unprecedent ways. The merging of these two ingredients, tailored light and chirality, has led to new methods for studying chiral molecules [1].

II. Methods

Microscopic tailoring includes shaping the electric field's polarization by mixing frequencies, which results in a collection of Lissajous curves. If the resulting polarization at one point in space is 3-dimensional in time (Fig. 1A), the field is locally chiral [2]. Macroscopic tailoring includes topological light, such as vortex beams, which carry orbital angular momentum due to its azimuthally-varying phase (Fig. 1B), and which have proven to be a valuable tool to obtain enantio-sensitive observables [3]. Another noteworthy type of topological light are vector beams, which possess a Poincaré index associated to its azimuthally-rotating polarization (Fig. 1C).

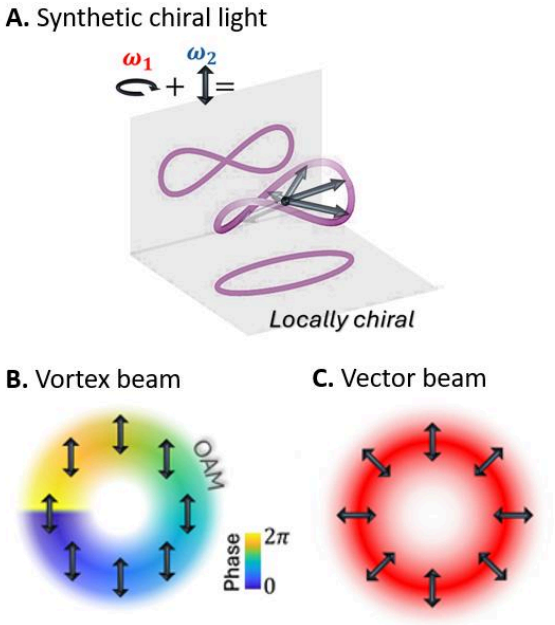

Fig. 1 Examples of tailored laser fields for studying chirality (the arrows indicate polarization). Synthetic chiral light presents a locally chiral (3-dimensional) polarization (A). Vortex beams (B) and vector beams (C) carry topological charges linked to their spatial structure. Figure adapted from [1].

III. Results and Discussion

Here, we present the first topological imaging technique that uses vector beams for enantiomeric discrimination. We shape a vector beam's polarization in 3D, creating topological locally chiral light. Then, we drive low-order nonlinear interactions, a combination of sum-frequency generation and third harmonic generation, in a sample of randomly oriented chiral molecules. This results in the handedness of chiral molecules being imprinted in the divergence of the emitted light, leading to

topological chiral rings.

IV. Conclusion

We propose an all-optical for enantiomer discrimination where, by shaping the light's polarization in 3D and driving nonlinear interactions, the handedness of the sample can be determined by measuring the divergence of the light emission. Our configuration is robust, requires gentle intensities, and results in chiral rings: spatially different rings for each enantiomer.

***Abstract*— Recently, plasmonic multilayered structures have been utilized to generate skyrmionic distributions of optical spin fields with deep subwavelength scale. We explore relationship between the details of such distributions and the structural properties of the multilayer/metasurface systems.**

***Keywords*— metamaterials, plasmonics, hyperbolic dispersion, metasurface, optical skyrmion.**

I. Introduction

Plasmonic structures have been known to enable focusing of light to deep subwavelength areas[1]. Recent results demonstrate that in addition to generating tight focusing, multi-layer structures yield non-trivial distributions of optical spin density that can be mapped to topologically-protected skyrmionics profiles[2]. The structure of field and spin distributions can be controlled by the interplay between the incident beam and the metasurfaces embedded into multilayer stack[3]. Here we demonstrate that complex metasurface-metamaterials structures can be utilize to engineer subwavelength distributions of both intensity and spin profiles.

II. Methods

Numerically, we investigate light propagation and interaction with metastructures via both finite-element solvers and analytical tools that assess the dispersion of the modes in the composites.

Experimentally, metastructures are fabricated using a combination of layer deposition and milling techniques, and their optical response is analyzed with microscopy and spectroscopy.

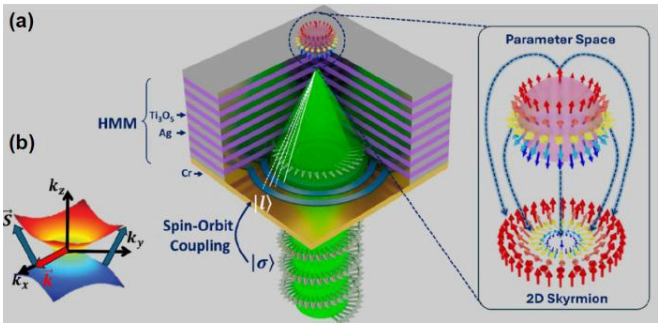

Fig. 1 Schematic of the plasmonic multilayer/metasurface structure generating the optical skyrmion [3]

III. Results and Discussion

The typical distributions of electric field achievable with metastructures are shown in Fig.2. It is seen that by adjusting the parameters of multilayer stack and the parameters of the circular metasurface the intensity can be engineered along the focal line, designing hot-spots across the multilayer thickness. Adding chirality to the metasurface breaks the rotational symmetry and introduces chiral response to the overall structure.

IV. Conclusion

We have developed a metastructure platform that combine the benefits of the bulk planar metamaterials and the ultra-thin metasurfaces to engineer field and spin distributions at deep subwavelength scales.

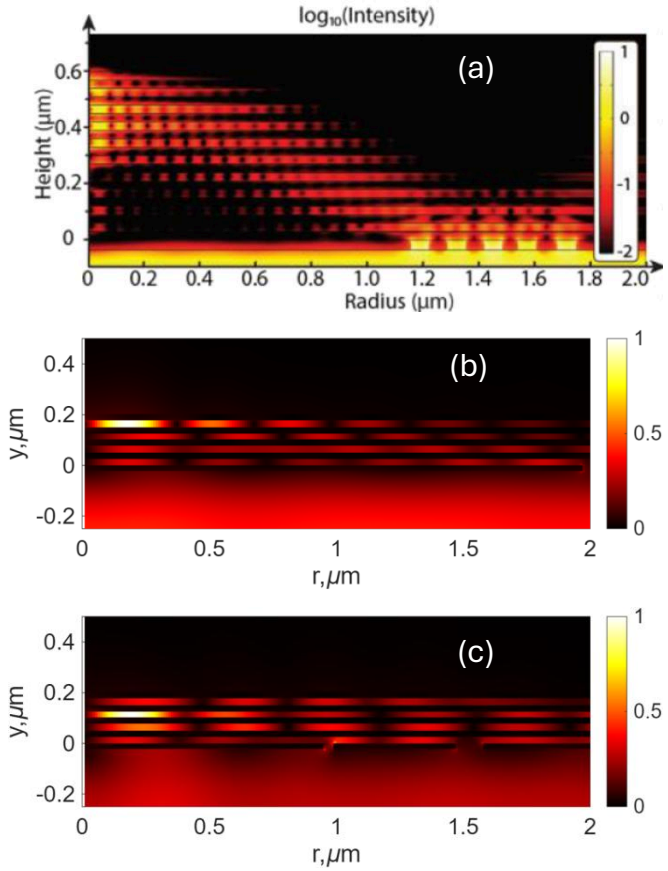

Fig. 2 Typical intensity distributions in plasmonic metastructures operating at free space wavelength of $\lambda_0 = 532\ nm$ (a) and $\lambda_0 = 1550\ nm$ (b,c)

***Abstract*— We present our work on metamaterial-integrated photonic devices for optical beam steering, including polarization-insensitive grating antennas and optical phased arrays. Moreover we discuss our work on singlet metalenses achieving broadband achromatic focusing and a large field of view.**

***Keywords*— metamaterials, metamaterials, metasurfaces, subwavelength gratings, optical beam steering, metalens, silicon photonics, optical phased arrays**

I. Introduction

Optical beam steering underpins key technologies including free-space optical communications, light detection and ranging (LiDAR), and 3D imaging. Photonic integration enables compact, scalable, and low-cost implementations of beam steering systems. For example. optical phased arrays (OPAs), exploiting arrays of integrated antennas, allow steering and shaping beams without bulky mechanical components [1,2]. Metalenses, based on arrays of subwavelength nanoscatterers, offer a complementary approach to achieve beam focusing and steering with ultra-thin devices [3]. The use of metamaterial and metasurface engineering, combined with innovative design approaches, provide powerful additional tools to overcome the limitations of current integrated solutions [4]. In this work, we present our recent results on metamaterial-integrated grating antennas, OPAs,, as well as singlet metalenses combining achromatic focusing with wide-angle beam steering.

II. Metamaterial based antennas

Surface gratings are commonly used as antenna elements in OPAs. However, their strong polarization dependence in radiation angle and efficiency can represent a major drawback, especially when the OPA is used for reception. We developed a polarization-insensitive grating antenna on a 500 nm SOI platform [5]. The grating unit cell combines an L-shaped structure, partially etched to 250 nm for high upward diffraction efficiency, with a subwavelength metamaterial section enabling independent tuning of the TE and TM Bloch mode effective indices. By adjusting the metamaterial duty cycle, the Bloch indices for the two polarizations are equalized, yielding polarization-insensitive operation. Experiemental results demonstrate a diffraction angle of 10° at λ = 1550 nm for both TE and TM inputs, with upward diffraction efficiencies of -4 dB for both polarizations, offering a very promising path for polarization insensitive phased arrays.

III. Optical metalenses

Metalenses demonstrated in the literature often achieve either achromatic focusing or a wide field of view, but rarely both simultaneously [3,6]. We designed and experimentally demonstrated a singlet metalens that combines these two properties [8]. A quadratic phase profile is adopted, which maintains a constant focal distance under wide-angle illumination. For each position in the metalens, the meta-atom dimensions are selected to minimize dispersion. The fabricated achromatic metalens exhibits a relative focal shift of only 1.1% over the 100 nm bandwidth, compared to more than 14% for a single-wavelength reference design. Experimentally, the illumination angle can be tilted up to ±43° while preserving achromatic focusing performance.

IV. Conclusion

We presented metamaterial-engineered photonic devices addressing key challenges in optical beam steering. These results highlight the effectiveness of metamaterial integration for advancing compact beam steering systems.

***Keywords*— silicon photonics, integrated optical phased arrays, LiDAR sensing, augmented-reality displays, optical trapping, trapped ions.**

I. Review of OPA-Based Platforms, Devices, Systems, and Applications

By enabling the integration of millions of micro-scale optical components on compact millimeter-scale chips, silicon photonics is positioned to enable next-generation optical technologies that facilitate revolutionary advances for numerous fields spanning science and engineering.

An emerging class of silicon-photonics systems is integrated optical phased arrays (OPAs), which enable manipulation and dynamic control of free-space light in a compact form factor, at low costs, and in a non-mechanical way.

This talk will highlight our work on developing novel integrated-OPA-based platforms, devices, and systems that enable chip-based solutions to high-impact problems in areas including light-detection-and-ranging (LiDAR) sensing for autonomous vehicles [1-12], free-space optical communications [13-14], three-dimensional (3D) holography for augmented-reality (AR) displays [14-28], laser-based 3D printing [29-33], optical trapping for biophotonics [34-44], and trapped-ion quantum engineering [45-53].

***Abstract*— The design, simulation and experimental realisation of various phase-change metasurface devices for the active and reconfigurable control of light is described. Particular emphasis is placed on metasurfaces for free-space implementations of optical image processing, optical mode conversion and optical orbital angular momentum control.**

***Keywords*— Phase-change metasurfaces, optical mode control, optical image processing.**

I. Introduction

Chalcogenide phase-change materials (PCMs), such as $Ge_2Sb_2Te_5$, Sb_2Se_3 and $Ge_2Sb_2Se_4Te$, exhibit huge differences in refractive index (real and imaginary parts) between their crystalline and amorphous states. They can be switched billions of times between such states (and to fractionally crystallised states) [1] on the (tens of) nanosecond time scales [2], and are stable in such states for years at room temperature (as opposed volatile reconfigurable materials such as VO_2). The inclusion of PCMs into metasufaces allows for both a dynamically active optical response, i.e. one that is changed frequently on relatively fast timescales such as in modulation and beam steering [3] and display applications [4], and to reconfigurability, where the functionality is switched from time to time for specific needs, e.g. in optical computing [5] and reconfigurable lensing [6]. In this paper we present some of our recent work in the area of the design, simulation and fabrication and testing of phase-change metasurface devices for free-space photonics applications, with special emphasis on PCM metasurfaces for free-space optical computing showing potential for applications ranging from analog image processing to optical telecommunications and more.

II. Results and Discussion

The design of typical unit cells – or meta-atoms – used in our PCM metasurfaces for active and reconfigurable photonics applications is given in Fig. 1, with Fig. 1a showing a design suitable for transmission type optical systems and Fig. 1b an example of a reflective design. The resonant frequency of the unit cell depends on the size of the meta-atom and the material properties. For a given material, we can control the resonant frequency by selecting appropriate feature sizes, in particular the radius of the resonator. For example, in Fig. 2a we show the transmission (intensity) and phase response at 1550 nm for a metasuface consisting of the unit cell shown in Fig. 1a and with a pitch of 1000 nm and height of 225 nm. Clearly, by controlling the meta-atom radius we can, when the Sb_2Se_3 is in its crystalline form, achieve dramatic changes in optical transmission (Fig. 2a) and optical phase (Fig. 2b). Upon switching the Sb_2Se_3 to its amorphous state, the transmission and phase responses demonstrate minimal dependence on meta-atom radius. This leads to the possibility of an ON-OFF type functionality in which the metasurface performs a targeted function with the PCM in one phase state (crystalline in this case), but interacts very little with incident light when the PCM is switched to its other state.

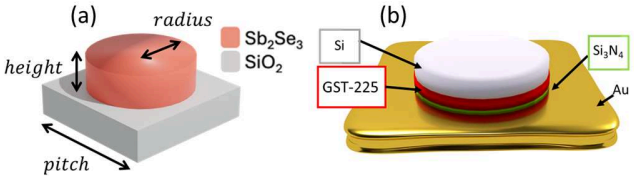

Fig. 1 Schematic of example PCM metasurface unit cells. (a) Shows a design suitable for use in transmission and uses the PCM composition Sb_2Se_3, whereas (b) shows a reflective design using the archetypal PCM composition $Ge_2Sb_2Te_5$.

We have exploited the ON-OFF capabilities of various PCM metasurfaces with device designs similar to those shown in Fig. 1, and optical responses as in Fig. 2, to deliver a range of interesting functionalities, including switchable image

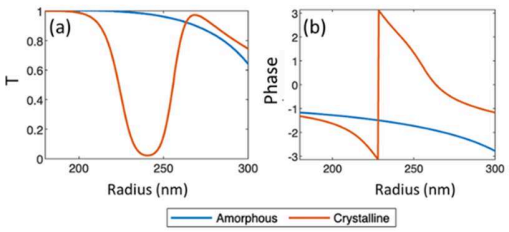

Fig. 2 Transmission (a) and phase response (b) at 1550 nm as a function of meta-atom radius for a PCM metasurface designed using the unit cell of Fig. 1a.

processing [7, 8], optical mode conversion and optical orbital angular momentum control. Examples of all of these applications will be showcased at the conference, but here, for brevity, we concentrate on optical mode conversion functionality.

The ability to manipulate optical modes is crucial for a variety of important applications in modern photonics, ranging from classical and quantum communication to advanced imaging and information processing, beam shaping and even nanoparticle manipulation via optical tweezing. Traditional approaches to optical mode control include the use of axicons, physical phase-plates, computer-generated holograms and multi-plane light converters [9, 10]. Metasurface optical mode converters have also recently been demonstrated [11]. However, conventional metasurfaces are static - that is to say their optical response is fixed at the point of fabrication – whereas the use of PCM metasurfaces introduces the opportunity for active and/or reconfigurable operation. An example of the latter is shown in Fig. 3, where a PCM metasurface (of the type shown in Fig. 1a) is designed to switch ON and OFF a mode conversion capability, here converting a fundamental Gaussian beam into a higher-order Hermite-Gaussian mode (here for concept demonstration, TEM_{00} to HG_{10} mode conversion). With the PCM meta-atoms in their crystalline state, the mode conversion proceeds as desired, but switching the PCM to its amorphous state allows the beam to pass through unaltered.

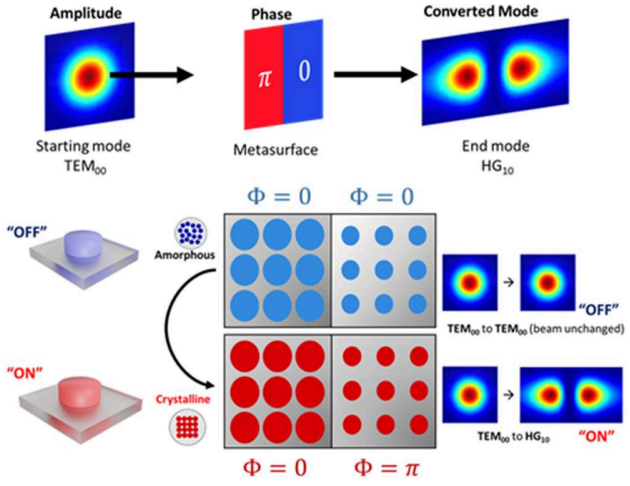

Fig. 3 Concept of an ON-OFF optical mode converter implemented using a phase-change metasurface.

Mode converter metasurfaces of the type shown in Fig. 3 and using unit-cells of the type shown in Fig. 1a were fabricated via magnetron sputtering and e-beam lithography. Exemplar as-fabricated structures are shown in Fig. 4a, and experimental mode conversion results are given in Fig. 4b. As predicted by simulation, the target mode conversion from TEM_{00} to HG_{10} modes is obtained with the PCM metasurface in its crystalline state, whereas with it in the amorphous state the TEM_{00} mode propagates essentially undisturbed.

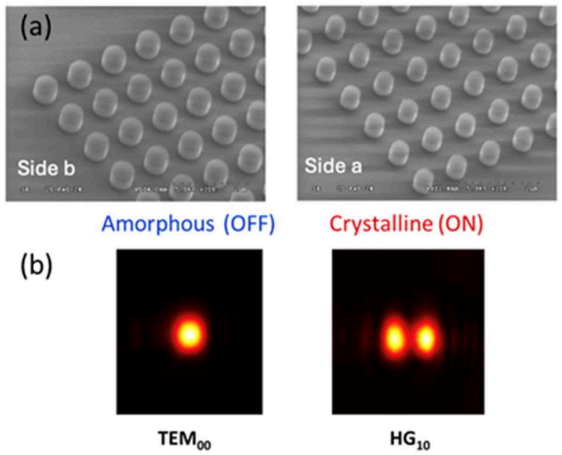

Fig. 4 (a) As-fabricated PCM (Sb_2Se_3) mode converting metasurface and (b) the optical response for an incident TEM_{00} mode when the metasurface is amorphous (left) and crystalline (right).

III. Conclusion

Phase-change metasurfaces provide a powerful platform for active and reconfigurable control of light. In the above we concentrated on optical mode conversion, but other functionalities also addressed at the conference include optical image processing, optical computing and optical orbital angular momentum control.

***Abstract*—GST and GSST enable tunable photonics but exhibit severe chemical and structural instability when uncapped at elevated temperatures. We quantify the magnitude of thickness, stoichiometry, crystallization, optical degradation in thermal evaporated GST and GSST films using EDX, XRD, topology, transmittance, and broadband ellipsometry, and discuss the implications for reconfigurable metalenses.**

***Keywords*— GSST, Phase-change materials, Ellipsometry**

I. Introduction

Phase-change materials such as Ge–Sb–Te (GST) and Se-doped GST (GSST) are central to tunable and reconfigurable photonic platforms due to their large refractive index contrast, reversible crystallization, and compatibility with thin-film processing. GSST, in particular, has emerged as a low-loss alternative to GST, offering improved transparency and broadband optical performance, making it highly attractive for metasurfaces, metalenses, and actively reconfigurable optical components.[1][2]

Despite these advantages, the chemical and structural stability of uncapped, thermal evaporated GST and GSST films at elevated temperatures remains insufficiently quantified. While encapsulation is commonly employed in device implementations, understanding the intrinsic environmental sensitivity of these alloys is critical for interpreting annealing-induced changes and for benchmarking material robustness. In particular, the magnitude of thickness loss, stoichiometry drift, often dominated by tellurium depletion, and crystallization pathway disruption at temperatures around 350 °C has not been systematically assessed for GSST compositions. [3][4]

Since photonic functionality depends critically on precise refractive index control across a broad spectral range, even moderate chemical instability can significantly impact device performance.

In this work, we investigate the environmental sensitivity of GST and GSST films by decoupling intrinsic thermal effects from oxygen-assisted degradation mechanisms. By correlating thickness evolution, chemical composition, crystallographic phase transitions, broadband transmittance, and spectroscopic ellipsometry, we assess how structural instability translates into changes in complex refractive index and ultimately affects the reliability of reconfigurable photonic and metalens platforms.

II. Methods

Thermal evaporated GST and GSST thin films with varying selenium content were deposited on optical substrates and subjected to post-deposition annealing at 200 °C and 350 °C under low-vacuum (LV) (10^{-2} mbar) and high-vacuum (HV) (10^{-5} mbar) conditions to decouple intrinsic thermal effects from oxygen-assisted degradation. Film thickness evolution was monitored to distinguish densification from material loss. Chemical composition changes were evaluated using energy-dispersive X-ray spectroscopy (EDX), while crystallographic phase transitions were characterized by X-ray diffraction (XRD). Optical performance was assessed through spectroscopic transmittance measurements. To directly quantify the broadband optical response, variable-angle spectroscopic ellipsometry was performed from 0.2 µm to 14 µm wavelength, enabling extraction of the complex refractive index (n and k) for both amorphous and crystalline states. Simulation of a metalens was done with FDTD and RCWA by

discretizing the phase map of a spherical lens into subwavelength lattices with GST/GSST nanostructures from a meta-atom library capable of 2π phase range. The nanostructures and their arrangement were tuned in order to allow for focusing performance in the amorphous and crystalline state, and therefore adaptive focus.

This comprehensive approach allows correlation of environmental stability, phase evolution, and broadband optical properties, providing a unified understanding of how chemical instability impacts reconfigurable photonic functionality.

III. Results and Discussion

Experimental results show:

- Up to ~66% thickness loss at 350 °C under LV (vs. ≤13% under HV)
- Degradation at 350 °C is oxygen-driven, not temperature-driven.
- Preferential Te depletion dominates chemical instability in low vacuum.
- HV allows for better hexagonal crystallization in GST and GSST
- Broadband ellipsometry show a 1.5 refractive index contrast for HV GST (Fig. 1).
- LV samples exhibit significant spatial and compositional heterogeneity, complicating reliable optical constant extraction.
- HV GST/GSST metalens simulation show a near diffraction limit performance.

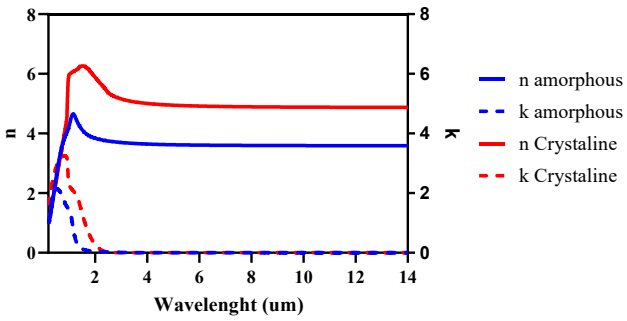

Fig. 1 Refractive index (n) and extinction coefficient (k) for HV GST

IV. Conclusion

We demonstrate that severe instability in uncapped, thermal evaporated GST and GSST films at 350 °C is predominantly oxygen-driven rather than thermally intrinsic. HV annealing preserves intrinsic crystallization behavior and enables reliable broadband refractive index extraction, directly impacting metalens performance. These findings establish quantitative stability limits for GST/GSST thin films and emphasize the necessity of environmental control for reconfigurable photonic applications operating at elevated temperatures.

***Abstract*— We resolved the entire switching cycle of a single-element phase change material (PCM) in optical pump-probe measurements with femtosecond resolution. Based on ab-initio simulations we revealed a complex multi-step process, where the intermediate transient states exhibit distinct optical properties with even larger contrasts than those observed between crystal and glass.**

***Keywords*— phase change materials, permittivity analysis, femtosecond resolution, density functional theory.**

I. Introduction

Where metamaterials or integrated photonics are based on phase change materials for their remanent permittivity contrast between amorphous and crystalline configurations, the transient path from one to the other deserves attention. Pure antimony is an attractive material choice due its extreme compositional simplicity.

II. Methods

Optical pump-probe measurements with femtosecond resolution are quantitatively described with a phenomenological model including thermalization of the hot electron–hole plasma, the formation of a quasi-equilibrium atomic structure with a lower distortion, coherent vibrational modes, strain waves due to thermal expansion, and heat dissipation into the surrounding. Atomistic simulations based on density functional theory are used to calculate structures, energy landscapes and optical spectra.

III. Results and Discussion

On ultrafast timescales, the excitation of charge carriers to antibonding states results in a shift in the quasi-equilibrium atomic structure towards a smaller Peierls distortion. Density functional theory calculations show that a small shift in distortion strongly influences the optical properties across the entire interband absorption region, from the visible to IR. As energy is transferred from the hot electron-hole system to the lattice, it melts after few picoseconds, initially transitioning to an undistorted, metallic liquid. Upon quenching, starting at around 600 K, it is again the formation of Peierls-like distortions that contributes decisively to the optical contrast that is observed on long timescales between crystal and glass.

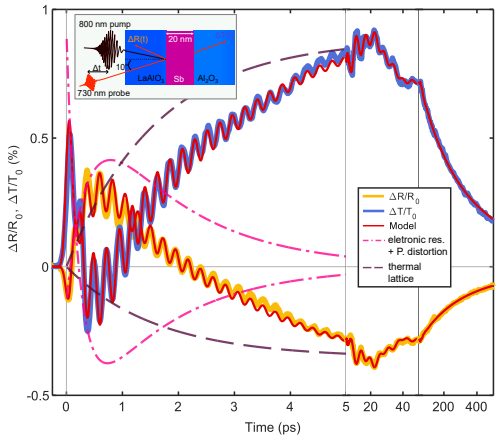

Fig. 1 The fast optical response to photo excitation resolved by pump-probe spectroscopy.

IV. Conclusion

It is evident that the switching of antimony involves multiple intricate processes through intermediate transient states. These states are characterized by distinct optical properties, with larger optical contrasts than the one usually exploited between the non-volatile crystalline and amorphous states of PCMs. For the application of PCMs as optical memory in tunable or reconfigurable photonics, setting a certain memory state is therefore inevitably accompanied by these orders of magnitude in time spanning dynamics. The provided quantitative understanding forms the basis for exploitation in high bandwidth photonic applications.

***Abstract*— The optical characteristics and device switching properties of a fabrication-friendly all-optical, plasmonically-enhanced phase-change memory are investigated through both finite-element modelling and a bespoke phase-change computational model. Rapid and low-energy (16 pJ to 50 pJ) optical switching is numerically demonstrated, and device optical contrast is enhanced through cascading multiple plasmonic nanoantennas.**

***Keywords*— All-optical Memory, Plasmonic-enhancement, Phase-change Integrated Photonics, In-memory Computation.**

I. Introduction

It has previously been demonstrated that the use of electric field enhancing plasmonic resonant structures can improve the switching energies and speeds of all-optical integrated-photonic phase-change memories [1]. However, such designs required the precise fabrication of a pair of plasmonic dimer nanoantennas on top of a Si_3N_4 waveguide with a nanoscale region of $Ge_2Sb_2Te_5$ (GST) phase-change material deposited into the antenna gap region [1]. In this work, we present a simpler, more fabrication-friendly plasmonically enhanced phase-change memory cell, substantially relaxing fabrication constraints. In contrast to the prior dimer-gap design which requires nanoscale GST alignment, this configuration relies on the use of a comparatively large 500 x 500 nm patch of GST with thickness 10 nm deposited directly on the (1200 x 334 nm) waveguide, upon which Au plasmonic nanoantennas are fabricated (here with a width of 40 nm and thickness of 30 nm).

A schematic of the conventional (non-plasmonically enhanced) integrated phase-change photonic memory/computing cell is shown in Fig. 1a, while the original plasmonically enhanced version is shown in Fig. 1b. A schematic of the modified fabrication-friendly design is shown in Fig 1c: here, the gap region between the nanoantennas is 40 nm in size; also included is a 5 nm thick ITO barrier layer between the GST and Au bars to prevent interdiffusion.

Phase-change materials such as GST can exist in two distinct structural phases based on atomic ordering – the amorphous and crystalline states – which exhibit dramatically different optical properties: most notably here, the crystalline phase is significantly more absorbing at 1550 nm. Reversible switching between the two phases can be triggered by heating, therefore, optical switching and also reading of the device state can be carried out by optical pulses sent through the waveguide where the plasmonic resonance enhances the interaction between the GST and the propagating optical mode.

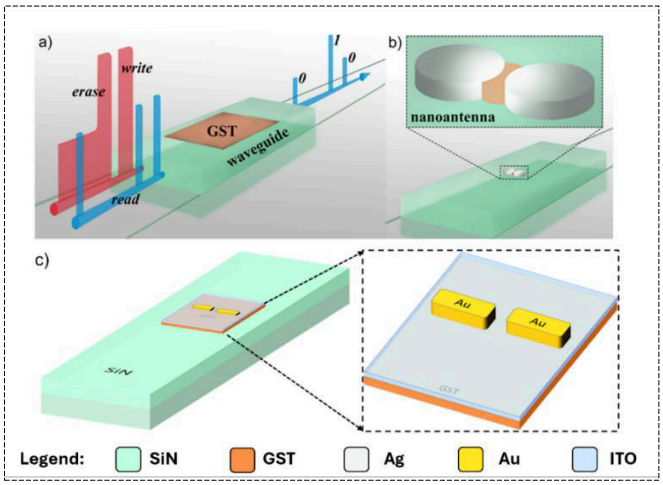

Fig. 1 Schematic of (a) the conventional integrated phase-change photonic memory/computing device, (b) the original all-optical plasmonically enhanced cell design (from [1]) and (c) the simplified fabrication-friendly all-optical plasmonically-enhanced device.

II. Methods

The optical performance and the switching characteristics of the cells are investigated through combined use of thermo-optic finite-element (FE) simulations [2] and a bespoke Gillespie algorithm-based phase-change model, already shown to accurately reproduce crystallisation dynamics in GST [3,4]. In the latter, the rates for crystal nucleation, growth and dissociation are taken from classical nucleation and growth theory and are applied across a computationally constructed grid of GST 'monomers' which represents the entire GST patch region within the device.

III. Results and Discussion

Using FE simulations, a very strong enhancement of the electric field can be observed between the Au nanoantennas for both GST phases when an optical pulse is sent through the waveguide (see Fig. 2a). When compared to the maximum electric field at the input, the central 50 x 50 nm region between the nanoantennas sees an electric field enhancement of up to 15–20 times for the amorphous phase and 4-5 times for the crystalline. This plasmonic enhancement triggers temperatures significant enough for crystallisation and amorphisation of the GST layer lying beneath the gap region of the nanoantennas. As the increase in temperature is very localised, only the GST within the gap region undergoes switching. Fig. 2b shows the device optical transmission contrast as a function of Au nanoantenna length assuming a central 50 x 50 nm region of GST between the bars switches. A maximum contrast of ~ 4.5% is achieved at bar length 185 nm.

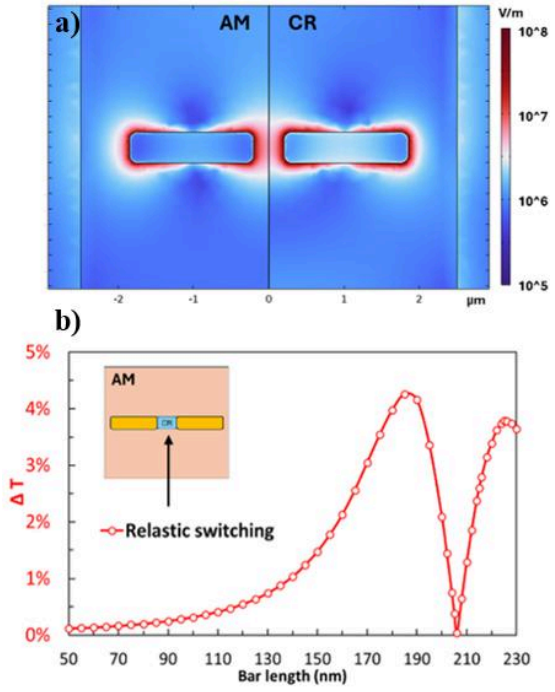

Fig. 2 a) Normalised E-field distributions within amorphous and crystalline GST. b) Optical contrast as a function of Au bar length assuming realistic switching (as seen in inset).

Using the previously described phase-change modelling techniques, reversible switching of the device is demonstrated. Starting in the fully amorphous phase, a train of 8 ns pulses with powers 2.8, 1.3, 1.2 and 0.95 mW at 1550 nm wavelength are applied to crystallise the GST in the gap region (multiple pulses are used to prevent unwanted melting of the GST as it crystallises). Re-amorphisation is achieved using a single 2.0 mW, 8 ns, 1550 nm pulse to melt and quench the material. Both crystallisation and amorphisation operations are shown in Fig. 3a,b respectively, here an optical contrast of ~4.5 % is achieved. The switching energies for the crystallisation and amorphisation are 50 pJ and 16 pJ respectively. These values are one order of magnitude smaller than those associated with conventional integrated photonic phase-change memory cell designs [5], and only slightly larger than the original - yet significantly more difficult to fabricate - plasmonically enhanced cell [1].

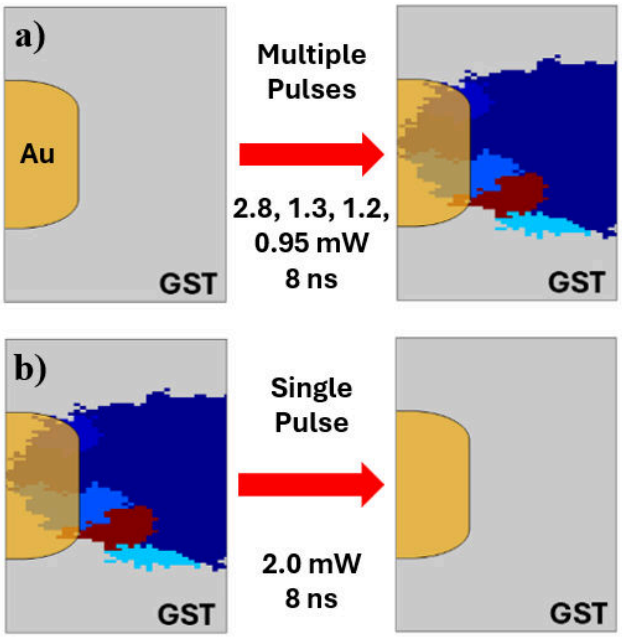

Fig. 3 a) Crystallisation and b) re-amorphisation of the phase-change cell (Coloured regions represent crystallite grains of different orientations, whereas grey is amorphous).

Finally, we look to enhance the relatively modest optical transmission contrast achieved in these devices. To do so the cascading of two pairs of plasmonic nanoantennas is investigated. Using FE simulations it was found that a maximum optical transmission contrast was seen at bar lengths of 185 nm (see inset of Fig. 4). An optimum separation between the two pairs of bars of 410 nm was determined. At this separation, both the maximum temperature and the temperature distributions in the GST are essentially identical in both gap regions, indicating that the switching behaviour should in turn be the same for both regions. For this thermally-optimum choice of antenna separation, the optical contrast is reduced slightly for the maximum achievable contrast, but still approaches a sizeable value of around 10%, as shown in Fig. 4.

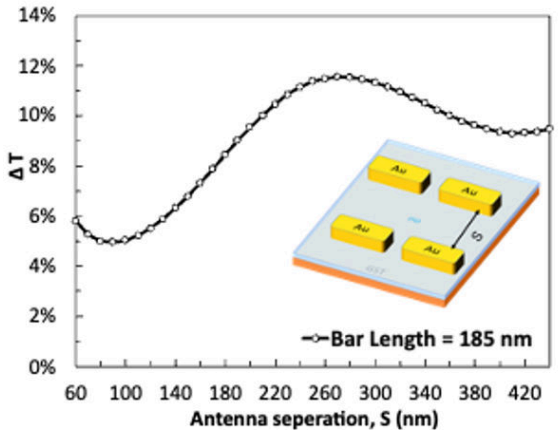

Fig. 4 Optical transmission contrast when two pairs of Au nanoantennas are cascaded on the GST patch.

IV. Conclusion

Simulations combining FE and phase-change models have demonstrated a fully rewriteable, simple-to-fabricate, all-optical, plasmonically enhanced phase-change memory cell with much improved switching properties as compared to conventional cells. Furthermore, the optical contrast can be enhanced through the cascading of plasmonic nanoantennas.

***Abstract*— This study investigates the photothermal dynamics of VO2 nanostructures through numerical simulations. We identify "nonlinear ignition," where plasmonic resonance triggers a positive feedback loop, causing abrupt temperature and optical jumps at specific intensity thresholds. Additionally, we optimize VO2-integrated SiN waveguides, demonstrating high-performance on-chip modulation for energy-efficient photonic applications.**

***Keywords*— phase-change materials, vanadium dioxide, photonic integrated circuits.**

I. Introduction

Vanadium dioxide (VO2) is a phase-change material exhibiting an insulator-to-metal transition near 68 °C, accompanied by pronounced changes in refractive index and absorption. These properties make VO2 attractive for tunable and nonlinear photonic devices. In this work, we present results of numerical simulations of the optical properties of VO2 nanostructures, specifically accounting for the coupled dynamics of heat propagation and temperature-induced electromagnetic effects. We utilize an iterative convergence algorithm to solve for the steady-state temperature of VO2 nanospheres and nanodiscs. Our results reveal a phenomenon termed "nonlinear ignition": the onset of a localized surface plasmon resonance in the metallic phase creates a positive feedback loop between absorption and photothermal heating. This leads to an abrupt, step-like jump in temperature and optical state once a critical threshold intensity is reached. We demonstrate that this threshold is highly sensitive to the thermal bias and refractive index of the substrate. Furthermore, we analyze the integration of VO2 into hybrid silicon nitride (SiN) waveguides for on-chip amplitude modulation. Contrary to intuition, we find that a direct-contact configuration can be superior to designs utilizing low-index buffer layers. By optimizing the VO2 patch thickness, high extinction ratios can be achieved with manageable loss. This work establishes a robust framework for designing scalable, energy-efficient photonic devices based on the intrinsic thermodynamics of VO2.

II. Methods

Optical cross sections were calculated using the commercial software COMSOL Multiphysics, using the radio-frequency and heat transfer toolboxes. The electromagnetic wave geometry is embedded within a larger geometry to facilitate convergence in heat propagation. The nanoparticle is illuminated by a background wave, taking the Fresnel coefficients into account. Heat transfer simulation is performed in all domains. We solve the heat diffusion equation to obtain the temperature. We then couple the radio-frequency and heat-transfer toolboxes via Multiphysics coupling, with the dissipated electromagnetic power serving as a heat source. The simulation iterates until the steady-state temperature converges.

Semimetallic nanostructures as multifunctional materials for nanophotonics

Fernando Chacon-Sanchez[1*], J. Toudert[1] and R. Serna[1]

[1]Laser Processing Group, Instituto de Optica (IO-CSIC), Madrid, Spain
*Corresponding author: fernando.chacon@csic.es

***Abstract*— Bismuth and Antimony are semimetallic materials, that displays a versatility unmatched by most widespread materials for nanophotonics. It behaves as a plasmonic, high refractive index and phase change material simultaneously on different wavelengths. We will show the potential of Bi metasurfaces for structural coloring, sensing and photonics.**

***Keywords*— Bismuth, antimony, plasmonics, phase change materials, structural color.**

I. Introduction

Nanophotonics is an emergent field that has a constant need for new materials in order to access novel functionalities. On the field of plasmonics, gold and silver are widespread, on the high-refractive index in the infrared silicon is the standard, and for tunable metasurfaces GeSbTe and similar compounds are very extended. Bismuth (Bi) and Antimony (Sb) emerge as promising materials towards multifunctional metasurfaces, as they show a unique combination of optical and structural-thermodynamical properties. In particular they behave as ultra-high refractive index (n up to 10) materials in the IR, as plasmonic materials in the VIS-UV and as phase change materials (crystalline-amorphous for Sb and solid-liquid for Bi).

II. Results and Discussion

On this invited contribution, we will explore how these advantageous properties are originated due to their intense interband transitions in the NIR, and how their dielectric response (refractive index and absorption) is successfully manipulated by modifying the film morphology at the ultrathin regime.

We will review our recent results and show the applications on nanophotonics for semimetallic thin films and nanostructures. They are exceptionally suitable for structural coloring, by using either plasmonic or interferential approaches [1], and extending this interferential approach they enable sustainable and efficient coloring of industrial materials [2]. We will show their capabilities to display subwavelength perfect absorption, both on the IR [3] and in the VIS, and we will evaluate their sensing potential. Finally, we will focus on the solid-liquid phase transition of Bi, designing metasurfaces where we tune the fraction of molten Bi to control the polarization of reflected light [4]. These metasurfaces can also display sub-ns melting upon laser irradiation, displaying great potential for optical switching [5].

Keywords -acoustic phonons, nanophononic platform, phase-transition materials; tunable nanoacoustics

Acoustic phonons govern fundamental solid-state properties through their direct coupling to atomic displacements, strain fields, and elastic energy transport. Recent advances in nanophononics have enabled the confinement and manipulation of GHz–THz acoustic modes in semiconductor and oxide multilayers, including acoustic nanocavities and opto-phononic micropillars[1]. However, most demonstrated nanoacoustic devices rely on static architectures with predetermined functionality. Introducing tunability into nanoacoustic systems remains a central challenge. A promising strategy consists in integrating responsive phase-transition materials whose elastic properties can be modified by external stimuli. Among such materials, vanadium dioxide (VO_2) is particularly attractive due to the significant structural reorganization occurring during its reversible transition between monoclinic and rutile crystalline phases, accompanied by the well-known insulator–metal transition.

Here, we experimentally investigate the dynamics of coherent GHz acoustic phonons in thin VO_2 films using ultrafast pump–probe transient reflectivity measurements. By thermally driving the material across the phase transition, we systematically compare the acoustic response in the insulating and metallic phases. The time-domain measurements, together with their Fourier analysis, reveal clear changes in both the temporal dynamics and the acoustic frequencies, indicating phase-dependent modifications of the interaction mechanisms governing the coherent acoustic response. Simple theoretical simulations further identify the origins of these differences and support the experimental observations. These results motivate the design of advanced hybrid nanoacoustic heterostructures integrating phase-transition materials within distributed Bragg reflector cavities and micropillar resonators. Such systems can enable tunable acoustic resonators through dynamic cavity switching, as well as reconfigurable phononic networks operating in the GHz regime. Beyond fundamental studies, this approach paves the way toward nanoacoustic sensing technologies and programmable optoacoustic nanodevices.

Nanoresonators and metasurfaces for nonreciprocal photonics

Sergey Kruk

[1]Faculty of Engineering and Natural Sciences, Tampere University, Finland
[2]School of Mathematical and Physical Sciences, University of Technology Sydney, Australia
*sergey.kruk@outlook.com

***Abstract*— Nonreciprocity underpins signal routing in modern technology. While nonreciprocal electronic components – diodes, transistors – have been miniaturized to the nanoscale, nonreciprocal photonics remains bulky. We develop pathways to nonreciprocal control of light at the nanoscale, enabling compact manipulation of amplitude, phase, and polarization, and opening new opportunities for integrated photonic systems.**

***Keywords*— metasurfaces, nonreciprocity, nonlinear photonics, phase change materials, epsilon-near-zero materials.**

I. Introduction

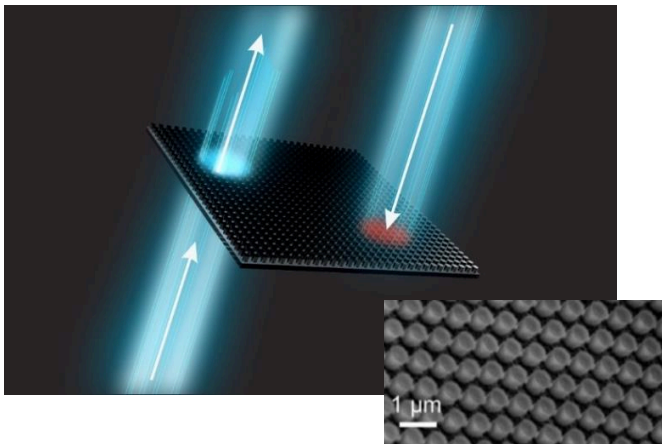
Contemporary optics is experiencing rapid advancements driven by nanotechnology. We can now mass-produce optical components that are hundreds of times thinner than a human hair, yet these components outperform conventional, bulky optical devices [1]. One crucial unresolved challenge in modern optics is how to achieve nonreciprocity at the nanoscale [2].

Nonreciprocity in a system means that the transmission of signals differs when the positions of the sources and detectors are swapped. This phenomenon is essential for controlling signal traffic and is vital in both optics and electronics. In electronics, tiny nonreciprocal components like diodes and transistors are common and indispensable. In optics, nonreciprocal components, like isolators and circulators, are much larger than their electronic counterparts, and much more expensive.

II. Results and Discussion

We present several approaches to achieving optical nonreciprocity at the nanoscale [3,4]. The building blocks are dielectric Mie-type nanoresonators hybridized with strongly nonlinear materials such as epsilon-near-zero materials [3] and phase-change materials [4].

Nonreciprocity achieved with this approach is passive, requiring no external bias. We demonstrated broadband nonreciprocal transmission covering over 100 nm in the telecommunication range (around $\lambda = 1.5$ μm). Moreover, nonreciprocity was observed down to modest light intensities of about 150 W/cm², comparable to the power density of a laser pointer. The first-generation nonreciprocal nanoresonators designed to work as isolators demonstrated



Optical isolation by a metasurface. Inset – electron microscope image of the nano-resonators.

15 dB isolation in simulations and approximately 5× isolation in experimental tests with estimated transmission fall time of 100 ps and a transmission rise time on the order of 100 ns.

We will discuss expansion of nonreciprocal nanophotonics from control of transmission amplitudes (like in isolators and circulators) to nonreciprocal control over phase and wavefront, polarization and other parameters of light.

Bias-free nanoscale nonreciprocal optics controlling forward-to-backward ratios of amplitude, phase and polarization will enable conceptually new optical components with independent pairs of on-demand functionalities for forward vs backward directions of light propagation.

***Keywords*— canalization, phonon polaritons, α-MoO$_3$, super-resolution imaging, s-SNOM.**

I. Introduction

Phonon-polariton (PhP) canalization is diffractionless transport enabled by flattened isofrequency contours (IFC), previously realized with twisted multilayers at selected angles [1–5]. We show [6] that stacks are unnecessary, engineering the substrate permittivity to an optimal negative value that flattens α-MoO$_3$ PhPs in a single layer on SiC, enabling shiftable $\sim\lambda_0/220$ imaging.

II. Methods

Design metric and variables. At a fixed optical frequency ω (cm^{-1}), the in-plane PhP wavevector $q(\omega,\varphi)$, where φ is the propagation angle in the flake plane with respect to a chosen laboratory axis x (the [100] α-MoO$_3$ crystal direction). The IFC is the curve in q-space containing all allowed q at fixed ω. Canalization corresponds to a locally flat IFC, meaning that the longitudinal wavevector component $q_x(\omega,\varphi)$, varies weakly with φ. We quantify this with the flatness factor $F(\omega) = dq_x/d\varphi$. Canalization corresponds to $|F| \approx 0$ over the relevant angular range.

Substrate-permittivity engineering. The α-MoO$_3$ layer is described by its anisotropic permittivity tensor components $\varepsilon_x, \varepsilon_y, \varepsilon_z$ along the crystallographic axes [100], [001], [010], respectively. The substrate is described by a complex permittivity $\varepsilon_{sub}(\omega) = \varepsilon'_{sub}(\omega) + i\varepsilon''_{sub}(\omega)$. From the analytical dispersion of the relevant polaritonic mode, we obtain an "optimal" substrate permittivity $\varepsilon_{optimal}$, with $\varepsilon'_{optimal} < 0$, that minimizes $|F|$, then we select a practical substrate whose ε_{sub} best matches this value across the target band (SiC in this work).

Modeling and extracted quantities. Full-wave simulations are used to compute near-field maps for realistic excitations (dipole and antenna launchers), for a given α-MoO$_3$ thickness d, substrate $\varepsilon_{sub}(\omega)$, and the in-plane azimuthal orientation angle θ of the crystal with respect to the laboratory axis or object/antenna axis. From simulated and measured interference fringes we extract $Re(q_x)$, the PhP wavelength $\lambda_{PhP} = 2\pi/Re(q_x)$, and the free-space wavelength $\lambda_0 = 2\pi c/\omega$. The propagation length L_p is defined as the 1/e decay length of the near-field amplitude envelope along x. The group velocity is obtained from the dispersion as $v_g = \partial\omega/\partial Re(q_x)$, and the PhP lifetime is estimated as $\tau \approx L_p/v_g$.

Experiments and imaging. α-MoO$_3$ flakes (thickness d from AFM) are transferred onto SiC and control substrates, Au nanoantennas launch phonon polaritons, and s-SNOM maps amplitude and phase. For nanoimaging, buried Au nanodisks are covered by α-MoO$_3$/SiC, and the reconstructed top-surface near field is analyzed as a super-resolved image whose lateral displacement Δ from the object's vertical projection is tuned by ω, d and θ.

III. Results and Discussion

1- **Substrate-engineered single-layer canalization**. Matching $\varepsilon_{sub}(\omega)$ to an analytically identified $\varepsilon_{optimal}(\omega)$, with negative $\varepsilon'_{optimal}(\omega)$, tlattens the α-MoO$_3$ IFC, making q_x nearly invariant with φ, this produces diffractionaless, strongly collimated propagation in a single unpatterned layer, avoiding twisted stacks and angle-specific "magic" conditions.

2- **Practical realization with SiC, broadband and low**

loss. SiC provides $\varepsilon_{sub}(\omega)$ close to $\varepsilon_{optimal}(\omega)$ in the relevant Reststrahlen band, yielding a canalization window of about 50 cm^{-1} (~850-900 cm^{-1}). From near-field dispersion measurements, $v_g \cong 10^{-3}c$ at 877 cm^{-1}, and combining v_g with the measured L_p gives PhP lifetimes of about 2 ps.

3- **Super-resolution imaging of buried nanostructures.** In the canalization regime, high-spatial-frequency (evanescent) information is transported with minimal diffraction, enabling imaging of buried Au disks. At ω_0= 885 cm^{-1}, disks separated by 50 nm (edge-to-edge) are resolved, corresponding to $\sim\lambda_0/220$.

4- **Shiftable imaging controlled by ω, d and θ** . The super-resolved image is laterally displaced from the vertical projection and can be repositioned by tuning ω_0, using different layer thickness d, and choosing a different azimuthal orientation θ. The frequency dependence is demonstrated for two devices with $d_1 =$ 415 nm and $d_2 = 340$ nm, showing tunable separation between image replicas as ω_0 varies.

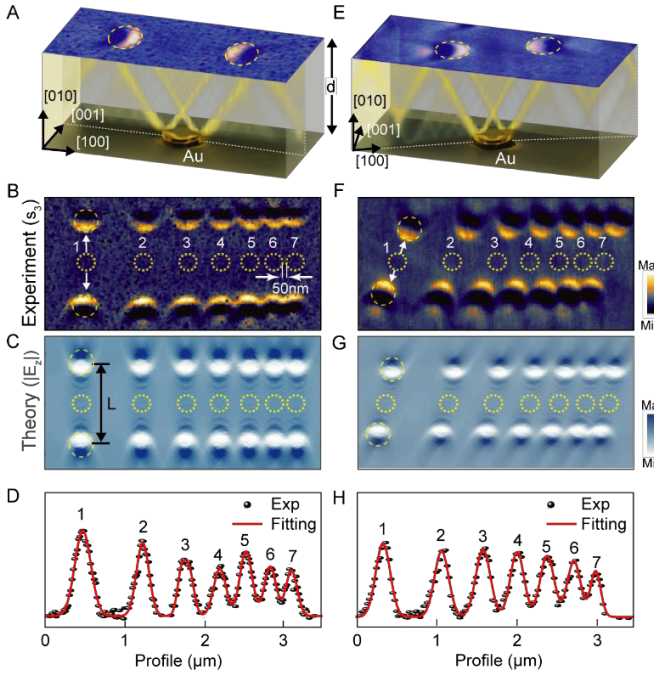

Fig. 1 Shiftable canalization-based super-resolution imaging through a single α-MoO_3 layer on SiC. Schematics (A,E), experimental and simulated s-SNOM near-field maps of buried Au nanodisks resolving 50-nm gaps (B,C,F,G), and corresponding line profiles with fits (D,H).

IV. Conclusion

Canalization is achieved in a single α-MoO_3 van der Waals layer by engineering the substrate permittivity to a suitable negative value, removing the need for complex twisted multilayers and finely selected twist angles. The resulting canalized PhPs are broadband (~50 cm^{-1}), slow ($v_g \cong 10^{-3}c$), and low-loss ($\tau \cong 2$ ps), enabling a shiftable superlens that resolves buried features down to $\sim\lambda_0/220$, with image placement controlled by ω, d and θ.

***Abstract*—In this work, we present room temperature zero differential thermal emitters based on strained Sm 1-x Nd x NiO3 thin films. By engineering the metal insulator transition, we obtain nearly constant long wavelength infrared emission over about 15 degrees Celsius, confirmed by outdoor thermal imaging experiments.**

***Keywords*— camouflage, infrared, LWIR, nickelates.**

I. Introduction

All objects at temperatures above absolute zero emit thermal radiation. For an ideal black body, the emitted spectral radiance is described by Planck's law, and the total radiated power follows the Stefan–Boltzmann relation, scaling as T^4. Real materials deviate from this ideal behavior through their emissivity, which depends on wavelength, angle, and temperature. While emissivity is often weakly temperature dependent, materials undergoing phase transitions can exhibit strong and abrupt variations in their optical properties, enabling control of thermal radiation. Such control is attractive for applications including spacecraft thermal management, energy harvesting, and thermal camouflage. An appealing concept for thermal camouflage is that of zero-differential thermal emitters (ZDTEs), whose radiated power remains nearly constant over a finite temperature range. This condition requires compensating the intrinsic T^4 increase of blackbody emission with a temperature-dependent emissivity. In practice, this can be achieved in materials displaying metal–insulator transitions (MITs), where large and reversible changes in optical properties occur. To date, most ZDTE demonstrations rely on VO_2 [1], whose sharp transition and pronounced hysteresis require careful compositional and structural engineering to achieve gradual emissivity modulation, motivating the search for alternative material platforms. Rare-earth perovskite nickelates, $RNiO_3$, offer a compelling alternative due to their chemically tunable MIT spanning a wide temperature range [2]. Their reversible changes in optical properties have already enabled ZDTE demonstrations in $SmNiO_3$ [3], [4]. Furthermore, alloying with $NdNiO_3$ allows continuous tuning of the transition temperature [5]. In this work, we investigate the MIT in $Sm_{1-x}Nd_xNiO_3$ thin films and demonstrate how compositional engineering enables ZDTE behavior in the long-wave infrared (8–14 μm), a spectral range relevant to atmospheric transmission and uncooled thermal imaging systems.

II. Methods

Perovskite nickelate thin films were synthesized using Pulsed Laser Deposition, allowing precise control over composition and thickness. To ensure optimal structural properties, X-Ray Diffraction pattern were measured. The electrical behavior of the films was characterized using transport measurements, revealing the temperature-dependent metal-insulator transition. Optical properties were investigated through Fourier-transform infrared spectroscopy, providing insight into the films' temperature-dependent optical response. In addition, outdoor thermal imaging measurements were performed to directly visualize the films' infrared emission and assess their thermal behavior under controlled heating, **Fig.1**.

III. Results and Discussion

In this work, we fabricated two ZDTE: ZDTE-1, a film of $Sm_{0.85}Nd_{0.15}NiO_3$ and ZDTE-2, a film of $Sm_{0.75}Nd_{0.25}NiO_3$; both grown on (001)-oriented $LaAlO_3$ substrates. During the MIT, the films undergo large changes in infrared reflectivity, which compensates for the temperature-dependent increase in blackbody emission, resulting in a nearly constant radiated power in the LWIR range. Infrared imaging under outdoor conditions demonstrates that the ZDTE films significantly reduce the apparent thermal contrast compared to the bare substrate, effectively masking temperature variations, **Fig.1**. These results illustrate that rare-earth nickelate films can act as single-layer thermal camouflage coatings, with their optical and electronic properties tuned via composition to achieve near-constant LWIR emission under ambient conditions.

IV. Conclusion

In this work, we demonstrated room-temperature zero differential thermal emitters based on the metal-insulator transition of rare-earth perovskite nickelates. Exploiting the modulation of infrared optical properties, we realized ZDTEs operating in

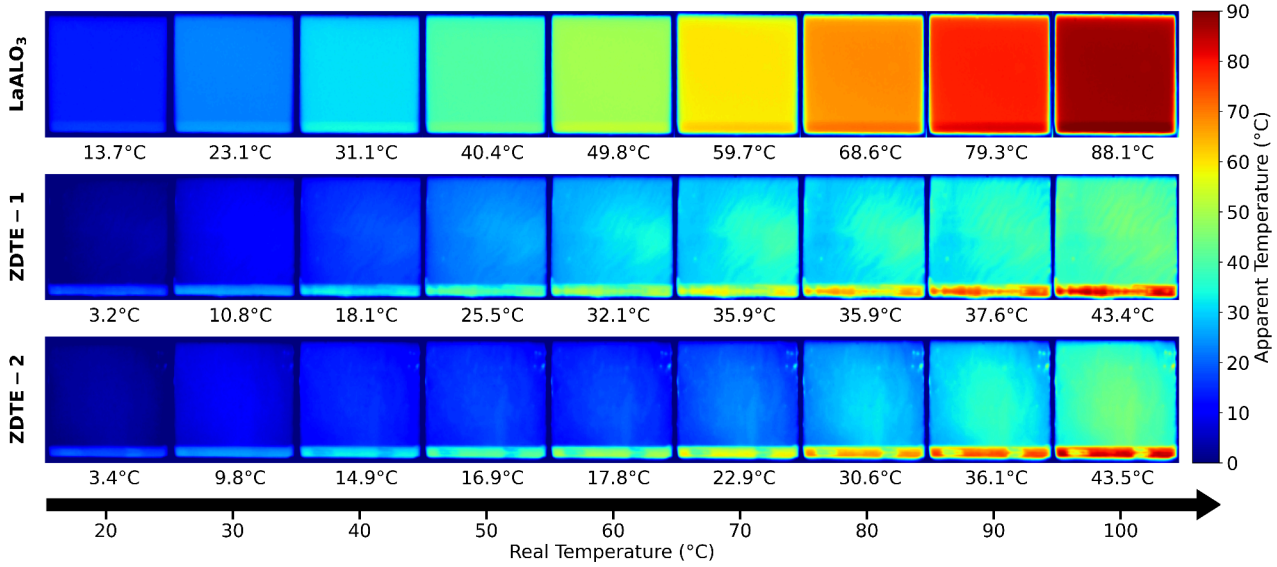

Fig. 1. Long-wavelength infrared (LWIR) images of nickelate samples held at temperatures from 20 to 100 °C (real temperature indicated by the bottom black arrow). The thermal camera was calibrated by using a black body (not shown here). To reduce reflections from surrounding objects, the experiments were conducted outdoors under a clear sky. The first row shows thermal camera images of the bare (001)-oriented $LaAlO_3$ substrate. The second and third rows show two different ZDTEs: ZDTE-1, a film of $Sm_{0.85}Nd_{0.15}NiO_3$ and ZDTE-2, a film of $Sm_{0.75}Nd_{0.25}NiO_3$; both grown on (001)-oriented $LaAlO_3$ substrates. The emissivity of the ZDTEs films decreases with increasing temperature, effectively masking variations in the real temperature as seen by the thermal camera (apparent temperature is indicated below each image). The lower part of each ZDTE image corresponds to the exposed substrate, which exhibits a higher apparent temperature, consistent with the bare substrate.

the long-wavelength infrared band, whose emissivity decreases as T^{-4}, compensating the intrinsic T^4 increase of blackbody radiated power. As a result, the LWIR radiated power remains nearly constant over a temperature range of approximately $15\,^{\circ}\mathrm{C}$, effectively masking real temperature variations, as confirmed by outdoor thermal imaging experiments. Beyond demonstrating room-temperature ZDTEs, this study establishes rare-earth nickelates as a versatile material platform for adaptive thermal emission control. More generally, the strong coupling between electronic correlations, lattice structure and optical properties in nickelates offers promising opportunities for next-generation dynamic thermal photonic devices, including tunable coatings for thermal management, infrared camouflage, and adaptive photonic applications.

***Abstract*—Rare-earth ions (REIs) are promising candidates for quantum hardware owing to their optically addressable, highly coherent spin states. Integrating these properties into scalable quantum architectures, however, remains challenging. Here, we introduce REI-based molecular materials that combine long optical and spin coherence with the synthetic versatility of coordination chemistry.**

***Keywords*— rare-earth ions, molecular materials, spin-photon interfaces, coherent spectroscopy.**

I. Introduction

Molecular systems that combine electron and/or nuclear spin states with optical transitions constitute a promising platform for quantum spin–photon interfaces. Their appeal lies in the atomically precise structure of molecules and the virtually unlimited diversity of accessible chemical compositions. By exploiting rational molecular design, both optical and spin properties can be finely tuned, enabling the development of optically addressable spin qubits, quantum transducers, optical quantum memories, and sensors [1].

Among optically active molecular systems, rare-earth ion (REI) complexes are particularly attractive, exhibiting record-narrow optical linewidths together with well-defined spin degrees of freedom. In this contribution, we review the major results reported for Eu(III) complexes [2,3] and present recent advances achieved through improved sample fabrication and coherent spectroscopic investigations. These studies allow us to elucidate the microscopic mechanisms that determine the Eu^{3+} homogeneous optical linewidth, including the roles of structural disorder and spin–environment interactions, which ultimately limit optical coherence in molecular REI materials.

II. Methods

A key figure of merit for quantum photonic applications is the homogeneous optical linewidth (Γ_h), which determines the optical coherence time (T_2) and ultimately sets the performance of spin–photon interfaces and quantum memories.

We have developed dedicated high-resolution spectroscopic methods to accurately determine Γ_h in challenging sample formats, including crystalline powders and thin films. These approaches enable reliable extraction of optical coherence properties beyond conventional bulk single-crystal measurements. We apply these techniques to a series of molecular crystals incorporating Eu^{3+} ions (Figure 1), allowing us to directly evaluate the impact of molecular design, local coordination symmetry, and solid-state organization on optical coherence.

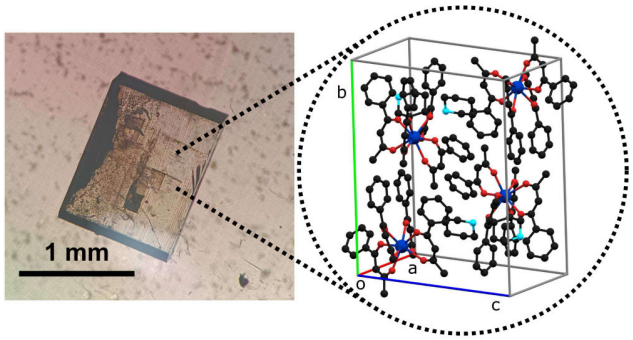

Fig. 1 High-quality molecular crystal of $Eu(BA)_4(pip)$

III. Results and Discussion

The optical homogeneous linewidth of Eu^{3+} has been investigated in two molecular crystals, $Eu(BA)_4(pip)$ and Eu(TMHD)(phen), as a function of temperature, waiting time, and average Eu–Eu distance. Detailed spectroscopic analysis reveals that, in the zero-temperature limit, Γ_h is not fundamentally limited by ion–ion interactions or magnetic noise. Instead, it remains strongly dependent on crystalline quality, highlighting the critical role of structural disorder and defects.

Nevertheless, the measured Γ_h values—reaching the tens of kHz range—are sufficiently narrow to enable optical addressing of nuclear spin levels and the demonstration of optical quantum storage. These results establish quantitative benchmarks for molecular REI systems in the context of quantum photonics.

Ongoing efforts toward robust and reproducible fabrication protocols for defect-minimized molecular REI materials, as well as controlled sample shaping for photonic integration, will also be discussed.

IV. Conclusion

REI-based molecular materials constitute an emerging platform for coherent spin-photon interfaces. In particular, Eu^{3+} complexes stand out for their exceptionally narrow optical linewidths in the tens of kHz range, enabling optical spin polarization and optical quantum storage. Continued advances in material quality and device integration are expected to further position molecular REI systems as scalable building blocks for quantum technologies.

***Abstract*— Phase-change materials enable optical switching devices with highly tunable optical behavior, ultrafast modulation speeds, and low energy requirements. In this work, we introduce a new optical amplitude switch that employs the phase-change material antimony trisulfide (Sb_2S_3) and exploits the Brewster-angle effect to achieve efficient, controllable modulation.**

***Keywords*— phase change materials, optical switching, Brewster effect.**

I. Introduction

The increasing importance of high-speed data processing with minimal energy consumption has spurred the utilization of light for signal transmission and processing. By employing nanostructures, the energy requirements and interaction timescales can be greatly reduced, enabling the integration of multiple devices that possess the ability to control, modulate, and process light signals with high speed and energy efficiency in the same chip [1]. The pursuit of more versatile nanophotonic devices has led to the exploration of phase-change materials (PCMs), offering the potential to create tunable and switchable nanophotonic systems through the modulation of their optical properties via external stimuli [2]. Reconfigurability offers significant advantages over conventional fixed-function devices by allowing dynamic adjustments in real-time, thus meeting the evolving demands of many photonic applications [3].

II. Results and Conclusion

Amorphous and crystalline samples of Sb_2S_3 are optically and structurally characterized to explore their potential in the design of an optical amplitude switch based on the Brewster angle phenomenon [4]. The Brewster angle value depends on the refractive index of both materials at the reflective interface. Thus, the Brewster angle is strongly affected by the phase of the PCM. When the non-reflection condition is met for one of the Sb_2S_3 phases (i.e., at the Brewster angle), upon phase-change the Brewster condition is broken, leading to light reflection at the interface and producing an optical contrast in reflection that can be harnessed for optical switching applications. Sb_2S_3 is the alternative low-loss PCM with larger transparency window. i.e. spectral range beyond which neither of the material's phases experience optical losses. This is important for the optical switch based on Brewster angle, as this phenomenon only takes place if the material is transparent to light (negligeable extinction coefficient, $k \simeq 0$). With this optical switch configuration, we experimentally demonstrate an optical contrast of 22 dB [5]. Noteworthy, we theoretically predict that this contrast could be further enhanced by tailoring the incident angle and the wavelength of the beam. These findings highlight the potential of using the old Brewster angle effect in developing new efficient optical switch devices based on low-loss wide band gap PCMs such as Sb_2S_3.

Abstract: Scalable phase-change metasurfaces combining soft nanoimprint lithography with GeTe, Sb_2S_3 and VO_2 are demonstrated for tunable visible and near-infrared photonics. Large-area hybrid dielectric/PCM architectures exhibit reversible optical switching, resonance modulation and strong electrical contrast. The approach enables low-cost, scalable fabrication of reconfigurable photonic devices compatible with industrial-scale manufacturing.

Metasurfaces composed of subwavelength nanostructures provide exceptional control of light propagation, but most demonstrated devices remain static and rely on costly nanofabrication methods. Integrating Phase Change Materials (PCMs) into metasurfaces enables dynamically tunable photonic systems through reversible structural or electronic transitions. However, scalable fabrication compatible with large-area manufacturing remains a major challenge.

Here, we present scalable approaches combining soft Nano Imprint Lithography (soft-NIL), sol-gel processing and PCMs to fabricate tunable metasurfaces operating from the visible to the near infrared. Three complementary strategies are demonstrated: (i) dielectric nanostructures fabricated by etch-free soft-NIL and used as templates for PCM conformal deposition, (ii) NIL-patterned dielectric masks enabling direct etching of PCM layers, and (iii) direct imprinting of PCM-based inks. These methods enable centimeter-scale metasurfaces with strongly reduced fabrication complexity compared with conventional electron-beam lithography.

Different PCMs were investigated, including GeTe, Sb_2S_3 and volatile VO_2. VO_2 thin films and metasurfaces were developed from a sol-gel route based on $VO(acac)_2$ precursors and optimized to achieve efficient and reproducible metal-insulator transition (MIT) switching near 53 °C. We show that crystallographic texture, particularly preferential M1(011) orientation, strongly influences optical and electrical switching performances. Optimized VO_2 films exhibit electrical resistance switching over more than two orders of magnitude together with refractive index modulation exceeding one unit in the near infrared.

The optimized PCM layers were integrated onto dielectric SiO_2 metasurfaces composed of submicronic periodic pillar arrays fabricated by soft-NIL. Upon thermal or laser-induced switching, the resulting hybrid metasurfaces exhibit reversible spectral modulation in reflection and transmission, with resonance shifts up to 70 nm in the visible and modulation depths reaching 7. These performances are comparable to state-of-the-art PCM metasurfaces despite the absence of advanced design optimization.

Finally, in situ synchrotron X-ray diffraction combined with simultaneous electrical measurements was used to investigate switching stability, phase-transition dynamics and structure–property relationships governing the optical response. The proposed approaches provide a versatile and scalable platform

compatible with flexible substrates, solution processing and large-area manufacturing for practical reconfigurable photonics and tunable meta-devices.

***Abstract*— We demonstrate high-throughput optical modulation in monolithic and hybrid Sb_2S_3/Si metasurfaces, where silicon-enhanced resonances enable 99% transmission modulation at telecom wavelengths using only ~3% optically induced crystallization in Sb_2S_3. This phase transition also allows large-scale tuning of nonlinear emission, offering a versatile platform for reconfigurable linear and nonlinear nanophotonics.**

***Keywords*— metasurfaces, optical switching, phase change materials, high-Q resonance, third-harmonic generation.**

I. Introduction

Dielectric metasurfaces, consisting of arrays of dielectric nanoresonators, have attracted growing interest in recent years, due to their potential for high-throughput optical switching in flat optical systems [1]. By supporting low-loss electric and magnetic resonances with strong field enhancement, these structures offer efficient light-matter interaction while maintaining high transmission, making them highly attractive for compact and energy-efficient photonic devices. However, traditional metasurface functionalities remain intrinsically static, limiting their integration into dynamic photonics systems. Enabling active and reversible control over the optical response of metasurfaces is therefore essential for realizing reconfigurable and programmable flat optics systems. Among various electrical, mechanical, and optical techniques for switching metasurfaces, contact-less switching via phase change materials (PCMs) has been proposed as a promising candidate due to their large refractive index contrast between the amorphous and crystalline phases and their low optical loss across the visible-to-near-infrared spectral window [2]. A key challenge, however, is to maximize optical modulation while minimizing the PCM's phase transition.

II. Methods

Our methodology is based on electromagnetic modeling, parametric optimization, nanofabrication, and linear and nonlinear optical characterization.

Among the multipolar responses supported by dielectric nanostructures, the conventional magnetic dipole resonance is well known for its strong near-field enhancement within the nanostructure and relatively larger mode volume compared to other multipoles [3]. Therefore, we first designed a Sb_2S_3 nanopillar metasurface on a silica substrate supporting a magnetic dipole resonance at the telecom wavelength region. To further enhance the light-matter interaction, we deposited a silicon layer with an optimized thickness on top of the metasurface to form a hybrid structure supporting Fano-like high-Q resonances. Intermediate phase change states were modeled to enable optical switching and tunable third-harmonic generation (THG). We performed experimental transmission measurements together with THG characterization on the selectively fabricated metasurfaces to validate the proposed concept.

III. Results and Discussion

Owing to the strong near-field enhancement associated with the magnetic dipole resonance, the monolithic Sb_2S_3 metasurface enables a broadband spectral tunability with only a partial phase transition. Specifically, a modulation depth of 92% at 1560 nm is achieved both numerically and experimentally, with only 53% crystallization of the phase change material induced by external laser illumination. As can be seen from Figure 1a, a pronounced resonance shift is observed from the amorphous to the poly-crystalline state, which is in excellent agreement with the experimental

measurements shown in Figure 1b. Furthermore, the integration of a thin silicon layer dramatically enhances the modulation performance, enabling a hybrid metasurface achieving 99% modulation depth with only 3% crystallization [4]. Figure 2b gives the simulated transmission spectra where the Fano-like high-Q resonance near 1457 nm, suggesting that a minimal crystallization of only 3% is sufficient to achieve complete optical switching with the designed hybrid metasurface. Subsequently, the experimentally measured modulation performance is shown in Figure 2b, where a modulation depth exceeding 90% is demonstrated with a twofold reduction in the required switching laser power as compared to the monolithic metasurface for switching.

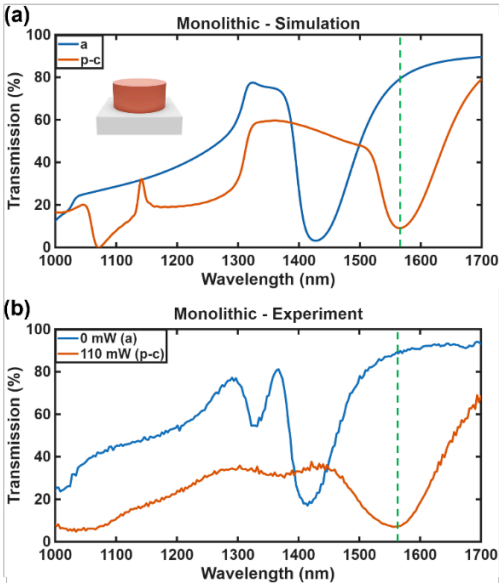

Fig. 1. Monolithic Sb_2S_3 metasurface optical switching. (a) Simulated and (b) experimental transmission spectra showing 92% modulation depth at 1560 nm with 53% crystallization. Adapted from Ref [4].

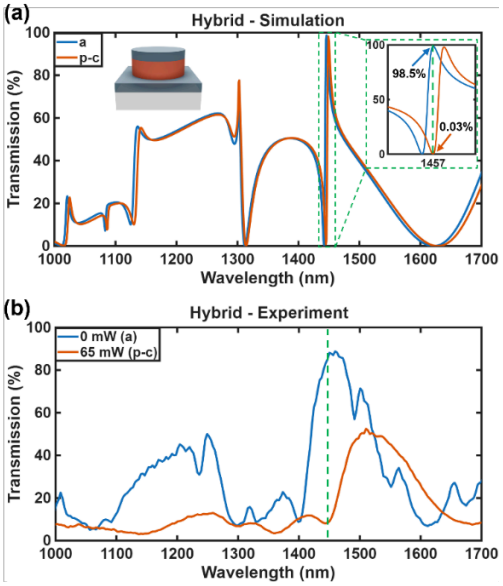

Fig. 2. Hybrid Sb_2S_3/Si metasurface optical switching. (a) Simulated transmission with 99% modulation (inset: Transmission conversion achieved with 3% crystallization). (b) Experimental validation showing over 90% modulation depth. Adapted from Ref [4].

This hybrid metasurface platform for optical switching can be further extended to the nonlinear regime [5]. The strong near-field enhancement associated with the designed high-Q resonance facilitates the nonlinear optical processes, leading to enhanced nonlinear generation. Moreover, the tunable resonant response allows large-scale, spectrally controllable nonlinear emission. We experimentally obtain efficient THG tuning with 20 nm spectral shift through partial crystallization, enabling switchable harmonic generation across different visible wavelengths (Fig. 3).

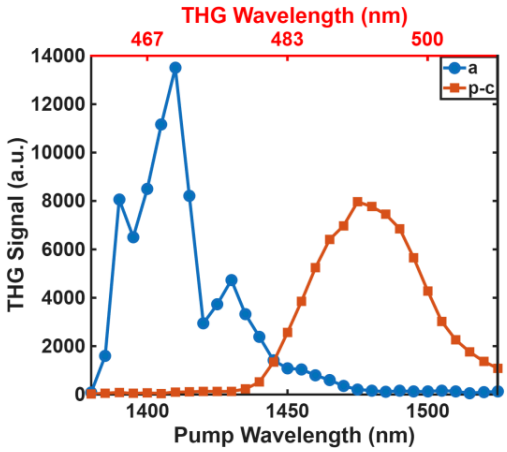

Fig. 3. Experimental THG signals from the hybrid design in amorphous and poly-crystalline states, demonstrating large-scale nonlinear tunability.

IV. Conclusion

We have demonstrated ultra-efficient optical switching through hybrid Sb_2S_3/Si metasurfaces, achieving 99% transmission modulation at telecom wavelengths with only 3% crystallization. This exceptional performance is enabled by high-Q resonances that amplify sensitivity to minimal refractive index changes ($\Delta n = 0.02$) in the phase change material. Furthermore, we demonstrated that the resonance-supported field enhancement in this hybrid system provides a powerful route for large-scale tuning of THG from the designed hybrid metasurfaces. These results suggest Sb_2S_3-based hybrid metasurfaces as a versatile platform for highly efficient tunable linear and nonlinear nanophotonic functionalities in integrated photonic devices.

***Abstract*— A well-designed 2D cube-array structural color platform was combined with a pH-responsive polymer to achieve sensitive optical pH sensing. The resulting color shift provides a reliable sensing element, offering a practical route toward integrating structural color architectures into real-world pH sensor devices.**

***Keywords*— photonic structures, pH sensing, two photon polymerization, digital analysis.**

I. Introduction

Photonic structures have drawn wide interest in recent years because their periodic micro- and nanoscale architectures provide an effective way to control light. Such structures can produce vivid structural colors through optical interference and diffraction, offering a simple colorimetric signal without the need for traditional pigments or dyes. Since these colors are highly dependent on geometry and local refractive index, photonic platforms have become an attractive choice for compact and reliable optical sensing.

By introducing stimuli-responsive polymers into photonic architectures, structural color systems can be further developed into practical sensing devices. Responsive polymers can swell or shrink under external conditions such as pH or chemical changes, which in turn alters the photonic geometry and leads to visible color shifts. This coupling between structural variation and optical response enables sensitive detection in a straightforward and intuitive manner [1-3].

Among these applications, pH-responsive photonic sensors are particularly promising for biomedical analysis, environmental monitoring, and microfluidic platforms. With the increasing demand for miniaturized and integrated lab-on-chip systems, reliable on-chip pH sensing remains an important challenge. Structural color-based photonic sensors provide a useful approach toward label-free, visually readable, and easily integrable pH detection at the microscale.

II. Methods

In this work, two-photon polymerization was employed to fabricate the designed cube-array photonic structures. The samples were produced using a commercial system (Photonic Professional, Nanoscribe GmbH, Germany), enabling high-precision microfabrication. A 63X oil-immersion objective (Zeiss, NA = 1.4) was used during the writing process. The structural design and optical response were modeled using Lumerical FDTD; detailed simulation results are not included in this short abstract.

For pH sensing measurements, a microfluidic chamber was constructed to deliver buffered solutions with five different pH values. The dynamic optical response of the samples under continuous flow was recorded using a 4X objective (Olympus, NA = 0.1) coupled with a CCD camera. The resulting dynamic structural color variations were subsequently analyzed using imageJ software.

III. Results and Discussion

The samples were fabricated using an acrylic acid-based pH-responsive polymer together with the commercial non-responsive IP-L resin. The schematic in Fig. 1a illustrates the dual-photoresist design, which significantly improves the mechanical stability of the structures.

The structural colors of the cube arrays are shown in Fig. 1b. A clear and pronounced color change is observed when the samples are immersed in pH 2.17 buffered solution, resulting from both the increase in the surrounding medium's refractive index and the swelling of the photonic structures. This vivid color response in solution forms the basis for pH detection.

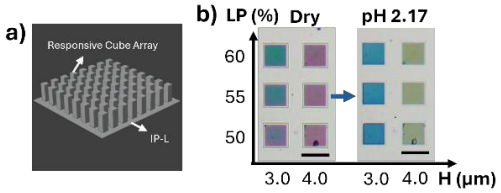

Fig. 1 a) Schematic of the cube array fabricated using a dual-photoresist approach. b) Structural colors of the cube arrays in dry state and in pH 2.17 buffered solution. The arrays have heights of 3.0 and 4.0 μm and were fabricated under laser powers of 50%, 55%, and 60%. The scale bars are 100 μm.

Fig. 2a compares the structural colors of the samples in five different buffered pH solutions. As the pH increases, the colors gradually shift toward blue in a clear and noticeable manner. Trainable Weka Segmentation, a machine-learning plugin in imageJ, was used to isolate the sensor regions in the images and quantify their structural color changes. Large image datasets were then processed in batch using custom imageJ macros. After processing, the RGB values were converted to CIE Lab coordinates and subsequently transformed into XYZ and chromaticity (x, y) values for representation on the CIE color space diagram. The color pixel data extracted from Fig. 2a i) using imageJ are presented in Fig. 2a ii) as a CIE chromaticity map. From the CIE plot, the samples show clear separation under different pH conditions, providing a potential basis for establishing standard colorimetric rules to quantify structural color variations across varying pH environments.

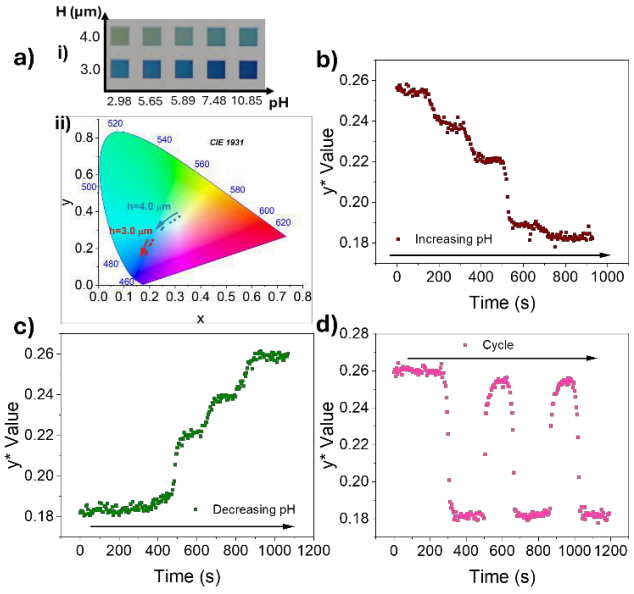

Fig. 1 a) i) Optical images showing the structural colors of the samples (h = 3.0 - 4.0 μm, LP = 60%) in buffered solutions with different pH values. ii) CIE chromaticity diagrams of the samples shown in i), plotted using imageJ digital image analysis. b) and c) "y" values of sample (H = 3.0 μm) extracted from the CIE diagram under increasing and decreasing pH conditions as a function of time, respectively. d) "y" values for the sample with height of 3.0 μm in acidic (pH = 2.98) and basic (pH = 10.85) solutions.

The sample was sealed in a microfluidic flow-in and flow-out chamber and driven by a syringe pump. Multiple dynamic pH response tests were performed to verify its effectiveness. The "y" values were extracted for quantitative analysis. During the experiment, buffered pH solutions were gradually introduced into the microfluidic chamber while the structural color response was recorded on video. Individual frames were then collected for processing. As the pH increased (2.98, 5.65, 5.89, 7.48, and 10.85), the extracted "y" values decreased consistently, as shown in Fig. 2b. The opposite trend was observed when the pH was lowered (Fig. 2c). The "y" values remained stable at each pH step, highlighting the pH responsive cube array's reliability as a pH sensing platform.

The repeatability and reproducibility of the sensor response are demonstrated in Fig. 2d. An acidic buffer (pH = 2.98) and a basic buffer (pH = 10.85) were selected as the two main solutions for three consecutive pH cycling tests. The extracted "y" values are plotted in Fig. 2d, showing consistent and repeatable behavior across all cycles. The signal returns reliably to its original level when switching between acidic and basic conditions, indicating good reversibility of the structural color response.

IV. Conclusion

The cube-array photonic structures provide stable and reproducible optical readouts under repeated pH variations. This repeatable step-like behavior highlights their potential as robust structural color platforms for practical on-chip pH sensing applications. In addition, the combination of digital image-based analysis with direct, label-free optical readout makes the pH detection approach more flexible and accessible for integration into compact sensing systems.

***Abstract*— Integrated single-photon emitters (SPEs) are pivotal for advancing quantum technologies, including quantum communication, computing, sensing, and simulation, as they serve as reliable carriers of quantum information within quantum systems. A promising strategy to enhance the capabilities of SPEs is to leverage plasmonic nanostructures, which can dramatically improve light-matter interactions. However, despite the potential, the use of plasmonic nanostructures for SPEs has encountered significant bottlenecks. We have made considerable progress in overcoming these challenges by incorporating techniques for efficient emission and extraction. Nevertheless, we have found that, beyond achieving efficient emission and extraction, substantial hurdles remain in realizing scalable quantum systems. The primary issue lies in the intrinsic randomness and uncertainty associated with practical SPEs. This unpredictability restricts precise control over photon emission, extraction, emitter orientation, and spatial positioning, ultimately limiting both integration density and device performance. To address these challenges, we propose a viable solution based on V-shaped plasmonic nanoantennas that enhance both photon emission and extraction for multiple SPEs, viewed through the framework of transformation optics. This innovation not only improves the performance of individual emitters but also enables their deterministic integration, thus facilitating the reusable, large-scale integration of SPEs into future quantum systems.**

***Abstract*—Photon-pair generation from ultra-thin nonlinear metasurfaces opens new possibilities for quantum technologies. We reveal that the quantum photon states can exhibit a strongly non-reciprocal behaviour, where the generation rate and quantum entanglement can dramatically vary depending on which side of the metasurface the pump light is incident from.**

***Keywords*— non-reciprocity; metasurface; biphoton entanglement**

I. Introduction

Optical metasurfaces incorporating nonlinear materials are emerging as new platforms for generating photon pairs through spontaneous parametric down-conversion (SPDC) at the nanoscale with tunable frequency [1] and polarization [2], [3], [4] entanglement. However, the directional control of quantum states was limited to nonreciprocal structures with a thickness of multiple wavelengths [5]. We reveal, for the first time to our knowledge, that photon generation from metasurfaces with sub-wavelength-thin nonlinear nanostructures can exhibit strong non-reciprocity. Specifically, we predict theoretically and establish experimentally that the rate and quantum state of the signal and idler photons can dramatically depend on their emission and the pump incidence directions, as schematically illustrated in Fig. 1.

II. Results and Discussion

We demonstrate nonreciprocity for a semiconductor metasurface incorporating [110] InGaP nano-resonators with approximately cylindrical shapes [4]. Whereas the presence of the substrate makes the whole metasurface asymmetric, the linear transmission and reflection remain independent of the pump direction.

Most remarkably, we find that the nonlinear process of SPDC can feature big differences in the generation of entanglement between various polarization components depending on the incidence direction, as sketched in Fig. 1. Our numerical simulations identify optimal metasurface designs that resonantly enhance nonreciprocity, enabling a generation rate contrast up to 20 dB and the creation of totally distinct quantum states. We further confirm these principles experimentally by fully characterizing the quantum states.

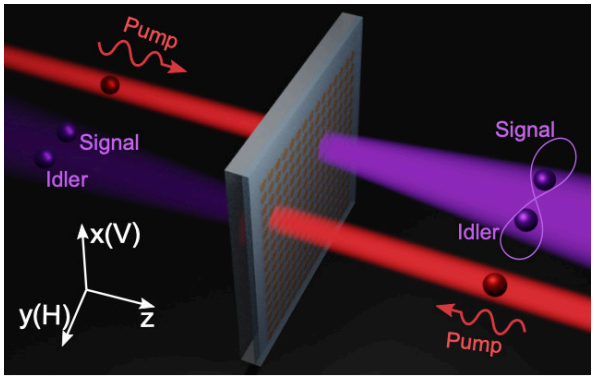

Fig. 1. Concept of non-reciprocal generation of quantum-entangled pairs of signal and idler photons from a nonlinear metasurface. The process efficiency and emerging quantum state can dramatically depend on the pump incidence and the corresponding photon emission directions.

III. Conclusion

In conclusion, we report the first prediction and experimental observation of quantum nonreciprocity in the generation of entangled photons from ultra-thin nonlinear metasurfaces, revealing new possibilities for multi-functional and reconfigurable operation of quantum nanophotonic devices.

***Abstract*—We experimentally demonstrate that a spin-dependent programmable plasmonic metamaterial can manipulate the propagation of surface spoof surface plasmon polaritons (SSPP) wave. The spin and coding information are used to independently control frequency and space routing, respectively. Our findings provide a surface EM wave platform for multi-channel signal communication systems.**

***Keywords*— metamaterials, spoof surface plasmon polaritons.**

I. Introduction

Spin is an intrinsic property of electromagnetic wave. There is a locking relationship between the spin and momentum of EM waves, which is called the spin-momentum locking.[1,2] The spin-momentum locking is that when the direction of spin is flipped, the direction of momentum is also flipped. In the SSPP wave platform, the momentum of the SSPP wave can be controlled by the spin of the incident source, so that the propagation direction of the SSPP wave can be changed and the information can be distributed to users at different locations. In previous literatures, seldom attempts have been made to achieve the manipulation of SSPP wave in the frequency and spatial domains simultaneously. In this work, we demonstrate a spin-controlled plasmonic metamaterial with varactors to manipulate the propagation of the SSPP wave.

II. Methods

We design a programmable metamaterial that realizes a four-channel SSPP wave transmission system via space and frequency routing. Firstly, the four raw datas are mapped to the spin information and coding information. Then, the spin information and coding information are used as the input of the programmable SSPP metamaterial. Spin information is the spin of the source and the coding information is the voltage value of the varactor in the SSPP unit. The information is transmitted to four users at different frequency bands or different positions in the form of SSPP wave. Among them, different coding information controls the frequency bands of information transmission, thereby determining frequency routing of metamaterials. Different spin information controls the direction of information transmission, thereby determining the spatial routing of metamaterials.

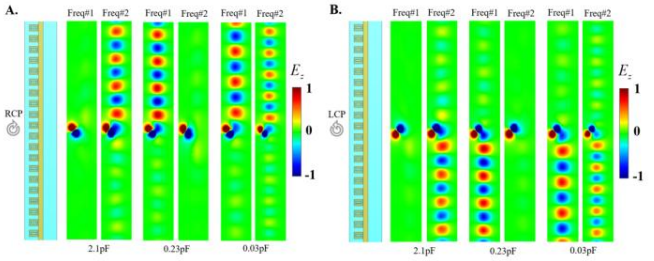

Fig. 1 Simulated results of the metamaterial with four-channel SSPP routing.

Figure 1 shows simulated results of the metamaterial with four-channel SSPP routing, in which three capacitance values are considered. The experimental results agree well with the simulated ones (not shown here). Obviously, the spin freedom controls the spatial routing and the coding freedom controls the frequency routing.

III. Conclusion

We have demonstrated a space- and frequency-routing device based on spin-controlled plasmonic metamaterial. Our findings provide a way for multi-channel signal communication systems.

***Abstract*— We propose a novel broadband polarimeter by employing a metasurface-based diffractive optical element and a vortex retarder to convert polychromatic waves into structured vector beams. Experimental validation demonstrates exceptional measurement accuracy, with RMS errors below 1% for each Stokes component across the visible range (400-700 nm).**

***Keywords*— metasurfaces, diffractive optical elements, vortex retarder, spectropolarimetry, broadband polarimeter.**

I. Introduction

Broadband polarization measurement plays a crucial role in numerous fields, spanning from fundamental physics to a wide range of practical applications [1-2]. However, traditional approaches typically rely on combinations of various dispersive optical elements, requiring bulky systems and complicated time-consuming multiple procedures [3-4]. As an emerging class of planar diffractive optical elements (DOEs), meta-surfaces can function as an ultracompact platform for polarization measurement[5]. In this paper, we have achieved broadband spectropolarimetry based on single-shot images for spatial intensity distributions of polychromatic vector beams. A custom-designed diffractive optical element and a vortex retarder convert the incident polychromatic waves into structured vector beams: the former diffracts light of different wavelengths into concentric circles of different radii while the latter codes their polarization information into intensity distributions along the azimuthal direction [6].

II. Methods

The incident broadband beam with unknown polarizations can be described by a wavelength-dependent Stokes vector $S(\lambda) = [S_0(\lambda) \quad S_1(\lambda) \quad S_2(\lambda) \quad S_3(\lambda)]^T$. To measure $S(\lambda)$, the incident light is firstly dispersed into a rainbow donut beam with different wavelength at different radii through a specially designed DOE. Therefore, the wavelength-dependent Stokes vector $S(\lambda)$ is mapped into a radius-dependent $S(r)$. The relation between wavelengths and the radii can be established by the dispersive regularities of DOE. Then a vortex retarder is employed to encode the donut beam into a polychromatic vector beam (PVB), whose Stokes vector can be described by $S(\varphi, r)$, where φ is the azimuth angle. The linearly polarizer is added between the vortex retarder and camera to analyze the PVB into a spatially varying intensity distribution. The recorded intensity $I(\varphi, r)$ is a function of the radius r and the azimuthal angle φ, which can be described by the Mueller-Stokes formula as $I(\varphi, r) = \vec{a}(\varphi, r) \cdot S(\lambda)$, where $\vec{a}(\varphi, r)$ is the first row of the total Mueller matrix of the PVB based spectropolarimeter.

The effective dispersion of broadband light into circular rainbow rings is realized through the DOE. The operational wavelength range of the DOE was designed to be 400-700 nm. The effective optical area of 4 mm × 4 mm was subdivided into 8000 × 8000 square cells, each with a side length of 500 nm. Within each cell, regular quadrilateral *SiNx* nanopillars (see Fig. 1(a)) with varying sizes (a) and a fixed height (H=1000 nm) were arranged. These *SiNx* nanopillars introduce spatially distributed phase shifts that cause beam diffraction and achieve the desired annular dispersion effect. Further, the phase shift profile for the annular dispersion function was calculated and shown in Fig. 1(b). Then the sizes a of the *SiNx* nanopillars with different phase shift between 0-2π were calculated by using finite difference time domain method, which are shown in Fig.1(c). As shown in Fig. 1(d), the DOE was then fabricated by using the photolithography technique.

The feasibility of the PVB based spectropolarimeter is demonstrated by using the configuration shown in Fig. 2. A broadband light, a polarizer (P), and a quarter wave plate (Q) are utilized to generate different incident spectral polarization states. The incident beam is then dispersed into a rainbow donut by the DOE, and an achromatic plano-convex lens (L) is utilized to collimate the divergent rainbow donut beam. A liquid crystal polymer vortex retarder (V) is utilized to convert the rainbow donut beam into PVBs. Then the PVBs are mapped into a unique spatially varying intensity pattern by an analyzer (A). Finally, the intensity image is recorded by a scientific CMOS camera (sCMOS) for further analysis.

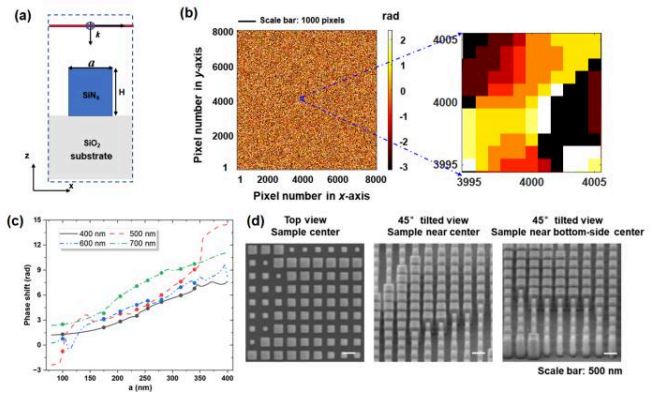

Fig. 1 Design and fabrication of DOE. (a) The schematic of one *SiNx* nanopillar; (b) The calculated phase profile and zooming in; (c) The phase shift of the 8 selected *SiNx* nanopillars at 4 representative wavelengths; (d) The SEM results of the fabricated DOE.

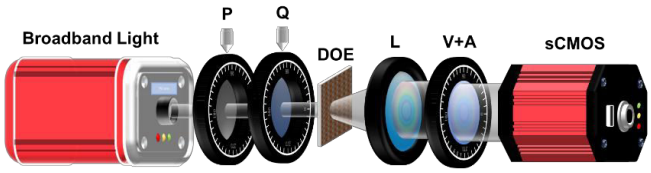

Fig. 2 Demonstration configuration of PVB based spectropolarimeter.

III. Results and Discussion

To validate the performance of the PVB based spectro-polarimeter, incident beams with various broadband polarization states are generated using different azimuthal combinations of P and Q, and subsequently measured by the spectropolarimeter. Fig. 3(a) shows the intensity images of a spectrally uniform linearly polarized beam generated by a 30° P, while Fig. 3(b) displays a spectrally varying polarized beam generated by a 40° P and a 5° Q. For the actual calculations, we employed the sCMOS camera, which provides superior image quality and allows for better computational accuracy. The measurement results and measured errors are shown in Fig. 4. The RMS errors of the measured Stokes parameters in VIS range (400-700 nm) are calculated, and an error of <1% for each vector component is obtained. In our experiment, the intensity image processing time is 9.895 ms (using an i7-10700F CPU @ 2.90GHz and Matlab R2021a software), yielding an output rate of 100 Hz. The measurement accuracy we obtained is comparable to the excellent full Poincaré polarimeter and is much better than the well-established traditional polarimeter and the modern light-matter interactions based polarimeters[7].

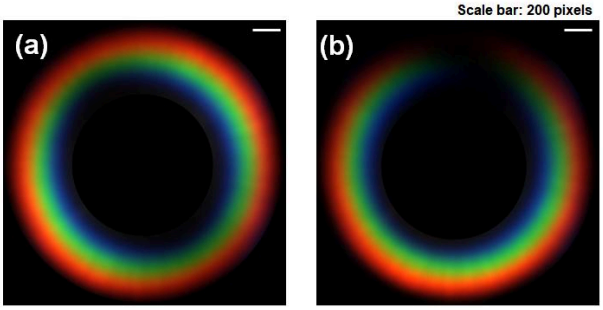

Fig. 3 Captured RGB intensity images. (a) 30° P, (b) 40° P and 5° Q.

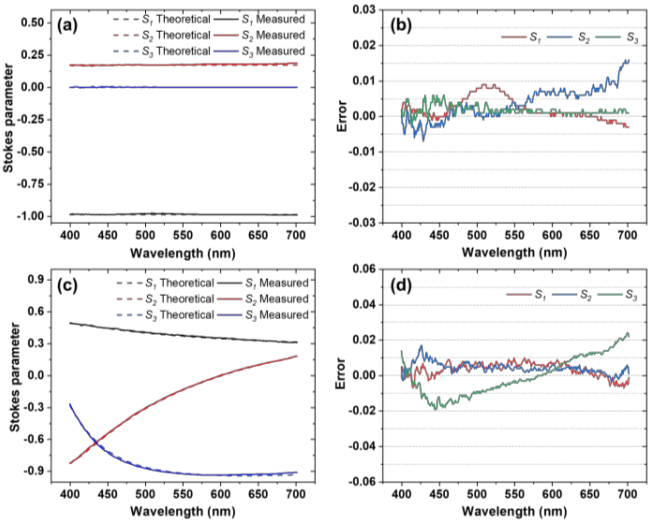

Fig. 3 Measured results and measured error for normalized Stokes vector. (a) and (b) Spectrally uniform linearly polarized beam generated by a 30° P; (c) and (d) Spectrally varying polarized beam generated by a 40° P and a 5° Q.

IV. Conclusion

We have demonstrated a single shot, accurate and simple approach for broadband polarization measurement. The concept relies on the mapping of any input broadband polarization into a polychromatic structured vector beams by using a specifically designed DOE with axisymmetric dispersion and a vortex retarder. Some broadband polarization states are experimentally measured to demonstrate the feasibility of the PVB based spectropolarimeter. The measured Stokes parameters in visible light range (400-700 nm) show excellent RMS errors of <1%, and its output rate can reach about 100 Hz. However, the system also faces some limitations, such as the lack of imaging capability and the unoptimized condition number, which will be considered in future work.

Nanomaterials and Nanostructures for Semi-Transparent and Color Photovoltaics

Ilya Sychugov

Department of Applied Physics, KTH Royal Institute of Technology, Stockholm
ilyas@kth.se

***Abstract*— Large-area luminescence solar concentrators with metal nanoclusters and Si quantum dots feature high visible light transparency (~ 70-80%) and generate ~ 1 W of electrical power under 1 sun. A sub-monolayer of silicon nanospheres, as selective Mie scatterers, improves device efficiency and color-neutrality, and can be used for color photovoltaics.**

***Keywords*— metal nanoclusters, silicon nanoparticles, Mie scatterers, luminescence solar concentrator.**

I. Introduction

As photovoltaic (PV) technology reaches industrial maturity, some niche applications remain less explored. Those include semi-transparent and color PV towards building-integrated photovoltaics, agrivoltaics and li-fi [1-2]. Control of transparency and color are crucial for his purpose. In his paper we demonstrate how selective Mie scatterers together with luminescent metal nanoclusters and silicon quantum dots can be used for such large-area PV devices.

II. Methods

Luminescent gold-silver metal nanoclusters (~ 1-2 nm size) were synthesized by metal salt reduction in a control environment [3]. Silicon quantum dots (5-10 nm) and Mie nanospheres (100-200 nm) were fabricated by annealing (disproportionation reaction) of silicon-rich silica pre-cursors [4]. Nanomaterials for LSC were dispersed in thiol-ene polymer layer sandwiched between two glass plates in a triplex geometry (Fig1). Quantum yield and photon budget were measured in an integrating sphere, and I-V curves were recorded under 1 sun.

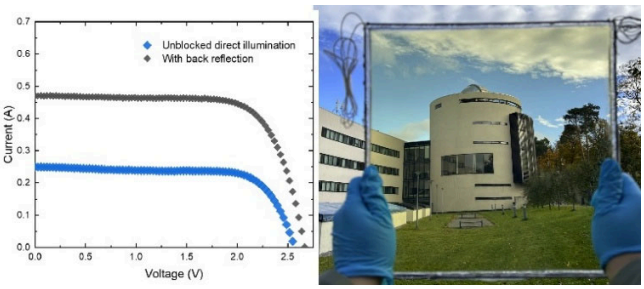

Fig. 1 (left) I-V curve of the 30x30 cm^2 LSC device with Si QDs, generating up to ~ 1W of electrical peak power under one sun illumination; (right) device photo shows high transparency.

III. Results and Discussion

Nanomaterial properties feature a large Stokes shift and a high luminescent quantum yield (up to 70-80%) [1-3]. LSC device has visible light transparency 70-80% and generates up to 1 W of electrical peak power under one sun.

Silicon nanosphere sub-monolayer selectively back-reflects incoming radiation, increasing optical path of the photons through the active layer [4]. This results in increase in LSC photocurrent by 10-15% and makes LSC devices more color neutral. Color coordinates (a*, b*) become (0, 4) from the original device (-1, 13) after the application of Mie scatterers.

IV. Conclusion

We have demonstrated how luminescent light converting nanomaterials (nanoclusters and quantum dots) in combination with dielectric Mie resonators in the form of silicon nanospheres can be utilized for transparent photovoltaics. Further applications of Si nanospheres will be in color PV to improve aesthetics of traditionally opaque black solar cells.

***Abstract*—Here, we report the use of open- and closed-loop pipelines for the synthesis and in silico design of gold nanoparticles, using global optimization algorithms (Bayesian optimization) to identify optimal experimental conditions for nanoparticle synthesis and to determine optimal dimensions for enhanced plasmonic performance.**

***Keywords*— gold nanoparticles, plasmonics, optimization algorithms**

I. Introduction

Plasmonic performance is inherently tied to nanoparticle (NP) geometry. The design and synthesis of NPs with optimal plasmonic performance are typically intuition-driven processes, in which a single parameter is adjusted at a time to evaluate performance through the so-called Edisonian approach. Finding the optimal dimensions for targeted performance is time-consuming and requires a trial-and-error approach. As a result, the field of plasmonics, both experimental and theoretical, is fragmented into multiple specialized areas, each optimized for specific applications.

Global optimization algorithms are increasingly important in materials design and synthesis.[1] For example, Bayesian optimization (BO) allows exploration and exploitation of the multidimensional parameter space to find a solution with fewer iterations, thereby accelerating the process. Despite recent progress, there is a lack of methods that integrate global optimization with numerical and experimental tools to design and synthesize NPs with desired optical properties and dimensions, thereby achieving desired plasmonic performance. Here, we discuss the development of pipelines that use a Bayesian optimizer to orchestrate electrodynamics simulations to find the optimal dimensions of gold bipyramids for a range of plasmonic applications, and to assist human experimenters in identifying experimental conditions to obtain gold nanorods.

II. Methods

To design nanoparticles in a closed-loop fashion, we developed a pipeline using an experimentally determined parameter space based on the recipe recently published by our group.[4] The BO process uses a random search sequence to generate priors from initial evaluations, then constructs a surrogate model using Gaussian processes to predict outcomes for unobserved parameter sets and quantify their uncertainty. At each iteration, the orchestrator executes numerical simulations of the electromagnetic response of nanoparticles by using MNPBEM toolbox. The simulation results were used to estimate the objective functions that optimize AuBP dimensions. To synthesize nanoparticles, we used an open-loop model in which the algorithms proposed the experimental conditions, followed by human-based execution. As an objective of the synthesis, we used numerical spectra featuring the position of the plasmon band at a given wavelength.

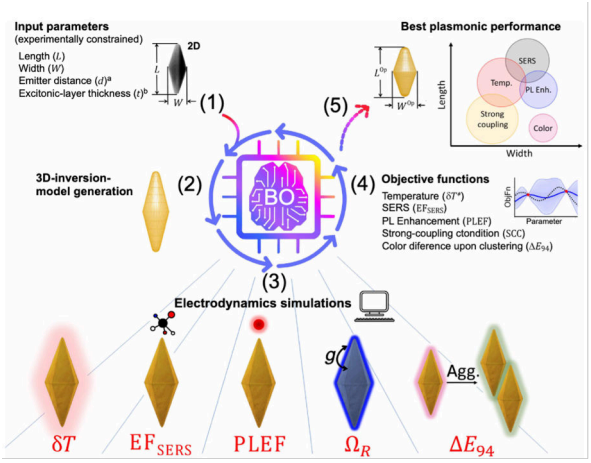

Fig. 1. An example of closed-loop design of nanoparticles. The algorithm suggests structural parameters for gold bipyramids that maximize targeted plasmonic performance. The workflow comprises (1) sampling a set of input parameters within experimentally constrained parameter space, (2) generating a 3D model, (3) calculating properties, (4) updating the surrogate model, and (5) selecting the next set of parameters to reach the highest objective function value.

III. Results and Discussion

In the computational design of gold bipyramids, BO achieves a 600-fold acceleration over traditional "human-in-the-loop" trial-and-error, enabling the precise identification of dimensions that maximize performance in applications such as SERS, photothermal heating, and strong plexcitonic coupling.[2] Key results include the identification of optimal dimensions for gold bipyramids (137 nm by 27 nm) for use in photothermal therapies or neuronal photo-modulation. In addition, we found that multi-objective optimization can successfully balance competing requirements, such as maximizing the photoluminescence enhancement factor while minimizing temperature increase to protect the thermal stability of the hybrid plasmonic system.

In open-loop synthesis, we found that BO-based protocols can uncover ”missed knowledge” by exploring a broader parameter space than intuition-guided methods. We identified viable synthesis conditions at elevated temperatures (up to 40 ºC), enabling high-quality nanoparticles 4.7 times faster than standard protocols.[3] An interpretative ML of the resulting dataset allowed us to establish a hierarchy of parameters, confirming that silver ions are the most critical factor for achieving specific spectroscopic features.

IV. Conclusion

The implementation of Bayesian optimization has emerged as a transformative strategy for designing superior plasmonic nanoparticles by providing a universal pipeline that bridges global optimization and numerical simulations. These algorithms are becoming critical in computational and experimental plasmonics for navigating the complex, nonlinear relationships in multidimensional parameter spaces and escaping the ”knowledge traps” inherent in intuition-guided methods. By utilizing multiobjective optimization, one can effectively balance competing requirements, thereby streamlining the transition from proof-of-concept research to real-world nanophotonic applications.

***Abstract*— In this work, we design plasmonic metasurfaces supporting surface lattice resonances (SLRs) and tailor their design to control optical modes and achieve high quality factors. Refractive index sensing measurements are performed to assess the sensitivity associated with different resonance modes, highlighting the potential of engineered SLRs for efficient plasmonic detection.**

***Keywords*— metasurfaces, plasmonics, lithography, sensing.**

I. Introduction

The confinement of light at the scale of metallic nanostructures has enabled numerous applications in nano-optics, molecular detection, and surface-enhanced spectroscopy. Metasurfaces, such as periodic arrays of metallic nanostructures, allow efficient coupling between localized surface plasmon resonances (LSPRs) and diffractive modes arising from lattice periodicity. This coupling leads to the formation of collective optical modes known as surface lattice resonances (SLRs), which have attracted increasing interest due to their highly tunable optical properties and exceptionally high quality factors.[1], [2] The spatial distribution of the electromagnetic field near these lattices makes them particularly suitable for biosensing applications.[3] In this work, we demonstrate the crucial role of the grating period in governing the refractive-index sensitivity of plasmonic lattice resonances. To highlight this dependence, we exploit diffractive coupling in square arrays of gold nanodisks deposited on an indium tin oxide (ITO) layer on a glass substrate.

II. Methods

Plasmonic metasurfaces were fabricated by electron-beam lithography in order to achieve large-area arrays with precise control over the geometrical parameters. Square lattices of gold nanodisks with a diameter of 100 nm and a thickness of 50 nm were patterned on glass substrates coated with a thin ITO layer. The lattice period was systematically varied from 300 to 600 nm to tune the diffractive coupling conditions and the resulting surface lattice resonances.

Optical characterization was carried out by extinction spectroscopy under normal incidence using linearly polarized light. Extinction spectra were recorded to identify resonance features, from which the spectral positions and quality factors of the SLR modes were extracted. Refractive index sensitivity measurements were performed by gradually increasing the refractive index of the surrounding medium using controlled water–ethanol solvent mixtures, enabling a quantitative evaluation of the resonance shifts induced by changes in the dielectric environment (Fig. 1).

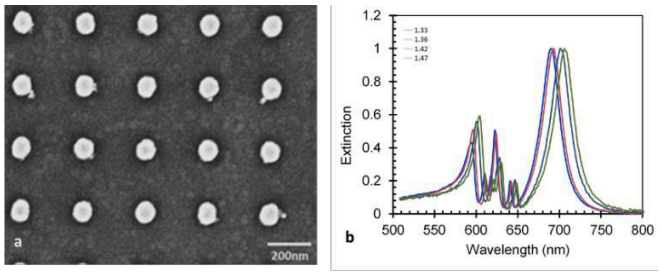

Fig. 1 (a) SEM image of the periodic array of gold nanodisks deposited on a glass substrate. (b) Extinction spectra of the periodic array, demonstrating a red shift in resonance response with an increasing refractive index of the surrounding medium.

III. Results and Discussion

The refractive index sensitivities of different plasmonic modes were systematically compared, including the localized surface plasmon resonance (LSPR) and two surface lattice resonance modes associated with the (1,0) and (1,1) diffractive orders of the array. Distinct spectral shifts were observed upon variation of the surrounding refractive index, revealing mode-dependent sensing responses. For certain lattice parameters, the resonances exhibit hybrid character arising from the coupling between LSPR and SLR modes, combining localized and collective plasmonic features. This hybridization was further confirmed by numerical simulations, which reproduce the experimentally observed resonance positions and dispersions.

Notably, SLR modes exhibit significantly enhanced refractive index sensitivities, reaching values up to 250 nm/RIU, substantially exceeding typical sensitivities associated with LSPR modes.

IV. Conclusion

We experimentally and numerically investigated the role of interparticle spacing in modulating resonance coupling in plasmonic metasurfaces. Increasing the interparticle distance enhances diffractive coupling, leading to resonances with reduced radiative and non-radiative losses, as evidenced by higher quality factors. We further demonstrate that the refractive index sensitivity of surface lattice resonances is strongly dependent on the coupling strength between localized plasmons and lattice diffraction modes. This coupling, governed by the lattice period, plays a key role in determining both the resonance quality factor and the sensing performance. Furthermore, the detection performance of SLRs is demonstrated to surpass that of localized surface plasmon resonances in terms of both sensitivity and figure of merit, confirming their strong potential for sensing applications.

I. Introduction

In recent years, all-dielectric metasurfaces have emerged as a highly versatile platform for engineering light-matter interactions at the nanoscale. By leveraging high-refractive-index materials such as silicon, these structures overcome the severe ohmic damping inherent to plasmonic devices, enabling operation with minimal absorption losses in the visible and near-infrared spectra. Furthermore, the strong electromagnetic confinement within subwavelength dielectric resonators allows for the excitation of both electric and magnetic multipolar Mie resonances.

A prominent mechanism for achieving extreme electromagnetic field enhancement and ultra-high-quality factors (Q-factors) in these architectures is the excitation of Bound States in the Continuum (BICs) [1,2]. True BICs are perfectly confined, non-radiating states that exist within the radiation continuum but possess theoretically infinite Q-factors and zero resonance linewidth. By introducing controlled structural perturbations, these "dark" states can be coupled to free-space radiation, transforming into accessible quasi-BICs (qBICs) characterized by sharp, asymmetric Fano lineshapes [3].

Historically, the design of qBICs has relied heavily on symmetry-protected mechanisms, wherein the radiative lifetime of the mode is dictated by the degree of structural asymmetry introduced into the metasurface unit cell. While architectures such as asymmetric silicon slots have demonstrated tremendous theoretical potential for ultra-sensitive refractometric sensing [4], translating these designs into robust experimental platforms remains a critical challenge. Experimental realizations consistently reveal that measured Q-factors are orders of magnitude lower than their theoretical predictions [5]. This performance degradation is primarily driven by resonance damping caused by statistical variations in nanoscale features during electron-beam lithography, etching roughness, and the angular spread of the probing beam [6].

To overcome the physical vulnerabilities associated with symmetry-breaking, current research is pivoting toward robust high-Q mechanisms that do not rely on structural asymmetry [7,8]. In this regime, radiative decay is suppressed not by altering the geometry, but through mechanisms such as the destructive interference of competing resonant channels (Friedrich-Wintgen BICs) or collective diffractive coupling (Lattice Resonances) within fully symmetric unit cells.

In this contribution, we present a comprehensive study on the evolution of radiative loss engineering by comparing two distinct robust mechanisms in silicon-based metasurfaces: localized single-particle multipolar interference and delocalized Surface Lattice Resonances (SLRs). We first demonstrate how the precise geometric tuning of hollow silicon nanocuboids induces the cancellation of electric and toroidal dipoles (anapole state), yielding an ultra-high-Q resonance that is highly resilient to environmental impedance mismatch and ideally suited for novel Surface-Enhanced Raman Scattering (SERS) applications. Subsequently, we introduce an alternative, highly simplified architecture utilizing solid nanocuboids to excite SLRs by coupling Mie resonances with the diffractive Rayleigh anomaly. By analyzing the inherent trade-offs between the highly localized fields of toroidal dipoles

and the loss-tolerant, delocalized fields of SLRs, we provide a unified design framework for optimizing all-dielectric platforms across a variety of advanced sensing applications.

II. Methods

We employ the Finite Element Method (FEM) via COMSOL Multiphysics and Rigorous Coupled-Wave Analysis (RCWA) to conduct both full-wave scattering and eigenfrequency analyses of the metasurface unit cells. To accurately account for material dispersion during eigenvalue extraction, we utilize an auxiliary-fields formulation that explicitly incorporates the dispersive optical properties of the constituent materials across the near-infrared spectrum. To unravel the physical mechanisms driving both symmetry-protected BICs and toroidal states, we apply the Cartesian Multipole Decomposition Technique (CMDT) to the polarization currents of the evaluated eigenvectors. This decomposition allows us to quantify the dominant radiating and non-radiating (dark) moments, such as Cartesian electric/magnetic dipoles and toroidal quadrupoles, and systematically observe how they couple to the radiation continuum upon symmetry reduction or geometric tuning.

III. Beyond Symmetry-Breaking

To overcome the stringent fabrication limitations inherent to symmetry-protected modes, we pivot toward robust high-Q mechanisms that do not rely on structural asymmetry. In this paradigm, radiative decay is suppressed through interference phenomena within fully symmetric unit cells, fundamentally improving resilience to fabrication tolerances. Within this framework, we highlight two distinct design trends, localized multipolar interference and delocalized SLRs, illustrating a critical trade-off between environmental index matching and fabrication complexity.

The first mechanism leverages the multipolar interference within symmetric, hollow silicon nanocuboids. We demonstrate that precise geometric tuning of the cuboid's aspect ratio and central hole size induces the exact cancellation of broad Cartesian electric dipoles and toroidal dipole moments. This configuration yields a highly confined, non-radiating dark mode. By engineering the metasurface array to couple this dark state with broader "bright" background modes, the anapole state evolves into an ultra-high-Q Fano resonance. Numerical analyses confirm high Q-factors with a near-field enhancement localized tightly within the central void and gaps. From an application standpoint, this extreme localization provides distinct advantages. Most notably, this resonance is remarkably robust against environmental impedance mismatch. It remains highly functional even with significant refractive index contrast between the substrate and superstrate (e.g., a glass substrate paired with an air or water superstrate), entirely eliminating the need for symmetric index-matching. Furthermore, this architecture allows for a double-resonance condition, aligning a sharp resonance with a broader mode, making it an exceptionally powerful and novel all-dielectric platform for Surface-Enhanced Raman Scattering (SERS). However, this exceptional near-field performance comes with a fabrication caveat: etching the precise nanoscale central void required to support the toroidal mode presents scalable manufacturing challenges.

To circumvent the fabrication complexity of hollow structures, we introduce an alternative architecture based on SLRs utilizing simple, solid nanocuboids. Moving beyond single-particle interference, this mechanism relies on collective, diffractive coupling across the metasurface array. By engineering the array pitch, we couple localized, broadband Mie resonances with the diffractive Rayleigh Anomaly (RA) to generate a high-Q collective radiative mode accessible at normal incidence. The physics of the SLR represent a fundamental shift toward delocalized field manipulation. Unlike the internally confined multipoles, the electromagnetic energy of an SLR is distributed across the metasurface interface via evanescent decay. This delocalized nature severely limits the interaction of the field with the bulk volume of the superstrate, making the SLR mode extraordinarily robust to absorption losses within the fluidic analyte, a major advantage for bulk sensing applications. While the use of solid cuboids vastly simplifies the lithographic and etching processes, the SLR mechanism imposes strict environmental constraints. Being a diffractive effect, the SLR is highly sensitive to the array pitch and, crucially, requires a homogeneous refractive index environment (a symmetric substrate and superstrate) to properly support the delocalized resonance.

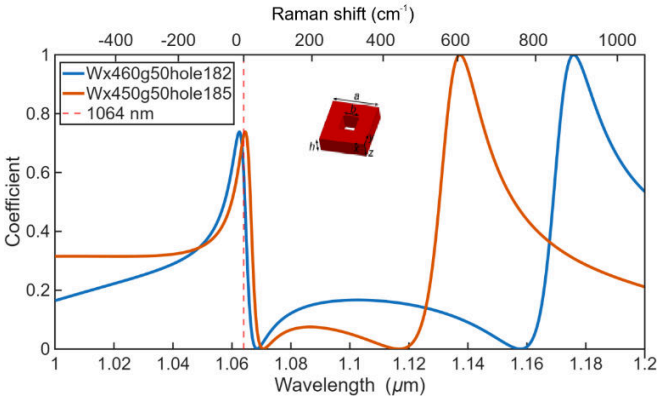

Fig. 1 Coefficient spectra of the fully symmetric hollow nanocuboid metasurface, highlighting a double-resonance condition. A sharp resonance is successfully tuned to the 1064 nm excitation line (red dashed line), alongside a broader localized mode. The inset depicts the 3D structural parameters of the unit cell.

In summary, these robust symmetric architectures provide a compelling alternative to symmetry-protected modes, but require a strategic choice based on the target application. Hollow metasurfaces offer unparalleled, localized near-field enhancement and immunity to index mismatch, ideal for SERS, but require complex fabrication. Conversely, solid SLR metasurfaces offer simplified fabrication and remarkable tolerance to analyte absorption losses, but demand strict refractive index matching to function.

IV. Conclusion

In conclusion, the successful translation of BICs from theoretical constructs into viable, real-world nanophotonic platforms necessitates a rigorous re-evaluation of radiative loss engineering. While our experimental implementations of

symmetry-protected quasi-BICs in silicon slot metasurfaces demonstrated competitive refractometric sensitivities and strong internal field confinement, they also revealed the inherent fragility of this physical mechanism. The reliance on nanoscale structural asymmetry makes these platforms highly vulnerable to fabrication tolerances, sidewall roughness, and angular dispersion, severely limiting their experimental quality factors. To address these vulnerabilities, we have demonstrated that pivoting toward robust high-Q mechanisms in fully symmetric unit cells offers a significantly more viable path.

Ultimately, there is no single "perfect" metasurface architecture. By understanding the distinct physical mechanisms driving both localized multipoles and delocalized SLRs, we can intelligently tailor all-dielectric silicon platforms to meet the specific fabrication and environmental demands of next-generation optical sensors and surface-enhanced spectroscopies.

***Abstract*—Soft nanoimprint lithography enables the scalable fabrication of nanophotonic architectures with high-resolution and over large areas. Here we demonstrate how the technique can be extended to create chiral metasurfaces (dielectric and metallic) exhibiting strong circular dichroism which can be transferred to nearby emitters to produce circularly polarized photoluminescence.**

***Keywords*— nanoimprinting, chirality, photoluminescence, lattice resonances.**

I. Introduction

Nanophotonic architectures enable advanced optical phenomena that can enhance optoelectronic device performance. However, large-scale integration requires fabrication methods that are cost-effective, scalable, and compatible with established device processing techniques. This is even more challenging in the are of chiral nanophotonics.

II. Methods

Soft nanoimprint lithography (s-NIL) relies in the use of pre-patterned elastomeric stamps to fabricate photonic structures from resists, biopolymers, colloids, and nanomaterials. This approach enables sub-50 nm resolution over large areas. In our variation of s-NIL we used elastomeric molds pre-patterned with chiral motifs to induce the order of different metal colloids (Fig 1) resulting in chiral plasmonic lattices. We also can pattern thin films which coated with titanium dioxide exhibit a broad set of chiroptical properties over the visible range.

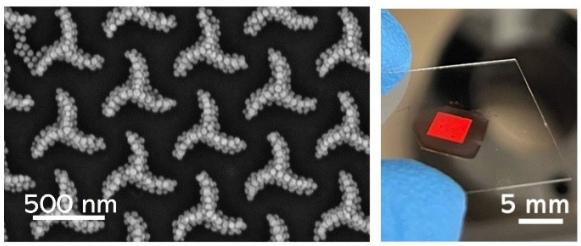

Fig. 1 SEM and photograph of a chiral plasmonic array made with silver colloids.

III. Results and Discussion

Chiral plasmonic gratings made with non-chiral metal colloids exhibit strong circular dichroism ($g \approx 0.4$) which can be transferred to an organic dye placed on top. The high refractive index counterparts made with titanium dioxide become a single chiral platform supporting broadband visible chiroptical resonances which are used to transfer chirality to multiple emitters, achieving glum > 1.

IV. Conclusion

Soft nanoimprint lithography provides a scalable route to high-performance nanophotonic and chiral architectures. The demonstrated structures offer strong optical activity, efficient chirality transfer, and compatibility with diverse materials, supporting practical integration into advanced optoelectronic and photonic applications.

***Abstract*— We demonstrate bottom-up chiral nanofabrication driven by circularly polarized light (CPL). CPL-induced chiral near-field distribution around plasmonic nanoparticles enables site-selective growth via photoelectrochemical reactions, leading to chiral nanostructures. Extending this concept to magneto-chiral nanocomposites yields directional dichroism under static magnetic fields, providing a scalable route to nonreciprocal metamaterials.**

***Keywords*— circularly polarized light, chiral near-field distribution, nanofabrication, magneto-chiral metamaterials.**

I. Introduction

Chiral nanostructures, a representative form of bianisotropic metamaterials, exhibit magnetoelectric coupling in which the magnetic field component of light can induce electric polarization even in the visible to near-infrared region, leading to strong chiroptical responses and optical nonreciprocity. However, the fabrication of chiral nanostructures remains challenging. Here, we present a bottom-up approach to chiral nanofabrication. A key feature of our method is that, whereas conventional bottom-up strategies typically rely on chiral molecules as the chiral source, we use CPL to induce the chiral shaping of nanoparticles (Fig. 1).[1-4]

II. Methods

As a representative example, Au nanocubes exhibiting localized surface plasmon resonance (LSPR) were immobilized on a TiO_2 film and irradiated with CPL in the presence of Pb^{2+} ions.[2] Electric field distributions and optical responses were calculated using finite-difference time-domain simulations.[1-5]

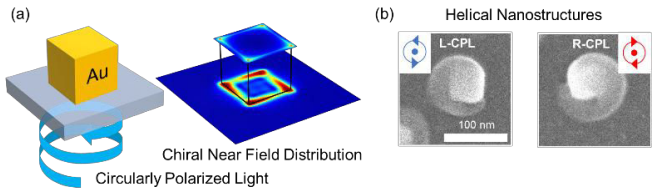

Fig. 1 (a) CPL induces a chiral near-field distribution. (b) Chiral Au–PbO_2 nanocomposites.

III. Results and Discussion

Under left- and right-handed CPL, the near-field distributions around a Au nanocube become mirror images of each other (Fig. 1a).[5] In regions where the near field is strongly enhanced, plasmon-induced electron–hole pairs are generated. In the presence of Pb^{2+} ions, its oxidation driven by the holes leads to site-selective deposition of PbO_2 and the formation of chiral Au–PbO_2 nanocomposites (Fig. 1b). As a result, the fabricated nanostructures exhibit clear circular dichroism at the LSPR wavelengths, with opposite signs depending on the handedness of the incident CPL.

Furthermore, we extend this concept to magneto-chiral nanocomposites, where superparamagnetic Fe_3O_4 nanoparticles serve as magnetic cores. CPL-induced reduction of Ag^+ ions and deposition of Ag, driven by photocatalytic reduction on Fe_3O_4 and plasmon-assisted reduction on deposited Ag[3,4], produced chiral Fe_3O_4–Ag nanocomposites, thereby breaking spatial inversion and time-reversal symmetries. Under an external static magnetic field, these nanocomposites exhibit directional dichroism in the visible range, demonstrating a feasible pathway toward magneto-chiral metamaterials with nonreciprocal optical responses. This light-driven shaping mechanism provides a scalable route toward chiral and magneto-chiral nanostructures.

IV. Conclusion

We have established CPL-driven chiral near-field engineering as a powerful strategy for constructing chiral and magneto-chiral nanomaterials. Future work will extend this approach to other classes of bianisotropic metamaterials, including omega- and Tellegen-type systems.

***Abstract*— We developed a novel method for refractive index (RI) sensing of materials under high-pressure using Mie voids fabricated on a 4H-SiC anvil in an anvil cell, enabling *in-situ* local measurement of RI in materials under high-pressure inaccessible by conventional methods including unknown water at interfaces between water and high-pressure ices.**

***Keywords*— Mie void, Refractive index sensing, High-pressure, Anvil cell, Homoimmiscible water.**

I. Introduction

Measurement of refractive index (RI) of materials under high-pressures is important in materials science for the clarification of dielectric properties of unique states of condensed matters under high-pressure such as unknown water, which macroscopically separates from bulk water, at non-equilibrium interfaces water and high-pressure ices (homoimmiscible water).[1] Conventional methods such as interferometry in conjunction with an anvil cell generally require technically challenging optical setups, complex analyses, and homogeneity of the target sample. Novel insights would be provided by the development of a simple method for *in-situ* measurement of local RI of materials under confinement by anvil cell. Here, we developed simple, *in-situ* and local RI measurement method by applying Mie-void-resonance-based RI sensing[2] to RI sensing under high-pressure by using Mie voids fabricated on a 4H-SiC anvil in an anvil cell.[3]

II. Methods

Reflection spectra of a Mie void array fabricated on a 4H-SiC anvil were obtained using a reflection-optical microscope connected to a hyperspectral camera in the process of depressurization of ultrapure water.

III. Results and Discussion

Figure 1 shows the optical micrographs and the reflection spectra of the Mie void array in the process of depressurization. The spectrum of the void array showed 25 nm blue-shift by depressurization. This suggests that the sensitivity was approximately 290 nm/RIU, which is comparable to that of plasmon-based RI sensing. Since Mie-void-based RI sensing can detect local RI change of materials inside of the void,[2] our method can measure RI of homoimmiscible water, which locally forms at water/high-pressure ices interfaces, in principle.

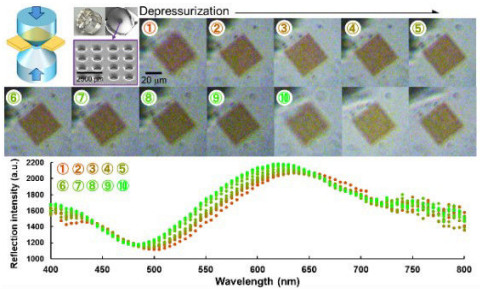

Fig. 1 Reflection optical micrographs and their reflection spectra in the process of depressurization. The figures were adopted from ref. 3 under the CC-BY-4.0 license.

IV. Conclusion

We first demonstrated Mie-void-based RI sensing of a high-pressure material under confinement by anvil cell as a novel, simple, *in-situ* and local RI sensing method.

Exploring the Origins of Circular Dichroic Optical Forces at the Nanoscale

Junsuke Yamanishi[1,*]

[1]Graduate School of Engineering Science, The University of Osaka, Japan
*Corresponding author: yamanishi.es@osaka-u.ac.jp

***Abstract*—We investigate the microscopic origin of circular dichroic optical forces at the nanoscale using photoinduced force microscopy. We reveal three distinct contributions: intrinsic material chirality, local chirality in achiral assemblies, and probe-induced symmetry breaking. Our results establish a unified framework for interpreting circular dichroic optical forces in near-field measurements.**

***Keywords*— circular dichroism, optical force, near-field optics.**

I. Introduction

Circular dichroism (CD) is a fundamental signature of structural chirality and plays a central role in chemistry, nanophotonics, and metamaterials. While conventional CD spectroscopy provides ensemble-averaged information, many artificial and natural nanostructures exhibit spatially localized or emergent chirality that cannot be resolved in the far-field [1].

Recent advances in photoinduced force microscopy enable nanoscale visualization of optical forces generated by light-matter interactions [2]. When circularly polarized illumination is applied, enantio-selective optical forces can emerge [3, 4]. However, the physical origin of circular dichroic (CD-) force signals remains unclear. It is not evident whether these forces arise solely from intrinsic material chirality or whether geometrical and probe-induced effects also contribute.

In this work, we systematically investigate the origins of CD-forces at the nanoscale and establish a unified framework for interpreting CD-forces in near field measurements.

II. Methods

CD-force measurements were performed using a heterodyne frequency modulation photoinduced force microscopy system combined with frequency modulation atomic force microscopy. This configuration enables selective detection of optical gradient forces while suppressing photothermal background contributions [5, 6].

Left and right circularly polarized laser light was introduced through the substrate to illuminate both the nanostructure and the probe apex. The modulation scheme allowed differential detection of forces under opposite circular polarizations, directly isolating the CD-force component.

To disentangle the physical origin of the observed signals, we investigated three representative systems: three-dimensional chiral gold nanoparticles, achiral gold nanoparticle dimers, and single spherical gold nanoparticles. All measurements were performed in the non-contact regime to minimize thermal and mechanical artifacts.

III. Results and Discussion

CD-force signals were clearly resolved at the nanoscale under circularly polarized illumination. For intrinsically chiral gold nanoparticles, the measured force contrast reverses sign with handedness, consistent with enantioselective light-matter interaction. The spatial distribution of the force signal follows the local CD of the near-field around the particle.

In achiral gold nanoparticle dimers, finite CD-force signals were observed despite the absence of intrinsic structural chirality. The signal magnitude and sign depend strongly on the position relative to the dimers, indicating that the locally induced chirality generates near-field CD responses.

For single spherical gold nanoparticles, CD-force signals were also detected. Since the particle itself is fully achiral, this observation reveals the contribution of probe-induced symmetry breaking inherent to photoinduced force microscopy. The interaction between the probe apex and the nanoparticle forms a chiral measurement configuration, generating a measurable force contrast.

These results demonstrate that CD-forces at the nanoscale arise from three fundamentally distinct mechanisms: intrinsic material chirality, local chirality, and probe induced symmetry breaking. The coexistence of these contributions explains previous ambiguities in interpreting near field CD signals and highlights the importance of carefully separating measurement-induced effects from genuine material chirality.

IV. Conclusion

We have demonstrated that CD-forces at the nanoscale originate from three distinct physical mechanisms: intrinsic structural chirality, local chirality in achiral assemblies, and probe induced symmetry breaking inherent to near field measurements. By systematically separating these contributions, we establish a unified physical framework for interpreting CD-force signals.

This work clarifies ambiguities in nanoscale CD measurements and provides a foundation for quantitative

analysis of chiral light matter interactions beyond conventional far field spectroscopy. The results open new possibilities for exploring structured light interactions and symmetry-controlled nanophotonic systems.

Ultimate Magneto-Optical Bounds at the Nanoscale

Jorge Olmos Trigo
[1]Departamento de Fısica de Materiales, Universidad Autonoma de Madrid, 28049 Madrid, Spain.
*Corresponding author: jolmostrigo@gmail.com

***Abstract*—Controlling light–matter interactions with external static magnetic fields is a central goal of non-reciprocal photonics. Despite the field's maturity, it remains unknown whether an upper bound on the magneto-optical activity of nanoparticles exists—and, if so, what its ultimate limit might be. In this work, we demonstrate that such an upper bound does exist. We derive a simple expression for this fundamental limit and show that it an be reached only by non-absorbing nanoparticles. This bound, rooted in energy conservation, constrains all observables derived from the polarizability tensor of magneto-optically active nanoparticles. As illustrative examples, we show how it limits the maximum attainable signals in Magnetic Circular Dichroism and the Faraday effect, two cornerstone techniques to detect magneto-optical activity at the nanoscale.**

***Keywords*— magneto-optics, nanoparticles, external magnetic fields.**

I. Introduction

An object is said to be magneto-optically active if its electromagnetic properties are modified under the action of an externally applied static magnetic field. Since the discovery of magneto-optical activity by Michael Faraday in 1845 [1], researchers have sought to enhance the intrinsically weak magneto-optical response of non-reciprocal nanoparticles (NPs) by optimizing the conditions under which light fields interact with them. At the material level, both metallic and dielectric NPs have been widely employed to strengthen magneto-optical interactions by leveraging their plasmonic and Mie resonances, respectively. Beyond controlling the response of magneto-optical NPs at the single particle level, arranging them into ordered lattices enables collective resonances that can further augment the magneto-optical activity.

Despite the ongoing interest in all these nanophotonic strategies, a fundamental understanding of the ultimate limit of magneto-optical activity at the nanoscale is lacking in the field. So far, no general framework exists to answer a deceptively simple but profound question: How large can the magneto-optical activity of a NP be? In particular, it remains unknown whether a upper bound exists and, if so, what determines its value, including possible dependencies on material composition, illumination conditions, and the strength and direction of the externally applied static magnetic field.

In this work, we analytically demonstrate that the magneto-optical activity of NPs is subject to an ultimate upper bound. We obtain a simple, explicit expression for its value and show that it can be reached if and only if the NPs are lossless. Importantly, this upper bound follows from an exact energy conservation law in magneto-optics and depends exclusively on scalar polarizabilities [2]; it therefore constitutes an inherent limit for any magneto-optical NP, independent of both illumination conditions and magnetic-field strength.

Moreover, this upper bound constrains all observables that are derived from the polarizability tensor of magneto-optical NPs. As examples, we show how the Magnetic Circular Dichroism and Faraday effect, two of the most widely employed techniques for probing magneto-optical activity at the nanoscale, are strictly constrained by this ultimate limit [3].

II. Methods

- To describe the optical response of magneto-optically active Nps we employ the widely used linear dipolar approximation.
- To find the energy-bounds we use the hermitian properties of a semipositive defined absorbance matrix. In particular, we use the Sylverter's criteria.
- To describe the polarizability of the system we use the widely used magneto-optical Drude model.

III. Conclusion

We have demonstrated that the magneto-optical activity of NPs has an ultimate upper bound. We have found its exact value and showed that this can be attained I and only if the NP is lossless. This limitation underscores the importance of selecting nonabsorbing NPs when seeking extreme magneto-optical responses at the single-particle level.

***Abstract*— We propose a feasible single-photon source that performs over the THz frequency regime based on a single quantum polar emitter coupled to a nanocavity. We demonstrate nonclassical photon correlations showing the single photon nature of its emission as well as the nonlinear production of multiphoton pairs.**

***Keywords*— Single photon sources, terahertz, quantum emitters,.**

I. Introduction

Terahertz (THz) radiation, spanning frequencies from 0.1 THz to 70 THz, is one of the latest explored gaps in the electromagnetic spectrum, with diverse applications in communications, biology and medicine, vibrational spectroscopy, and materials characterization [1]. The historical lag in the advancement of classical THz technology, combined with the lack of bright and efficient photonic transitions at THz frequencies—typically found in molecules, superconducting junctions, or semiconductors— has hindered the experimental discovery of THz single-photon emitters (SPEs). Developing such THz SPEs would establish an alternative quantum optical platform, bridging the challenges of the visible and microwave spectra while paving the way for innovative quantum optics sources and experiments in this frequency range. In this work, we present a design strategy for a tunable single-photon source operating in the THz regime [2].

II. Methods

Our methodology integrates quantum optical simulations and analytical calculations based on feasible electromagnetic calculations and experimental parameters [2].

III. Results and Discussion

- Our approach converts incident visible photons into THz output photons using three key components: an optical laser, a nanophotonic THz cavity, and a single polar quantum emitter. The interaction between the emitter and the laser fields induces THz transitions via the emitter's permanent dipole moment, which couples to the THz nanocavity (see Fig.1). We demonstrate that this setup can generate strongly antibunched THz radiation with significant brightness, while enabling optical tunability of key properties, such as emission frequency and quantum statistics [2]. Finally we also perform time domain excitations to demonstrate deterministic and heralded emission in THz hybrid nanocavity scenarios [3].

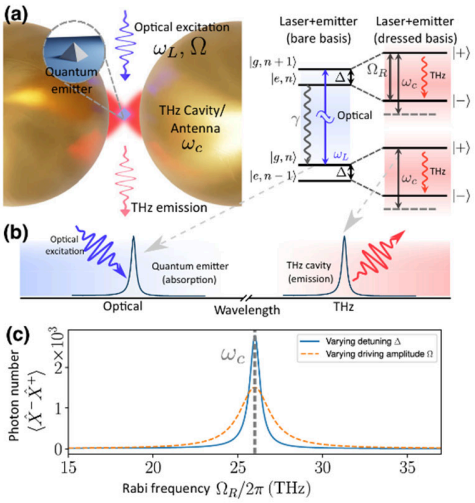

Fig. 1 (a) Sketch of the implementation (left) and energy levels (right): the left side represents the bare states basis while the right one represents the dressed-state basis highlighting THz transitions (red). (b) Absorption and emission properties in the THz and the optical domain. (c) Resonance in the cavity population as the Rabi frequency crosses the cavity frequency.

IV. Conclusion

We have demonstrated the design of CW and deterministic single photon sources for the THz regime based on polar quantum emitters coupled to a THz nanocavity. We show that this scheme is feasible with current state-of-the-art nanophotonic technology, providing a new pathway for exploring quantum optics in the THz regime [4,5].

Optically Enhancing or Detecting Single Molecules on DNA Origamis

Sebastien Bidault

Institut Langevin, CNRS, ESPCI Paris, PSL University, Paris, France
sebastien.bidault@espci.fr

***Abstract*— We demonstrate how plasmonic dimers on DNA origamis are a versatile platform to sense or detect single molecules. In particular, we develop a colorimetric biosensor for single DNA strands with femtomolar sensitivity and single-mutation specificity. We also demonstrate bright single photon sources with picosecond lifetimes at room temperature.**

***Keywords*— Plasmonics, DNA origamis, biosensing, enhanced fluorescence, single molecules.**

The ability to monitor single molecules or biomolecules with light is at the heart of numerous technologies ranging from diagnostic tools in biotechnology to single-photon sources in quantum technologies. However, single molecules interact extremely weakly with optical electromagnetic fields at room temperature: a fluorescent molecule resonantly interacts with less than one in a million photons that are focused on it, while, for a typical biomolecule, this value drops by a further 6 orders of magnitude. Using DNA origamis in conjunction with gold nanoparticles, we craft complex hybrid nanostructures that are capable of translating the detection of single short DNA strands into macroscopic color changes (Figure 1, left) or of enhancing the fluorescence of single molecules by several orders of magnitude (Figure 1, right). These architectures open exciting perspectives for the development of new biosensing strategies with single molecule sensitivity, as well as for the study of coherent interactions between light and single quantum emitters at room temperature.

Modelling the Purcell Enhancement on Nonlocal Metasurfaces

Joshua T. Y. Tse[1,*], Taisuke Enomoto[2], Shunsuke Murai[1], Katsuhisa Tanaka[2]

[1]Department of Physics and Electronics, Osaka Metropolitan University, Japan
[2]Department of Material Chemistry, Kyoto University, Japan

***Abstract*— Spontaneous emission of photons can be enhanced with metasurfaces. Yet, accurately predicting the enhancement factor has presented a challenge for empirical systems. We proposed a versatile analytical model that describes the Purcell effect of metasurfaces coupled with a photoluminescence thin film with spectral parameters.**

***Keywords*— Purcell effect, nonlocal metasurfaces, analytical modelling.**

I. Introduction

Metasurfaces supporting optical resonances have been widely utilized to enhance the Purcell effect, through both increased local density of states (LDOS) for enhanced spontaneous emission rate and redirecting the emitted photons to specific out-coupling channels.[1,2] Theoretically, we know that the Purcell enhancement is proportional to Q/V, where the quality factor Q is divided by the effective modal volume V. This represents the temporal and spatial confinement of the metasurface respectively. However, while Q is straightforward to define and measure, V was known to be difficult to determine experimentally or analytically.

II. Methods

We recently reported about our new analytical model that predicted the Purcell enhancement factor of nonlocal metasurfaces through parameters fitted from spectral measurements.[3,4] In particular, our model predicts the photoluminescence enhancement (PLE) to follow:

$$\mathrm{PLE}(\omega_0) = \frac{c\Gamma_{\mathrm{rad}}}{\omega_0 t \Gamma_{\mathrm{tot}}{}^2} \frac{\Gamma_{\mathrm{abs,dye}}}{\kappa}$$

where ω_0 is the resonant frequency, t is the dye layer thickness, κ is the extinction coefficient of the dye layer, and c is the speed of light in vacuum. $\Gamma_{\mathrm{tot}} = \Gamma_{\mathrm{rad}} + \Gamma_{\mathrm{abs,dye}} + \Gamma_{\mathrm{abs,NP}}$ is the total decay rate where Γ_{rad} is the radiative decay rate, $\Gamma_{\mathrm{abs,dye}}$ and $\Gamma_{\mathrm{abs,NP}}$ are the absorptive decay rates contributed by the dye layer and the nanoparticles. This model dissects the underlying mechanisms of the Purcell effect into the contributions from the quality factor, the spatial confinement and the out-coupling efficiency of emitted photons.

III. Results and Discussion

We then verify our analytical model with numerical and experimental metasurfaces. We analyzed the Purcell effect and the out-coupling of the enhanced luminescence on metasurfaces supporting *quasi*-bound states in the continuum (q-BIC) and surface lattice resonances (SLR). As illustrated in Fig. 1, the analytical model accurately predicted the numerical and experimental PLE of a variety of metasurfaces.

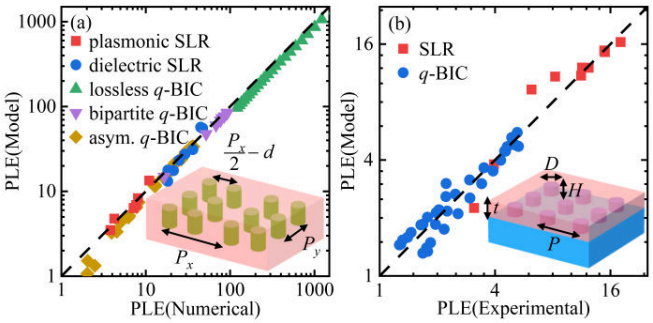

Fig. 1. The analytical PLE accurately predicts the (a) numerical and (b) experimental PLE. Insets: Metasurfaces supporting (a) q-BIC and (b) SLR.

IV. Conclusion

In conclusion, we developed an analytical model that describes the Purcell effect on metasurfaces and predicted the PLE that can be observed from resonant modes. This result presents a useful analytical framework for optimizing metasurfaces for luminescence applications.

***Abstract*—We introduce transiton metal-dichalcogenide (TMD) nanostructures as a promising platform for the realization of structural colours. Processing of semianalytically calculated reflectance spectra of TMD nanosphere arrays shows a wide range of colours, which are obtained simply through tailoring the radius and separation of spheres in the array. *Keywords*— structural colours, nanostructures, TMDs, light-matter interactions.**

I. Introduction

The continuous interest in structural colours as a route towards sustainable and recyclable products [1], or for efficient anti-counterfeiting tools [2] has been driving advances in material science and nanoengineering. One avenue of progress is expanding our arsenal of materials and architectures for producing colours. Here, we propose transition metal dichalcogenides (TMDs), which have the advantage of being high-index materials and important components in the research of optoelectronics. In this work we theoretically explore the possibility of structural colours stemming from TMD nanostructures in the form of arrays of spherical nanoparticles (NPs).

II. Methods

All results were obtained using semi analytical methods, specifically using the T-matrix-based software Treams [3]. The permittivity for WS_2, used for the computation of the data in Fig. 1, comes from the experimental results of [4].

III. Results and Discussion

As can be seen in Fig. 1c and Fig. 1e, our investigation [5] has shown that it is possible to create a range of colours utilising arrays of spherical NPs made from one of the most commonly used TMDs (WS_2). NP arrays present a superior platform for structural colours compared to slabs of the same materials, as shown in [5], due to the tailoring possibilities and the effect of multiple scattering as opposed to cavity resonances. Additionally, the interaction of the NP Mie modes with TMD excitons presents itself as an additional mechanism for controlling spectral features. Further tuneability, and experimental feasibility, can be achieved through TMD nanodiscs.

IV. Conclusion

Arrays of spherical NPs made from TMDs provide a good platform for the realization of structural colours, especially due to their many tailorable parameters allowing to reproduce much of the colour spectrum.

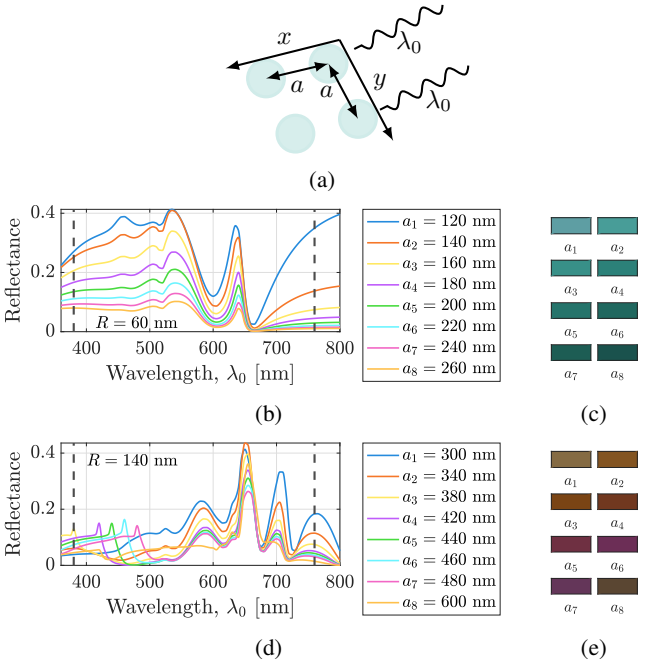

Fig. 1: Reflectance spectra and resulting colours for square arrays of spherical WS_2 NPs, see sketch in (a), with radii of (b),(c) 60 nm and (d),(e) 140 nm and variable separation a_i.

Few-molecule nonlinear vibrational spectroscopy with dual-resonant plasmonic nanocavities

Christophe Galland[1,*], Zhiyuan Xie[1], Nobuaki Oyamada[1], Francesco Ciccarello[1], Wen Chen[2]

[1]Institute of Physics, Ecole Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland
[2]State Key Laboratory of Precision Spectroscopy, East China Normal University
*Corresponding author: chris.galland@epfl.ch

***Abstract*—We implement high-resolution (< 1 cm^{-1}), coherent nonlinear vibrational sum- and difference-frequency spectroscopy from 860 to 1670 cm^{-1} on dual-resonant antennas under ambient conditions, with commercial continuous-wave lasers. The spectra exhibit interference between resonant (vibrational) and nonresonant (electronic) contributions to the second-order nonlinear response, previously accessible only under pulsed excitation.**

***Keywords*— Nanocavities, nanoplasmonics, molecular vibrations, nonlinear spectroscopy, sum frequency generation**

I. Introduction

Vibrational absorption spectroscopy in the mid-infrared (MIR, 400–4,000 cm^{-1}) and vibrational Raman spectroscopy in the visible (VIS) wavelength domain underpin label-free molecular identification across chemistry, materials, and biology. Field-enhanced implementations, namely, surface-enhanced Raman scattering (SERS) and surface-enhanced infrared absorption (SEIRA), have expanded their sensitivity down to molecular monolayers and nanomolar concentrations in liquids.

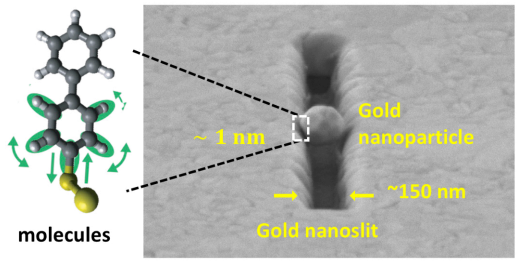

Fig. 1. Scanning electron micrograph on a dual-particle Nanoparticle-in-Slit cavity. The chosen molecule is introduced as a spacer between the gold nanoparticle and the slit etched in the gold film.

Beyond these single-frequency excitation schemes, simultaneous driving of molecular vibrations with MIR and VIS fields coherently interrogates modes that are both IR- and Raman-active through nonlinear frequency mixing. Here, we show that self-assembled plasmonic nanocavities allow ultra-broadband photonic engineering and illustrate this opportunity with a nanocavity supporting colocalized mid-infrared and visible resonances. This is realized using the "nanoparticle-on-slit" (NPoS) concept (see Fig. 1) and is used for vibrational sum- and difference frequency (SFG, DFG) spectroscopy on a small ensemble of molecules.

II. Methods

We design and fabricate nanoparticle-on-slit (NPoS) cavities as first demonstrated in [1] and theoretically analysed in [2]. The experimental setup in sketched in Fig. 2a. We are able to resolve all the nonlinear processes described in Fig. 2b under simultaneous illumination with weak continuous wave lasers at MIR and VIS frequencies.

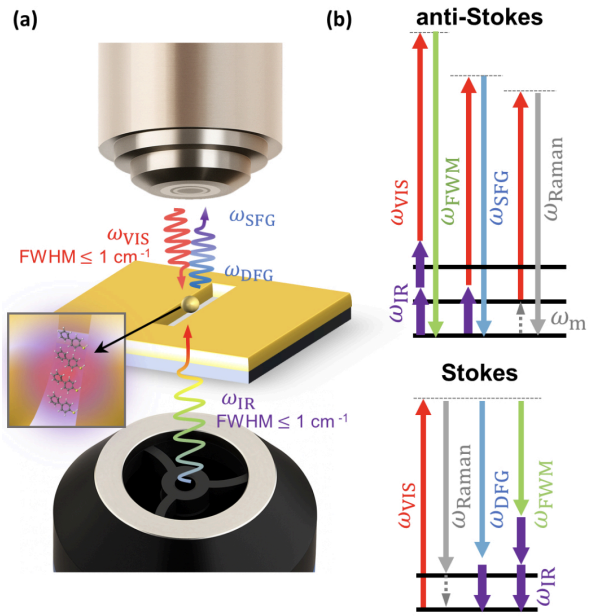

Fig. 2. **(a)** Experimental scheme. A 780 nm laser and a tunable MIR laser are co-focused onto an NPoS nanocavity. The analyte layer resides in the nanometer gap between the gold nanoparticle and the slit walls (inset). **(b)** Energy-diagram representation of photon scattering pathways under simultaneous VIS (ω_{VIS}) and MIR (ω_{IR}) excitation. *Adapted from Ref. [3]*

III. Results and Discussion

Compared to previous results [1], I will show data covering an extended spectral range from 860 to 1670 cm^{-1}, giving access to the full IR vibrational fingerprint of the molecules and revealing coherent interference between resonant (vibrational)

and nonresonant (electronic) contributions to the effective $\chi^{(2)}$ response [3]. To test the versatility of our platform, we measured single–NPoS spectra for biphenyl-thiol (BPhT), 4'-cyanobiphenyl-4-thiol (cn-BPhT) and 4-nitrothiophenol (4-NTP) molecules embedded in the gap. We could measure reproducible spectra by either functionalising the nanoparticles our forming a self-assembled monolayer on the gold substrate. Some illustrative spectra are shown in Fig. 3.

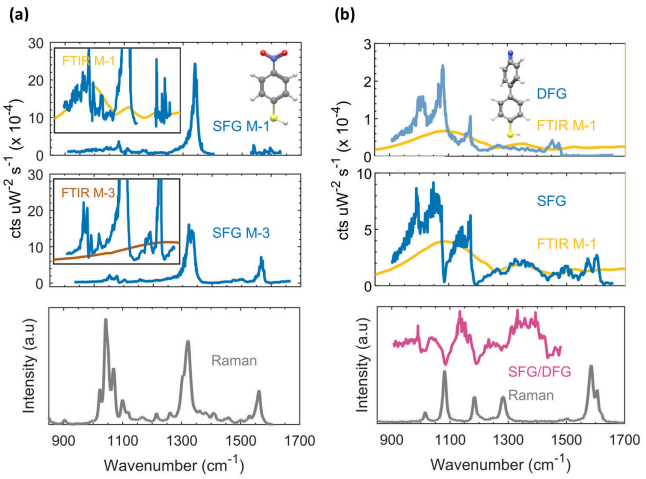

Fig. 3. **(a) 4-NTP on two metasurfaces.** Top: SFG spectrum from a single NPoS on a nanoslit metasurface having its main resonance around 1100 cm^{-1} (see FTIR spectrum in the inset, yellow line). Middle: SFG spectrum from a single NPoS on another metasurface having its main resonance around 1600 cm^{-1} (see FTIR spectrum in the inset, orange line). Bottom: corresponding SERS spectrum. The visible laser power was limited to 1 µW to avoid triggering photochemical reactions with 4-NTP. **(b) cn-BPhT on a metasurface resonant at 1100 cm^{-1}.** Power-normalized DFG (top) and SFG (middle) from a single NPoS, overlaid with the metasurface FTIR spectrum (yellow); bottom: SFG/DFG ratio and co-recorded SERS. *Adapted from Ref. [3]*

The SFG and DFG spectra obtained for the two molecules featured in Fig. 3 illustrate two qualitative regimes of nonlinear polarization interference. For 4-NTP, the vibrational mode involving the electron-withdrawing nitro- group exhibits large IR and Raman dipoles. Consequently, its resonant second-order (SFG and DFG) response is much stronger than the off-resonance response and it dominates the overall spectrum. In contrast, cn-BPhT exhibits pronounced interference between the resonant response of its IR+Raman active vibrational modes and the broad non-resonant nonlinear electronic response. The latter is assigned to the molecule-metal interface, where inversion symmetry is broken, and can be possible enhanced by charge-transfer resonances.

IV. Conclusion

Our work establishes a robust platform for nonlinear molecular spectroscopy under weak continuous-wave drive. Its extended optical bandwith is useful for disentangling resonant and non-resonant contributions, probing charge-transfer–assisted nonlinearities, and characterizing surface nonlinearities of the nanostructure. Compared to conventional SFG spectroscopy, our approach bridges coherent nonlinear spectroscopy with chip-integrated chemical analysis. It offers high spectral resolution, much lower molecular detection limits, compact implementation, and direct compatibility with commercial MIR-Raman microscopes. I will conclude with some prospects for using this system in the single-molecule regime for physical chemistry and quantum optics. [4].

***Abstract*— Tip-enhanced sum-frequency generation (TE-SFG) beyond the diffraction limit is achieved using a scanning tunneling microscope (STM), enabling nanoscale vibrational detection with spatial resolution smaller than 30 nm, molecular orientation analysis, and >10^7 signal enhancement. Furthermore, giant signal enhancement was observed under an applied bias between the STM tip and substrate.**

***Keywords*— tip-enhanced spectroscopy, sum-frequency generation, vibrational spectroscopy, electrophotonic effect, near-field scanning optical microscopy.**

I. Introduction

Vibrational sum frequency generation (SFG) is a nonlinear spectroscopic technique widely used to study molecular structures, orientations, and dynamics at surfaces and interfaces [1]. However, the spatial resolution achieved by far-field observations is constrained by the diffraction limit, obscuring molecular details in inhomogeneous structures smaller than the wavelength of light. To overcome this limitation, we developed a system for tip-enhanced SFG (TE-SFG) spectroscopy based on a scanning tunneling microscope (STM) (Fig. 1) [2] and successfully observed signals from molecular vibrations [3].

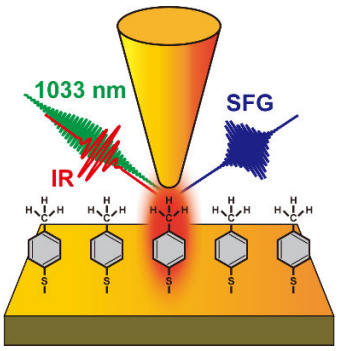

Fig. 1 Schematic of TE-SFG spectroscopy. Tunable IR and 1033 nm laser beams were collinearly focused onto the nanojunction formed between a STM tip and a sample substrate.

II. Methods

The experimental setup of the TE-SFG system is schematically illustrated in Fig. 2. The output from an Yb-fiber laser (1033 nm, 280 fs, 40 W, 50 MHz) was divided into two arms by a beam splitter. The first arm served to pump an optical parametric oscillator (OPO), which generated two output beams: a signal (1.3–2 μm) and an idler (2.1–5 μm). The second arm was directed through an air-spaced Fabry–Pérot etalon to narrow the spectral bandwidth and make the pulses temporally asymmetric. The idler and spectrally narrowed beams were combined collinearly at a dichroic mirror and simultaneously focused onto the nanojunction between a gold tip and a sample substrate in an STM system at an incident angle of 55°. The beams were linearly polarized along the tip axis (*p*-polarization) to effectively excite the gap-mode plasmon. Two identical CaF_2 aspherical lenses were employed to focus the incident beams and collect the emitted signals. The emitted signals were passed through a short-pass filter (transmissive over the 500–900 nm range) and then coupled into an optical fiber. The fiber-coupled signals were spectrally dispersed by a spectrometer and detected using an electronically cooled CCD camera. The sample was a self-assembled monolayer (SAM) of 4-methylbenzenthiol (4-MBT, CH_3–C_6H_4-SH) on a Au(111) substrate.

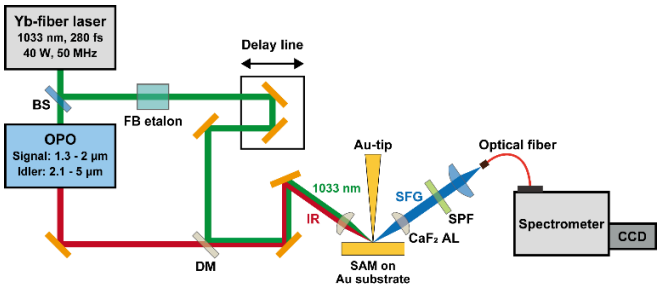

Fig. 2 Experimental setup of the TE-SFG system. BS: beam splitter, FB etalon: air-spaced Fabry–Pérot etalon, CaF_2 AL: CaF_2 aspherical lens, SPF: short-pass filter. The delay line was used to adjust the delay between the idler and the 1033 nm pulses.

III. Results and Discussion

The observed TE-SFG spectra are shown in Fig. 3. The idler central wavenumber was varied from 2800 to 3150 cm^{-1}, and eight spectra were recorded. The broad spectral shape of each spectrum originates from the spectrum of the incident idler pulse, resulting from the vibrational non-resonant contribution. Furthermore, dip structures are observed at the three positions indicated by the red arrows. These features are attributed to the interference between the vibrational resonant signal and the non-resonant signal.

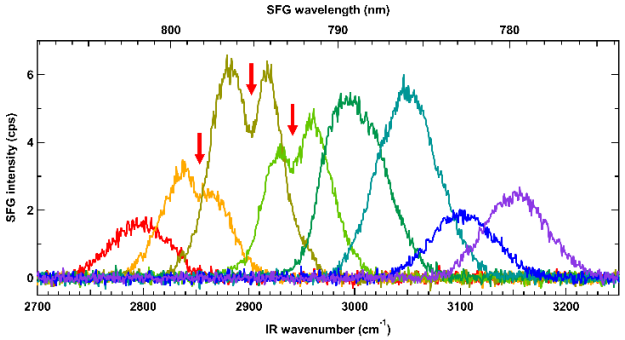

Fig. 3 TE-SFG spectra for different IR central wavenumbers ranging from 2800 to 3150 cm^{-1}. The spectra obtained at a tip-sample distance of 50 nm were subtracted as background for each dataset. Dip structures are observed at the three positions indicated by the red arrows. Intensities are normalized to counts per second (cps) [3].

To extract the molecular vibrational information, we performed a fit using the following equation,

$$I(\omega_{\mathrm{IR}}) = \exp\left[-\frac{(\omega_{\mathrm{IR}}-\omega_0)^2}{\sigma_{\mathrm{IR}}^2}\right]\left|A_{\mathrm{NR}}e^{i\theta_{\mathrm{NR}}} + \frac{A_q}{\omega_q-\omega_{IR}-i\Gamma_{\mathrm{q}}}\right|^2, \quad (1)$$

where ω_0 and σ_{IR} are the central wavenumber and spectral width of the incident idler pulse, respectively. The resonant term is expressed as a vibrational mode with amplitude A_q, resonant frequency ω_q, and damping constant Γ_q, while the non-resonant term is characterized by a constant amplitude A_{NR} and the phase factor θ_{NR}. In addition, we calculated the imaginary part of the resonant contribution to the second-order susceptibility ($\mathrm{Im}\left[\chi_{\mathrm{R}}^{(2)}(\omega_{\mathrm{IR}})\right]$), using the same parameters as those used in the fitting, which corresponds to the purely absorptive response of the vibrational mode, given by

$$\mathrm{Im}\left[\chi_{\mathrm{R}}^{(2)}(\omega_{\mathrm{IR}})\right] = \mathrm{Im}\left[\frac{A_q}{\omega_q-\omega_{IR}-i\Gamma_q}\right]. \quad (2)$$

The fitting results using Eq. (1) are shown in Fig. 4(a) as black curves, which agree well with the experimental results. The light red curves in Fig. 4(b) represent $\mathrm{Im}\left[\chi_{\mathrm{R}}^{(2)}(\omega_{\mathrm{IR}})\right]$, calculated using Eq. (2), and the sum of these contributions is plotted as the red line. The extracted three vibrational modes are assigned to (1) methyl stretching (CH_3–SS) vibration, (2) Fermi resonance (CH_3–FR) between CH_3–SS and an overtone of a methyl bending vibration, and (3) degenerate methyl stretching (CH_3–DS) vibration. The negative sign of $\mathrm{Im}\left[\chi_{\mathrm{R}}^{(2)}(\omega_{\mathrm{IR}})\right]$ indicates that the terminal methyl group is oriented with its hydrogen atoms pointing away from the substrate. This result show that TE-SFG can determine absolute molecular orientation at the nanoscale with high precision.

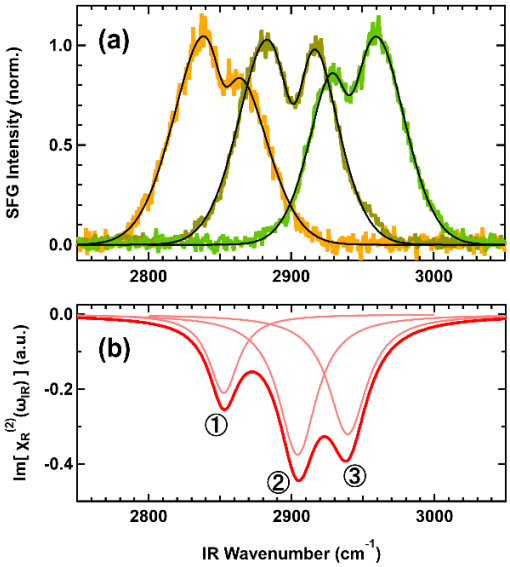

Fig. 4 (a) Three TE-SFG spectra in Fig. 4 were fitted using Eq. (1). The fitting results are shown as black curves. (b) The light red curves represent the respective imaginary parts of the resonant contribution to the second-order susceptibility ($\mathrm{Im}\left[\chi_{\mathrm{R}}^{(2)}(\omega_{\mathrm{IR}})\right]$), which correspond to the purely absorptive responses given by Eq. (2). The extracted peaks are assigned to (1) CH_3–SS, (2) CH_3–FR, and (3) CH_3–DS. The red curve is the sum of these three contributions [3].

Moreover, by introducing a controlled delay between the first idler pulse and the second 1033 nm pulse, the non-resonant background was effectively suppressed, which led to an optimized ratio between the resonant and non-resonant signals, thereby maximizing the contrast of the interferometric signal and improving the detectability of weak vibrational signals, enabling the detection of an aromatic CH mode that had not been observed previously [4]. The signal enhancement factor was also estimated to be $6.3 \times 10^6 - 1.3 \times 10^7$ based on the experimental data [4].

Furthermore, we measured TE-SFG spectra across the boundary between different SAM domains while scanning the sample. The observed TE-SFG spectra showed a rapid change at the boundary, and this change was confirmed to occur over a spatial range of 30 nm around the boundary [5].

In addition, we investigated the effects of a bias voltage applied to the STM nanojunction on the intensity of the second harmonic generation (SHG) and SFG signals. The results revealed a significant enhancement of the signals as the applied bias increased [6]. This signal enhancement is attributed to so-called electric-field-induced SHG and SFG processes. Unlike typical cases, the signal exhibited a quadratic dependence on the applied voltage rather than a linear one due to the very strong electric field generated across the STM nanojunction ($\sim 10^9$ V/m).

IV. Conclusion

We have demonstrated TE-SFG measurements on a SAM of 4-MBT adsorbed on a Au surface. The observed signals

exhibited dips arising from vibrational modes within the broadband non-resonant background spectrum. These three dips are assigned to vibrational modes of the terminal methyl group of 4-MBT molecules. By introducing a delay between the two pulses, the ratio between the resonant and non-resonant signals was optimized, and the vibrational signal arising from an aromatic CH mode was additionally detected. The spatial resolution was confirmed to be within 30 nm. Furthermore, a giant signal enhancement due to the applied voltage between the STM tip and the substrate was observed.

***Abstract*—We experimentally realize an optical field with spatially uniform energy density and periodically sign-reversing optical chirality using two orthogonally polarized beams. Polarimetric imaging confirms chirality fringes without intensity modulation. Circular dichroism mapping of chiral gold nanoparticles reveals position dependent enantioselective interaction, evidencing optical chirality gradients toward chiral selective trapping.**

***Keywords*—optical chirality, chiral gradient force, circular dichroism, enantioselective interaction, nanophotonics.**

I. Introduction

Chirality plays a central role in chemistry, biology, and materials science. Although opposite enantiomers share identical bulk physical properties, their interaction with chiral environments differs fundamentally. Circularly polarized light represents the simplest form of optical chirality, with left and right circular polarization corresponding to opposite signs of optical chirality density. This quantity governs enantioselective light–matter interaction and forms the physical basis of circular dichroism (CD).

Beyond spectroscopy, it has been theoretically predicted that spatial gradients of optical chirality density can generate chiral optical forces acting in opposite directions on opposite enantiomers [1]. Interferometric schemes capable of producing spatially alternating optical chirality have been proposed theoretically [2,3] and later demonstrated experimentally [4]. These studies established the feasibility of structuring optical chirality in free space. However, direct verification that spatially structured optical chirality couples enantioselectively to nanoscale chiral objects has not yet been directly demonstrated. Moreover, previously demonstrated chirality patterns were realized on spatial scales much larger than the optical wavelength [4].

In this work, we experimentally realize wavelength-scale modulation of optical chirality under spatially uniform energy density conditions and directly confirm enantioselective interaction with chiral nanoparticles through position-resolved CD mapping. This architecture provides a physically consistent platform for isolating genuine chiral optical forces toward future chiral trapping and separation.

II. Field Design and Experimental Approach

The optical field is constructed by coherently superposing two orthogonally polarized beams propagating in a common plane. Due to their polarization orthogonality, the superposition produces no intensity interference, resulting in a spatially uniform optical energy density. At the same time, the relative phase between the two field components varies along one spatial direction, leading to periodic conversion between linear and circular polarization states. As a result, the optical chirality density undergoes periodic sign reversal while the total intensity remains invariant.

The generated field is experimentally visualized using polarization selective imaging. Intensity measurements confirm the absence of spatial interference fringes, whereas circular polarization resolved detection reveals clear periodic modulation consistent with theoretical expectations.

To probe enantioselective interaction, individual nanoparticles are scanned across the structured field. The local optical chirality is inverted through controlled manipulation of the incident polarization state, enabling differential transmission measurements corresponding to CD at each spatial position.

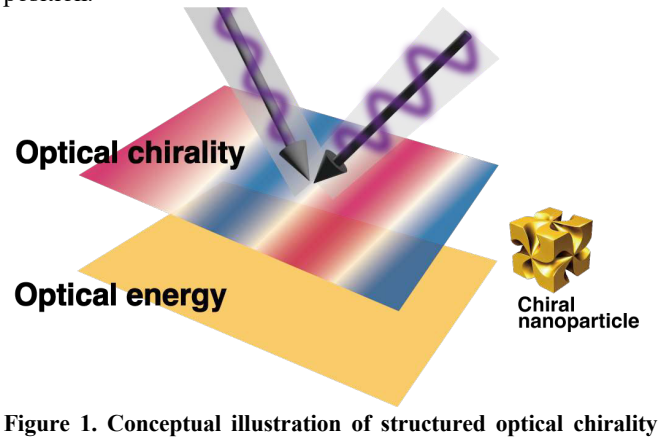

Figure 1. Conceptual illustration of structured optical chirality under uniform energy density. Two orthogonally polarized beams incident at ±θ create spatially uniform energy density while generating alternating regions of opposite optical chirality. A nearby chiral nanoparticle experiences position-dependent enantioselective interaction governed by the local chirality distribution.

III. Results and Discussion

Achiral nanoparticles exhibit negligible differential transmission throughout the field, confirming effective suppression of conventional gradient contributions.

In contrast, chiral nanoparticles display position dependent CD signals that follow the periodic modulation of optical chirality. The sign of the response reverses upon inversion of the optical chirality distribution, demonstrating enantioselective interaction governed by the local optical chirality density.

Importantly, the absence of correlated intensity modulation indicates that the observed effect does not originate from conventional interference or energy density gradients. These results provide experimental evidence that spatially structured optical chirality selectively couples to chiral nanoparticles under suppressed achiral force conditions.

The demonstrated architecture therefore constitutes a viable platform for future realization of chiral gradient force driven trapping, spatial separation, and ordered assembly of enantiomeric particles.

IV. Conclusion

We have experimentally realized optical fields with spatially modulated chirality and uniform energy density and demonstrated enantioselective interaction with chiral nanoparticles. By suppressing achiral gradient contributions, this approach establishes a practical platform for isolating chiral optical forces and advancing optical enantioseparation strategies.

In this report, we developed a plasmonic metasurface biosensor of which sensitivity is tunable to match the required limit of detection and dynamic range in miRNA detection in human serum. Our metasurface biosensor is promising as reliable and highly sensitive biosensing platform for simple and rapid diagnostic technologies.

***Keywords*— miRNA, biosensor, plasmonics, Bound states in the continuum**

I. Introduction

Minimally invasive biomarkers are essential for early diagnosis. Circulating microRNAs (miRNAs) are short (~22 nt) noncoding RNAs that remain stable in biofluids and are linked to diverse diseases.[1] Practical miRNA testing requires assays that work in complex samples with femtomolar sensitivity, sequence specificity, rapid readout, simple protocols, and multiplexing.[2] Label-free transducers that directly report nucleic-acid hybridization at a surface offer an alternative; optical refractometric sensing can monitor binding-induced refractive-index changes in real time and readily supports parallelized measurements.[3] In particular, resonant metasurfaces—periodic nanostructures supporting optical resonances—convert molecular adsorption into measurable resonant shifts, with performance governed by the resonance quality factor (Q) for resolutions and enhanced near-field hot spots at the interface for responsivites.[4] Balancing high-Q resonances with strong surface overlap between enhanced near-field and molecules is therefore critical for detecting miRNA-scale small molecular targets. Dielectric metasurfaces can provide ultrahigh Q via (quasi-)bound states in the continuum (q-BICs), but diffraction-limited mode volumes and internal field localization reduce interaction with nm-scale analytes. Plasmonic metasurfaces provide strong surface near-fields yet often suffer reduced Q due to ohmic loss.[5] Here we propose a symmetry-broken plasmonic lattice that couples localized surface plasmons (LSPs) to surface lattice resonances (SLRs) to jointly tune radiative and absorptive losses, enabling high-Q resonances with dense and intense hot spots on gold nanostructured surfaces; symmetry breaking in unit-cell offers the radiative loss tunability supported by q-BICs based LPSs while hybridizing with SLRs yields the absorptive loss tunability. Therefore, critical coupling condition, at which the electric-field enhancement factor (EF) is maximized, can be achieved with desirable Q. Joint parametric tuning provides the tunability of Q, EF, and hot spot density on the metasurface. In this work, we experimentally and numerically investigated the tunability of bulk and surface refractive index sensitivity via parametric tunning in our metasurface to realize sub-femtomolar limit of detection and sub-femtomolar-to-picomolar dynamic range in label-free detection of miRNA in human serum. Our metasurface sensor provided the required dynamic range in sub-femtomolar-to-picomolar with sub-femtomolar limit of detection in miR-29c-3p sensing, which is known to implicate to neurodegenerative diseases.

II. Methods

1. Optical characterization. Metasurface spectra were recorded with a custom microscope–spectrometer setup. The reflectance spectrum $R(\lambda)$ was obtained by normalizing the measured intensity from the metasurface to that from a flat gold reference. Absorptance was calculated as $A(\lambda) = 1 - R(\lambda)$. Resonance parameters were extracted by Lorentzian fitting to the absorptance peak; the quality factor was computed as $Q = \frac{\lambda_{peak}}{FWHM}$ Finite-difference time-domain simulations (Ansys Lumerical) reproduced the fabricated geometry and measurement configuration. Periodic boundary conditions were applied in the in-plane directions (x,y) and perfectly matched layers along z. Gold was modeled with Palik optical constants; the MgF_2 spacer was treated as a dielectric with $n = 1.37$.

2. Theory for refractive index sensitivity. In electromagnetic perturbation theory, the plasmonic resonance is treated as an eigenmode of Maxwell's equations. A small permittivity perturbation Δε(r) produces a first-order eigenwavelength shift.

$$\Delta\lambda = \frac{\lambda}{2} \cdot \frac{\int \Delta\varepsilon(r)|E(r)|^2 dV}{\int \varepsilon(r)|E(r)|^2 dV}. \quad (1)$$

Bulk refractive index sensitivity (BRIS) is defined by a uniform index change in the sensing region, $n_{bg} \rightarrow n_{bg} + \Delta n$. With spatially constant $\Delta\varepsilon \approx 2\, n_{bg} \Delta n$, the response is linear, $\lambda_{bulk} = BRIS\, \Delta n$. For non-uniform perturbations we write $\Delta\lambda = BRIS\, \Delta n_{eff}$, where Δn_{eff} is obtained by weighting the local index change $\delta n(z)$ with the normalized normal-direction intensity profile $W(z) \propto |E(z)|^2$. For a thin overlayer of index n_s and thickness t on a background n_{bg} (z = 0 at the metal–dielectric interface, z > 0 into the dielectric), the perturbation is $\delta n(z) = n_s - n_{bg}$ for $0 \le z \le t$ and $\delta n(z) = 0$ for $z > t$. Assuming an exponential near-field decay $|E(z)|^2 \propto$

$\exp\left(\frac{-2z}{l_d}\right)$, we use $W(z) = \left(\frac{2}{l_d}\right)\exp\left(\frac{-2z}{l_d}\right)$. The effective index change becomes

$$\Delta n_{eff(t)} = (n_s - n_{bg})\int_0^t W(z)dz = (n_s - n_{bg})\left[1 - \exp\left(\frac{-2t}{l_d}\right)\right] \quad (2)$$

and the corresponding resonance shift is

$$\Delta\lambda(t) = BRIS\,(n_s - n_{bg})\left[1 - \exp\left(\frac{-2t}{l_d}\right)\right]. \quad (3)$$

The surface refractive index sensitivity is defined as

$$SRIS(t) \equiv \frac{\partial^2\Delta\lambda}{\partial t\,\partial n_s} = \left(\frac{2\,BRIS}{l_d}\right) \quad (4)$$

For a homogeneous film (index n_s, thickness t_{anal}) that fully covers the responsive metal area, integrating SRIS yields

$$\frac{\partial\Delta\lambda}{\partial n_s}\Big|_{t\,=\,t_{anal}} = \int_0^{t_{anal}} SRIS(t)dt\,. \quad (5)$$

In the dilute-coverage regime, a finite number of analyte objects (cross-sectional area s_{anal}, height t_{anal}) covering only a fraction f of the responsive surface scales the response linearly:

$$\frac{\partial\Delta\lambda}{\partial n} = f\int_0^{t_{anal}} SRIS(t)dt\,. \quad (6)$$

Relating f to the metasurface geometry using the unit-cell area A_{cell}, the responsive gold area per cell A_{gold}, and analyte number density ρ (per total metasurface area), we have $f = \frac{\rho\, s_{anal} A_{cell}}{A_{gold}}$.

3. MiRNA sensing protocol. Disulfide-modified probe DNA (22 nt with a C6 spacer) and miRNAs (miR-29c-3p and miR-19) were purchased commercially. Thiolated probes (1 μM) were immobilized on gold by overnight incubation at 37 °C in PBS (pH 7.4) containing EDTA (0.04 wt%) and Tween-20 (0.5 wt%), followed by sequential rinses to remove weakly adsorbed species. For quantitative assays, sensors were exposed to miRNA-spiked 10% plasma (1 fM–1 μM, 10 μL) containing RNase inhibitor (500 U/mL). After hybridization (37 °C, 20 min) and rinsing, spectral shifts were again analyzed in air (N = 5 independent sensors).

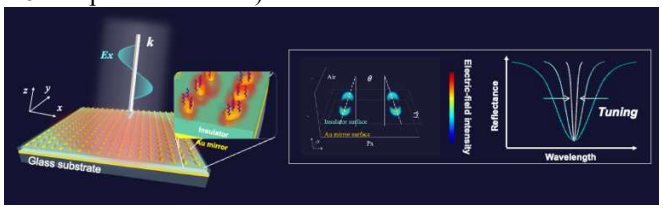

Fig. 1 The schematis for plasmonic metasurface sensor.

III. Results and Discussion

The sensor is a periodic array of gold elliptical nanopillar dimers on a 150-nm dielectric spacer backed by a gold mirror. The mirror suppresses transmission, producing a high-contrast absorptance resonance in the near infrared, and the gold surface supports robust thiol probe chemistry. We tune the unit cell using the long-axis period *Px* and the in-plane orientation angle θ (Fig. 1a). The resonance is a mirror-coupled plasmonic quasi–bound state in the continuum (q-BIC), where radiative leakage follows $\gamma_{rad} \propto sin^2\theta$ thus θ provides a direct "radiation knob" to satisfy critical coupling ($\gamma_{rad} = \gamma_{abs}$) and maximize absorptance. Independently, sweeping Px through the Rayleigh-anomaly region tunes the linewidth over ~1–2 orders of magnitude. Temporal coupled-mode theory predicts $EF = \left|\frac{E_{max}}{E_0}\right|^2$ peaks at critical coupling. Numerical simulation over *Px* = 400–900 nm and θ = 5°–40° reveal a critical-coupling locus (near-unity absorptance for each *Px*) along which *EF* increases with Q, reaching $EF > 10^4$ with $Q > 150$.

We benchmarked refractometric performance using bulk refractive-index sensitivity ($BRIS = \frac{\Delta\lambda}{\Delta n_B}$) and $FOM = BRIS/FWHM$. For *Px* = 400–800 nm at θ = 20°, both BRIS and FOM increase with *Px* because lattice assistance boosts bulk responsivity while narrowing the resonance. The best experimental values reached BRIS = 1270 nm/RIU and FOM = 205 RIU^{-1}. For biosensing, the relevant metric is surface refractive-index sensitivity (SRIS). Using a thin-film perturbation model with exponential field decay, $SRIS(t) = \left(2\cdot\frac{BRIS}{l_d}\right)\cdot\exp\left(-\frac{2t}{l_d}\right)$, so SRIS(0) highlights the trade-off between large BRIS and tight confinement (small l_d). Numerical simulation fits show that increasing Px lengthens l_d, so SRIS(0) decreases with *Px* even though BRIS rises—smaller *Px* favors interfacial sensitivity for nm-scale layers (Fig. 2a). Partially perturbed refractive index sensitivity, which is defined by $\Delta\lambda \approx f\cdot SRIS$ (f is a partial coverage factor) for effective sensitivity to finite number molecules, was reached its maximum around Px = 700–800 nm, agreed between experimental results with miRNA detection and simulated values.

By using metasurface which provided the highest partially perturbed sensitivity (Px = 800 nm), we quantified miR-29c-3p in 10% diluted serum (10-μL aliquots) from 1 fM to 1 μM and fitted Hill–Langmuir curves to extract LOD (blank + 3σ), and dynamic range (C10–C90). As a result, we achieved the LOD of 0.110 fM with dynamic range from 0.4 fM to 0.5 nM, meeting the demands for label-free miRNA sensing (Fig. 2b).

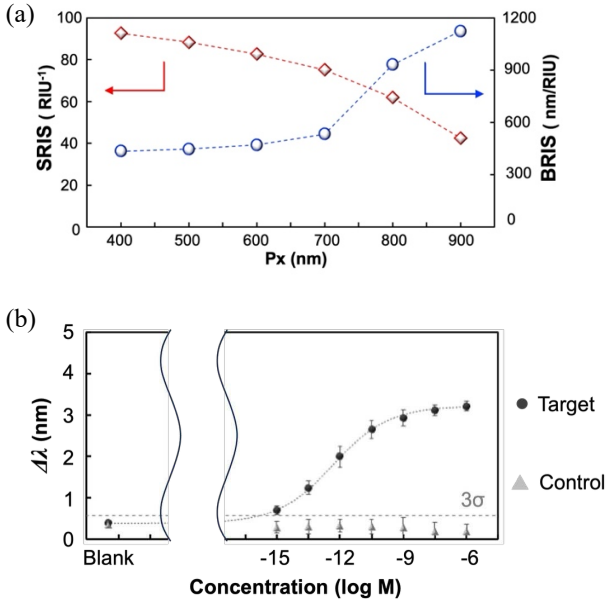

Fig. 2 (a) The plots of BRIS (Blue) and SRIS (Red) across Px. (b) Response curves in miRNA sensing by metasurface with Px 800 nm.

IV. Conclusion

In this report, we developed a plasmonic metasurface biosensor of which sensitivity is tunable to match the required limit of detection and dynamic range in miRNA detection in human serum. Q and EF of our metasurface are tunable by jointly engineering radiative and absorptive loss via symmetry breaking-induced q-BICs coupled to SLRs. Cooperative parametric tuning provides critical coupling condition with wide-range Q to control density and intensity of hot-spots. We experimentally and numerically evaluated BRIS and SRIS to reveal that they are in tread-off to strength of the coupling between LSPs and SLRs which was controlled via lattice pitch. In addition, SRIS per responsive surface, i.e., the sensitivity to molecules, was also tuned to maximize the sensitivity to miRNAs and minimized the limit of detection to sub-femtomolar in 10 μL human serum with suitable dynamic range from sub-femtomolar-to-picomolar. We achieved 0.110 fM (1.10 zmol) limit of detection of miR-29c-3p in human serum. Our metasurface biosensor is promising as reliable and highly sensitive biosensing platform for next-generation simple and rapid diagnostic technologies.

***Abstract*— We demonstrate label-free single-molecule detection of proteins using high-Q silicon nitride microring resonators. Immunoglobulin M (~970 kDa) and thyroglobulin (~660 kDa) are measured, revealing multimodal mass distributions. Results are compared against iSCAT, DLS, and gel electrophoresis. Plasmonic enhancement enables the detection of proteins with 100× lower molecular weight.**

***Keywords*— single-molecule sensing, microresonators, plasmonics, Immunoglobulin M, thyroglobulin.**

I. Introduction

Label-free single-molecule sensing enables analysis of protein mass distributions in solution. We investigate Immunoglobulin M (IgM, ~970 kDa) and thyroglobulin (Tg, ~660 kDa) using integrated photonic microresonators, and compare results with established techniques including iSCAT, dynamic light scattering (DLS), and gel electrophoresis.

II. Methods

Silicon nitride microring resonators (20–150 µm) were fabricated and optically interrogated using a 950 nm laser. Protein samples were introduced via microfluidics. Binding events were detected via resonance shifts. Comparative measurements were performed using iSCAT, DLS, and gel-based assays.

III. Results and Discussion

IgM and Tg show discrete binding events with multimodal step-height distributions corresponding to different oligomeric states. Measured distributions agree with benchmark techniques (iSCAT, DLS, gels). Plasmonic enhancement (via attaching resonant Au nanorods to the SiN resonator) significantly increases sensitivity, enabling detection of proteins with ~100× lower molecular weight.

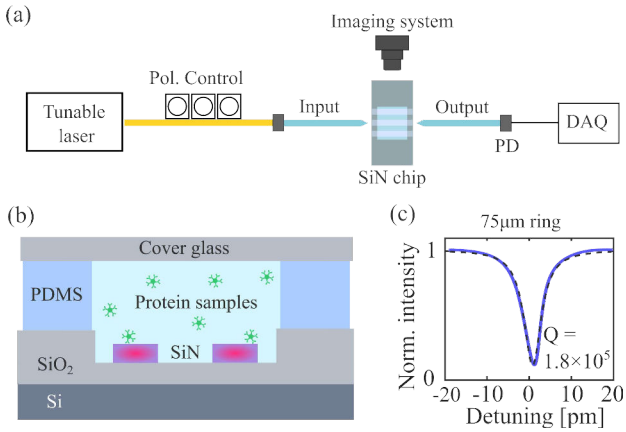

Fig. 1 Experimental Setup. (a) Optical measurement setup. (b) Cross-section of the sensing chamber. (c) Representative resonance dip in the transmission of the 75 µm ring measured in PBS buffer with Lorentzian fit: $Q = 1.8\times10^5$.

IV. Conclusions

The platform enables label-free determination of protein mass distributions in solution. With plasmonic enhancement, detection extends to much smaller biomolecules, providing a

scalable tool for biochemical sensing.

***Abstract*—Nature provides advanced strategies for managing infrared radiation through micro- and nanostructures. By studying biological examples, from insects to mammals, we derive principles for engineered materials enabling efficient insulation, passive cooling, and selective IR management. This work highlights how bioinspired designs support sustainable thermal technologies.**

***Keywords*— Bioinspired materials, infrared control, thermal management, thermal insulation, photonic structures, energy efficiency, bioinspiration.**

I. Introduction

Many organisms rely on finely tuned thermal-radiation control to survive, especially species exposed to extreme climates or lacking internal thermoregulation, so-called "ectotherms" or "cold-blooded animal". Over millions of years, evolution has produced sophisticated natural structures capable of absorbing, emitting, or redirecting infrared radiation. Examples such as nanostructured butterfly scales or the specialised fur of Arctic mammals reveal exceptional biological strategies for modulating heat transfer [1].

II. Methods and Results

This work examines several biological systems that demonstrate highly optimised forms of thermal regulation. Cold blooded insects, which depend heavily on environmental temperatures, use precise infrared interactions (Fig. 1), while desert adapted mammals like dromedaries employ structural features that enable efficient heat control. These micro- and nanoscale architectures often serve multiple roles, integrating thermal management with functions like camouflage or communication [1].

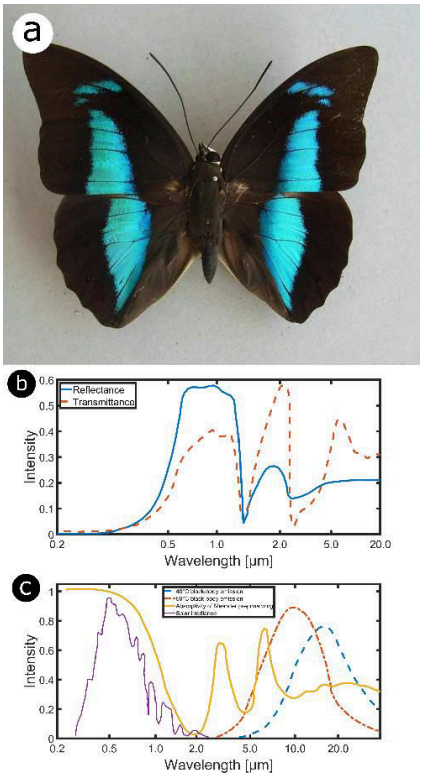

Fig. 1 Radiative cooling contributes significantly to the thermal regulation of some butterfly species, such as *Archaeoprepona meander* (a). This effect stems from the specific structure of the scales forming the dark wing regions. Measurements show a pronounced contrast between visible and near infrared reflectance and transmittance (b). By comparing black body emission curves at 40°C and 50°C with solar irradiance and the wing's absorptance (c), Berthier [23] demonstrated that the thermoregulation mechanism is linked to the chitin C=O absorption band near 6 µm. Fig. (a) and (b,c) were reproduced from Notafly, https://commons.wikimedia.org/wiki/File:Archaeoprepona_meander_(Cramer,_-1775-).JPG, License CC-BY-SA-3.0 and ref. [1], License CC-4.0, respectively. Data in fig. (b,c) are from [2].

Recent progress in bioinspired materials science has enabled the reproduction of such natural designs. By analysing photonic structures and thermal strategies observed in nature [3], we extract design guidelines that support the development of multifunctional materials capable of selective IR absorption and enhanced insulation.

Our findings highlight the interdisciplinary potential of bioinspiration, linking biological insight with physics and materials engineering. The resulting concepts show promise for applications requiring passive and energy efficient thermal regulation. Ultimately, the study underscores how nature's innovations, when carefully studied and adapted, can lead to sustainable and high-performance solutions for modern engineering challenges.

III. Conclusion

Biological systems offer many strategies for managing infrared radiation, and translating these mechanisms into engineered materials opens pathways to sustainable thermal technologies. By integrating principles derived from evolution with modern fabrication techniques, we can develop versatile, energy efficient solutions that address growing needs in thermal management across diverse engineering sectors.

***Abstract*—We present two types of tunable collective lattice resonances (CLRs) through conducting polymer metasurfaces, with resonance wavelengths ranging from 4500 to 640 nm. Poly(3,4-ethylenedioxythiophene) nanoantenna arrays either form plasmonic CLRs by themselves or serve as "optical gate" to switch light confinement and Mie CLRs in low-index organic dielectrics.**

***Keywords*— Active Organic Metasurfaces, Collective Lattice Resonances, Conducting Polymers**

I. Introduction

Conducting polymers, with tunable refractive index (or permittivity) induced by redox reactions, have been exploited as active materials for optical metasurfaces. Since 2020, conducting polymer metasurfaces have been applied for switchable surface plasmon resonances, beam steering and tunable lensing. However, conducting polymer plasmonics suffer from low resonance intensities and low quality factors ($Q < 2$), which are detrimental to metasurfaces' performances such as high-resolution and high-contrast switching. Meanwhile, due to the low charge carrier density in conducting polymer films, it is rather difficult to induce dynamic organic plasmonics within visible/NIR-I wavelength ranges (<960 nm). Here, we address these problems by inducing collective lattice resonances (CLRs) based on poly(3,4-ethylenedioxythiophene) (PEDOT) nanoantennas. Within the IR range (2-4.5 μm), PEDOT nanoantenna units in metallic state can fulfill the matching conditions between their isolated polarizability and the array factor of lattice [1]. This realizes the narrow plasmonic resonances (linewidth up to 300-400 nm) with Q-factors reaching 12. On this basis, the isolated polarizability of PEDOT nanoantenna units is tuned by redox reactions, enabling the dynamic control of CLR-matching states and the switching of surface plasmon resonances with a large extinction contrast (30-40%). Apart from the switching of plasmonic CLRs, PEDOT nanoantennas can also serve as the "optical gate" when combining with organic low-index nanocylinders (refractive index < 1.7). In the metallic state, PEDOT nanoantennas work as the "closed gate" to block the optical leakage between dielectric nanocylinders and substrate, and thus enhance the electric dipole resonance within dielectric nanocylinders [2]. By utilizing a dielectric nanocylinder array, this enables Mie CLRs within a wavelength range of visible-NIR-I region (< 950 nm). The Q-factors of these Mie CLRs reach 25, as 16 times higher than previous works of organic metasurfaces near this wavelength range. When performing reduction reactions, PEDOT nanoantennas in dielectric states behave as the "opened gate" to allow the light leakage into the substrate and eliminate the light confinement and Mie CLRs.

We believe our studies put forward important steps for active conducting polymer metasurfaces by breaking through key limitations of both low Q-factors and IR wavelength regimes. This provides potential feasibility for more extensive practical applications, such as in photonic circuits and biosensors.

II. Conclusion

We developed tunable nonlocal organic metasurfaces by inducing plasmonic and Mie CLRs through PEDOT nanoantennas. The nonlocal resonance wavelengths range from mid-infrared to visible regimes, and the Q-factors are improved up to 25. Future work will include the practical applications of these active metasurfaces in nano-optic systems and sensors.

***Abstract*— Enhancing light-matter interactions on a chip is important for classical and quantum photonics, sensing, and energy harvesting applications. We demonstrate that bio-inspired aperiodic arrangements of air holes in suspended membranes represent a platform for enhancing the light-matter interaction in active on-chip nanophotonic devices embedding light emitters.**

***Keywords*— photoluminescence spectroscopy, quantum dots, photonic crystals, cavity quantum electrodynamics**

We report on the demonstration of enhanced light-matter interaction and Purcell effects on a chip, based on bio-inspired aperiodic photonic devices fabricated in silicon nitride and gallium arsenide. We fabricate silicon nitride [1] and gallium arsenide [2] devices where aperiodic patterns of air holes, are written by electron-beam lithography, followed by dry-etching and chemical undercut of a sacrificial layer to create free-standing membranes (see Fig.1a). By using defects in silicon nitride and indium arsenide single quantum dots as internal light sources, we image, by means of micro-photoluminescence [3], the optical modes supported by photonic devices with aperiodic patterns of air holes (Fig.1b).

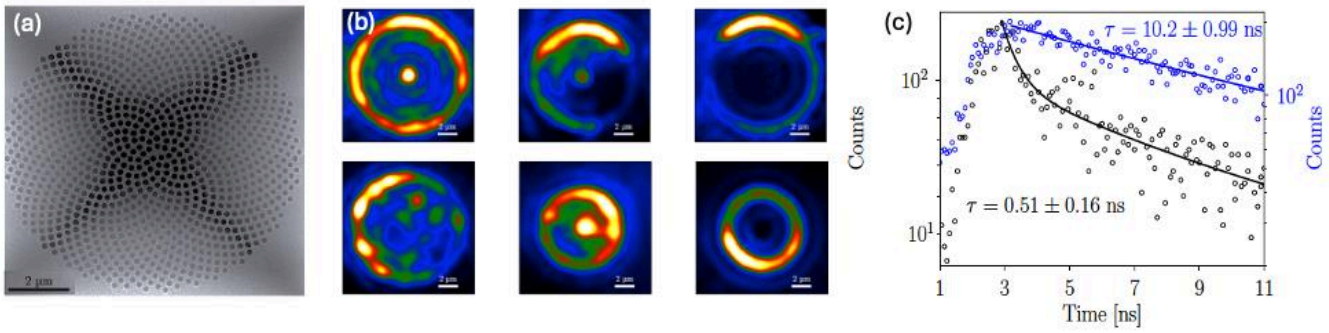

Fig.1: (a) Scanning electron micrograph of a suspended silicon nitride membrane with an etched aperiodic pattern of air holes. (b) Photo-luminescence images of the optical modes confined by an aperiodic nano-photonic devices (c) Time-resolved measurement of the intensity of the light emitted by quantum dots emitting at different wavelengths, collected by an avalanche photo-diode. Solid lines are exponential fits to the data (symbols) and decay time characteristics (lifetimes τ) are shown.

Our results show cavity quantum electrodynamic effects, providing strong modifications of the spontaneous emission dynamics of single quantum dots (see Fig.1c). In particular, thanks to the significant modification of the density of optical states due to the aperiodic structure, we show control of the decay lifetime of single quantum dots, with reduction of the lifetimes of up to a factor 2 and increase in the lifetimes by up to a factor 10.
Our results show that aperiodic nano-photonic devices based on bio-inspired aperiodic geometries are a novel and effective platform for efficient light confinement on a chip and for cavity quantum electrodynamics experiments with single emitters.

***Abstract*— We investigate disordered aluminum nanoparticle ensembles generating structural colors via localized gap plasmons. Combining near-field imaging and ultrafast spectroscopy, we reveal that plasmon-induced hot carriers retain partial spatial localization for hundreds of picoseconds. This unexpected spatial memory links disorder, confinement, and energy dynamics, offering new bio-inspired design principles for nanophotonic and hot-carrier devices.**

***Keywords*— Gap plasmons, Hot carrier localization, Near-field imaging, Ultrafast spectroscopy.**

I. Introduction

Structural colors in nature arise from complex nanoscale architectures that combine order and disorder to achieve robust optical functionalities. Inspired by such bio-photonic systems, disordered plasmonic nanoparticle ensembles provide a powerful platform to explore how nanoscale localization and ultrafast energy dynamics govern optical responses. Here, we investigate aluminum nanoparticle-based structural colors and reveal that plasmon-generated hot carriers partially retain spatial localization memory long after plasmon dephasing, introducing a new spatiotemporal dimension to hot-carrier physics and bio-inspired nanophotonics.

II. Methods

We study self-assembled aluminum nanoparticles coupled to a metal–dielectric–metal cavity that display strong, yet broadband plasmonic response from 450-800 nm. Scattering-type scanning near-field optical microscopy (s-SNOM) is used to visualize nanoscale gap plasmon modes with ~20 nm spatial resolution. Ultrafast transient reflection spectroscopy with narrowband, tunable pump and broadband (450-800 nm) probe investigates the temporal evolution of plasmonic and electronic dynamics with 150 fs temporal resolution. By comparing resonant (630 nm and 700 nm) and non-resonant (415 nm) excitation, we distinguish global and spatially localized plasmon responses and extract key parameters such as dephasing time, spectral shifts, and effective linewidths. Resonant excitation "activates" a homogeneously broadened sub-ensemble through spectral-hole-burning and eventually diphase and generate hot carriers. We track the temporal evolution of the hot carriers and correlate how the LGP-assisted hot carriers affect the broadband, resonant probe.

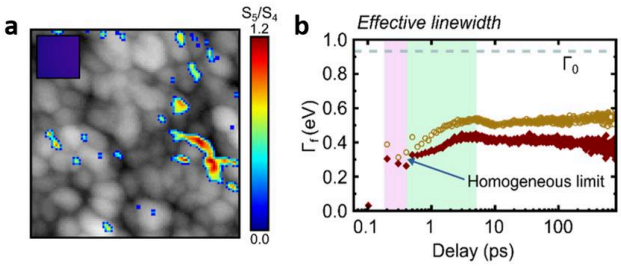

Fig. 1 (a) Overlay of the high near-field scattering amplitude corresponding to gap plasmons with the AFM height profile. LGPs can be observed as brighter intensities within nanoparticle gaps. (b) Ultrafast spectroscopy reveals pump-induced linewidth dynamics of the selective LGP modes upon 630 nm (yellow) and 700 nm (brown) excitation, representing their spatial localization.

III. Results and Discussion

Near-field imaging reveals randomly distributed, strongly localized gap plasmon (LGP) modes concentrated in interparticle gaps, forming wavelength-dependent hot-spot landscapes analogous to biological photonic structures (see Fig. 1(a)). Ultrafast spectroscopy shows that resonant excitation selectively addresses a homogeneously broadened sub-ensemble of plasmon modes, leading to spectral hole burning and a plasmon dephasing time of ~4 fs. Following dephasing, plasmon energy is transferred to hot carriers that exhibit only partial spatial delocalization. Remarkably, the effective plasmon linewidth does not recover to its steady-state value even after hundreds of picoseconds (Fig. 1(b)), demonstrating that hot carriers preserve a memory of the original plasmonic localization. This behavior highlights the critical role of disorder in controlling nanoscale energy flow.

IV. Conclusion

Our results uncover an unexpected spatial memory in plasmon-assisted hot carriers within disordered nanoparticle-based structural colors. By linking disorder, localization, and ultrafast dynamics, this work provides new design principles for bio-inspired nanophotonic materials and devices, with implications for plasmonic memory, sensing, and hot-carrier-based energy harvesting.

***Abstract*— We present a reusable plasmonic metasurface "tongue" that generates distinctive hyperspectral patterns for complex liquid mixtures through cross-reactive sensing. Simple machine learning enables both holistic quality assessment and targeted event detection. A single 24-element metasurface architecture supports universal deployment across diverse liquid-sensing tasks without bespoke receptors.**

***Keywords*— Plasmonics; sensor array; chemical sensor; nanophotonics; metasurface; taste; cross reactive sensing; food; beverage; environmental sensing.**

Industries centred on liquid products, from beverage manufacturers to drinking water providers, must manage chemically complex, dynamically evolving systems. Yet these sectors still rely heavily on centralised laboratory testing or sensory panels to track the quality of their product. These approaches are slow, episodic, and poorly suited to real-time decision-making, leaving operators unable to detect quality drift, emerging faults, or contamination events as they occur. This talk will describe the development of new bio-inspired metasurface sensors designed to address this gap.

We have developed a cross-reactive plasmonic metasurface platform that functions as an artificial "tongue" for liquids. A single 24-element metasurface chip, engineered with distinct non-binding surface chemistries, is interrogated using hyperspectral imaging to generate rich, multidimensional optical response patterns when exposed to a liquid sample. Rather than targeting individual analytes, the metasurface architecture amplifies subtle, collective interactions with the surrounding chemical environment, producing reproducible patterns that reflect overall composition. The device is fully reusable and requires no bespoke receptors or reconfiguration between applications.

In this presentation, I will survey our work applying this platform across two challenging and economically important domains: high-value beverages and drinking-water treatment. In both contexts, simple machine-learning models enable the chip's output to be interpreted either holistically (as continuous measures of quality and process stability) or in a targeted manner, flagging specific events or threshold exceedances.

Taken together, these studies demonstrate how a single metasurface "tongue" can be deployed as a universal liquid sensor, capable of supporting diverse sensing tasks without redesign. More broadly, this work illustrates how bio-inspired sensing principles, implemented through nanophotonic metasurfaces, can shift liquid analysis from retrospective laboratory testing to real-time, point-of-need insight.

Structural Dyes by Design: Physics-Guided Photonic Color Modules on Commodity Substrates

Hannah Sanford-Crane[1,*]
[1]MAAD Scientist Technologies Inc., Vancouver, BC, Canada
*Corresponding author: drhannah@maadscientisttech.com

Abstract—Structural color arises from nanoscale scattering architectures rather than molecular absorption, but translating optical design targets into chemically realizable materials remains difficult. Here we introduce structural dyes: modular molecular shells on commodity particle cores that function as programmable optical layers, whose refractive index and absorption define chromaticity. Designed from first-principles Mie scattering, Percus-Yevick structure factors, and CIE colorimetry, these modules attach to diverse substrates via silane and click chemistry without specialized infrastructure.
Keywords— structural color, structural dyes, inverse design, photonic glass, Mie scattering, click chemistry, colloidal assembly.

1 Introduction

Structural color in nature—beetle cuticles, bird feathers, *Morpho* wings—arises from scattering geometry rather than pigments. While the forward physics is well understood [1], translating optical predictions into chemically deployable materials remains an open problem. Vacuum-deposited multilayers, lithographic metasurfaces, and proprietary block copolymers all produce structural color, but require infrastructure that limits deployment to specialized facilities.

We propose *structural dyes*: modular photonic color units in which the target color is specified from first-principles scattering physics and implemented using molecular shells on commodity particle scaffolds. The shell acts as a programmable optical layer—its refractive index n and absorption k define the chromaticity of the assembled film—while its chemical handles (silane coupling, click tags) enable attachment to SiO_2, FeO_x, TiO_2, polymer, and textile surfaces. Color-bearing photonic modules can thus be designed computationally and deployed on arbitrary substrates using solution-phase chemistry at ambient conditions.

2 Physics-Guided Design

The inverse design engine (MABE) chains four modules with zero parameters fitted to structural color data. **Mie scattering** provides single-particle form factors $|F(q)|^2$. **Percus-Yevick structure factors** $S(q)$ provide the interference peak for disordered films. **Bragg diffraction** ($\lambda_{\text{peak}} = 1.633 D n_{\text{eff}}$) handles ordered assemblies [2]. **CIE colorimetry** converts predicted $R(\lambda) \propto S(q)|F(q)|^2$ to perceptual color using the Maxwell-Garnett effective index [1].

As a consistency check, predicted peaks for PMMA photonic glasses ($\phi = 0.55$) match Magkiriadou *et al.* [1] with MAE = 15 nm and zero fitted parameters. The model also reproduces the red problem (Fig. 1): for $D = 330$ nm, Mie backscattering from cavity-like modes floods the blue channel, producing purple rather than red—exactly as reported experimentally. The engine identifies reduced-index shells (e.g. porous silica, 30% porosity) as extending the accessible gamut toward red by suppressing this Mie bias.

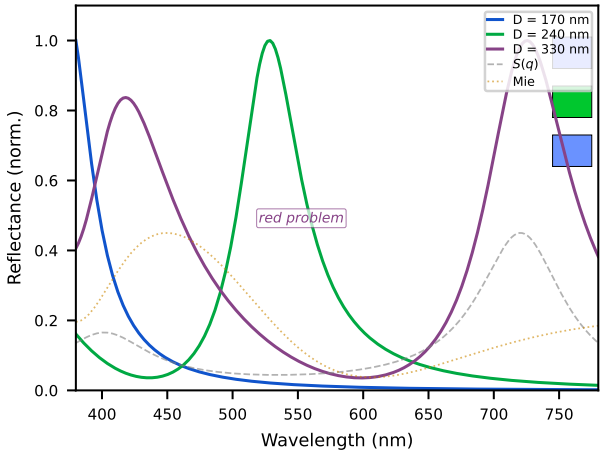

Figure 1: Predicted reflectance for PMMA photonic glasses, reproducing the red problem of [1]. The $D = 330$ nm spectrum shows competing Mie (dotted) and structural $S(q)$ (dashed) resonances. MAE = 15 nm vs. experiment, zero fitted parameters.

3 Shell Programmability: Bridging Binding to Optics

The molecular shell is the design variable. On a common SiO_2 core, different shells produce different optical responses—each a distinct structural dye (Fig. 2). Rather than inserting Δn and Δk as free parameters, the binding engine derives them from coordination chemistry.

Absorption (Δk): The donor set determines ligand field splitting Δ via the spectrochemical series. A tetradentate nitrogen chelator (2 pyridyl + 2 amine) coordinating Cu^{2+} produces $\Delta \approx 15{,}200$ cm^{-1}, placing the d-d band at $\sim$680 nm. Since d-d transitions are Laporte-forbidden ($\varepsilon \approx$ 50–100 M^{-1}cm^{-1}), k remains small ($\sim$0.01). A bidentate bipyridyl shell produces a weaker field ($\Delta \approx 13{,}800$ cm^{-1}, d-d at $\sim$750 nm). Pb^{2+} ($d^{10}s^2$) has no d-d transitions: $\Delta k = 0$.

Refractive index (Δn): Metal coordination replaces six water molecules (combined $\alpha \approx 8.8$ Å^3) with a metal-ligand complex of higher total polarizability. The net $\Delta\alpha$ enters the Lorentz-Lorenz relation to give Δn. Pb^{2+} produces the largest $\Delta n \approx 0.12$ despite weaker binding than Cu^{2+}, because its $6s^2$ lone pair makes it 5.6× more polarizable ($\alpha \approx 6.8$ vs. 1.2 Å^3). The binding engine ranks Cu^{2+} as the stronger binder; the optical engine ranks Pb^{2+} as the stronger color shifter. Different rankings for different

functions—from the same platform.

All three shell–metal combinations produce chromaticity shifts exceeding the perceptual threshold ($\Delta E_{xy} > 0.03$): $+5$ nm for the nitrogen chelator, $+10$ nm for the thiolate-amine, $+5$ nm for bipyridyl.

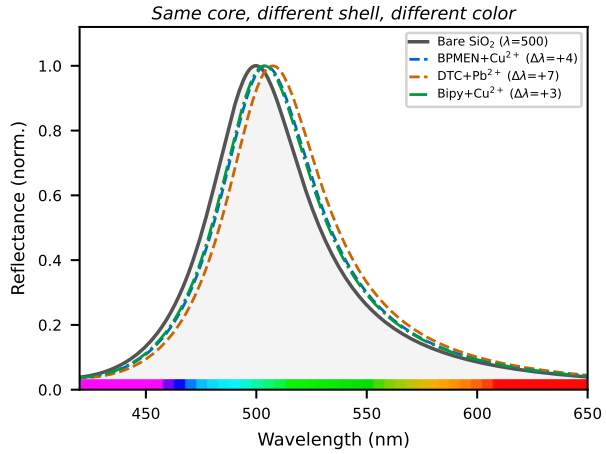

Figure 2: Three molecular shells on the same SiO_2 core produce distinct chromaticity shifts via $\Delta n + \Delta k$ (nitrogen chelator, bipyridyl) or pure Δn (thiolate-amine). Same core, different shell, different color.

4 Assembly and Deployment

Given a target chromaticity, the engine returns a complete layer specification: Fe_2O_3 hematite primer silane-coupled to the substrate and DBCO-functionalized, onto which azide-bearing structural dye particles are click-assembled via SPAAC into a disordered photonic glass. The primer provides both adhesion and spectral shaping—its wavelength-dependent reflectance selectively recycles transmitted light [3], producing a predicted chromaticity displacement $|\Delta E_{xy}| = 0.12$ relative to a flat absorber. Each layer is chemically locked to its neighbors through orthogonal click handles.

5 Outlook

Structural dyes establish a path from physics-first optical design to chemically deployable structural color. The same modular pattern—computed function, commodity scaffold, click-attached surface—already achieves $R^2 = 0.89$ for molecular binding prediction across 500 NIST metal-ligand complexes, suggesting the architecture generalizes beyond photonics. Experimental validation of the predicted shell chromaticity shifts on fabricated films is in progress.

Dynamically Tunable Structural Colors

Aritra Biswas, Debashis Chanda

Abstract: Structural coloration offers many advantages over conventionally used pigment-based colors due to their non-toxic, fade-resistant, and environmentally friendly nature. These colors arise from the structural arrangements of colorless materials at the nanoscale, which create optical resonances and vibrant hues. Over the last decade, dynamic color generation has been the subject of extensive research across various scientific disciplines. However, commercial adoption has been limited by the absence of effective tuning mechanisms, structural complexities and fabrication challenges. In this work, we demonstrate active color tuning based on phase modulation of a multilayer stack composed of a phase-changing material (PCM) and a high-index material on a reflective surface. We elucidate the underlying interfacial and cavity phase modulation mechanisms responsible for the dynamic color changes, highlighting the potential for tailoring the optical properties of this thin-film stack for a wide range of practical applications. Furthermore, we showcase the lithography-free implementation of this concept for large-area, color-tunable textiles, complex surfaces, and temperature sensitive consumer product labeling, highlighting its efficacy in tunable, scalable, and sustainable coloration. Leveraging dynamic phase modulation, this concept holds immense promise for applications in thermal sensing, advanced textile engineering, camouflage, and reconfigurable displays.

Reversible and Dynamic Photonic Bandgap Modulation via Chemical Reactions in Liquid Crystalline Polysaccharides

Cécile A. C. Chazot[1,*], Simona G. Fine[1], Nina Hildenhagen[2], Bart Jan Ravoo[2]

[1]Department of Materials Science and Engineering, Northwestern University, USA
[2]Organisch-Chemisches Institut and Center for Soft Nanoscience, Universität Münster, Münster, Germany

***Abstract*— We develop chemically responsive liquid crystalline polysaccharides whose hierarchical organization enables reversible modulation of photonic bandgaps. By coupling molecular transformations with chiral self-assembly, we create dynamic photonic materials in which optical function is encoded at multiple length scales and tunable through targeted chemical reactivity, expanding design rules for adaptive soft matter.**

***Keywords*— liquid crystals, structural color, photoswitches, cellulose**

I. Introduction

Structural colors in non-living natural materials, particularly those derived from liquid crystalline polysaccharides,[1] are remarkable yet fundamentally constrained. Their photonic responses are typically static, or they react only to global stimuli such as temperature, mechanical stress, or humidity, triggers that are difficult to localize and challenging to modulate with spatial or temporal precision.[2], [3] As a result, while these chiral biopolymer mesophases offer sustainable, self-assembled photonic architectures, their functional tunability remains limited by the nature of the stimuli that affect their photonic crystal structure.

Here, we will discuss how targeted chemical modification of polysaccharides can overcome these limitations. By incorporating moieties that undergo molecular transformations (such as light-responsive photoswitches or groups activated by other localized chemical reactions)[4] we directly couple chemical reactivity to liquid crystalline order. Embedding reactive units into the mesogen itself enables local modulation of chain conformation, hydration, and twisting power, unlocking reversible and spatially programmable control over the photonic bandgap. This strategy shifts the design paradigm of liquid crystalline biopolymers: instead of relying on external physical fields to perturb the mesophase, we engineer materials in which molecular-scale chemistry drives mesoscale optical function.

II. Methods

Our methodology relies on the functionalization of cellulose ethers and esters with reactive moieties that undergo reversible transformations, such as isomerization or oxidation state, to locally alter sterics, polarity and interchain interaction. These reactions, in turn, modify the mesogens geometry or their packing. Concentrated aqueous mesophases are prepared to probe how small chemical modifications propagate up length scales, from molecular conformation to cholesteric pitch and domain organization. We combine reflection spectroscopy, angle-resolved scattering, circular dichroism, X-ray scattering, and solution-state and solid-state NMR to map these changes across hierarchical structure. Time-resolved optical experiments allow us to disentangle the fast kinetics of the chemical reaction from the slower evolution of cholesteric order and resulting photonic bandgap shifts.

III. Results and Discussion

Chemical reactivity within the mesogen produces reversible and dynamic photonic responses that diverge significantly from traditional stimulus-responsive polysaccharides. Molecular transformations (such as photoswitching) are completed on short time scales, yet the cholesteric rearrangement they initiate unfolds more slowly, revealing the multistep pathway through which molecular events reconfigure mesoscale order. We observe spectral shifts in the selective reflection wavelength that depend sensitively on the density and placement of reactive groups, demonstrating that even subtle modifications to mesogen geometry control the twisting power, hydration, and unfolding of the polysaccharide chain.

Importantly, we observe that the photonic bandgap response does not always stem from large-scale domain reorientation or changes in inter-mesogen spacing. Instead, chemical reactivity induces local changes in chain conformation that propagate upward, expanding the cholesteric pitch and producing

dynamic optical states, including reversible bimodal bandgaps in highly substituted systems. These findings clarify how chemical transformations reshape hierarchical self-assembly in polysaccharides and establish new structure-reactivity-function relationships for chiral soft matter.

IV. Conclusion

By embedding reversible molecular chemistry directly into the mesogenic unit, we access a new modality for dynamically reconfiguring photonic behavior in liquid crystalline polysaccharides. This approach yields materials with tunable bandgap shifts, reversible color changes, and distinct optical states inaccessible by conventional stimuli. More broadly, it demonstrates how chemical reactivity can act as a molecular lever for programming adaptive function across hierarchical biopolymer assemblies. These insights open new pathways for designing sustainable, stimuli-responsive photonic materials and lay foundational principles for reactivity-driven control of self-assembled structure.

***Abstract*—** Optical endoscopes are critical for surgical and diagnostic applications, allowing for direct, real-time, and non-invasive imaging of internal biological structures. However, conventional optical fiber endoscopes are bulky, which increases procedural complexity and restricts their operation largely to the interior of hollow organs. Here, we demonstrate the first implementation of optical fiber tip-integrated metasurfaces combined with wavefront shaping of a multimode fiber output to realize tunable "meta"-optical fibers capable of active, continuous beam steering, achieving an ultrawide field of view of up to 140°. We further apply these devices for fluorescent bio-imaging and observe significantly enhanced imaging fidelity, with a minimum detectable feature size below 1 μm. This approach extends endoscopic imaging access to deep and previously inaccessible tissue regions, while the versatility of the underlying platform enables compact, multifunctional, and highly miniaturized fiber-based imaging technologies.

***Abstract*— Plasmonic nanocavities can realise extreme confinement of light. Here we discuss hybrid metamaterials, produced by self assembly of quantum dots, metal nanocrystals, and plasmonic particles, stabilized by robust molecular scaffolds. These artificial structures harness plasmonic confinement to enable infrared sensing, control of emission, and hot carrier physics on the nanoscale.**

***Keywords*— Plasmonics, quantum materials, chemical self-assembly, nanoparticle aggregates.**

I. Introduction

Using ultrathin gaps between noble metals allows confinement of light to ultra-small volumes, realizing extreme regimes of light-matter interaction. This has enabled many intriguing demonstrations including strong coupling to individual quantum emitters[1], nanoscale sensing[2], and few-molecule optomechanics[3]. An archetypal plasmonic nanocavity – the gold nanoparticle-on-mirror (NPoM), allows one to trap light to unprecedented volumes below 1 nm^3, and can be engineered to host a variety of gap materials, including self-assembled molecular monolayers, quantum dots, and 2D materials, realizing hybrid structures. Building upon the rich physics of NPoM nanocavities, and robust machinery of chemical self-assembly, we realize a hybrid metamaterial approach to harness strong confinement of light in extended plasmonic systems.

II. Results and Discussion

Our approach utilizes chemical self assembly of hybrid structures, with the help of selected scaffolding molecules. We demonstrate how the assembly of gold nanoparticles allows one to effectively create three-dimensional metamaterials in the mid-infrared spectral range, featuring high effective refractive indices (even $n > 10$) with surprisingly low loss. We show that optical Fabry-Perot modes in such structures confine mid-IR light into sub-1 nm gaps and realize efficient surface-enhanced IR absorption (SEIRA), enabling real-time IR sensing. We show extended tuneability of the optical properties of the IR metamaterials through selective electrochemical growth, and use selective dissolution[4] in co-assembled bimetallic Au:Ag structures, to tune fill fractions and nanogap area and control resonance positions. We demonstrate applicability of such metamaterials for real world sensing applications.

We further discuss the emission properties of hybrid structures featuring self-assembled layers of quantum dots and metal nanocrystals, in this plasmonic environment. We show that construction of nanoparticle-on-nanocrystal-on-mirror structures increases the efficiency of usually very weak hot-carrier-driven light emission from noble metals by several orders of magnitude compared to the state of the art. This allows us to study nonequilibrium features of the emission in great detail. We discuss the origin of this emission within two existing paradigms - hot carrier photoluminescence and electronic Raman scattering and experimentally compare the emission of Au, Au:Ag nanocrystals and quantum dots in the same plasmonic environment. We further discuss hot electron-induced birefringence on ultrafast time scales in such self-assembled plasmonic metamaterials in the near-IR spectral domain, and its connection to light localization, disorder, and heat dissipation.

Finally, we discuss the control of collective emission in such self-assembled plasmonic metamaterials incorporating light-emitting dyes in the plasmonic nanogaps. We demonstrate the emergence of a long-range power-dependent superradiant state in the structure, enabled by dipole-dipole coupling between emitters in plasmonic gaps[5].

***Abstract*— Recent experiments have discovered light at the nanoscale (polaritons) exhibiting strongly anisotropic propagation (hyperbolic) and extreme field confinement in 2D materials, such as α-phase molybdenum trioxide (α-MoO_3) [1]. In this talk, we will demonstrate that this exotic nanolight enables, for the first time, the visualization of directional-dependent strong coupling phenomena with organic molecules (pentacene) (Fig.1). To support this claim, we will show near-field images taken by scattering-type scanning near-field optical microscopy (s-SNOM), which allow to directly corroborate the strong coupling variation as a function of in-plane angle. This result opens the door to several new applications such as directional sensing or directional local control of chemical properties at the nanoscale [2].**

***Keywords*—2D materials, Mid-IR, strong coupling, s-SNOM.**

Publishing in Nature Portfolio

Rachel Won

Nature Reviews Electrical Engineering
Springer Nature Limited, 4 Crinan Street, London N1 9XW, United Kingdom
r.won@nature.com

***Abstract*—This talk will give you an overview of Nature Portfolio, with emphasis on *Nature Reviews Electrical Engineering*, before detailing the editorial and peer review processes for its research and review journals. The editorial criteria and editorial policies of these journals will also be presented.**

***Keywords*— publishing, Open Access, AI, metamaterials, electrical engineering.**

I. Nature Portfolio Journals

Nature Portfolio journals[1] can be categorized into Communications journals, npj Series, Scientific Reports, Scientific Data and Nature journals that include Nature, Nature Research journals, Nature Reviews journals, Nature Communications and Nature Protocols.

II. Why Publishing with Nature Portfolio

Nature Portfolio publishes high-quality, independently peer-reviewed research and reviews, as well as comment and news, for the scientific and clinical research communities. Nature Portfolio uses pioneering technologies, innovative formats and first-class editing to provide cutting-edge, timely yet readable information for researchers in the public and private sectors, government agencies, educators, clinicians and the general public. Nature Portfolio has a close relationship with the scientific community. By working with scientists, listening to what they say, and always placing emphasis on quality, it is the leading publisher for innovative solutions to scientists' information needs. Publishing with the Nature Portfolio family provides an author with a wide range of benefits.

III. Nature Research Journals vs Nature Reviews Journals

Nature Research journals publish selected research of the highest quality and impact in their specific disciplines. They publish papers online weekly, with an issue compiled monthly. Besides original research, these journals include informal material and reviews.

With the expanding volume of data generated by the research community, it is becoming increasingly difficult for researchers to find the information they need in a format that is reliable and immediately useful. Nature Reviews journals address these needs, publishing high-quality content that highlights and reviews the latest information for a broad range of disciplines, n a way that addresses the inter- and multi-disciplinary nature of research today.

IV. Nature Reviews Electrical Engineering

Nature Reviews Electrical Engineering[2] is an online-only journal aiming to cover the breadth and depth of modern electrical engineering by publishing timely and accessible top-quality Reviews, Perspectives and Comments encompassing every aspect of electronics, photonics, power and energy, control systems, signal processing and telecommunication engineering. The journal also aims to bring to the attention of its readers topics beyond engineering research with particular focus on societal, ethical, environmental and commercial aspects of electrical engineering.

It publishes a range of content types, including Reviews, Perspectives, Roadmaps, Comments, News & Views, Lab to Fab, Viewpoints, Research Highlights, Q&As, Journal Club and Correspondences, that elaborate on significant advances in the field and cover topical issues.

V. Editorial and Peer Review Processes

What are Nature Research journals' editors looking for? What are Nature Reviews journals' editors looking for? They are editorially independent and have their own editorial criteria and processes. General information can be found in the "How to publish your paper" site[3].

VI. Editorial Policies

Although the journals are broadly similar and share editorial policies[4], all authors should consult the author information pages of the specific journal before submitting, to obtain detailed information on criteria for publication and manuscript preparation for that journal, as some differences exist.

Interband plasmonic elemental materials for sustainable nanophotonics: widening the spectral range

Johann Toudert[1], Fernando Chacón-Sánchez[1] and Rosalia Serna[1]

[1] Laser Processing Group, Instituto de Optica, IO-CSIC, Serrano 121, 28006 Madrid, Spain

*Corresponding author: rosalia.serna@csic.es

***Abstract*— We will show how interband transitions in semimetals and semiconductor nanostructures enable an alternative plasmonic response that expands from far-UV to the IR, therefore allowing the development of sustainable and reliable platforms for nanophotonics that will support advanced functionalities such as perfect absorption, structural coloration, and tunable optical response.**

***Keywords*— Plasmonics, nanophotonics, metamaterials, semimetals, semiconductors, Bi, Sb, Si**

I. Introduction

Conventional plasmonic platforms based on noble metal nanostructures, Au and Ag, offer a unique strong field enhancement but rely on scarce and expensive materials whose integration into large-scale photonic technologies remains limited. In this invited talk, we will review and critically discuss recent advances that point toward an alternative paradigm based on the interband plasmonic response exhibited by sustainable elemental materials, including semimetals and amorphous semiconductors. These findings open the path towards the development of alternative nanophotonics platforms for next-generation optoelectronics.

II. Results and Discussion

Studies of the optical response of semimetal nanostructures of the p-block (such as Bi and Sb) have demonstrated to be crucial to unveil the existence of unconventional plasmonic phenomena based on interband transtitions. The optical response of these semimetal is dominated by strong interband transitions that provide a plasmonic behaviour in the UV-visible, and enable an extraordinary high refractive index in the infrared [1-3]. These complementary features have facilitated the design of both narrowband, spectrally selective components and broadband light-trapping architectures [4-6]. Moreover, a final advantage of Bi is the ability of modulation of its optical response through phase change thanks to its low melting temperature, opening routes to dynamically reconfigurable devices [7-8]. Their spectral tunability and compatibility with thin-film deposition methods have allowed to demonstrate their successful application from structural coloring to optical switching [5-7].

In this context of sustainable elements for photonics, more recently we have unveiled the plasmonics properties of amorphous silicon (a-Si) nanostructures. Experimental results and simulations show that they can sustain plasmonic-like resonances extending deep into the far-UV [9]. This finding is remarkable because it shows that crystalline order is not a necessary condition for sustaining strong plasmonic resonances: the response is once again governed by interband transitions, which in a-Si produce strong absorption plasmonic peaks. It is noteworthy that these results significantly expand the spectral reach of sustainable plasmonics, covering wavelengths inaccessible to most conventional plasmonic materials and suggesting new opportunities for UV photonics, and high-energy photodetectors.

***Abstract*— We demonstrate chiroptical activity in disordered ensembles of plasmonic nanospheres despite showing no chirality in their retrieved coordinates. Optical simulations verify the experimental results and reveal that the observed circular dichroism emerges from mesoscopic electromagnetic correlations rather than local chiral coupling, establishing a new paradigm for scalable self-assembled chiral metamaterials.**

***Keywords*— plasmonics, disorder, mesoscopic correlations, metamaterials, chirality.**

I. Introduction

Optical activity such as circular dichroism and circular birefringence are traditionally associated with geometrically chiral architectures, including helices, twisted assemblies, or intrinsically chiral nanoparticles. In plasmonic systems made from achiral components, strong optical activity typically arises from engineered near-field coupling in well-defined chiral arrangements.

Here we report a counterintuitive result: a statistically isotropic and homogeneous ensemble of spherical silver nanoparticles exhibits reproducible and significant chiroptical activity. The particles themselves are achiral and sparsely distributed, with densities on the order of one particle per cubic wavelength at resonance. Several structural chirality metrics fail to detect any dominant handedness in the spatial distribution. Nevertheless, both experiment and theory reveal a robust electromagnetic chirality emerging at mesoscopic scales.

II. Methods

Silver nanoparticles were nucleated within a chiral nematic template formed by self-assembled chitin nanocrystals. The template pitch lies in the micrometer range and is optically inactive.

Three-dimensional particle coordinates were retrieved using FIB-SEM tomography, yielding spatial information for more than 30,000 nanoparticles in a volume of approximately 1,800 cubic micrometers. Multiple conventional and also proposed structural chirality measures were evaluated, including pseudoscalar and Hausdorff-distance-based metrics. None showed statistically significant deviation from random point distributions that show no dominant handedness.

To analyze the optical response, we employed a coupled-dipole formalism treating each nanoparticle as an isotropic point dipole. Circular dichroism and circular birefringence cross sections were computed and combined into a complex-valued chiroptical index. The chiroptical index capture both absorptive and dispersive components of electromagnetic chirality in a unified representation.

Statistical significance was assessed by subdividing the reconstructed volume into independent voxels and applying both univariate and multivariate tests.

III. Results and Discussion

Experimentally, the composite Ag-Chitin films exhibit a bisignate circular dichroism spectrum centered at the plasmonic resonance, with dissymmetry g-factors in the order of 10^{-3}.

Conventional and a proposed structural analysis confirms the absence of structural chirality. However, coupled-dipole simulations reproduce the measured spectra and reveal that the ensemble-averaged chiroptical index is much larger than that of purely random particle configurations of identical density.

Importantly, statistical significance emerges only when electromagnetic interactions are considered over length scales comparable to the micrometer-scale pitch of the original template. Short-range particle clusters do not produce

distinguishable electromagnetic chirality. This demonstrates that the effect is intrinsically non-local and mesoscopic in origin.

Together, these results establish that electromagnetic chirality can arise without measurable structural chirality.

IV. Conclusion

We demonstrate that macroscopic disordered ensembles of achiral plasmonic nanospheres can exhibit statistically significant chiroptical activity. Structural chirality measures fail to detect dominant handedness, yet mesoscopic electromagnetic correlations generate a robust optical response.

This work challenges the conventional paradigm that evident structural chirality is a prerequisite for optical chirality. Instead, it reveals disorder-enabled mesoscopic correlations as a new route toward scalable chiral plasmonic metamaterials. The findings open opportunities for disorder engineering in chiral metamaterials and complex photonic media.

***Abstract*— Passive radiative cooling rejects heat to outer space through the 8–13 µm window, enabling sub-ambient temperatures without power. We develop disordered SiO_2-microsphere coatings combining >93% solar reflectance with strong mid-IR emissivity. Their microstructure, optical response, and outdoor thermal behavior are experimentally validated, confirming effective cooling under direct sunlight.**

***Keywords*— radiative cooling, atmospheric transparency window, disorder, silica.**

I. Introduction

Sustainable thermal management technologies have driven renewed interest in passive radiative cooling (RC). By reflecting incident solar radiation while emitting thermal radiation toward cold outer space, RC devices can achieve net cooling even under solar illumination [1]. Over the past decade, these technologies have gained prominence as a complementary mechanism for heat dissipation alongside conduction and convection. Their potential was first experimentally confirmed in 2014, when Raman et al. [2] demonstrated cooling below ambient temperature.

Achieving daytime radiative cooling requires minimizing solar absorption while maximizing mid-IR emission. Silica (SiO_2) enables this because its particles support surface phonon-polaritons (SPhPs) near the Si–O vibrational resonances (8–10 µm), which fall within the atmospheric window. When arranged as microspheres or shells, these modes couple efficiently to the far field, boosting mid-IR emissivity. As a result, SiO_2 acts as a selective emitter that reflects sunlight and radiates strongly in the mid-IR, making it highly effective for sub-ambient daytime cooling. Randomly packed silica microparticle coatings, or SiO_2-based disordered photonic structures, have emerged as a cost-effective pathway to obtain high solar reflectance and strong selective mid-IR emission.

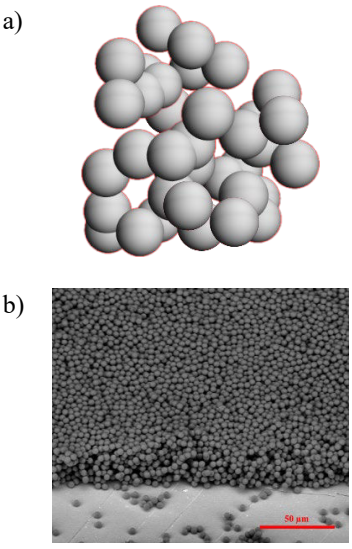

Fig. 1 *Structural characterization of randomly packed silica microsphere coatings: (a) Schematic of the disordered photonic structure. (b) Cross-sectional SEM image of ~25 µm thick coating (scale bar: 50 µm).*

II. Methods

Photonic-glass coatings were produced by depositing polydisperse suspensions of commercial SiO_2 microspheres (2–8 µm) onto highly reflective substrates (Fig 1a-b). A 15 mL dispersion (0.4–0.5 wt%) was allowed to settle under controlled temperature and humidity, and drying at 45 °C yielded uniform, mechanically stable coatings ~25 µm thick.

Optical characterization used UV–Vis spectroscopy with an integrating sphere to measure broadband solar reflectance, and FTIR spectroscopy with a gold-coated integrating sphere to determine mid-infrared emissivity within the atmospheric window. Coherent-backscattering measurements employed a TEM_{00} He–Ne laser; the backscattered light was polarization-

filtered, recorded with a CCD camera, and the cone's angular profile was analysed to obtain the transport mean free path.

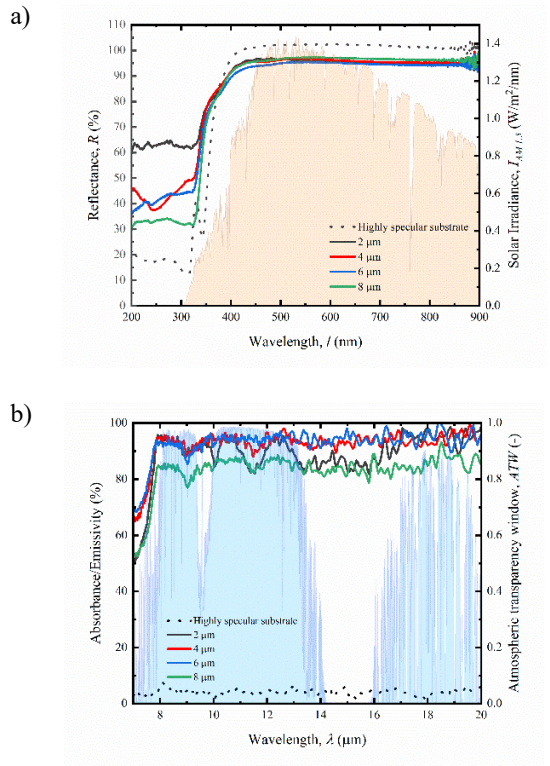

Fig. 2 *Optical characterization of randomly packed silica microsphere coatings: (a) Solar reflectance >93%. (b) Mid-IR emissivity in the 8–13 µm atmospheric window.*

Thermal performance was tested outdoors under clear skies in Barcelona. Samples were placed on an elevated reflective platform inside a non-emissive enclosure to reduce parasitic heat exchange. Sample and ambient temperatures were measured with calibrated PT100 sensors, while irradiance and meteorological data were recorded continuously. Cooling power was determined using a PID-controlled resistive heater that maintained a fixed temperature offset above ambient; the electrical power required at steady state quantified radiative heat dissipation.

III. Results and Discussion

All coatings exhibit excellent radiative properties, with solar reflectance between 93.6–95.3% and mid-infrared emissivity of 0.85–0.93 in the 8–13 µm atmospheric window (Fig 2a-b). Coherent-backscattering measurements confirm operation deep in the multiple-scattering regime, with transport mean free paths of 2–7 µm, always far below the 25 µm coating thickness. Despite this variation in scattering strength, the optical response remains essentially invariant with particle size, as both reflectance and emissivity vary by less than 10% across all samples. Under outdoor conditions with peak irradiance around 800 W m^{-2}, all silica-coated surfaces remain at or slightly below ambient temperature, while reference substrates heat up by more than 5 °C compared to those with silica microspheres. Sub-ambient cooling appears as irradiance decreases, reaching up to 4.8 °C relative to references in the late afternoon and 3.7 °C below ambient at night. Night-time cooling powers of 44–61 W m^{-2} and low integrated solar absorption (5–8%) confirm efficient radiative performance with no measurable dependence on microsphere diameter.

IV. Conclusion

In summary, we demonstrate that silica-microsphere coatings can provide effective passive radiative cooling, achieving temperature drops below ambient under direct sunlight and delivering net cooling powers on par with leading radiative-cooling materials. By systematically tuning the microsphere diameter and combining spectral, thermal, and power-based analyses, we show that the cooling performance remains essentially unchanged across the full particle-size range examined. This size-independent behaviour stems from the dominance of collective multiple-scattering processes in these optically thick layers, which makes the overall response insensitive to the specifics of individual particle resonances. Consequently, precise size control is not required, easing fabrication demands and enabling integration with the broader design flexibility offered by colloidal chemistry. This opens opportunities for scalable, multifunctional cooling coatings that can incorporate surface treatments, chemical functionalization, or other modifications without compromising thermal performance.

***Abstract*— We investigate resonant, thermo-optically reconfigurable silicon metasurfaces modulating light in the classical and quantum regime. Thermo-optic effect enables dynamic modulation of photon pairs and efficient control of the transmittance via engineering of heat and optical time scales, opening interesting avenues for optical modulation and computing.**

***Keywords*— metasurfaces, thermo-optic effect, optical computing.**

I. Introduction

Optical metasurfaces, consisting in 2D artificial arrangements of subwavelength nanostructures (i.e., meta-atoms) with sub-micrometer thickness, are a unique platform to tailor light-matter interactions and modulate freely-propagating light in small-footprint optical devices [1]. In recent years, actively reconfigurable metasurfaces have attracted a growing interest, driven by the quest for fast, efficient, and miniaturized components capable of dynamically controlling the various properties of light. Different physical mechanisms are exploited to modulate light properties [2,3], like amplitude, phase, and polarization. Here, we leverage thermo-optic (TO) nonlinearity in semiconducting materials, like silicon, to produce a change in the refractive index Δn upon a variation in material's temperature; this last can be induced either *via* a direct heat stimuls or by light absorption through photo-thermal (PT) heating. Although limited in speed by the heat dynamics, TO effect brings about a strong nonlinearity in the optical response of the system, which can be further enhanced and tailored by leveraging optical resonances. Moreover, the different time scale of heat and optical dynamics is a feature with interesting perspectives in metasurface-based optical modulation optical computing.

II. Results and Discussion

We investigate optical metasurfaces fabricated by nanostructuring a thin layer of amorphous silicon (aSi), deposited by chemical vapour deposition on an insulating, low index, SiO_2 substrate. We leverage the high refractive index contrast between aSi and SiO_2 to engineer electromagnetic resonances in the visible and near infrared, to enhance the TO nonlinearity. We exploited TO effect to manipulate entangled photons pairs generated by spontaneous four-wave mixing in aSi metasurfaces[4]. Here, electric- and magnetic-dipole resonances hosted by the meta-atoms enhance the rate of photon pairs up to 3.6 kHz. Moreover, the shift of the resonant modes spectral position induced by the heating from same laser pump modulates photon pairs generation, opening the way for dynamic tuning of thermally reconfigurable quantum light sources. The same platform served to demonstrate a dynamic modulation of the transmittance[5]. Here, the thermal and optical response is engineered, allowing a modulation of more than 30% at 100 kHz through an optimization of the heat diffusion process and PT heating area. In addition, the resonant nature of the system allows encoding different optical states in the same modulation cycle, with interesting perspectives in free-space optical computing.

III. Conclusion

The presented studies report engineered nanoscale platforms exploiting TO effect to achieve an efficient control of light in the classical and quantum regime. In perspective, the modulation efficiency can be further enhanced by exploiting high-quality-factor resonances like quasi-bound-states-in-the-continuum. Moreover, the complex interplay of PT heating and TO effect, eventually leading to peculiar phenomena like optical bistability, is of great interest for optical computing and for the rapidly growing field of optical neural networks.

Designer metasurfaces from the bottom-up

Beniamino Sciacca*[1]

[1]CNRS, Aix-Marseille University, CINaM, Marseille
*Corresponding author: beniamino.sciacca@cnrs.fr

***Abstract*— The development of cost-effective approaches to fabricate metasurfaces at a macroscopic scale is essential for their spread in industrially-relevant products. We show how templated assembly of colloidal building blocs, such as nanocubes, can be employed to fabricate functional metasurfaces with an arbitrary design.**

***Keywords*— metasurfaces, templated assembly, epitaxy, nanocubes.**

I. Introduction

High-quality monocrystalline materials and nanostructures are key to high-efficiency optoelectronic devices, plasmonic materials and metasurfaces. A large variety of materials can be synthesized at low temperature in solution as colloidal single crystals, combining the advantages of high-quality material and low-cost fabrication, but the potential for large area integration into nanophotonic and plasmonic devices via nanoparticle assembly techniques still remain elusive. The two major bottleneck are:

-Difficulty to achieve defect-free colloids self-assembly in truly arbitrary patterns;

-Poor optical and electronic properties resulting from the discreetness of individual building blocks.

II. Results and Discussion

In this invited talk I will present recent breakthroughs from our team tackling both challenges with a new approach that we have introduced based on nanocube epitaxy. In the first part I will focus on advances on templated-assembly with detailed insight into the mechanisms. I will show the fabrication of complex and truly arbitrary organisation of nanocubes on a large surface, with a single nanocube resolution. Examples includes 1D linear assembly[1], 2D nanocube grid arrays for transparent electrodes[2,3], highly dense split-ring resonator absorbers and Pancharatnam–Berry metasurfaces[4].

In the second part I will focus on advances on nanocube epitaxy, showing a general methodology to transform an arbitrary assembly of nanocubes into defect-free continuous nanostructures and operando mechanistic insights[5,6]. This approach enables to obtain monocrystalline plasmonic and nanophotonic surfaces that can be readily printed on any substrate (flat, microstructured), but also to make nanocrystals with unconventional (à la carte) geometries, that can be used as colloids to go beyond Platonic solids.

Finally, I will show optical characterisation of the resulting large area metasurfaces, supported by numerical simulations.

IV. Conclusion

I believe that this constitute a major breakthrough in the field, can inspire many scientists and lead the way for a new generation of bottom-up functional nanocomposites and their spread in industrially-relevant products.

***Abstract*— The self-assembly of block copolymers is used here to fabricate sub-10 nm gold nanocrevices metasurfaces (that are used as sensitive and polarization-dependent SERS substrates) as well as 1D responsive photonic crystals.**

***Keywords*— block copolymers, self-assembly, metasurfaces, SERS, photonic crystals.**

In various plasmonic and photonic applications, generating high-density large-area, and high-resolution features remains a bottleneck for conventional lithography due to throughput and cost constraints. Block copolymer (BCP) self-assembly offers a highly effective bottom-up route for generating a rich variety of nanoscale geometries, including lamellae, cylinders, spheres, and gyroids, simply by tuning the polymer block composition. This versatility allows for the selection of an optimal morphology for a specific function. Indeed, leveraging BCP nanostructurations as templates for metasurface fabrication is highly desirable.

In a first part, we demonstrate here a scalable fabrication route for dense arrays of gold (Au) nanocrevices using the directed self-assembly (DSA) of a high-χ poly(1,1-dimethylsilacyclobutane)-block-polystyrene (PDMSB-b-PS) block copolymer with a 9 nm half-pitch. This approach produces periodic, anisotropic Au nanocrevice metasurfaces with ultrasmall gap features. Comprehensive optical characterization and finite-difference time-domain (FDTD) simulations reveal a robust, tunable plasmonic resonance across the visible spectrum (550–635 nm). We show that these resonant properties are exquisitely sensitive to Au film morphology. The platform delivers exceptional SERS sensitivity, with signal enhancements significantly surpassing those of reference planar Au films and conventional Au gratings. Optimal SERS performance is achieved at a specific Au thickness using 638 nm excitation, a condition that aligns with both the simulated resonance and experimental reflectance, thereby maximizing plasmonic enhancement. Furthermore, we demonstrate precise control over the SERS response by showing that the polarization anisotropy ratio can be tuned simply by varying the metal thickness. This work establishes DSA as a scalable route to designer plasmonic metasurfaces, providing a versatile platform for advanced plasmonics and quantitative surface-enhanced spectroscopy.

In a second part, a new series of well-defined and novel carbohydrate-based bottlebrush BCPs are introduced, that self-assemble into 1D photonic crystals (1D-PCs), and their self-assembly in lamellae structures is investigated using a wide range of techniques. The 1D-PCs formed from different bottlebrushes display a full spectrum of colors, ranging from colorless to rainbow colors, including blue, green, orange, and red, effectively spanning the entire UV–vis range. Remarkably, a very fast (a few seconds) change in the color is obtained simply by different solvent, a consequence of the lamellae domain swelling. Furthermore, by mixing the bottlebrushes with small carbohydrates, their optical properties can be further modified, achieving a red shift in reflective colors from orange to red. This approach provides a flexible strategy for tailoring the optical characteristics of photonic crystals without the need for synthesizing new carbohydrate-based bottlebrushes, thus offering a versatile platform for controlling their properties.

***Abstract*— We report the fabrication of Topological Insulator heterostructures using a scalable solidification method, achieving atomically smooth interfaces. ARPES data confirms that topological surface states coexist with giant-Rashba states. Observed charge transfer and robust electronic features establish this system as a premier platform for advancing spintronics, quantum computing, and next-generation optoelectronics.**

***Keywords*— topological insulators, eutectics, heterostructure, metamaterials.**

I. Introduction

Three-dimensional topological insulators (TIs) have attracted considerable attention due to their topologically protected, gapless surface states, which arise from strong spin–orbit coupling and time-reversal symmetry. These surface states host Dirac-like fermions with suppressed backscattering from nonmagnetic impurities, making TIs promising candidates for topological spintronics and quantum information technologies [1].

One promising strategy to expand the application paradigm, is the deliberate engineering of TI heterostructures, where interfaces are used as an additional degree of freedom to tailor electronic states [2]. In this context, heterostructured and composite materials can be viewed from a metamaterial perspective, in which macroscopic functionalities emerge from the periodic arrangement of distinct quantum materials and their interfaces. Ordered TI-based composites provide enhanced interfacial area, improved robustness, and new pathways for engineering spin-orbit-coupled electronic structures beyond those available in single-phase crystals.

II. Methods

The TI heterostructures were prepared by directional eutectic solidification methods [3]. The sample quality and crystallinity were verified by different characterization methods. ARPES measurements were performed at CASSIOPEE beamline of SOLEIL Synchrotron.

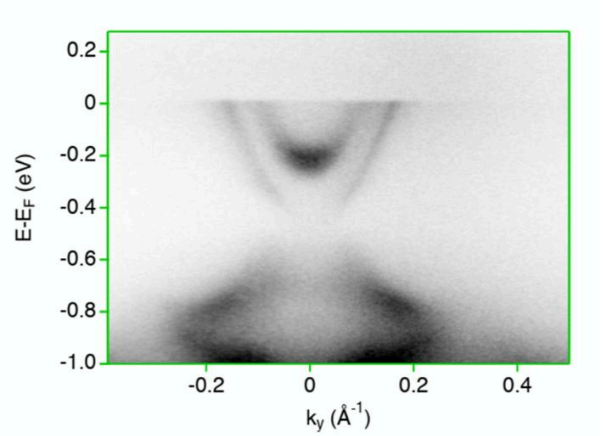

Fig. 1 ARPES intensity map of the Bi_2Te_3-BiTeI heterostructure.

III. Results and Discussion

Figure 1 shows an ARPES cut along the k_y direction. A V-shaped dispersion centered at $k_y = 0$ is observed, characteristic of the topological surface state of Bi_2Te_3.

At higher binding energies, additional dispersive features with a broad parabolic character are observed. Their momentum offset and energy scale are consistent with Rashba-split states previously reported in BiTeI [4].

Importantly, the Dirac-like and Rashba-like states overlap in both momentum and energy, in contrast to conventional band-bending-induced 2DEGs where these states are typically well separated.

IV. Conclusion

We have demonstrated the coexistence of a Dirac-like topological surface state and Rashba-type dispersions within the same momentum-energy window. These findings demonstrate the robustness of the Bi_2Te_3 topological surface state at the interface with an intrinsic giant-Rashba

semiconductor and highlight the potential of such heterostructures for studying interface-driven spin-orbit physics.

***Abstract*—The realization of an electrically driven Tamm laser diode, a new type of laser diode based on surface-confined Tamm plasmon modes, will be presented. The device is based on the integration of a silver microdisk with a quantum-well-embedded distributed Bragg reflector (GaAs/AlAs) presenting Tamm surface resonances. In a second part, the integration of metasurfaces in Tamm structures will be described.**

I. Introduction

The integration of metallic components into semiconductor laser architectures has proven to be a highly effective strategy for enhancing device efficiency through optical confinement at the micro- and nanoscale. Tamm plasmons, which are optical modes occurring at the interface between a distributed Bragg reflector (DBR) and a metallic layer, lie between metal-semiconductor cavities and spasers. A Tamm mode can be interpreted either as a cavity mode in a zero-thickness cavity or as a surface mode, since its field amplitude decays away from the metal/semiconductor interface. Owing to their surface-bound nature, microscale optical confinement in Tamm plasmon structures is achieved through straightforward patterning of the thin metallic layer, which defines the modal geometry[1]. This approach enables the realization of complex confinement geometries that would be extremely challenging to fabricate by etching several hundreds of nanometers into a semiconductor medium within a vertical cavity structure. Furthermore, the metallic patch responsible for optical confinement can simultaneously serve as an electrical contact for current injection.

For Tamm lasers, subwavelength structures, engraved in the metal part of Tamm devices, can significantly modify the laser properties. Indeed, due to the Tamm surface mode character, the nanostructure is inserted within the cavity, thereby directly influencing the laser emission behavior.

II. Results and Discussion

Based on these principles, we demonstrate an electrically injected Tamm plasmon laser obtained by integrating a silver microdisk with a GaAs/AlAs DBR incorporating InGaAs quantum wells positioned at the antinodes of the electric field. Under electrical injection and cryogenic operation (95 K), the device exhibits clear lasing behavior, with a maximum emitted power of 200 µW at 906 nm. Spectral measurements reveal the onset of optical gain and strong mode confinement, ultimately leading to lasing characterized by pronounced spectral and angular narrowing[2]. Dispersion imaging further confirms these observations, evidencing lasing from the fundamental confined Tamm mode. These results establish Tamm plasmon lasers as a promising platform for compact, integrable, and potentially reconfigurable coherent light sources.

In addition to demonstrating a Tamm laser diode, we investigate the incorporation of nanostructuring within the metallic film to tailor the emission properties. In particular, unconventional polarization behaviors are observed. The polarization characteristics and spatial intensity distributions are presented and discussed.

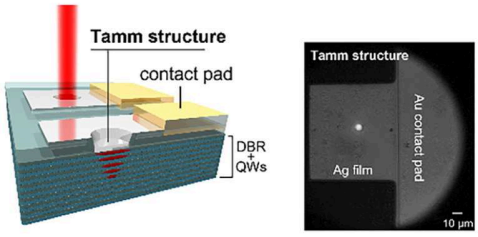

Fig. 1 Left: Schematic of the Tamm laser diode structure. Right: Top-view optical image of the fabricated device.

III. Conclusion

These results establish Tamm plasmon lasers as a promising platform for compact, integrable, and potentially reconfigurable light sources. First experiments on the integration of nanostructuration in Tamm devices show the capability of this approach to engineer novel emission properties and expand the functionality of semiconductor lasers.

Photoluminescence Modulation in Self-Coupled Molecular Cavities

Evan S. H. Kang[1,*]

[1]Department of Physics, Chungbuk National University, Republic of Korea
*Corresponding author: eshkang@chungbuk.ac.kr

***Abstract*— Self-coupled molecular cavities, formed by organic dye nanostructures without external resonators, enable tunable photoluminescence through geometry-controlled resonances. By combining experiments and FDTD simulations, we show that emission modulation arises from excitation-dependent nearfield enhancement and cavity-modified radiative quantum efficiency.**

***Keywords*— photoluminescence modulation, self-coupling, metasurfaces, organic nanophotonics**

I. Introduction

Organic dye molecules with large oscillator strengths can support strong light–matter interactions and are promising building blocks for compact photonic and optoelectronic devices. In particular, nanostructures composed of such molecules may sustain cavity-like optical resonances within the molecular assembly itself, without requiring a separate external cavity. In these systems, molecular excitons interact with the internally supported resonant modes, forming what can be described as self-coupled molecular cavities.

This concept provides a route toward highly compact and structurally simple nanophotonic platforms, where optical emission can be modulated directly through the molecular cavity geometry. Despite growing interest in light–matter interactions in organic nanostructures, the mechanisms governing photoluminescence (PL) modulation in self-coupled molecular cavity systems remain insufficiently understood. In this work, we investigate how cavity geometry influences PL peak position and intensity, and clarify the physical origins of this modulation by combining optical measurements with numerical simulations.

II. Methods

Self-coupled molecular cavity structures were prepared using organic dye-based nanostructures designed to support cavity-like resonances. Photoluminescence spectra were measured as a function of excitation and emission wavelength. To interpret the experimental observations, finite-difference time-domain (FDTD) simulations were performed. From the simulated optical fields, an enhancement factor was calculated to evaluate the effect of cavity resonance on the excitation and emission processes.

III. Results and Discussion

The experiments reveal that the PL response of self-coupled molecular cavities can be systematically modulated by tuning the cavity geometry. As the resonance condition shifts with geometry, both the absorption and PL spectra change in a controllable manner. This demonstrates that the internal cavity mode of the molecular structure plays an active role in shaping the emission spectra. The FDTD simulations successfully reproduce the measured PL by calculating enhancement factors. The PL modulation does not arise from a single mechanism, but rather from the interplay of multiple cavity-mediated effects. First, the spatial distribution of the nearfield depends strongly on the excitation wavelength, which affects how efficiently excitons are generated within the molecular structure. Second, the cavity resonance modifies the radiative quantum efficiency, thereby altering the probability that excited states contribute to far-field emission. The results, therefore, establish that self-coupled molecular cavities provide a platform for controlling light emission, even in the absence of an external resonator.

IV. Conclusion

We have demonstrated photoluminescence modulation in self-coupled molecular cavity systems formed by organic dye nanostructures. By tuning cavity geometry, the resonance condition can be controlled, leading to systematic changes in PL spectra. FDTD simulations show that the modulation originates from excitation-dependent nearfield distributions and cavity-modified radiative quantum efficiency. These findings can enable tunable organic emitters and nanophotonic devices based on controlled cavity geometry and self-coupling.

US Defense Perspective on Past and Future of Metamaterials

Mark S. Spector

Office of Naval Research, USA
*Corresponding author: mark.spector.civ@us.navy.mil

***Abstract*— The field of metamaterials began through initiatives sponsored by the US Department of Defense (DoD). The first comprehensive metamaterials program was a 2001 Multidisciplinary University Research Initiatives (MURI) effort sponsored by the Office of Naval Research (ONR) in collaboration with the Defense Advanced Research Projects Agency (DARPA). Research programs at ONR and other DoD agencies continue to support fundamental and applied research with the aim of mapping out the potential of metamaterials for a variety of applications. These programs are pursuing optical, RF and acoustic materials for applications across the electromagnetic spectrum, from novel RF antennas to devices utilizing optical magnetism. Acoustic metamaterials are of unique interest to the Navy for underwater applications. In recognition of the 25th anniversary of the ONR MURI program, this talk will provide a historical perspective of significant US Defense contributions to this field and future areas of interest. Common challenges associated with loss, bandwidth, and scalability will be discussed along with the needs for innovative designs, materials, and fabrication approaches.**

***Abstract*—The Geometry Matrix formalism provides a unified framework for modeling active plasmonic nanoparticles across quasi static and Mie regimes. It enables prediction of emission thresholds, spectra, and modal instabilities in gain assisted nanostructures. We present its implementation as a modular open library for reproducible nanophotonics modeling.**

***Keywords*— active plasmonics, nanophotonics modeling, Mie scattering, computational electromagnetics.**

I. Introduction

Metamaterials and metasurfaces derive their optical properties from the response of fundamental building blocks. Among these, active plasmonic nanoparticles have repeatedly emerged as promising elements for nanoscale light sources, spasers, and gain assisted nanophotonic devices. Understanding their emission dynamics and stability therefore remains an important problem in nanophotonics.

II. Geometry Matrix Formalism

In previous work we introduced the Geometry Matrix formalism, an analytical framework describing the electrodynamic behavior of gain assisted plasmonic nanoparticles by solving a self consistent eigenvalue problem. The approach establishes a direct connection between nanoparticle geometry, multipolar plasmonic modes, and stimulated emission dynamics.

The system evolution can be expressed in compact matrix form

$$\frac{d\mathbf{q}}{dt} = \mathbf{A}\mathbf{q} + \mathbf{b} \tag{1}$$

where the vector $\mathbf{q}$ contains the electromagnetic mode amplitudes. The matrix $\mathbf{A}$ encapsulates both structural and gain dependent properties of the system and is therefore referred to as the geometry matrix. This formulation enables direct prediction of emission thresholds, spectral properties, and dynamical instabilities in gain assisted plasmonic nanostructures.

The time dependent formulation of the model also enables the investigation of transient emission dynamics. In particular, it allows the study of phenomena such as gain switching, relaxation oscillations, and other time resolved processes in active plasmonic nanoresonators.

This framework applies both in the quasi static approximation and in the full Mie regime. In the quasi static limit compact analytical expressions can be derived for dipolar nanoshell systems, while the Mie formulation incorporates full electrodynamic effects, enabling accurate modeling of subwavelength plasmonic resonators and their emission spectra.

III. From Model to Computational Framework

In this work we present the transition of the Geometry Matrix formalism from a theoretical model to a reusable computational framework. The method has been implemented as a modular open source library named

https://github.com/lexwolf/nano_geo_matrix

released under the MIT license.

The library provides reusable tools for constructing geometry matrices, solving emission eigenvalue problems, and analyzing modal instabilities in gain assisted nanostructures. By separating the physical formalism from specific implementations, this framework facilitates reproducible simulations and simplifies the development of new models for active nanophotonic systems.

IV. Conclusion

The Geometry Matrix formalism provides a unified approach for modeling active plasmonic nanoparticles across different electrodynamic regimes. Its implementation as an open computational library enables reproducible modeling and supports the development of new theoretical and numerical studies of active nanophotonic structures.

Silicon Nanoparticle Monolayer Coating for Glossy, Non-Iridescent and Tunable Reflective Colors

Hiroshi Sugimoto*, Jialu Song, Keisuke Moriasa, Mojtaba Karimi Habil, Minoru Fujii

Department of Electrical and Electronic Engineering, Graduate School of Engineering, Kobe University, Kobe, Japan
*Corresponding author: sugimoto@eedept.kobe-u.ac.jp

***Abstract*— We report a core–shell architecture composed of Mie-resonant Si core and SiO_2 shell for nanocoating that enhances both structural color reflectance and surface gloss. By optimizing the SiO_2 shell thickness, we achieved the total reflectance >70% experimentally. By leveraging this coating strategy, uniform color coatings on 3D objects, enabling diverse visual appearances, are demonstrated. This work establishes a new design strategy for lightweight, durable and tunable structural color coatings suitable for practical applications.**

***Keywords*— Mie resonances, nanoparticles, structural color, core-shell particles.**

I. Introduction

Color coatings are widely used across industries, where not only hue but also brightness, saturation, and surface gloss critically determine visual quality. However, conventional coloration strategies face intrinsic trade-offs among gloss, durability, thickness, and angle dependence. Here, we introduce a Si@SiO_2 core–shell nanosphere (NS) architecture that simultaneously enhances structural color brightness and surface gloss in a single-particle monolayer. The low-index SiO_2 shell introduces refractive-index contrast, enabling total reflectance exceeding 70% experimentally. The Mie-resonant coloration offers a practical route toward bright, high-gloss, non-iridescent color coatings.

II. Results and Discussion

Monodisperse Si NSs are developed in our group using a density-gradient centrifugation process.[1,2] Figure 1a presents photographs of the size-separated colloidal suspensions, displaying vivid and distinct structural colors ranging from pink to orange as the average diameter increases from 109 to 207 nm. The corresponding normalized extinction spectra confirm a redshift of the resonance peaks with increasing Si NS size.

Figures 1b display TEM images of Si@SiO_2 NSs prepared using a modified Stöber method. A clear core-shell contrast is clearly observed in all samples, indicating the successful formation of SiO_2 shells.

We then fabricated large-area (>1 cm^2) densely packed NS monolayers on 3D objects using the modified Langmuir-Schaefer method. In contrast to the original black surface, the coated cars exhibit brilliant, metallic-like structural colors ranging from purple to reddish, and the coloration remains highly uniform even over the steep curved surfaces of the car bodies. These confirm that Si@SiO_2 NS monolayers can achieve conformal and continuous coverage on 3D objects. The SEM images in Fig. 1d show the monolayer formed on a flat substrate. This capability addresses a key limitation of many lithography-based structural color approaches, which are typically restricted to small-area and flat substrates.

In the presentation we will discuss the mechanism of the high reflectance and the other applications using Si@SiO_2 NS monolayers.

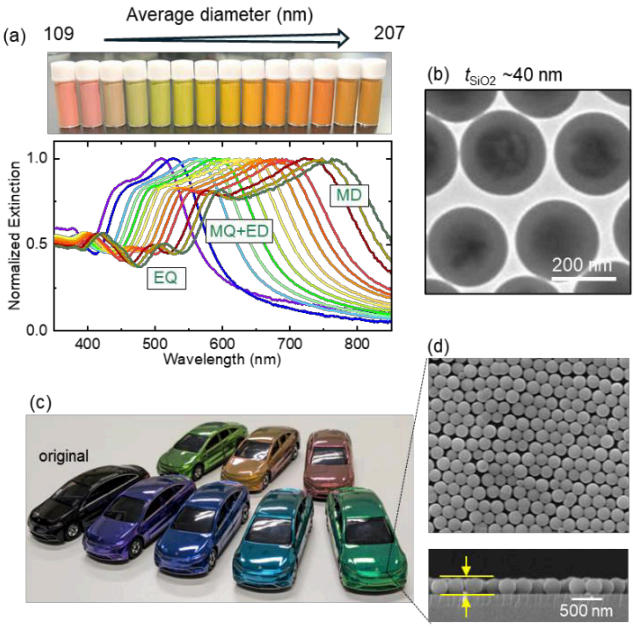

Fig. 1 (a) Photos and extinction spectra of Si NS suspensions after a size-separation process with different average diameters from 109 to 207 nm. (b) TEM image of Si@SiO_2 NS with shell thickness of 40 nm. (c) Photograph comparing an original black toy car with those coated by Si@SiO_2 NS monolayer. (d) Top-view and cross-sectional SEM images of fabricated Si@SiO_2 NS monolayers.

***Abstract*— We present a non-destructive optical metrology method for wafer scale inspection of large area plasmonic metasurfaces. Angle resolved scatterometry implemented in a Fourier microscope enables nanometer sensitive mapping of structural uniformity. Comparison with simulations and microscopy links optical signatures to nanoscale variations in nanoparticle geometry.**

***Keywords*— Metasurfaces, Optical Scatterometry, Fourier Microscopy, Wafer-Scale Metrology, Nanoimprint Lithography.**

I. Introduction

Scaling metasurfaces toward practical optical devices demands fabrication methods that deliver high uniformity over large areas, as well as metrology tools capable of detecting nanometer-scale deviations. Even small variations in feature size or height can significantly modify diffraction efficiency, angular response, and resonant behavior, particularly in plasmonic systems. Conventional techniques such as scanning electron microscopy and atomic force microscopy offer high spatial resolution but are limited in throughput, field of view, and suitability for inline inspection.

II. Methods

We employ Fourier-microscope-based scatterometry using collimated, angle-controlled illumination to probe periodic plasmonic nanopillar arrays. Gold nanopillars on indium phosphide and aluminum nanopillars on ITO-coated glass are fabricated by nanoimprint lithography over areas exceeding tens of square millimeters. Angle-resolved reflectance and diffraction intensities are measured at a fixed wavelength and compared with finite-difference time-domain simulations. A variation index is introduced to quantify deviations from a reference optical response and to map structural uniformity across the metasurface.

III. Results and Discussion

The measurements reveal a strong correlation between the angular scattering profile and nanoscale variations in nanopillar geometry. Regions with increased variation index exhibit reduced specular reflection and enhanced diffraction, consistent with simulations incorporating small changes in height and diameter. Independent verification by dark-field microscopy and atomic force microscopy confirms that nanometer-scale morphological deviations, rather than changes in lattice periodicity, dominate the observed optical variations. This approach enables rapid, spatially resolved inspection of large-area metasurfaces with sensitivity beyond the diffraction limit.

IV. Conclusion

Fourier-microscope scatterometry provides a powerful, non-destructive metrology platform for quantitative quality inspection of large-area plasmonic metasurfaces. By linking angle-resolved optical signatures to nanoscale structural variations, this method enables wafer-scale uniformity mapping with nanometer precision. The technique is well-suited to inline quality control during the fabrication of metasurface-enabled devices, including (O)LEDs and optical sensors.

***Abstract*— Metasurface stickers—flexible, transferable nanoantenna arrays—enable post-fabrication control of light–matter interactions on diverse substrates. By stacking and twisting layers, photoluminescence can be enhanced, redirected, and spectrally tuned, while moiré coupling induces controllable chirality for reconfigurable optical functionalities.**

***Keywords*—Metasurface stickers; Directional emission; Polymer-embedded nanostructures**

I. Introduction

Metasurfaces enable compact and versatile control of light using subwavelength nanostructures; however, most realizations remain confined to rigid, planar platforms. Extending their functionality toward three-dimensional architectures while preserving fabrication simplicity and post-assembly reconfigurability is highly desirable, particularly for tailoring emission from incoherent light sources. Here, we introduce flexible and stackable metasurface stickers as a practical approach to quasi-3D metasurface design, enabling directional emission and tunable light–matter interactions through layer-by-layer integration.

II. Methods

The metasurface was designed as a periodic nanoantenna array to tailor angular radiation through collective lattice effects. The nanostructures were first fabricated on a sacrificial substrate and subsequently embedded in a flexible polymer, yielding a freestanding metasurface sticker [1,2].

The resulting stickers can be laminated onto light-emitting substrates or vertically stacked to form quasi-3D configurations [3]. Optical characterization was carried out by measuring far-field emission patterns under incoherent illumination, enabling direct evaluation of angular radiation distributions and emission directionality. For same stickers stacked in twisted geometry, circular dichroism (CD) was evaluated [4].

III. Results and Discussion

A single metasurface sticker markedly reshaped the emission profile of an incoherent light source, producing pronounced intensity enhancement in selected angular directions (Fig. 1, top panel)[5]. Stacking multiple stickers provided additional degrees of control over the radiation distribution, evidencing effective out-of-plane structuring through vertical layer integration [3].

For the bilayer twist moiré metasurfaces, the magnitude and spectral position of CD signal are tunable via twist angle and interlayer spacing (Fig. 1, bottom) [4].

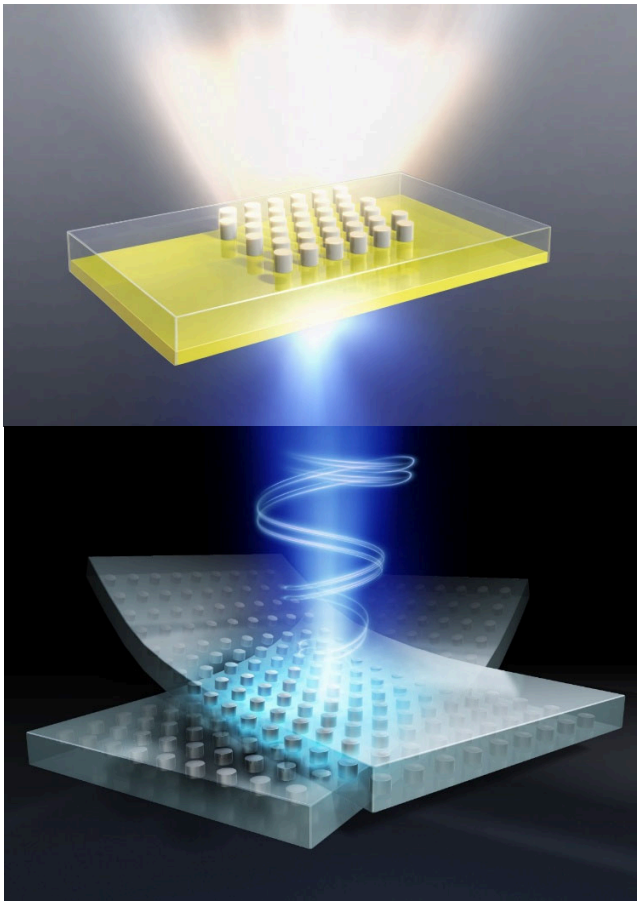

Fig. 1: Sketches of the stickers; (top) Monolayer sticker on the phosphor plate [5], (bottom) Bilayer Moire Metasurface made from stack of metasurfaces [4].

IV. Conclusion

Metasurface stickers provide a simple yet powerful route for tailoring emission from incoherent light sources. Even a single sticker markedly reshapes the emission profile, while stacking multiple layers enables additional control over radiation distribution through effective out-of-plane structuring.

This approach achieves angular emission engineering without complex fabrication or stringent alignment, while maintaining mechanical flexibility and post-fabrication reconfigurability. Metasurface stickers therefore represent a scalable platform for quasi-3D photonic architectures and adaptive control of light–matter interactions.

***Abstract*— This work demonstrates the potential for creating patterns of nanoparticle groups formed in a liquid crystal base material. Nanoparticles coated with a carefully selected ratio of two types of ligands are used. This selection of materials allows for the control of the preferential positioning of nanoparticles within the liquid crystal.**

***Keywords*— nanoparticles, self-assembly, liquid crystals, .**

I. Introduction

If a composite material consisting of a liquid crystal doped with gold nanoparticles (LC/NP) is heated to the phase transition temperature, the phase transition will disrupt the uniform spatial distribution of gold nanoparticles, leading to a distribution characterized by areas of high and low concentration (Fig. 1), and thus areas of increased and decreased light absorption. This phenomenon results directly from the fact that gold nanoparticles are surrounded by pro-messogenic ligands to prevent nanoparticle aggregation on the one hand and to achieve homogeneous mixing with the nematic liquid crystal on the other [1]. At the phase transition temperature, the nanoparticles are pushed, and the direction of this movement depends on the ratio of pro-mesogenic ligands to non-mesogenic ligands surrounding the nanoparticle. A properly selected ratio of both types of ligands allows control over the preferential positioning of the nanoparticles — depending on the proportion, they can cluster in either the nematic or isotropic phase. This concentration of nanoparticles can be distributed in a more or less orderly manner in space.

In this paper, we will demonstrate that individual parameters, such as heating or cooling rates and the type of dopant, can influence the resulting pattern. As seen in Fig. 1, both the transition to the isotropic phase (heating) and the return to the nematic phase (cooling) influence the positioning of nanoparticles. Furthermore, if the process is repeated, groups of nanoparticles can either group or split. However, using only the temperature changes, we cannot control the positioning of nanoparticle groups. A solution could be to heat the liquid crystal to a temperature close to the phase transition temperature (while still maintaining the nematic phase) and then illuminate the system with a light beam. This approach allows for a more deterministic arrangement of nanoparticle groups.

***Abstract*— Metal-assisted chemical etching (MACE) enables scalable, solution-based nanostructuring of silicon with precise control over its optical response. This talk highlights key parameters to achieve homogeneous MACE and optimize field enhancement in silicon nanowire arrays, for SERS, photocatalysis, solar hydrogen generation, and microchip authenticaton.**

***Keywords*— silicon, nanowires, metal-assisted chemical etching, SERS, photocatalysis**

I. Introduction

Nanostructuring silicon provides unique properties with potential applications in electronics, photonics, sensing, photocatalysis, and photovoltaics. When structured into vertically aligned Si nanowires (VA-SiNW) arrays, Si can sustain a variety of optical resonances, such as Fabry-Pérot and Mie resonances, and leaky waveguide modes.[1] Despite this potential, structuring silicon with nanoscale precision is synthetically demanding. Metal-assisted chemical etching (MACE) provides a solution-based, benchtop and versatile alternative, compatible with the high-resolution structuring of silicon (Fig. 1a), which can be used to finely tune the optical properties of silicon (Fig. 1b-e).[2]

II. Methods

During MACE, a metal catalytic mask etches through silicon in presence of an oxidant and HF. [2] The oxidizing agent, usually H_2O_2, is preferentially reduced at the surface of the metal catalyst, generating holes (eq. 1) that are injected through the metal/silicon Schottky barrier, which, in the presence of HF, oxidizes silicon into a soluble product and generates hydrogen gas as a byproduct (eq. 2).

$$H_2O_2 + 2H^+ \rightarrow 2H_2O + 2h^+ \quad (1)$$

$$Si + 4HF_2^- + 2h^+_2 \rightarrow SiF_6^{2-} + 2HF + H_2(g) \quad (2)$$

where h^+ is a hole. As a result, the silicon in contact with the metal catalyst dissolves, leading to a highly anisotropic etching: during MACE, isolated metal catalyst particles sink into the silicon, forming vertical and straight pores, while continuous metal nanomeshes can be used to produce VA-SiNW arrays. Achieving large-scale homogeneity can be challenging because of the instability of the metal catalyst when the experimental parameters are not set appropriately.

III. Results and Discussion

I will discuss the critical parameters that influence the stability of the metal catalyst layer for achieving homogeneous MACE.[2] I will present how optically active metal nanostructures can be interfaced within VA-SiNW arrays using (electro-)chemical approaches,[3] used for surface-enhanced Raman spectroscopy,[4] water-splitting,[5] and photocatalysis. The use of nanoscale silicon fingerprints prepared *via* MACE for counterfeit prevention in microchips will also be discussed (Fig. 1f).[6]

***Abstract*—Recent advancement in experimental Photoacoustic and Photothermal techniques has enabled a large number of interesting observations and understanding of heat transfer processes on metamaterials at the nanoscale**

***Keywords*— Metamaterials, Eutectics, Nanoscale Optics, Heat Transfer, Photothermal and Photoacoustic Technique.**

I. Introduction

We review recent advances in the methodology of Photoacoustic and Photothermal techniques. In particular we applied photoacoustic spectroscopy (PAS) to detect circular dichroism of intrinsic chiral materials [1] as well as extrinsic chiral metasurfaces [2-4].

In disordered media PAS is confirmed to be the most appropriate technique to determine separately the absorption and the scattering coefficients allowing to determine the size of both metallic (AgNP) [5], or semiconductor nanospheres (ZnO) [6, 7], or clusters of nanospheres bridged by the ligands [8], in contrast to nanolayered samples [9] or self-organized eutectic composites [10, 11].

On the other hand photothermal deflection spectroscopy (PDS) may be used as a complementary technique to measure the absorbance spectrum in nanostructures so to detect absorption lines, or photonic band gap in photonic crystals [12, 13], or to measure the out-of/in-plane thermal diffusivity in 2D materials [14].

We also underline some applications of photothermal radiometry (PTR) used to localize the internal heat sources where the pump light is absorbed, and to measure the effective thermal diffusivity. The modulation frequency obtained by an acousto-optical modulator ranges from 1 Hz up to 100 kHz, allowing the improvement of the thermal resolution till submicron range. We have applied PTR and IR Thermography techniques to PCM-VO_2 nanolayered samples [15-17], nanodisks [18] and W-doped VO_2 thin films [19, 20]. Such a technique has been applied also to carbon nanotube film deposited onto a silicon substrate: in this case PTR allows to detect the thermal wave interference in the film and to measure the effective thermal diffusivity of the CNT, and the thermal resistance with the substrate [21]. Photothermal radiometry and thermography can be also used to measure the emissivity of nanostructured materials, nanoantennas and metasurfaces designed so to have specific directional emittance properties [22, 23]. The invited talk summarizes several research topics and recent works done in collaboration with many partners (Universities, Research Centres and the European Centre of Excellence Ensamble3).

***Abstract*—We demonstrate a Non-Ergodic Extended phase with fractal states for electromagnetic waves in 3D non-Hermitian disordered systems. Unlike scalar waves that localize, electromagnetic waves remain in the fractal phase due to their vector nature, enabling anomalous light transport without spatial correlations.**

I. Introduction

Wave transport in complex media exhibits a wide range of regimes, from conventional diffusion to Anderson localization. While scalar waves in three dimensions undergo a localization transition, Anderson localization is absent for electromagnetic (EM) waves in ensembles of dielectric scatterers due to their vectorial character [1], [2], [3]. Recent advances in many-body localization and random matrix theory predict the emergence of a Non-Ergodic Extended (NEE) phase, in which states are spatially extended but occupy a vanishing fraction of the available volume in the thermodynamic limit [4], [5], [6]. In this work, we demonstrate the existence of such a NEE phase for three-dimensional optical systems composed ensembles of randomly distributed point-like scatterers.

II. Microscopic Model

Collective excitations are described by an effective non-Hermitian Hamiltonian [7]

$$\mathcal{H} = (\omega_0 - i\Gamma_0/2)\mathbb{1} - (\Gamma_0/2)\mathbb{G},$$

where ω_0 and Γ_0 denote the resonance frequency and natural linewidth, respectively [8], [9]. For electromagnetic waves, $\mathbb{G}$ corresponds to the dyadic Green's function coupling dipoles at positions $\mathbf{r}_i$ and $\mathbf{r}_j$ [9],

$$\mathbb{G}_{ij} \propto \frac{e^{ikr_{ij}}}{kr_{ij}} \left[P(ikr_{ij})\mathbb{1}_3 + Q(ikr_{ij}) \frac{\mathbf{r}_{ij} \otimes \mathbf{r}_{ij}}{r_{ij}^2} \right], \quad (1)$$

where $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$. The scalar-wave case is obtained by replacing $\mathbb{G}$ with the scalar Helmholtz Green's function [8]. Anderson and Ergodic transitions are investigated through the Ioffe-Regel parameter $k\ell$ as a function of the dimensionless density $\rho\lambda^3$ [7].

III. Results and Discussion

To characterize the spatial structure of the eigenstates, we analyze the scaling of the inverse participation ratio (IPR), defined as $\mathrm{IPR}_n = \sum_{i=1}^{N} |\psi_n(\mathbf{r}_i)|^4$. A scaling behavior $\langle \mathrm{IPR} \rangle \sim N^{-D_F}$ defines the fractal dimension D_F of the eigenstates, normalized by the Euclidean dimension [4], [5], [6]. The value of D_F provides a criterion for ergodicity, as it determines whether the occupied fraction of space remains finite or vanishes in the thermodynamic limit $N \to \infty$ [4].

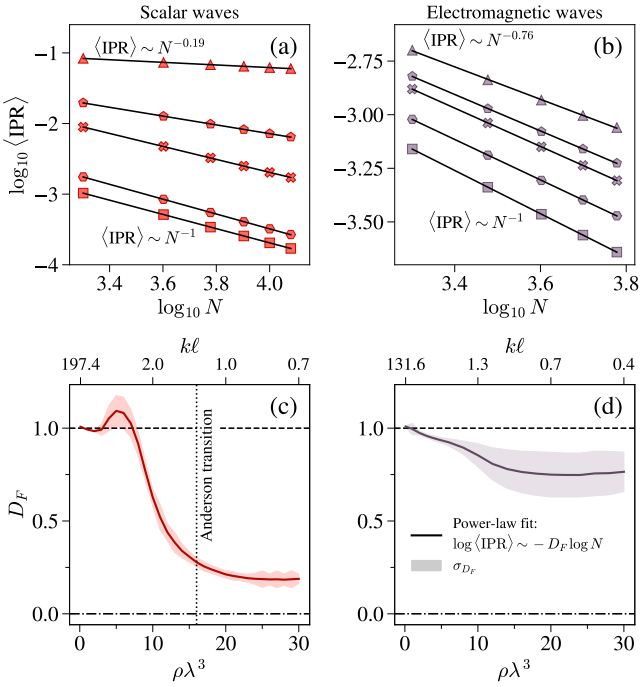

Fig. 1. (a),(b) Scaling of the inverse participation ratio (IPR) with system size N for scalar and electromagnetic waves, respectively. Symbols correspond to $\rho\lambda^3 = 0.1, 4, 8, 10, 30$, increasing from bottom to top. Solid black lines are power-law fits. Panels (c) and (d) present the normalized fractal dimension D_F for the whole range of density. Solid lines show the result of the fitting analysis and the shaded region corresponds to standard deviation. Horizontal dashed (dash-dotted) lines are the predictions for the extended (localized) regime. The vertical line in (a) shows the Anderson transition.

As shown in Fig. 1(a–b), a clear power-law scaling $\langle \mathrm{IPR} \rangle \sim N^{-D_F}$ is observed for all densities. At low densities ($\rho\lambda^3 \lesssim 8$), both scalar and electromagnetic waves exhibit $D_F \approx 1$, corresponding to an ergodic, fully extended phase. At higher densities ($\rho\lambda^3 \gtrsim 20$), scalar waves display a reduced fractal dimension $D_F \approx 0.2$, approaching the expected value $D_F = 0$ of the Anderson-localized regime. In contrast, electromagnetic waves retain a significantly larger value, $D_F \approx 0.8 < 1$, indicating the presence of the extended phase.

While the analysis of the Thouless number signals the absence of an Anderson transition in the vectorial case [1], [3], the fractal-dimension analysis reveals a qualitative change in the nature of the eigenstates responsible for wave transport. Interestingly, both scalar and vectorial models exhibit the onset of fractality at comparable densities $\rho\lambda^3 \approx 8$, below the localization threshold $\rho_{\mathrm{AT}} \approx 16/\lambda^3$ for scalar waves, corresponding to the Ioffe–Regel criterion $k\ell \sim 1$. This crossover regime suggests that near-field interactions play a limited role before the Ioffe-Regel limit is reached.

To further confirm the existence of a NEE phase in the thermodynamic limit, we perform a finite-size scaling analysis based on the participation entropy [10]

$$\mathcal{S} = \left\langle \sum_{i=1}^{N} |\psi(\mathbf{r}_i)|^2 \log |\psi(\mathbf{r}_i)|^2 \right\rangle,$$

and its normalized derivative $\tilde{\mathcal{S}}' = \partial_{\rho\lambda^3}\mathcal{S}/\log N$ [10]. This quantity is known to capture both ergodic and Anderson transitions in the Rosenzweig-Porter model, where a NEE phase has been analytically established [4]. As shown in Fig. 2, for scalar waves a size-independent crossing point appears at $\rho\lambda^3 \approx 3$, signaling the transition from an ergodic to a NEE phase. A similar transition is found for electromagnetic waves at $\rho\lambda^3 \approx 4$, further supporting the existence of a NEE phase despite the absence of Anderson localization.

IV. Conclusions

We demonstrate a transition to a non-ergodic extended phase of fractal quasimodes for both scalar and electromagnetic waves in randomly distributed point-like scatterers in 3D, beyond the conventional diffusive-to-localized scenario. A direct determination of the fractal dimension shows that, for scalar waves, this fractal phase emerges at densities below the Anderson localization threshold. As fractal states are expected to support anomalous diffusion, such transport may occur even where Thouless-number scaling predicts conventional diffusion [7]. To our knowledge, this constitutes the first prediction of a non-ergodic extended phase in a realistic 3D optical system, featuring a crossover between different degrees of ergodicity with increasing disorder. Our results provide a framework for interpreting observations of subdiffusive light transport [11], [12] and suggest new routes for engineering light transport in non-hermitian random media without relying on spatial correlations.

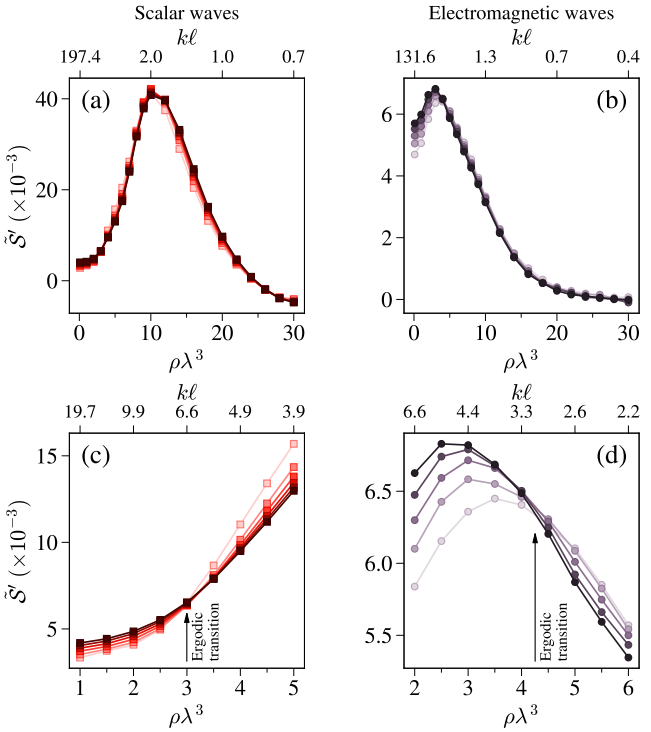

Fig. 2. Derivative of the normalized participation entropy $\tilde{S}'$ as a function of the scatterer density $\rho\lambda^3$ for (a) scalar and (b) electromagnetic waves. Darker colors correspond to larger system sizes N. Panels (c) and (d) show an enlarged view of the curves from (a) and (b) around the crossing points corresponding to the ergodic transition, whose location is indicated by the arrows.

***Abstract*—The profound connection between band topology and field theoretic anomalies has recently been generalized to a non-Hermitian (NH) Weyl semimetal. We show that the NH anomaly is mediated by exotic states called continuum Landau modes (CLMs), giving rise to a dramatically higher density of surface states scaling with the volume, not surface area.**
***Keywords*— Non-Hermitian physics.**

I. Introduction

The bulk and edge states of various topological materials can serve as manifestations of field theoretic anomalies (violations of classical symmetries by quantum fields [1]), such as quantum Hall edge states and Weyl semimetal states with the chiral anomaly [2]. Recently, this link between topological states and anomalies was generalized to non-Hermitian (NH) topological phases [3], [4].

In this work [5], we show that the manifestation of an NH anomaly in a three-dimensional (3D) Weyl semimetal occurs via unusual surface states called continuum Landau modes (CLMs) [6]: eigenstates that form a continuous spectrum but are spatially localized, in violation of the usual dichotomy between bound and free states exhibited by Hermitian wavefunctions. CLMs were originally discovered in models with no evident connection to NH band topology [6], but here they emerge as surface states of a 3D NH Weyl semimetal (WSM) under an applied magnetic field. Strikingly, we find that the density of surface states is proportional to the sample volume $V = L_x L_y L_z$. By contrast, in the usual Hermitian anomaly inflow mechanism, this scales with surface area $A = L_x L_y$ [1], and this had been expected to be the case in the NH system [4]. This previously unaccounted-for feature seems to be tied to the unusual properties of CLMs.

Fig. 1. (a) Complex spectrum for a NH Weyl semimetal under an applied magnetic field $\mathbf{B} = 2\pi/30\,\hat{z}$, with lattice size $L_x = L_z = 11$, $L_y = 22$. The states in $|E| < 1$ are CLMs on the $-z$ surface. (b) Plot of $d\Delta n/dB \cdot (L_x L_y L_z)^{-1}$ versus B. Here, $\Delta n = n_- - n_+$ is the difference in the number of in-gap modes ($|E| < 1$) localized on the bottom and top surfaces, and the derivative is estimated using $\delta B = 0.02$. Results are plotted using $L_x = L_y = 11$, with different values of L_z. Excerpted from [5].

Solitons Mediated by Skin-Mode Localization and Band Nonreciprocity

Kun Ding

***Abstract*— By clarifying a classification criterion intrinsic to the non-Hermitian skin effect, we distinguish two soliton families supported in non-Hermitian lattices and further construct the soliton threshold diagram as a function of nonreciprocity and dimensionality.**

***Keywords*—Non-Hermitian skin effect, nonreciprocity, solitons.**

I. Introduction

Solitons, typically arising from a competition between band dispersion and nonlinearity, occur in lattices featuring the non-Hermitian skin effect as nonlinearity increases, accompanied by a transition in localization from linear skin modes to solitons. However, localization does not disentangle the role of skin modes in soliton formation from that of band dispersion, nor does it clarify their impacts on soliton classifications. By mapping out a soliton diagram, we here establish a universal framework for characterizing solitons in nonreciprocal lattices with non-Hermitian skin effect [1,2].

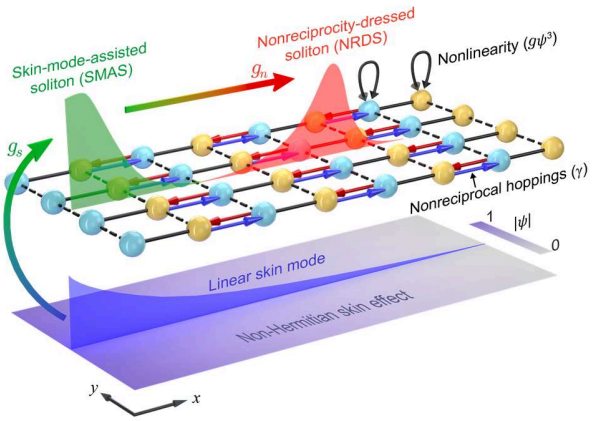

Fig. 1 Schematic illustration of transitions among skin modes and various solitons. The upper panel shows a two-dimensional lattice featuring nonreciprocal hoppings and nonlinearity, with their respective strengths characterized by γ and g. Two arrows with gradient color sketch the sequential transitions from non-Hermitian skin modes (blue) to skin-mode-assisted solitons (SMASs, green), and subsequently to nonreciprocity-dressed solitons (NRDSs, red), driven by variations in g. .

II. Results and Discussion

We uncover two distinct soliton phases, skin-mode-assisted solitons (SMASs) and nonreciprocity-dressed solitons (NRDSs). Rooted in fundamentally different mechanisms, SMASs originate from skin effect, while NRDSs stem from band nonreciprocity, each exhibiting unique spatial profiles. Using a stacked Su-Schrieffer-Heeger-like model as a prototype (Fig. 1), we delineate the phase diagram of SMASs and NRDSs, each having clear phase boundaries.

To interpret them, we formulate a Wannier-function-based nonlinear Hamiltonian, showing that soliton formation depends critically on how skin-mode localization and band nonreciprocity suppress or enhance wave dispersion. For SMASs, skin-mode localization reduces wave broadening at the localization sites, thereby lowering the formation threshold. This soliton phase is observable from edge dynamics and accompanied by a dynamical stability reentrance when transitioning from linear skin modes. In contrast, NRDSs, as well as their thresholds, arise from bulk-band nonreciprocity and persist under periodic boundary conditions.

With such a framework, we further demonstrate that soliton classifications in nonreciprocal lattices, independent of dimension and lattice types, are determined by skin-mode localizations rather than geometry. Therefore, our framework offers predictive tools for characterizing and engineering solitons in experimentally realizable non-Hermitian systems, spanning optics to mechanics.

III. Conclusion

We identify two soliton families from numerically obtained nonlinear eigenstates in non-Hermitian lattices, dubbed SMAS and NRDS, which respectively arise from skin-mode localization and band nonreciprocity. Using this classification, we construct the soliton threshold diagram as a function of nonreciprocity and dimensionality. To interpret and predict these thresholds, we develop a Wannier-projected effective nonlinear Hamiltonian that captures the threshold values and

reveals the dominant mechanisms for each soliton family. We further demonstrate that, regardless of dimensionality and lattice intricacy, SMASs (NRDSs) emerge at the lattice sites where skin modes are localized (or not), highlighting the generality of our framework.

***Abstract*—Identifying dynamical phases in nonlinear systems is a central challenge in nonlinear dynamics, particularly for complex nonlinear optical systems. Here, we propose two machine-learning approaches—augmented dynamic mode decomposition and a convolutional neural network—to construct phase diagrams of the Su–Schrieffer–Heeger model with Kerr nonlinearity.**

***Keywords*— phase diagram, photonic topological insulator, optical nonlinearity, machine learning**

I. Introduction

The topology of photonic bands enables the design of novel photonic devices supporting unique modes known as topological modes. For example, topological edge and corner modes that are robust against local perturbations can be realized in two-dimensional photonic crystals and metamaterials by appropriately tailoring their geometries [1], [2]. Moreover, topological design principles can be applied to semiconductor microlasers [3]. On the other hand, combining optical nonlinearities with topological designs opens new opportunities for achieving diverse optical functionalities, ranging from bistable states in Kerr nonlinear ring resonators to novel thermodynamic behavior in multimode waveguides [4]. Understanding the dynamics of nonlinear optical systems requires constructing phase diagrams. However, most existing approaches rely on numerical simulations combined with heuristic identification of phases. Recently, a machine-learning approach based on augmented dynamic mode decomposition (aDMD) has been successfully applied to coupled topological lasers in one-dimensional SSH and two-dimensional kagome lattices with saturable gain [5], [6].

In this work, we apply both aDMD and convolutional neural networks (CNNs) to construct phase diagrams for one-dimensional SSH ring resonator arrays with Kerr nonlinearity.

II. Methods

A. Phase diagram using aDMD

The unsupervised aDMD method builds a library of time-augmented DMD bases from representative trajectories. A bottom-up step adds bases when the reconstruction error exceeds $\epsilon_{\text{add}} = 0.20$, and a top-down step merges equivalent bases when their subspace alignment $\gamma_{ij} > \gamma_{\text{merge}} = 0.50$ [6].

B. Phase diagram using CNN

The supervised CNN method involves training on heuristically labelled trajectories from 70% of the parameter grid, with labels assigned from steady-state intensity statistics, spectral peak ratios, and counter-propagating mode switching. The remaining 30% of grid points are classified solely by the trained network without further simulation.

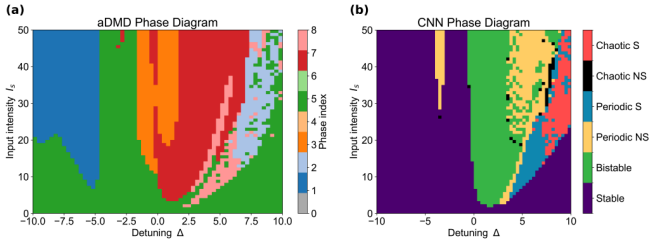

Fig. 1. (a) Phase diagram obtained using the aDMD method, with colours indicating distinct, unlabelled phases identified through bottom-up library construction and top-down merging. (b) Phase diagram obtained using a CNN trained on heuristic labels, showing stable, bistable, periodic, and chaotic regions with switching (S) and non-switching (NS) sub-phases

III. Results and Discussion

Figure 1 shows the phase diagrams obtained from both methods over the detuning Δ and input intensity I_s parameter space. The aDMD result [Fig. 1(a)] successfully identifies the periodic and chaotic switching phases (pink, light blue) and clearly separates the stable behaviours. However, the bistable phase is incorrectly split across two clusters (red, orange), and the periodic non-switching phase (blue) is greatly overestimated at negative Δ and missing at positive Δ. Furthermore, the total amount of phases is overestimated. The CNN result [Fig. 1(b)] identifies regions consistent with the six expected phases across the parameter space, though a few grid points are falsely classified as chaotic non-switching.

IV. Conclusion

We have demonstrated that the phase diagrams of nonlinear optical systems can be obtained using machine learning approaches. The aDMD method, an unsupervised learning technique, was able to identify the different dynamical phases despite ambiguous phase boundaries and occasional misclassification. In contrast, the CNN method, based on supervised learning, clearly distinguished and identified all phases with fewer misclassification.

***Abstract*—We find a nontrivial crossover of subsystem fluctuations of quantum jumps in many-body systems under continuous measurement [1]. Whereas the fluctuations exhibit the conventional volume law following Poissonian statistics for sufficiently weak measurement strength, anomalous yet universal scaling law exhibiting super-Poissonian statistics appears for strong measurement strength.**

***Keywords*— measurement, quantum jumps, many-body systems.**

I. Summary

Open quantum systems under measurement have now been extensively studied because they exhibit interesting nonequilibrium dynamics absent in isolated quantum systems [2]. Of particular interest is the physics of quantum trajectories, where one tracks the monitored dynamics with the measurement outcomes (i.e., quantum jumps) retained. Indeed, such quantum trajectories concerning many-body systems can exhibit interesting phenomena represented as measurement-induced phase transitions (MIPT) [3], which cannot be obtained by the dynamics where measurement outcomes are averaged. However, the MIPT generally requires the postselection of the same quantum measurement outcomes, which causes experimentally unfriendly exponential cost.

Our work [1] shows that a nontrivial crossover of subsystem fluctuations of quantum jumps in many-body dynamics, which does not require the aforementioned postselection problem because quantum jumps are directly obtained in a single quantum trajectory. Whereas the fluctuations show the conventional volume law ($\sim L$) following Poissonian statistics for sufficiently weak measurement strength, anomalous universal scaling law ($\sim L^{2.7}$) exhibiting super-Poissonian statistics appears for strong measurement strength. We also discuss that this crossover significantly affects the precision of estimating the rate of quantum jumps. That is, for strong (weak) measurement, the estimation uncertainty is enhanced (suppressed) as the system size increases. Moreover, we demonstrate that the obtained anomalous scaling of the subsystem fluctuation results from an integrated many-body autocorrelation function. We can access the measurement-induced crossover only through the postselection-free information, i.e., the time and the position of quantum jumps, which can be tested in ultracold atom experiments.

***Abstract*— Topological insulator (TI) materials like $InBi_2Se_3$ are highly sensitive to external electrical & magnetic fields, both at RF and optical frequencies, making for an emerging quantum sensing platform. In this work, we calculate the optical conductivity of TIs using Quantum Espresso, and design optical sensing devices and arrays.**

***Keywords*— topological insulators, Density Functional Theory, quantum sensing, optical conductivity.**

I. Introduction

The growing desire to achieve improved sensitivity and speed in sensing applications has given rise to the field of quantum sensors. This includes sensing optical, electric & magnetic fields, applied strain, and other approaches [1]. While the most common platforms are spins, trapped ions, and quantized fluxes, many of these approaches require cryogenic temperatures or other complex support mechanisms for use in many applications. This gives rise to interest in specifically quantum photonic platforms. While color centers like NV centers have received a great deal of interest, they can also be limited by complex fabrication techniques. Another emerging approach utilizes topological materials that exhibit topological phase transitions [2]. The transition is of first order, which leads to emergence of *helical states*. In this approach, we can envision an array of detectors, in which the quantum spin Hall helical states will entangle. Coupling these edge states to the interior regions of the detectors results in magnetochiral anisotropy (MCA) and potential topological-trivial phase transitions. Both phenomena can result in heightened sensitivity to electric and magnetic fields, including optical frequencies. In this work, we aim to explore the potential of this approach to provide the basis for a distinct type of quantum optical sensing platform.

II. Methods

Our first-principles simulations of topological insulator materials use Quantum Espresso and WannierTools to compute the electronic structures of topological materials in both bulk and nanosheet structures. From these calculations, we derive optical conductance, using the following expression [3]:

$$\sigma_{\alpha,\beta}(\omega) = i\frac{e^2\hbar}{V}\int \frac{d^2\mathbf{k}}{(2\pi)^2}\sum_{m,n}\frac{n_F(\varepsilon_{n,\mathbf{k}}) - n_F(\varepsilon_{m,\mathbf{k}})}{\varepsilon_{m,\mathbf{k}} - \varepsilon_{n,\mathbf{k}}}\frac{\langle n,\mathbf{k}|j_\alpha|m,\mathbf{k}\rangle\langle m,\mathbf{k}|j_\beta|n,\mathbf{k}\rangle}{\hbar(\omega+i\eta) - (\varepsilon_{m,\mathbf{k}} - \varepsilon_{n,\mathbf{k}})}$$

where n_F denotes the Fermi occupation, $|m,\mathbf{k}>$ and $\varepsilon_{m,\mathbf{k}}$ are the eigenvectors and eigenvalues for band m at momentum $\mathbf{k}$, $\hbar\eta$ is the lifetime broadening, and j_α is the current operator.

Special attention is given to understanding how strain and electrostatic gating can modulate the topological phase transitions essential for sensing mechanisms.

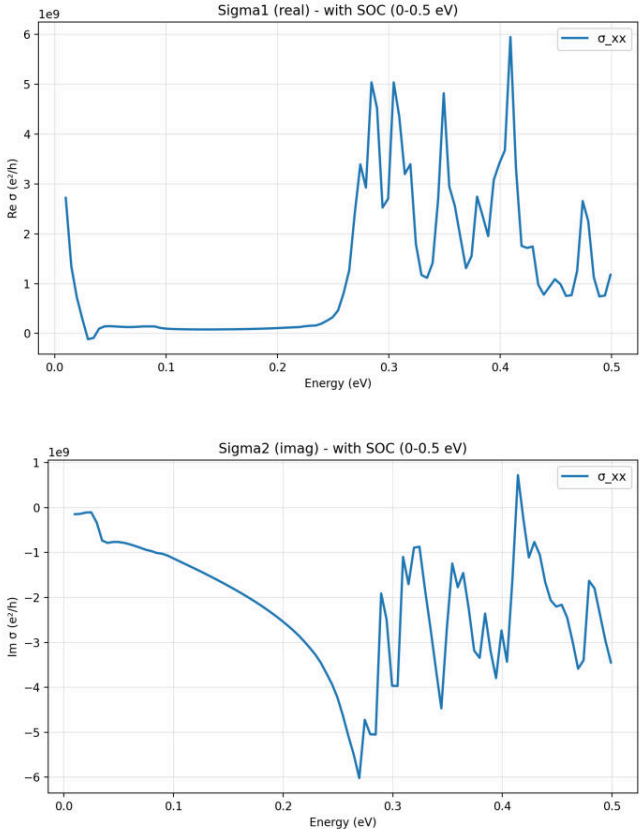

Fig. 1 (a) Real and (b) imaginary components of optical conductivity for $InBi_2Se_3$ topological insulators, calculated using Quantum Espresso, Wannier Tools, and an analytical formula [3].

III. Results and Discussion

As shown in Figure 1, we are able to calculate the optical conductivity for topological insulator materials such as $InBi_2Se_3$. Similar to previous related work [3], we find that the optical conductivity has a large DC (Drude-like) component, as well as a significant number of higher frequency components in the infrared. Furthermore, we are able to verify that the real components of the diagonal components exhibit sharp jumps that are sensitive to the Fermi level (doping) or quasi-Fermi

level (photon detection rate).

IV. Conclusion

We have demonstrated that topological insulators have strong and highly sensitive response as measured in optical conductivity. Ongoing work to be included in this presentation will incorporate these calculated properties into semiclassical device simulations to estimate the degree of sensitivity under various conditions.

Scattering Properties of non-Hermitian Resonant Systems Explored Through the Generalized Wigner-Smith Operator

Nadav Shaibe[1], Jared Erb[1], Thomas M. Antonsen[1,2], Steven M. Anlage[1,2]*

[1]Physics Department, University of Maryland, College Park, MD 20742-4111 USA

***Abstract*— We explore uses of the generalized Wigner-Smith operator in understanding the scattering properties of non-Hermitian systems with many embedded parametric perturbers. We focus on the statistical properties of complex parametric derivatives of the scattering matrix and compare them to those of the Wigner-Smith time delay, both obtained from experiments.**

***Keywords*— metamaterials, microwave, time delay, non-Hermitian physics, scattering matrix, generalized Winger-Smith operator.**

I. Introduction

The Wigner-Smith operator has a long history since it was first introduced in the context of nuclear scattering, and has found varied applications such as wavefront shaping [1] and identifying complex poles and zeros of the scattering matrix [2]. However, the operator is still mainly used today as it was decades ago, whereas more can be learned from the Wigner-Smith operator with just a few simple generalizations. In this talk, we generalize the Wigner-Smith operator in the following three ways: (a) from operating on unitary to sub-unitary scattering matrices which results in the complex Wigner-Smith time delay $\tau_{WS} = \frac{-i}{M}\frac{\partial}{\partial f}\ln[\det[S]]$ [3], where $S(f)$ is the $M \times M$ frequency-dependent scattering matrix, (b) from the complete scattering matrix to subblocks and functions of the elements of the scattering matrix, which results in a myriad of complex time delays such as transmission time delay $\tau_T = -i\frac{\partial}{\partial f}\ln[T]$ (where T is an off-diagonal element of S) [2], and (c) from a derivative with respect to frequency to a derivative with respect to other parameters p which results in another multitude of complex *generalized* delays, such as Wigner-Smith generalized delay $g_{WS}^{p} = \frac{-i}{M}\frac{\partial}{\partial p}\ln[\det[S(f,p)]]$ [4].

Experiments

Our experimental work is done in one-dimensional microwave graphs, two-dimensional billiards, and three-dimensional cavities, all with embedded analog tunable perturbers, such as reflective metasurfaces on the walls of a cavity [5], which endow the measurements with multiple parameters p. Because the systems used have a dense set of modes, we are able to see a large variety of phenomena, including extreme events such as scattering singularities [6], allowing us to studying the statistical properties of the generalized Wigner-Smith operator.

II. Results

In the experiments we utilize the parameters to alter the locations of poles and zeros of the scattering matrix in the complex frequency plane. In a graph we vary the length of a bond as the parameter p of interest. We have previously found that complex g_{WS}^{p} diverges at scattering singularities (see Appendix G of [7]), such as g_{WS}^{p} diverging at Coherent Perfect Absorption, and transmission generalized delay g_{T}^{p} diverging at transmission nulls. Because the divergence of g^{p} has the form of a simple pole, we expect the PDFs of any complex generalized delay g^{p} to have -3 power-law tails [7, 8]. It should also be noted that since both the real and imaginary components of the complex generalized delay independently diverge at singularities, it can be used as a method to more accurately determine the existence and location of singularities, as compared to linear-response measurements.

In our graph experiments we recover very clear -3 power-law tails for both the positive and negative tails of both the $Re[g_{WS}^{p}]$ and $Im[g_{WS}^{p}]$ distributions, extending the range of validity of our observed super-universality of delay statistics [7, 8]. An interesting question that arises is whether or not the mean of the real part of the distribution $\langle Re[g_{WS}^{p}]\rangle$ can be used to count the number of poles in the lower half of the complex plane, as we previously demonstrated for τ_{WS} [9].

III. Conclusion

The generalized Wigner-Smith operator shows potential for extracting more information about the scattering matrix of

complicated non-Hermitian systems, with the advantage that it does not require multi-frequency measurements. We have shown that densely-moded microwave cavities with multiple *in-situ* continuously-tunable parametric perturbers serve as ideal platforms for studying the statistical properties of generalized Wigner-Smith operators.

***Abstract*—We study one-dimensional (1D) photonic lattices on a topologically trivial phase for S mode excitation. We demonstrate how the excitation of dipolar P states together with the engineering of the coupling angle induce a zero dimerization regime on a SSH-like model, including the emergence of an all flat band regime.**

***Keywords*— photonic lattices, topological lattices, evanescent coupling, femtosecond laser writing.**

I. Introduction

The ability to freely varying the coupling constants on a given lattice geometry is one of the key of success for light manipulation on photonic systems [1]. This could be achieved by different means; however, the constraint on the waveguide distance for evanescent coupling finally determines the experimental possibilities and concrete dimensions of the system. For example, the SSH 1D lattice model [2] is very well known for showing a topological phase transition depending on a lattice dimerization. This lattice possesses intra C_1 and inter C_2 coupling constants, which determines the respective regime. At $C_1 = C_2$ the lattice is a simple 1D dispersive lattice. For $C_1 < C_2$ the lattice enters into a topologically non-trivial phase, and the bulk-edge correspondence allows the emergence of a non-trivial exponentially localized edge state. At zero dimerization C_1, the lattice transforms into a set of uncoupled dimers with frequencies $\pm C_2$ forming two flat bands (FB), plus two isolated single-site states at zero frequency. These perfectly localized states are the origin of the edge modes, which acquire an exponential tail as soon as $C_1 > 0$. To achieve a zero coupling, on evanescently coupled systems, implies an abrupt increment of the waveguide separation, as the coupling constant decreases exponentially with the inter-site distance [3]. This limit is therefore not available in standard configurations [4] and constitutes a mathematical dream.

II. Methods

We fabricate different photonic structures by means of the fs laser writing technique [1], [3]. We tightly focus a pulse of $\sim$ 200 fs, with a wavelength of 1030 nm, inside a borosilicate glass wafer. The laser induces a weak modification of the refractive index contrast, estimated as $\Delta n \sim 10^{-3}$ over $n_0 = 1.48$ (wafer). A full waveguide is fabricated after translating the glass along its length (coordinate z), at a given writing velocity and power. By carefully selecting these parameters, we can transit from single-mode waveguides having only S-like modes into multi-mode waveguides having multi-orbital states [1]. The performance of the waveguides not only depends on the fabrication parameters, but also on the excitation wavelength: for shorter λ's a larger number of modes are available in the same photonic structure.

III. Results and Discussion

Multi-orbital interactions [1] allow the control of the coupling constants depending on the specific orbital states as well as on their orientation. Figs.1(a)–(c) show pictorially this interaction picture for S and P states. Fig.1(d) describes how the couplings vary depending on the rotation angle θ. Interestingly, we can achieve a zero coupling interaction for P-P and S-P interactions, independently of the distance in between waveguides. Focusing on a dipolar coupling C_p only, we find an invisibility angle at around $\theta_i \approx 32$ degrees [5] for 730 nm, as shown in Fig.1(e).

We fabricate new photonic couplers and perform a full characterization of C_p versus θ and versus excitation wavelength. Fig.1(f) shows the extracted data for the respective coupling constants, where red and blue data indicate positive and negative values, while a white fringe implies a zero value. We notice how this transition region shifts to larger angles for larger wavelengths, as the guided modes become broader as well. The black line indicates the position for which $C_p(\theta, \lambda) = -C_p(0, \lambda)$.

Now, we implement these findings on a lattice geometry, where the intersite distance is kept constant and the dimerization is inserted by modifying the lattice angle. Fig.2(a) shows a 1D dipolar lattice, for which all horizontal couplings ($C_p(0)$) are positive and $C_p(\theta)$ varies according to Fig.1. Therefore, by sweeping on the angle θ we can transform the lattice geometrically, but also topologically. If we apply the SSH model to this configuration $C_1 = C_p(\theta)$ and $C_2 = C_p(0)$. Therefore, in the region defined by $\theta = 0$ and the black line of Fig.1(f), $|C_1| < C_2$ and the lattice is in a topologically non-trivial phase. However, this is only true if the system size is infinite. For finite lattices the topological transition is shifted into smaller values of $|C_1|$. We fabricate several lattices with different angles θ and excite them at the bulk and the edges. Fig.2(b) top and bottom shows the respective output

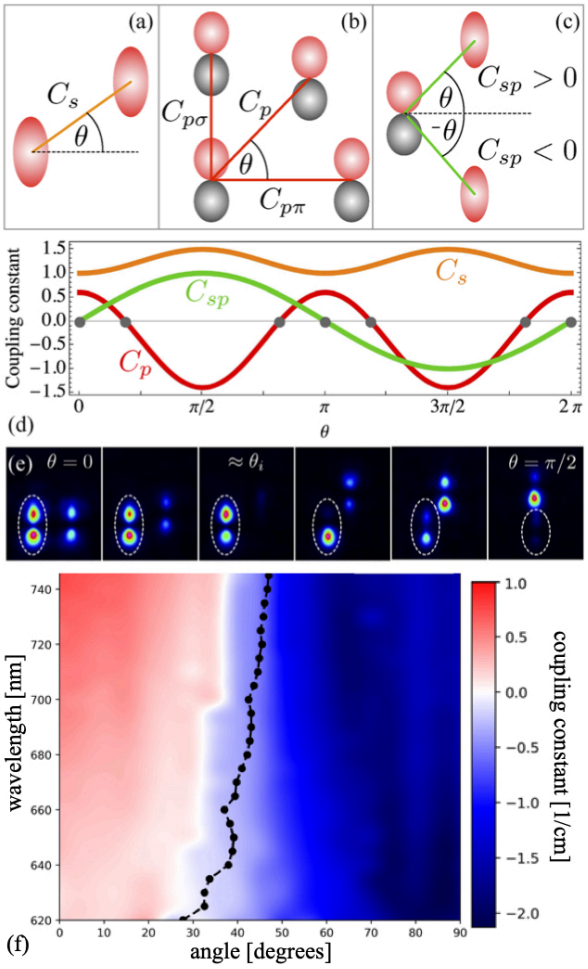

Fig. 1. (a)–(c) Coupling diagram for S-S, P-P, and S-P interaction cases, respectively. (d) Coupling constant vs θ for C_s (orange), C_p (red), and (d) C_{sp} (green). Dots show the angles for zero coupling. (e) Experimental output profiles for P-P photonic couplers at different values of θ, after exciting the encircled waveguide. (f) Experimentally obtained coupling constant C_p versus θ and versus excitation wavelength.

profiles, obtained for 730 nm. We clearly observe the transition into localization for both excitations at the invisibility angle (see dashed area). There, the two bands transform into two FBs, and the edge topological state collapses to a single-site mode. Around this collapse, a well-defined SSH edge state is observed with the respective staggered phase at a given lattice polarization [5].

Fig.2(c) shows the extracted output participation ratio as a measure of the wavepacket size, where the black (yellow) color indicates a value close to 1 (9) implying localization (delocalization). The data describes quite clearly the transition into localization around the invisibility angle. This is very well defined for bulk excitation, implying an all FB lattice regime which interestingly coincides with the highest topological regime for this lattice.

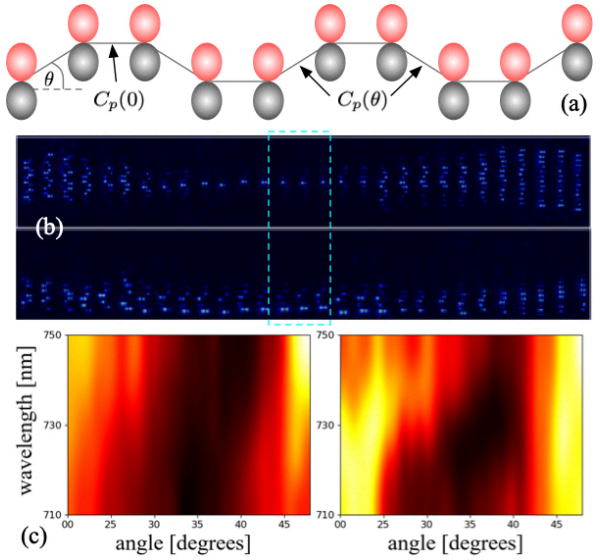

Fig. 2. (a) Dipolar lattice configuration. (b) Output profiles at $\lambda = 730$ nm for different angles θ from 0 (left) to 50 (right) degrees, and for bulk (top) and edge (bottom) excitations. (c) Averaged output participation ratio for bulk (left) and edge (right) excitations.

IV. Conclusion

We have discussed how we can switch the dipolar coupling by varying the rotation angle among P waveguides. The obtained degree of control is very high, allowing to transit from positive to negative values, including zero at the invisibility angle. We study a 1D zig-zag-like geometry as a dipolar realization of an SSH lattice. By varying the lattice angle θ, we observe an abrupt and clear transition into localization for bulk localization as a manifestation of an all FB regime. Edge localization is also very sharp around the invisibility angle and a perfect zero dimerization is clearly evidenced. This is a remarkable result as it constitutes the first experimental demonstration of a physically inaccessible regime when considering standard S modes.

***Abstract*—Exceptional points are spectral degeneracies of non-Hermitian operators. We show that a passive multiport network can be programmed to exhibit exceptional-point behaviour in a measured-port subspace, even though the full scattering matrix is unitary. By tuning internal phases, we engineer anisotropic eigenvalue splitting and prescribe sensitivity directions in parameter space.**

***Index Terms*—exceptional points, non-Hermitian physics, scattering networks, metamaterials, programmability**

I. Introduction

Exceptional points (EPs) represent spectral singularities in non-Hermitian operators where the eigenvalues and their corresponding eigenvectors coalesce, giving rise to non-analytic responses and unique topological features [1], [2], [3]. Whilst early studies focused primarily on gain-loss engineering, recent attention has shifted toward *anisotropic* EP behaviour, wherein the spectral scaling is dictated by the direction of approach in parameter space [4]. Such directionality offers attractive capabilities for sensing and reconfigurable wave devices, however, current demonstrations predominantly rely on limited mode spaces and active, non-passive constituents [5]. In this work, we address this limitation by targeting a complementary regime: a strictly *passive* multiport scattering network. Whilst the full scattering matrix of the network is assumed unitary, a measured port subspace can nevertheless exhibit effective non-unitary behaviour arising from controlled leakage into unobserved ports. Utilising such a complex optical network as a platform to achieve a programmable scattering matrix [6], [7], we show that internal phase control alone is sufficient to facilitate the formation of scattering EPs and shape their anisotropic response along a user-defined direction in parameter space.

II. Concept and design principle

We consider an M-port lossless network operating at a fixed frequency. The full scattering matrix $\mathbf{S}$ is strictly unitary and cannot host an EP. A sub-scattering block $\mathbf{A}$, however, obtained by restricting attention to a specific subset of ports, is generally non-unitary and thus potentially defective. Restricting to, for example, a 2-port subsystem, an EP within the 2×2 matrix $\mathbf{A}$ can be achieved by tailoring the propagation phases along a subset of the network's internal links so that the discriminant of the characteristic polynomial of $\mathbf{A}$ vanishes (corresponding to two real parametric constraints that the system must satisfy). A conventional EP would exhibit a square root dependence for perturbations in any direction in parameter space. Imposition of an anisotropic response along a specific direction in parameter space, however, imposes further conditions, thereby necessitating tuning of additional propagation phases. Realisation of anisotropic EP behaviour therefore can be formulated as a programmable objective function which then can be used for system design. The wealth of links in a complex network affords increased degrees of freedom, providing us with the ability to achieve customisable EP responses tailored to, for example, specific sensing requirements.

III. Anisotropic response and EP verification

We validate our theoretical framework using a four-port cross network equipped with multiple tunable internal phases (Figure 1), which can be realistically adjusted through the refractive index (we assume a wavelength of $\lambda = 600$ nm in our simulations). By systematically scanning the phase

Fig. 1. **Passive programmable multiport network.** The full scattering matrix is unitary, but the measured two-port subsystem (top and right ports) is non-unitary due to leakage into unobserved ports (bottom and left ports). Tunable internal phases provide a high dimensional control space for programming EP behaviour.

Fig. 2. **Anisotropic exceptional-point response and verification.** (a) Eigenvalue splitting $|\lambda_+ - \lambda_-|$ of the measured-port sub-scattering matrix $\mathbf{A}$ versus perturbation magnitude $|\delta\phi|$ for a generic direction (orange) and the programmed design direction (purple). The generic perturbation exhibits the conventional square-root scaling (slope ≈ 0.5 on the log–log plot), whereas the design direction exhibits a linear scaling (slope ≈ 1.0), demonstrating anisotropic sensitivity. (b) Phase rigidity of the eigenmodes of $\mathbf{A}$ as a function of $\delta\phi$ for the same two perturbation directions. The rigidity vanishes at the operating point ($\delta\phi = 0$), confirming eigenvector coalescence and thereby the exceptional-point character.

of four individual network links (as indicated in Figure 1), we locate a network configuration that achieves the specified constraints. In this case the system was programmed such that the EP exhibited a linear response to refractive index variations of one specific network link, whereas other perturbations gave rise to the conventional square-root type dependence. To verify the anisotropic nature of the singularity, we compared the perturbations along (i) the specified anisotropic response direction and (ii) a generic direction. As shown in Figure 2(a), the eigenvalue gap exhibits distinct local scalings depending on the perturbation trajectory. Specifically, the purple curve, corresponding to perturbation of the design link, exhibits a linear dependence, while the orange curve, corresponding to a generic perturbation scales as $|\delta\phi|^{1/2}$, thereby demonstrating the desired anisotropy. Furthermore, in Figure 2(b) we observe that the phase rigidity vanishes at the nominal operating point, confirming the coalescence of the eigenvectors of $\mathbf{A}$. This combination of metrics explicitly precludes the possibility that the observed behaviour arises from a diabolic point (DP) type degeneracy, confirming the genuine EP character of the system.

IV. Conclusion

In conclusion, we have presented a passive route to achieve programmable anisotropic EP responses in multiport scattering networks. Our results underscore that unitary scattering at the global device level is fully compatible with realisation of non-Hermitian degeneracies in a measured subspace. Moreover, we have demonstrated that phase-only control is sufficient to both place and shape the EP response in parameter space. This architecture is particularly relevant for reconfigurable metamaterial and photonic network platforms where phase shifters are easily realisable.

***Abstract*— This work investigates the room-temperature temporal coherence properties of a solid-state plasmonic nanolaser made of a hexagonal array of tapered aluminum nanocones coupled to a dye-doped polymer film. The device shows exceptionally long coherence, with a measured coherence time of ~30 ps and a corresponding coherence length of ~8.8 mm.**

***Keywords*— plasmonic lattice lasers, nanoarrays, temporal coherence.**

I. Introduction

In recent years, plasmonic lattice lasers have emerged as a promising platform, drawing growing interest for their potential as compact, coherent light sources integrated at the nanoscale [1]. In these systems, lasing emerges from the interaction between a gain medium and the collective modes supported by periodic arrays of plasmonic nanostructures, namely surface lattice resonances (SLRs). Extensive studies have examined the lasing behavior of these devices by analyzing key parameters such as lasing threshold, temporal dynamics, emission polarization, and the influence of structural disorder [2]. Coherence is a defining feature of lasers, yet at present only a limited number of studies have investigated the coherence properties of plasmonic nanolasers. In the present work, we experimentally investigated the lasing emission properties in the visible range and at room temperature of a fully solid-state plasmonic array nanolaser consisting of a hexagonal array of Al nanocones coupled to a dye-doped polymeric film [3]. The temporal coherence properties of the lasing mode are characterized by interference measurements.

II. Methods

The plasmonic lattice laser consists of a hexagonal array of tapered aluminum nanocones (a_0 = 475 nm) coupled with an organic dye (Lumogen Red 305) in a 300 nm-thick PMMA matrix. Lasing emission is optically excited at 532 nm by pumping with a picosecond laser and is characterized by a wavevector-resolved photoluminescence (PL) setup as a function of the excitation fluence. Room temperature PL spectra are recorded by an optical fiber-coupled spectrometer (Ocean Optics HR4000). Temporal coherence measurements of the lasing emission are performed with a tilted-mirror Michelson interferometer [4].

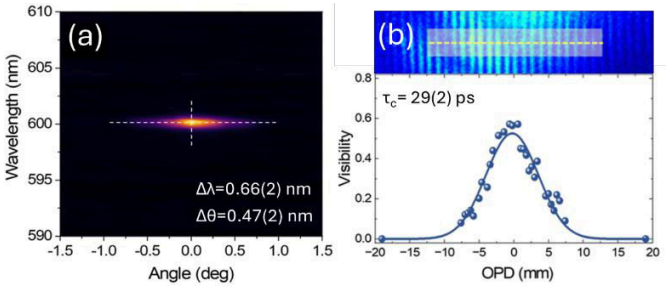

Fig. 1 (a) Map of the lasing emission. (b) Top: interference image at the optical path difference OPD = 1.8 mm; bottom: visibility as a function of the OPD.

III. Results and Discussion

Efficient mono-modal lasing emission at λ_{em} = 600 nm was measured at the Γ-point by pumping at the incidence angle θ_{exc} = 18.1°. This corresponds to the (1,0) Rayleigh anomaly of the nanoarray, which enables optimal in-plane coupling and confinement of the pumping field within the PMMA layer, resulting in the highest excitation energy density in the active layer volume. The lasing threshold results F_{th} = 0.51 ± 0.02 mJ/cm^2 and, above threshold, the emission has a spectral bandwidth (limited by the spectral resolution of the spectrometer) $\Delta\lambda$ = 0.66 ± 0.02 nm and an angular divergence $\Delta\theta$ = 0.47 ± 0.02 deg (Fig 1a). The lasing mode exhibits an ultralong temporal coherence (Fig. 1b), with a coherence time of τ_c = 29 ± 2 ps, (corresponding to a coherence length of L_c = 8.8 ± 0.5 mm and to an actual spectral line width of 0.04 nm). Such a long coherence can be related to a reduced scattering dephasing by the nanoparticles promoted by high Q-factor modes in the nanoarray and by the small thickness of the active layer, both of which contribute to the coherent feedback throughout the entire nanoarray.

IV. Conclusion

We have investigated the room temperature lasing emission properties of a solid-state plasmonic lattice laser, consisting of

a hexagonal array of Al nanocones coupled with a dye-doped polymeric layer. A record-long temporal coherence of the lasing mode was measured, which exceeds the state-of-the-art values reported for plasmonic lattice nanolasers by more than an order of magnitude, highlighting the remarkable potential of this system for the development of coherent nanoscale sources operating at room temperature.

We theoretically study [1] the optical response of a coherently driven periodic lattice of quantum emitters. Unlike lattices of classical resonators, we find that a resonant plane wave can populate excitonic Bloch states with parallel wavevectors different from that of the incident field, including states lying outside the light cone.

***Keywords*—quantum emitters, nonlinearities, subradiant states.**

Recently, advances in the creation and manipulation of quantum emitter (QE) ensembles [2] have sparked an intense research into the optical response of these systems. Many studies have focused on the single excitation limit, which allows for a linearization of the emitters. Within this approximation, it has been shown that QE lattices and metasurfaces can implement strong magnetic responses or deeply subradiant modes. In our work, we go beyond the single excitation limit, revealing the impact of quantum nonlinearities in the optical response of coherently driven QE lattices by a laser. We find that, in contrast to the classical (bosonic) case, the incident plane wave populates not only the excitonic Bloch states with the same parallel wavevector as the driving laser, but a continuum of states with different parallel wavevectors, including those lying outside the light cone. Therefore, we provide an alternative approach to excite subradiant states in atomic arrays, which currently rely on more complicated mechanisms [3]. Moreover, for periods approaching the driving wavelength, the emitter lattice enters in a bistable regime due to the renormalization of the driving rate [4]. We show how this bistable behavior enables the selective activation and deactivation of the optical quantum nonlinearities of the system.

***Abstract*—We propose and experimentally demonstrate an orbital angular momentum nanolaser array arranged in a ring geometry on an InP-based photonic crystal membrane. Our approach leverages exceptional-point singularities with net phase circulation. These results demonstrate a robust and scalable strategy for engineering compact, phase-locked laser arrays with controllable angular momentum output.**

***Keywords*— nanolasers, non-Hermitian photonics, photonic crystals.**

I. Introduction

Thanks to the increasing flexibility of parameter tuning in photonic designs, micro and nanophotonic coupled cavity arrays —such as coupled micropillars, microrings and photonic crystal nanocavities— are ideal platforms to investigate topological photonics [1, 2]. Symmetry and/or topologically protected modes may arise in such lattices, which prove robust against some kind of disorder. Importantly, III-V semiconductor materials enable non-zero imaginary parts of the electrical susceptibility, leveraging active —e.g. lasing— regimes, and also nonlinear and non-Hermitian operation in the form of gain/loss spatial modulations.

In the context of topological lasers [2,3], devices able to generate vortex beams from modes with nonzero orbital angular momentum (OAM) have attracted considerable attention. In Ref. [4] a six-coupled micropillar laser in a ring with uniform couplings —or photonic "benzene" molecule— has been utilized to generate non-zero OAM laser beams. In this case, the pump is uniformly distributed in the system, therefore the ring can be mapped to a Hermitian system in which clockwise (CW) and counter clockwise (CCW) modes are degenerated. This can be seen as a consequence of the eigenmodes of a symmetric real matrix: these can always be rescaled to be purely real functions, i.e. standing waves. Hence, chiral modes $e^{im\pi}$, where m is an integer, are linear superpositions of pairwise degenerated standing waves. In Ref. [4] mode selection is realized using pump beams with circularly polarized light (nonzero spin). Noticeably, pure chiral modes are no longer possible for arbitrary Hermitian couplings because degeneracies become lifted in general. In such a case, (non-Hermitian) gain/loss distributions can restore OAM. In this work, we show that $e^{im\pi}$ chiral modes and phase singularities can be generated at the exceptional points (EPs) of a four coupled nanolaser ring with alternating couplings and sublattice pump imbalance. Such a nanocavity ring can be seen as a non-Hermitian version of the Rice-Mele model, where the on-site potentials are originally real.

II. Methods

We first performed finite-element simulations (COMSOL Multiphysics®) to identify chiral EPs (CEPs) in a photonic crystal nanocavity ring (Fig. 1a). The coupled cavity geometry imposes a detuning between the two sublattices: the two cavities featuring gain in Fig. 1a on the top belong to sublattice A (cavity 1, top, and cavity 3, bottom), while the two others belong to sublattice B (cavities 2 and 4 at the left and right sides, respectively), verifying $\omega_A - \omega_B \approx 50$ GHz. Additionally, in order to produce an EP, the couplings between cavities 1 and 2, and cavities 3 and 4 (t_1) is designed to be slightly larger than the one between 1 and 4, and cavities 2 and 3 (t_2), such that $t_1 - t_2 \approx 7$ GHz. In this design, the CEP can be restored provided $\omega_A - \omega_B \approx 2\alpha(t_1 - t_2)$, where α is the Henry parameter of the semiconductor quantum wells ($\alpha \sim 3$), pumping sublattice B with a higher intensity (Fig. 1a, bottom), leading to a CCW chiral mode.

Experiments are implemented on a III-V semiconductor photonic crystal (PhC) platform. PhCs enable extreme device miniaturization and, at the same time, a large control over the system parameters. Here we realize a ring nanocavity array with tailored couplings by employing photonic barrier engineering [5], [6]; furthermore, quantum well (QW) InGaAs/InGaAsP materials provide optical gain that can be locally induced by means of spatial light modulation of the pump beam, eventually leading to the imaginary detunings. We fabricated four coupled PhC nanolasers in an InP suspended membrane (Fig. 1a) and used PhC L3 nanocavities as the building blocks. The leading evanescent coupling takes place along the $\pm 60°$ direction, whereas horizontal and vertical coupling can be neglected, therefore forming a four-coupled nanocavity ring. The different coupling coefficients t_1 and t_2 are designed using a photonic barrier engineering technique, which consists in modifying the size of the nanoholes between the cavities.

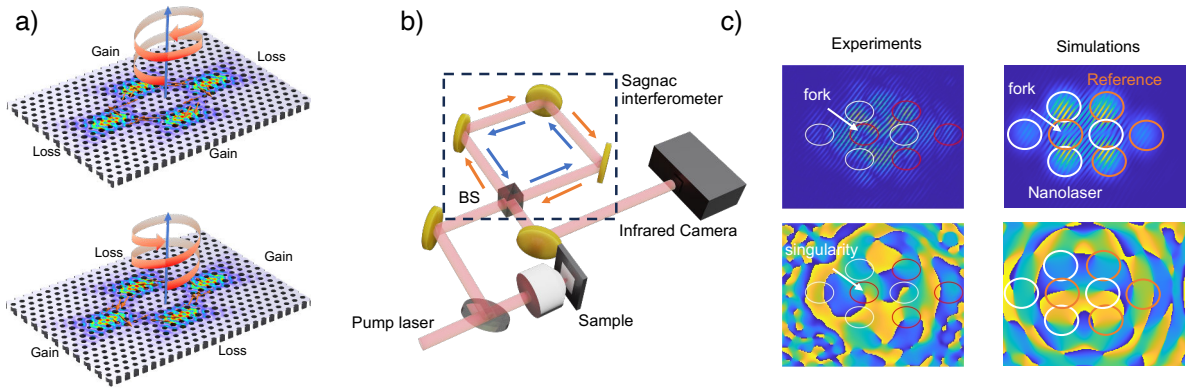

Fig. 1. a) Schematic of the chiral mode operating at the EP in a complex Rice-Mele photonic crystal coupled nanolaser array, with arrows indicating the Poynting vector, under nonuniform (sublattice) pump distribution. (b) Experimental setup for the near-field interference measurements. (c) Near-field interference pattern near the EP (left). The circles mark the positions of the cavities, and a fork-shaped feature appears at the center of the structure. The lower panel shows the corresponding phase distribution, revealing a clear phase singularity. The right panel presents the corresponding simulation results.

III. Results and Discussion

The nonzero OAM in our system is enabled by the consecutive $\pi/2$ phase change along the PhC nanolaser array. This guiding principle is largely model independent, and we only require a tight-binding description of our nanolaser array, where each nanolaser is represented by a lattice site and coupled to its nearest neighbors. Denoting ψ_n, θ_n as the complex light amplitude and its phase at the nth site, it can be demonstrated that the flux $J_{n+1,n}$ from cavity n to its neighbor cavity $n+1$ is maximized when

$$\delta\theta = \theta_{n+1} - \theta_n = \mp\pi/2, \tag{1}$$

where the sign determines the *local* chirality of wave propagation, i.e., whether the flux is in the CW or CCW direction. Furthermore, it can be shown that the dimensionless OAM number is directly related to the optical flux with the normalization $\sum_n |\psi_n|^2 = 1$:

$$\langle L_z \rangle = \frac{1}{2} \sum_n \frac{J_{n+1,n}}{t_{n+1,n}} = \sum_n |\psi_{n+1}\psi_n| \sin\delta\theta. \tag{2}$$

where t_n are the Hermitian couplings in the ring. To achieve a chiral state and a nonzero OAM, we unbalance the pump in the sublattice. With sufficient gain (loss) in the left cavity, we find $\delta\theta = \pi/2$ $(-\pi/2)$ in a non-Hermitian zero mode.

Figure 1(a) shows that two chiral modes with opposite OAM are generated at the EPs by inverting the sublattice pump imbalance. Using both COMSOL and a tight-binding model, we calculated the OAM perpendicular to the PhC $\langle L_z \rangle$ using the near field distribution, and obtained $\langle L_z \rangle \sim 1$ for a sublattice pump imbalance of nearly $r = (P_B - P_A)/(P_B + P_A) \approx 0.5$.

Experimentally, a Sagnac interferometer [Fig. 1(b)] enables robust near-field interference measurements with spatially shifted patterns to determine the phase distribution of these chiral modes. When operated close to the EP, a fork-shaped feature appears at the center of the structure [Fig. 1(c), left panel]. Furthermore, off-diagonal Fourier filtering [4] provides direct evidence of the formation of the phase singularity.

IV. Conclusion

This work presents a flexible approach to achieving nonzero OAM via non-Hermiticity in a coupled semiconductor nanolaser array, potentially benefiting various applications in fields such as optical communications.

***Abstract*— We demonstrate a surface lattice resonance (SLR)-based plasmonic nanolaser that leverages the bulk production of colloidal nanoparticles and their organization via template-assisted assembly. Unlike conventional top-down fabrication methods, this approach utilizes monocrystalline silver nanocubes to reduce absorptive losses associated with grain boundaries. Using capillary-assisted particle assembly, we created periodic arrays of silver nanocubes that support high-quality SLRs. Furthermore, utilizing transient absorption spectroscopy, we discuss the impact of ultrafast photophysical processes on these systems. Specifically, we analyze how coherent optomechanical vibrations of the nanocubes modulate the localized surface plasmon resonance (LSPR) and, consequently, the lattice resonance on picosecond timescales. When combined with the gain medium Pyrromethene-597, these arrays demonstrate lasing at 574 nm with competitive characteristics despite the assembly-related disorder. Our results indicate that eliminating ohmic losses via monocrystallinity is more critical for nanolasing than achieving perfect geometric periodicity, validating low-cost assembly as a superior fabrication route.**

***Keywords*— nanolaser, lattice resonance, self-assembly, plasmonics.**

I. Introduction

Plasmonic metal nanoparticles support localized surface plasmon resonances (LSPRs), which are collective oscillations of conduction electrons. While individual LSPRs often suffer from broad extinction peaks due to radiative damping, arranging these particles into periodic arrays can generate surface lattice resonances (SLRs). SLRs arise from the diffractive coupling between neighbors (Rayleigh anomalies) when the scattering spectrum of the constituent particles overlaps it. This hybridization results in high quality factors (Q-factors) and delocalized electromagnetic fields. These properties make SLRs good candidates for feedback mechanisms in nanoscale coherent light sources.[1]

However, a significant challenge in the field has been the fabrication of these arrays. Most SLR-based nanolasers are produced using top-down techniques like electron-beam lithography and physical vapor deposition. These methods result in polycrystalline nanoparticles with rough facets and grain boundaries, leading to diminished scattering properties and increased absorptive losses compared to theoretical models. To address this, we propose the use of chemically synthesized colloidal nanoparticles. Colloidal synthesis yields monocrystalline particles with smooth facets, offering superior scattering-to-absorbance ratios.[2]

The primary challenge lies in organizing these colloids into the precise geometries required for lasing. By utilizing capillary-force-assisted particle assembly (CAPA), we can achieve single-particle resolution on large scales, bridging the gap between high-quality colloidal materials and functional nanophotonic devices.[3]

II. Methods

Monodisperse silver nanocubes were synthesized using a modified polyol method, producing single-crystal particles coated with a thin layer of polyvinylpyrrolidone (PVP) surfactant. The assembly templates were fabricated by molding a polydimethylsiloxane (PDMS) replica from a silicon master stamp patterned with periodic pillars. This soft-lithography approach allows for the repeated reproduction of templates without continuous reliance on expensive lithography steps.

The assembly was performed using a custom setup where a droplet of colloidal solution is confined between the PDMS template and a glass slide. Dimethylformamide (DMF) was selected as the solvent because it acts as a theta-solvent for the PVP coating, preventing aggregation and ensuring the particles behave as hard spheres. By controlling the temperature and the translation speed of the meniscus across the template, convective currents and capillary forces trap individual nanocubes into the template voids. This method achieved high yield (>99%) over areas larger than 1 cm².

Transient absorption spectroscopy (TAS) was employed to probe the ultrafast dynamics of the nanocrystal lattices, using a variable pump-probe delay to monitor the evolution of the plasmonic response. For the nanolaser device, assembled Ag nanocube arrays (periodicity Λ = 400 nm) were soaked in a solution of Pyrromethene-597 (P597) dye. P597 was selected for its high quantum yield and spectral overlap with the lattice resonance. The device was pumped with a 515 nm femtosecond pulsed laser (270 fs pulses, 50 Hz) to drive the gain medium.

III. Results and Discussion

The fabricated nanolaser device was designed such that the lattice periodicity (400 nm) in the PDMS environment (n = 1.42) created a flat band at the Γ point near 562 nm, overlapping with the emission of the P597 dye. Upon optical pumping, the device exhibited clear lasing behavior. We observed a nonlinear increase in emission intensity with a distinct threshold at approximately 80 μJ/cm^{-2}. This transition was accompanied by a dramatic spectral narrowing, where the emission linewidth collapsed from ~45 nm (spontaneous emission) to <1.2 nm above the threshold (limited by spectrograph resolution).

The emitted beam profile displayed a fan-like pattern characteristic of 1D distributed feedback lasers, suggesting that the 2D array functions as a collection of 1D feedback channels aligned with the lattice directions. The emission was linearly polarized, following the resonator geometry. Crucially, the superior scattering-to-absorbance ratio of the monocrystalline silver compensates for the minor positional disorder inherent to self-assembly. We demonstrate that perfect periodic order is less critical for low-threshold lasing than the elimination of grain-boundary losses found in top-down fabricated structures.[4]

While the static design of the lattice is critical for lasing, the ultrafast dynamics of the gain and the resonator also play a vital role. Nanoparticles are not static structures; following photon absorption, they undergo rapid heating and expansion via electron-phonon coupling, exciting coherent optomechanical breathing modes. Transient absorption spectroscopy (TAS) of our arrays reveals that silver nanocubes support two primary breathing modes: a tip mode (approx. 27 GHz) involving deformation of the corners, and a face mode (approx. 38 GHz) involving the facets. These vibrational modes dynamically alter the shape of the nanocubes on picosecond timescales. Because the SLR depends on the spectral overlap between the localized surface plasmon resonance (LSPR) and the Rayleigh anomaly, modulations in the particle shape—which shift the LSPR—consequently modulate the SLR.[5]

Our analysis shows that these optomechanical modes cause the SLR to oscillate and transiently red-shift. In the context of a nanolaser, where the feedback mechanism relies on a precise spectral match between the gain bandwidth and the high-Q lattice mode, these ultrafast fluctuations are non-negligible. While this does not prevent lasing, it introduces a dynamic detuning between the gain medium and the cavity mode, potentially broadening the linewidth or destabilizing the output intensity during long-pulse operation. Specifically, the modulation depth is sufficient to alter the optical density of the array. This suggests that future designs of SLR-based active devices must account for these optomechanical effects, particularly for applications requiring ultrafast switching or high-stability pulsed emission.

IV. Conclusion

We have successfully demonstrated a scalable, cost-effective route to fabricating plasmonic nanolasers using template-assisted colloidal assembly. The resulting devices utilize monocrystalline silver nanocubes to achieve low-threshold lasing with high coherence, challenging the necessity of perfectly ordered, lithographically produced lattices. Furthermore, we highlight that the stability and performance of such devices are intricately linked to the intrinsic optomechanical vibrations of the constituent nanoparticles. By understanding the interplay between the mechanical breathing modes of the nanocubes and the photonic modes of the lattice, we can better design robust plasmonic devices for applications in on-chip optical communications and sensing.

***Abstract*—Photonic topological insulators that exploit topological defects of disclinations provide a robust solution for light manipulation to form compact optical vortices and on-chip integration with reduced scattering loss and energy consumption. In this work, we demonstrate wavelength-scale, low-threshold, vortex and anti-vortex nanolasers in an optical cavity formed by a topological disclination. Various photonic disclination cavities are designed and analyzed using the similarities between tight-binding models and optical simulations. Unique resonant modes are strongly confined in these cavities, which exhibit wavelength-scale mode volumes and retain topological charges in the disclination geometries. In the experiment, the optical vortices of the lasing modes are clearly identified by measuring polarization-resolved images, Stokes parameters and self-interference patterns. Specifically, we measure topological charges of 1 and 2 in C_5 and C_6 disclination cavities, respectively. This work paves the way for the application of advanced nanophotonic devices in laser technology and high-precision optical communications.**

***Keywords*—Nanolaser, disclination, topological charge, optical vortex**

I. Introduction

Optical vortices [1, 2], which manifest as singularities in either the phase or polarization of light, are categorized as phase vortices and polarization vortices, respectively. Phase vortex beams, characterized by their helical wavefronts and orbital angular momentum (OAM), have found widespread application in fields like optical trapping, tweezers, spanners, and high-resolution microscopy. Their ability makes them valuable in quantum information technologies, where precise OAM control supports innovative quantum computing strategies. Recent developments have realized vortex microlasers through novel microstructures, including microring resonators and spiral nanostructures.

Polarization vortex beams, defined by spatially varying polarization states, are employed to manipulate atomic spin and light polarization, aiding in the development of hybrid quantum memories that store both polarization and OAM information. These beams also contribute to secure and high-capacity communication systems through quantum encryption. Meanwhile, topological photonics offers a robust platform for guiding and confining light, with topological photonic insulators enabling disorder-resistant waveguides and lasers. By exploiting topological defects, researchers can generate novel optical vortex states and engineer light-matter interactions that lead to compact, efficient photonic devices.

Developing compact vortex lasers involves several fundamental challenges, including achieving strong optical confinement within wavelength-scale cavities, minimizing scattering losses, and lowering the lasing threshold. Conventional approaches for generating optical vortices, such as spiral phase plates and metasurfaces, are inherently bulky and unsuitable for chip-scale integration. As device sizes are further reduced, these issues become more critical, threatening both performance and reliability. Ensuring that vortex modes remain robust under varying environmental and operational conditions—and making them compatible with existing photonic platforms—is essential for real-world implementation.

Although considerable progress has been made in the design and nanofabrication of photonic devices, a major bottleneck in realizing highly compact and efficient vortex lasers lies in the lack of mechanisms that allow for strong light confinement without degrading the vortex nature of the modes. Current designs often depend on iterative, trial-and-error approaches that require tuning of cavity geometry and material parameters to achieve desired performance. Moreover, achieving versatile and precise control over vortex properties such as OAM, wavelength, and spatial distribution remains a major challenge. Managing multiple singularities simultaneously and tuning them flexibly calls for advanced material platforms and design strategies beyond what conventional photonic architectures can provide.

II. Results

In response to the above challenges, a promising new strategy based on the concept of photonic disclination cavities has been introduced [3]. Drawing inspiration from topological defects in structured matter, this approach enables the formation of ultra-compact optical cavities capable of generating and confining vortex modes with well-defined topological properties. Specifically, the design mimics atomic disclinations by replacing lattice sites with air holes in a photonic crystal structure, allowing electromagnetic modes to localize in the disclination core. By applying tight-binding (TB) theory—particularly the 2D Su–Schrieffer–Heeger (SSH) model—researchers can identify interface states of higher-order topological insulators (HOTIs) and map them to optical analogues. A bulk lattice with C4 symmetry can be transformed into a C_5 disclination cavity, featuring tunable intra-cell, inter-cell, and next-nearest-neighbor couplings. The TB model solutions reveal spatially confined resonant modes whose topological characteristics inform the design of the actual photonic cavity. Comparing the tight-binding charge distributions with the electromagnetic field profiles in full-wave optical simulations helps optimize these cavities for strong confinement and desired vortex characteristics.

Experimentally, nanolasers based on C_5-symmetric photonic disclination cavities have been demonstrated, successfully generating vortex and anti-vortex modes with topological charges of ±1 [3]. These lasers operate under room-temperature optical pumping and display hallmark lasing features, such as sharp spectral peaks and super-linear intensity increase beyond the threshold. The threshold pump power was notably low—an order of magnitude smaller than prior vortex laser demonstrations—thanks to the effective confinement and symmetry-engineered mode structure. Polarization-resolved imaging further confirms the unique vortex characteristics of the emitted light. Without a polarizer, the far-field patterns appear doughnut-shaped, while inserting a polarizer reveals azimuthal and hybrid polarization states, depending on whether the cavity structure is expanded or shrunken.

Furthermore, we successfully demonstrated a wavelength-scale photonic disclination nanolaser with a topological charge of 2 [4]. A C_6 disclination structure formed by the Volterra's process supports a variety of bound states with angular momenta of 0, 1, 2, and 3, and the energy levels of these in-gap states can be tuned by adjusting the position of the atoms in the core region and the coupling strength. In the photonic disclination cavity corresponding to this TB model, a vortex mode with a topological charge of 2 was excited, and by adjusting the position of the air holes in the core region, only this single mode was located inside the photonic band gap, resulting in a relatively high Q and a small mode volume on the wavelength scale. The designed cavity was experimentally fabricated, and clear lasing action was measured. In particular, the polarization-resolved mode images showed excellent agreement between calculation and measurement: when the polarization direction rotates twice, the mode image rotates once, indicating a winding number of 2.

III. Conclusion

The disclination-based design framework offers a robust path forward for overcoming longstanding obstacles in vortex nanolaser development. It enables the realization of stable, low-threshold, and highly compact OAM light sources that are suitable for integration into photonic chips. Ultimately, this advancement opens the door to scalable on-chip implementations of vortex-based devices, potentially transforming high-bandwidth optical communications through enhanced data transmission rates and improved compatibility with modern photonic infrastructure.

Optical Response of Active Plasmonic Nanoshells with Retardation and Gain Saturation Effects

Luis Cerdán[1,*]

[1]Instituto de Química Física "Blas Cabrera", Consejo Superior de Investigaciones Científicas, Spain
*Corresponding author: l.cerdan@csic.es

***Abstract*—In this communication, we report a semianalytical model to analyze plasmonic nanoshells with gain including retardation (radiative and dynamic depolarization corrections), that is valid for any strength of the pump and probe fields. We analyze the retardation effects on both in its laser performance and its nonlinear optical response.**

***Keywords*— plasmonics, spasers, nanolasers, Mie resonances, simulation.**

I. Introduction

The incorporation of optical gain into metallic nanostructures not only mitigates their inherent nonradiative losses, but also enables the development of active nanophotonic devices with enhanced optical responses, suitable for advanced sensing and nanoscale light-emission applications [1]. However, a rigorous theoretical description of these systems remains challenging. Their complexity often forces researchers to adopt simplified gain models –whose range of validity is not always clear– or to rely on fully numerical approaches, which may obscure the underlying physical mechanisms. Most semianalytical treatments of the laser and optical response of active nanoparticles or core-shell structures rely on the quasistatic (QS) approximation [2,3], implicitly neglecting retardation effects such as radiative damping and dynamic depolarization. Yet spasers (plasmonic nanolasers) are inherently radiative systems, and this approximation can therefore constitute an excessive oversimplification.

To address this issue from first principles, we have developed an intuitive yet accurate semianalytical model that replicates the dipolar Mie response, incorporating both radiative and depolarization corrections, as well as the inherently nonlinear behavior of the gain medium. This framework allows us to analyze the optical and lasing characteristics of small-to-medium active metallic nanoshells under arbitrary pump and probe strengths, and to quantitatively assess the limits of validity of the quasistatic approximation.

II. Methods

The system under study consists of a spherical nanoshell with a radius a and inner-to-outter radii ratio ρ embedded in a dielectric medium (Fig. 1a). The nanoshell has a plasmonic nature arising from the presence of a metallic shell and an active character resulting from a dielectric core doped with a gain medium. We consider the nanoshell to be incoherently excited by a pump field with rate $\mathcal{P}$ and analyze its optical responses with a probe field of amplitude E_0 and frequency ω. To study the response of the active nanoshell, we resort to a conventional time-domain approach to capture the nonlinear nature of the gain and then look for the steady-state (SS) solutions. There are two contributions to the total polarization of the active nanoshell: one from the polarization of the free electrons and another from the gain medium. The dynamics of the former is described by a modified Drude model with plasma frequency ω_{m} and non-radiative damping $2\Gamma_{\mathrm{m}}$. This model incorporates second and third derivatives to account for dynamic depolarization and radiative damping corrections [4], respectively, which allow us to obtain an exact dipolar Mie-like response. To model the gain medium, we assume a conventional 4-level system (Fig. 1a), whose polarizability is described with a forced Lorentz oscillator with frequency ω_{g} and linewidth $2\Gamma_{\mathrm{g}}$ [2]. By virtue of the small size of the nanoshell, the fields and polarizations inside its different regions are analytical [3]. Under these conditions, and assuming a continuous wave excitation, the time harmonic dependency can be removed, and a SS solution can be found. The resulting system of coupled equations, that correlates the metallic and gain polarizations with the population inversion (gain) and the parameters accounting for radiative damping and depolarization effects, can be readily solved by converting it into a multidimensional root-finding problem similar to the one reported in [2].

III. Results and Discussion

The optical response of the active nanoshell under probe excitation is fully characterized by its polarizability, α, which in the far field is directly reflected in the extinction cross section, σ_{ext}. Figure 1b shows σ_{ext} for an active silver nanoshell pumped at a rate $\mathcal{P}$ just below threshold, $\mathcal{P}_{\mathrm{th}}$, as computed either with the QS model adapted from Ref. [3] (left) or with our Mie-based approach (right), for different probe field amplitudes E_0. In the small-signal regime, where the probe is too weak to significantly deplete the excited-state population, both models predict progressive narrowing of the plasmon linewidth and up to a 40-fold enhancement of the peak extinction relative to the passive case (gray dashed curves). These effects, consistent with previous observations [2,3], arise from the reduction of metallic nonradiative losses produced by the gain medium. However, the QS model predicts a more energetic resonance and a narrower, higher peak than the Mie

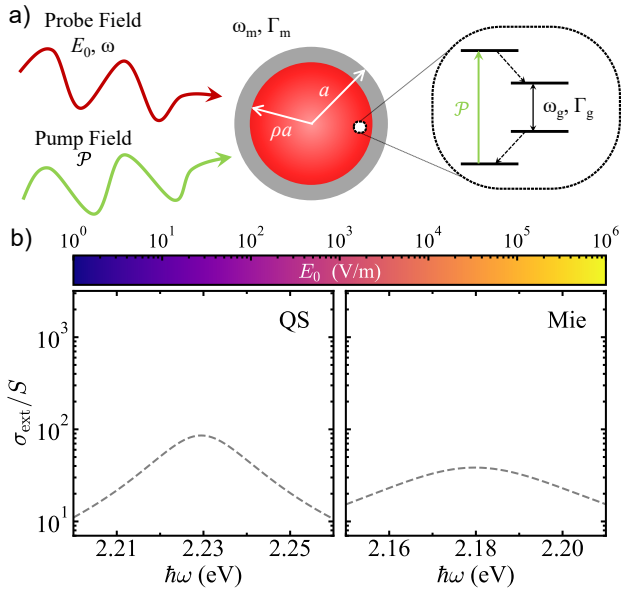

Fig. 1. (a) Schematics of the system under consideration, consisting of a silver nanoshell of $a = 20$ nm and $\rho = 0.8$ with a dielectric core doped with a gain medium described by a 4-level energy diagram. (b) Extinction cross-section normalized by the nanoparticle geometric cross-sectional area $S = 4\pi a^2$ of an active (solid coloured curves) and a passive (dashed gray curves) nanoshell as a function of the probe field frequency, ω, for different values of the probe field amplitude, E_0 (see the colour bar), for a quasi-static model (left panel) and that computed with our methodology (right panel). In both cases, the gain frequency ω_g is tuned to the passive nanoshell resonance and the pump rate is $\mathcal{P} = 0.95\mathcal{P}_{\rm th}$, with $\mathcal{P}_{\rm th}$ the threshold pump rate.

model. This discrepancy is expected: dynamic depolarization shifts the plasmon resonance to lower frequencies, while radiative corrections increase the total damping, both of which reduce the achievable response. Importantly, even for such a small nanoshell, retardation effects already produce substantial deviations from the QS prediction. This highlights important limitations of the QS approximation and highlights the need to incorporate these corrections, especially when modeling lasing behavior.

The response of active nanoshells changes drastically when the probe-field amplitude exceeds the small-signal regime. As E_0 increases, the polarization of both the free electrons and the gain medium grows accordingly. This enhanced polarization accelerates the depletion of the upper laser level, reducing the population inversion and therefore diminishing the effective gain. As shown in Fig. 1b, both models predict that the plasmonic resonance broadens and the overall magnitude of $\sigma_{\rm ext}$ decreases as the probe-field amplitude becomes larger. In fact, for $E_0 \geq 10^5$ V/m, the extinction cross section of the active nanoshell becomes indistinguishable from that of the passive system, irrespective of the pump level. This behavior is fully consistent with gain saturation, originating from the intrinsic nonlinear response of the gain medium and the depletion of the population inversion induced by the probe field [2].

IV. Conclusion

In summary, we have developed an intuitive yet accurate semianalytical model that combines the semiclassical laser equations for a four-level gain medium with the fully retarded electromagnetic response of a nanoshell. We have verified that, under weak probe excitation, the optical response of an active plasmonic nanoparticle is strongly enhanced as the pump rate approaches threshold. However, the QS approximation systematically predicts narrower resonances and larger enhancements than our Mie-based model, highlighting the importance of including retardation effects. Furthermore, both approaches reveal that increasing the probe-field strength leads to saturation behavior that progressively suppresses the influence of the gain, rendering the nanoshell effectively passive regardless of the pump level. These results highlight the need to account for both retardation and saturation effects when modeling loss-compensated or gain-assisted plasmonic systems, from both theoretical and practical perspectives.

***Abstract*— Control of light-matter interaction is demonstrated in 3D arrays of nanoresonators (i) filled with, (ii) randomly arranged and embedded into, (iii) composing multilayer complex metamaterials and coated by appropriate gain medium. Spectral engineering of passive nanoresonator configurations and optimization of dye-concentration – pump-E-field parameters enables to tailor complete lasing characteristics.**

***Keywords*— nanoresonator arrays, metamaterials, lasing, spasing, optimization.**

I. Introduction

Active plasmonic metamaterials are intriguing quantum optical systems with inherently large degrees of freedom in amplification, lasing and spasing [1]. Exploration of the key nanophotonical phenomena enables to control near-field modes and far-field characteristics [2], while exploitation of critical parameter regions opens novel avenues in light-matter interactions [3]. In our previous steady-state and time-domain studies distinctly different operation regions were demonstrated for various plasmonic active nanoresonators [4] and the dynamics of energy deposition and near-field enhancement (NFE) in random plasmonic nanoantenna arrays was controlled via distribution and pump-parameters [5].

II. Methods

The method of plasmonic spectral engineering was generalized, and the active medium and illumination parameters were added to the configuration optimization realized with GLOBAL algorithm implemented into COMSOL Multiphysics software. First the passive nanoresonators were tuned to enhance lasing, thereafter the coupled Maxwell and rate equations were solved numerically in pump-and-probe scheme, and the active metamaterial was evaluated via retrieval method. In steady-state computation the active metamaterial responses were mapped above the dye-concentration and E_{pump}-field strength parameter plane, in addition the time-domain response was also inspected to uncover the nanophotonical phenomena. Parameter regions resulting in (i and ii) large and uniform NFE, (ii) as well as uniform phase distribution and epsilon-near-zero (ENZ) characteristic, (iii) enhanced and direction specifically polarized emission, were determined.

III. Results and Discussion

Hybridization of plasmonic resonances on multilayers of spherical nanoresonators results in multiple peaks, a broader (narrower) one is capable of resulting in homogeneous field inside core (dipolar distribution on outer layer), with maximal NFE~50. It is possible to enter into spasing operation region at smaller pump through large concentration region. When a quad-layer is created from periodic nanoresonator patterns, similar NFE with good FOM=NFE/δ_{NFE} is achievable at perpendicular incidence, but tilting enables to reach even larger NFE values. Optimization of quad-layers constructed with sub-wavelength patterns of spherical nanoresonators with gain-metal-dielectric core-shell composition using ENZ operation as objective function allows for achieving NFE~10 uniformly at small tilting.

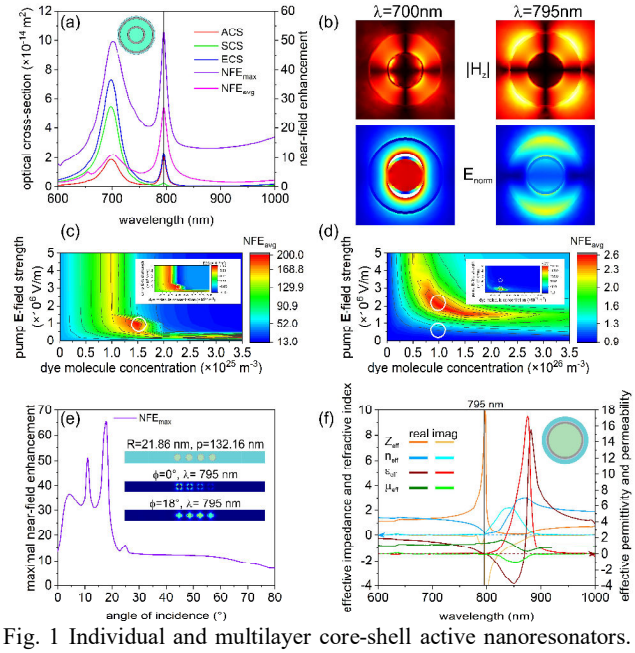

Fig. 1 Individual and multilayer core-shell active nanoresonators. (a, b) Optical cross-sections and NFE of a multishell; (c, d) maps of NFE_{avg} and ECS (FOM) of individual (periodic) multishell; (d, e) NFE and effective properties of active ENZ-like core-shell quad-layers.

Plasmonic nanoantennas of different, e.g triangular, shapes distributed even randomly, enable to enhance the NFE, absorbed power (PL) and deposited energy (E), when the target is illuminated with counter-propagating laser pulses (120 fs, 795 nm). Besides the nanoantennas number density distribution which was pre-optimized in passive targets, dye concentration distribution was also adjusted in active targets, while the average concentration corresponded to the maximum in NFE map. Active targets turned to be better in the standard deviation of the monitored quantities (δNFE, δPL, δE), moreover allowed to reach larger $FOM_x = X/\delta_X$. Also the temporal dynamics was different, namely the minimal standard deviation /it's delay compared to pulses overlap, was smaller compared to the passive target for NFE/E&PL in case of silver triangles.

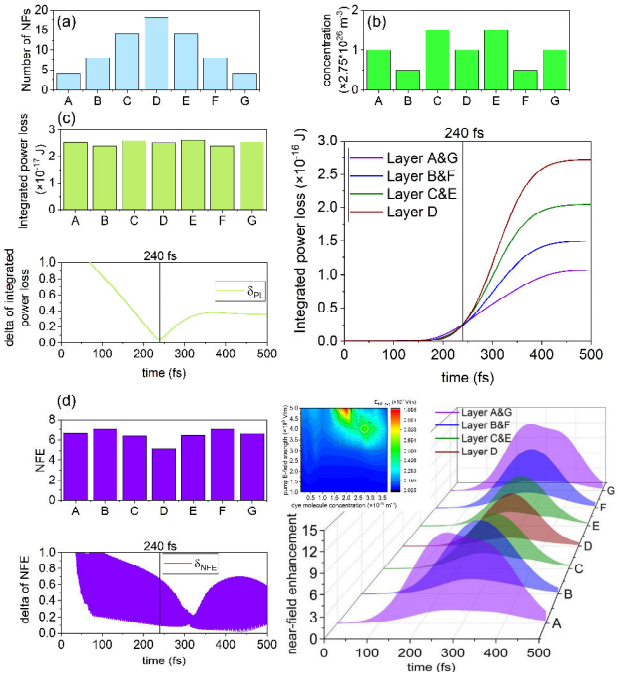

Fig. 2 Silver triangular nanoantenna seeded active targets, 120 fs pulsed illumination. (a, b) Number density and dye concentration distribution; (c, d) Power loss and NFE distribution with the temporal evolution of quantities and their standard deviations in different layers.

Tri-layers of complex patterns constructed with Babinet complementary miniarrays allows for asymmetric transmission (AT) due to bianisotropy. However, the achievable AT is limited by the loss in the layers of convex-concave-convex plasmonic components, therefore an active layer was positioned in close proximity of the multilayer to ensure gain. Appropriate spacing and layer thickness of the active medium, as well as E_{pump} and concentration parameters enable two /one order of magnitude enhancement of AT computed in the mixed bases corresponding the Generalized Faraday Rotation (GFR), in case of the inspected Pattern-I/II. GFR occurs, when nonreciprocal rotation approximates 90° in propagation direction dependent azimuthal orientations, while the forward leaving polarization is entering in backward direction. The ellipticity of emitted light polarization is slightly increased /decreased in forward /backward direction in both inspected multilayers.

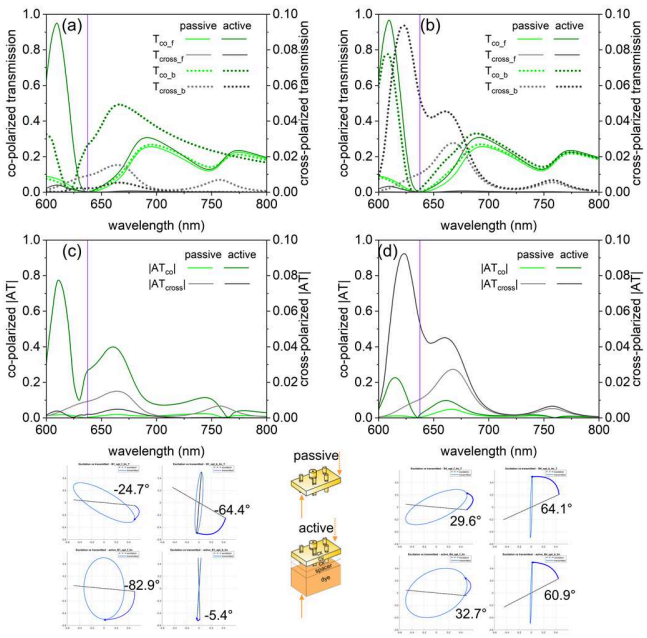

Fig. 3 Tri-layers of Babinet complementary (convex, concave-convex) patterns in GFR configuration with loss compensation and enhanced AT. (a, c) Pattern-I, (b, d) Pattern-II, with transmission and AT in mixed bases as well as entering and leaving polarization ellipses in forward and backward propagation directions.

IV. Conclusion

Optimized active plasmonic metamaterial configurations were demonstrated with potential to achieve resonant gain phenomenon, ENZ medium, uniform and enhanced energy deposition and improved NFE, as well as more efficient unidirectional enhanced optical signal transfer.

***Abstract*—We propose a design for a linear polarizable laser in the visible wavelength range. Consisting of a TiO_2 metasurface with a pronounced quasi-bound state in the continuum (qBIC) and utilising high quantum yield colloidal quantum dots as a gain material.**

***Keywords*— Dielectric metasurface, Quasi-Bound States in Continuum, Laser, TiO_2, Enhanced light-matter interaction.**

I. Introduction

Dielectric metasurfaces, engineered to manipulate light primarily by controlling the phase and amplitude of the scattered light have garnered significant interest in recent years, particularly because they can support quasi-Bound States in the Continuum (qBIC-modes) [1]. This resonance can be either created by breaking the inversion symmetry in the unit cell of the metasurface or by breaking the symmetry with the incoming or outgoing light. The qBIC has really high Q-factors and is therefore a perfect candidate to build 2D-lasing devices. Most qBIC lasers used dyes [2] as the gain material, with pervoskites [3] also being used. Both gain materials lag in photostability and tunability. Therefore, quantum dots with high quantum yields are the material of choice. has been tuned to have the qBIC resonance at 655 nm, corresponding to the emission wavelength of the quantum dots.

II. Design and Fabrication

A tilted ellipse metasurface [4] has been tuned to have the qBIC resonance at 655 nm corresponding to the emission wavelength of the quantum dots. A direct etch process produces the 50 µm×50 µm metasurface. The mode verification is done via a normal transmission measurement. Afterwards, the colloidal quantum dots are spin-coated onto the metasurface and photoluminescence and the interaction between the emitters and the cavity are investigated.

A high quality 120 nm thick TiO_2 layer is deposited on a SiO_2 using low-pressure chemical vapour deposition (LPCVD). Ellipsometry measurements have confirmed insignificant optical losses in the visible wavelength range between 400 and 800 nm. With the height fixed due to fabrication processes, this leaves three design parameters: the periodicity a and the length of the long (r_l) and short axes (r_s) of the ellipses. The dependencies of the transmission on these can be found in the figure 1 (a-c). Further, the dependence on the asymmetry parameter, the tilting angle θ, and the scaling behaviour s and the polarisation dependency of the angle φ are also shown in figure 1 (d-f).

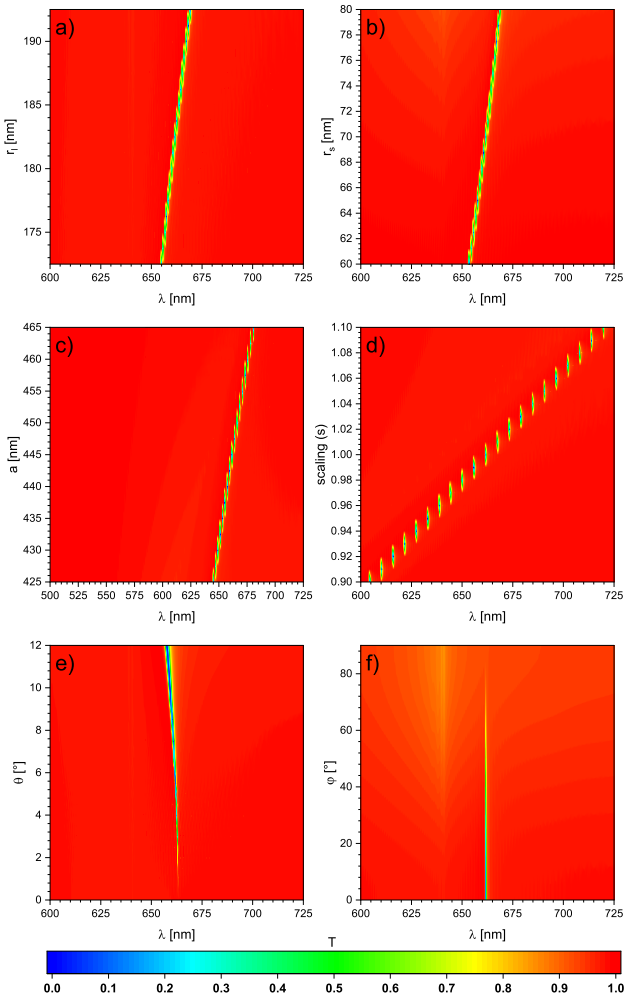

Fig. 1. Simulated transmission spectra for different design parameters. The optimal parameters that are kept constant are a height of $h = 120\,\text{nm}$, a periodicity $a = 445\,\text{nm}$, a short radius of $r_s = 70\,\text{nm}$, a long radius of $r_l = 182.5\,\text{nm}$, a tilting angle of $\theta = 6°$ and a polarization in x-direction with $\varphi = 0°$.

One can generally observe the trend that if one size parameter increase the qBIC mode red shifts. Further, it is noticeable that

there is no other mode for this polarisation spectrally close by. As expected for a qBIC mode, it blue shifts with increasing asymmetry parameter, and the Q factor decreases as it couples more with the continuum.

In addition to the Q factor, the electric field enhancement and its accesibilty, is important for the Purcell factor, which describes the interaction between the gain material and the mode. The electric field enhancement of the qBIC mode is shown in figure 2. The left-hand side shows the enhancement in the x-y plane at z=10 nm, and the right-hand side shows the slice through the centre of the ellipse in the y-z plane. One

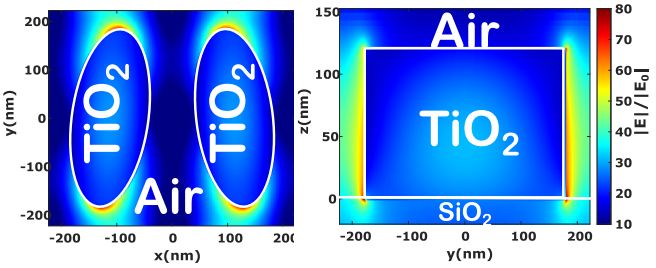

Fig. 2. Electric field enhancement $|E|/|E_0|$ of the qBIC mode on the left in the x-y plane at $z = 10$ nm. On the right-hand side, a cut through the ellipse in the y-z plane is shown.

can see in the field maps an enhancement factor of 80 and that the field is well localised outside the TiO_2 structures. This, in combination with the high Q-factor, makes the tilted ellipse design an ideal candidate for a qBIC lasing device.

To reduce the steps of the top-down fabrication process and achieve higher fidelity structures, no etching hard mask is used, instead the negative resist is used directly as a mask. This eliminates one evaporation step and one lift-off step, leaving the following fabrication procedure:

- Negative resist lithography, utilising a high precision He-ion microscope.
- Reactive ion etching (RIE) of the TiO_2 using the negative resist as a mask.
- Wet chemical removal of the remaining negative resist.

A SEM image of the produced structures can be seen in the inset of figure 4. This shows the high quality of the produced structures achiving high Q-factors up to 700.

III. Experimental evidence

After fabricating the TiO_2 metasurface, normal transmission measurements are performed to characterise the qBIC mode. The polarisation dependent transmission measurements are shown in figure 3 as well as measurements for different tilting angles of the ellipses. The experimental results show the same behaviour as predicted by the simulations. On the one hand, the high extinction of the qBIC mode with the change of polarisation, and on the other hand, the broadening of the qBIC mode with increasing asymmetry parameter. Further, the blue shift with increasing asymmetry parameter can also be observed.

After the spin coating of colloidal quantum dots on the sample,

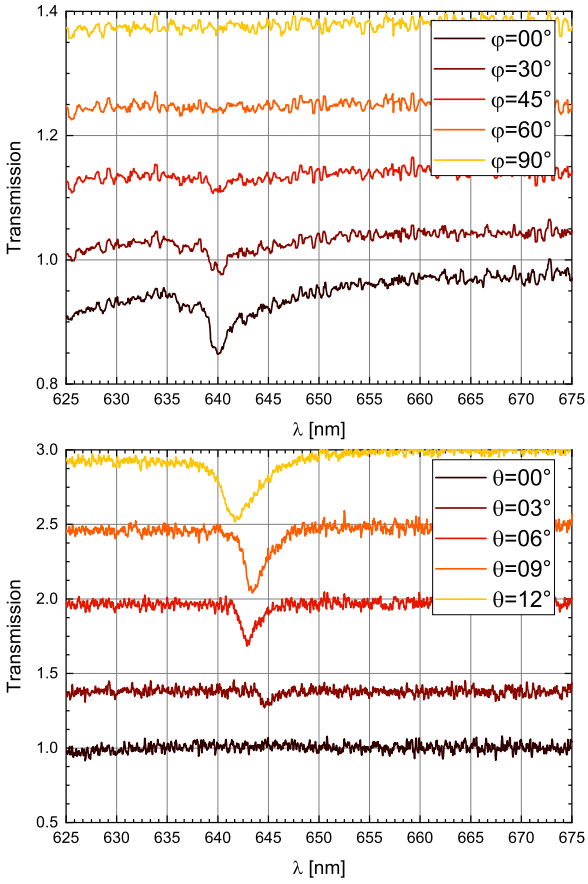

Fig. 3. Normal transmission measurements in dependence on the polarisation of the light displayed in the upper graph. In the bottom graph, the transmission for different tilting angles of the ellipses is shown.

the photoluminescence intensity is measured. This shows a coupling between the emitters and the cavity and is also highly polarised, as can be seen in the figure 4. One can also see that the photoluminescence enhancement aligns perfectly with the qBIC mode. Further lifetime measurements indicate a reduction in emitter lifetime by one nanosecond, indicating the possibility of achieving qBIC lasing with higher pump powers.

IV. Conclusion

We designed an all-dielectric metasurface of TiO_2 supporting a quasi bound sate in the continuum. It is tuned to the QD emission wavelength and the mode properties were investigated using FDTD simulations. With a novel reactive ion etching process using the photoresist directly as a mask, a high Q-factor metasurface is fabricated. Normal transmission measurements confirm the highly polarised qBIC mode and its dependence on the asymmetry parameter. Further, the coupling between colloidal quantum dots and the qBIC mode is observed, paving the way for a low-threshold qBIC lasing device.

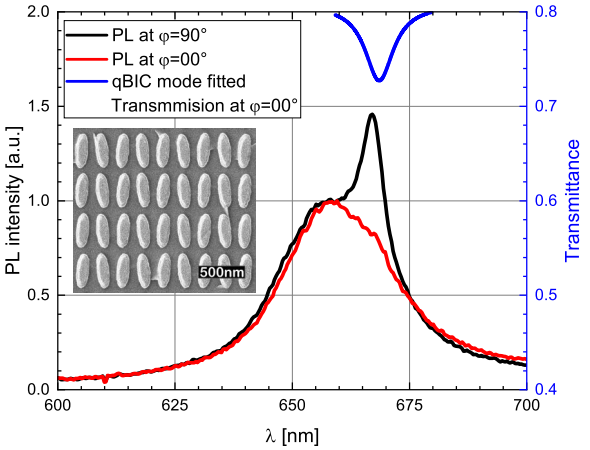

Fig. 4. The polarisation-dependent photoluminescence emitted from the metasurface pumped with a 532 nm continuous wave laser. For reference, the corresponding transmission measurement of the qBIC mode is shown on the right-hand side axis. In the inset, an SEM image of a TiO_2 metasurface is shown, the scale bar corresponds to 500 nm.

***Abstract*— Quantum confined perovskite quantum dots integrated with optical microcavities exhibit remarkable environmental stability and versatile emission behavior at room temperature. We report sustained luminescence in water, temperature dependent excitonic responses, cavity enhanced emission, and strong light matter interactions, establishing a robust platform for nanoscale photonics and stable quantum light emitters.**

***Keywords*— Perovskite quantum dots; optical microcavities; quantum confinement; cavity enhanced emission; light matter interaction.**

I. Introduction

Perovskite quantum dots are promising light-emitting materials because of their high photoluminescence efficiency, strong excitonic effects, and spectral tunability[1-5]. Their practical use in microcavity photonics, however, remains limited by poor environmental stability, particularly under moisture exposure. Spatial confinement in a porous host offers an attractive route to simultaneously improve stability and preserve nanoscale optical properties. In this work, we study quantum-confined perovskite quantum dots embedded in a Metal Organic Framework and integrated with optical microcavities. We highlight their sustained luminescence in water, temperature-dependent excitonic responses, cavity-enhanced emission, and the broader implications of this platform for stable nanophotonic emitters and light-matter interaction studies.

II. Methods

Quantum-confined perovskite quantum dots were prepared within defective UiO-66 hosts through a two-step conversion route[5]. Lead species were first immobilized in the porous framework, and subsequent treatment with a cesium bromide precursor generated the emissive perovskite phase inside the host matrix[5]. The resulting composites were examined by structural and optical characterization to verify confined formation and environmental durability. For photonic studies, the composite was incorporated as the active medium in planar optical microcavities formed by two distributed Bragg reflectors. Room-temperature and temperature-dependent photoluminescence measurements were then used to evaluate emission stability, excitonic response, and cavity-modified optical behavior.

III. Results and Discussion

The porous host provides nanoscale confinement while preserving the structural integrity of the composite. Nitrogen sorption and diffraction results support successful incorporation of perovskite quantum dots into pores on the order of one to two nanometers, which is consistent with a confined emitter configuration rather than a conventional bulk-like phase. This confined architecture also leads to remarkable environmental robustness: the composite maintains nearly unchanged photoluminescence over extended ambient storage and still preserves substantial emission after prolonged immersion in water[5]. The median emission wavelength remains around 530 nm, which was used as a practical reference for subsequent cavity design. Temperature-dependent photoluminescence further reveals pronounced excitonic behavior and a confinement-modified thermal response, indicating that the optical properties of the embedded dots remain well defined over a broad temperature range[5]. When the material is integrated into a distributed Bragg reflector microcavity, the emission evolves from a broad spontaneous band into a much narrower cavity-dominated feature near 532 nm as the pump density increases. The linewidth contracts from about 16 nm to 0.5 nm, accompanied by a clear nonlinear rise in output intensity with a threshold near 2 kW/cm^2, as shown in Figure 1. Together, these results show that the confined perovskite quantum dots function as a stable active medium for cavity-enhanced emission and provide a versatile platform for discussing broader microcavity light-matter phenomena in the invited presentation.

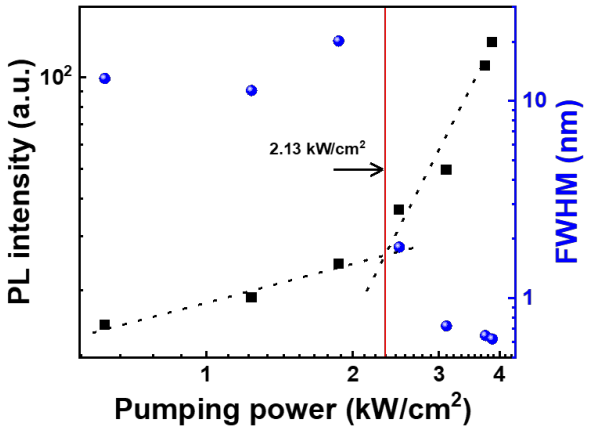

Figure 1. Light-in/light-out (L-L) characteristics of the $CsPbBr^3$@UiO-66 device. The left axis (black) depicts the PL intensity as a function of increasing pump power, and the right axis (blue) shows the corresponding FWHM of the emission peak. The nonlinear trend in the light-in/light-out curve confirms the achievement of lasing at a threshold power density of 2 kW/cm².

IV. Conclusion

In summary, this work demonstrates that quantum-confined perovskite quantum dots can combine environmental durability with rich optical functionality in resonant microcavities. Their sustained emission in water, excitonic optical response, and cavity-enhanced spectral evolution highlight their promise as stable building blocks for compact light sources, nanophotonic devices, and future studies of light-matter interaction in confined photonic systems.

***Keywords*— nonlinear optics, twist photonics, two-dimensional materials.**

I. Introduction

Twist photonics exploits interlayer rotation in two-dimensional stacks to create moiré superlattices with programmable symmetry and electronic structure. By engineering the structural chirality, linear and nonlinear circular dichroism is modulated, offering a versatile platform for tunable light–matter interactions and chiral optoelectronic devices.

II. Methods

Twist photonics, defined by the interlayer twisting in two-dimensional material stacks, creates a new paradigm for engineering optical phenomena[1]. Precise control of the twist angle creates a moiré superlattice, a long-wavelength periodic potential that reconstructs electronic bands and gives rise to moiré excitons, flat bands, and correlated quantum states, thereby offering unprecedented control over optical absorption and emission. Concurrently, this engineered lattice symmetry breaking induces and dramatically enhances intrinsic chiral optical activity, such as strong circular dichroism (Fig. 1).

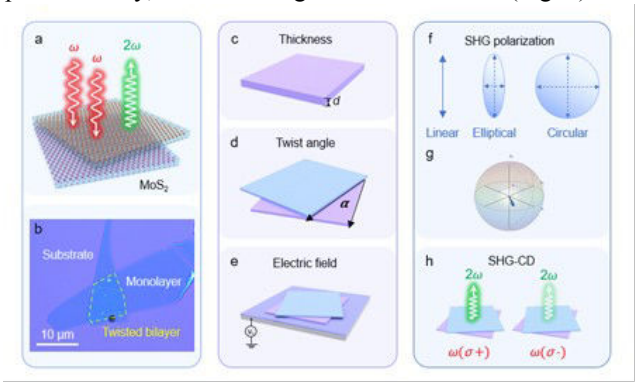

Fig. 1 Chiral optical nonlinearity in van der Waals materials.

III. Results and Discussion

By engineering the twist angle, layer thickness and the incident polarization, the ellipticity and the chirality of the nonlinear optical response can be precisely modulated. The synergistic interplay between the tailored moiré landscape and the engineered chirality defines a new paradigm for controlling light-matter interactions.

IV. Conclusion

This field of twist photonics provides a powerful platform for programming novel photonic functionalities, paving the way for advanced applications including twist-tunable polaritonic devices, quantum light emitters, and chiral optoelectronic sensors.

***Abstract*—We demonstrate a universal plasmon-enhanced Raman spectroscopy strategy using gold/silver nanocavities to detect layer-breathing modes in multilayer graphene, hBN, and their heterostructures. By developing an electric-field-modulated interlayer bond polarizability model, we quantitatively explain the observed intensity profiles with synergistic roles of localized plasmonic field enhancement and interfacial polarizability modulation.**

***Keywords*— plasmonic cavities, layer-breathing modes, two-dimensional materials, electric-field-modulated interlayer bond polarizability.**

I. Introduction

The metallic nanocavities enables localized surface plasmon resonance to confine the optical field into sub-wavelength volumes, providing unprecedented opportunities for plasmon-enhanced Raman spectroscopy (PERS) to uncover light-matter interactions at the nanoscale. A promising application of PERS lies in the investigation of low-frequency interlayer modes in two-dimensional materials, where the inherent Raman inactivity or inherently weak electron-phonon coupling (EPC) of some interlayer modes prevents their observation via conventional Raman spectroscopy.

II. Methods

We fabricated Au or Ag nanocavities by thermally evaporated an 8 nm-thick Au or Ag films on two-dimensional materials and related heterostructures. The different morphologies and densities of Au or Ag nanocavities were obtained by changing annealing temperature and time.

To understand the observed PERS of layer-breathing modes, we established the electric-field-modulated interlayer bond polarizability model, integrating simulation, optimization algorithms:

$$I_j \propto \frac{n_j+1}{\omega_j}\left|\sum_l (\eta_{l,x}-\eta_{l+1,x})\Delta z_{j,l} E^2_{Loc,l,x}\right|^2,$$

Where $\eta_{l,x}$ is interlayer bond parameter related to the x component of the interlayer bond, $E_{Loc,l,z}$ is the z-component of plasmonic field obtained by finite-difference time-domain method, $\Delta z_{j,l}$ is the layer displacement of the l-th layer in $LB_{N,N-j}$ mode, ω_j is the frequency of $LB_{N,N-j}$ mode and n_j is its corresponding Bose-Einstein factor.

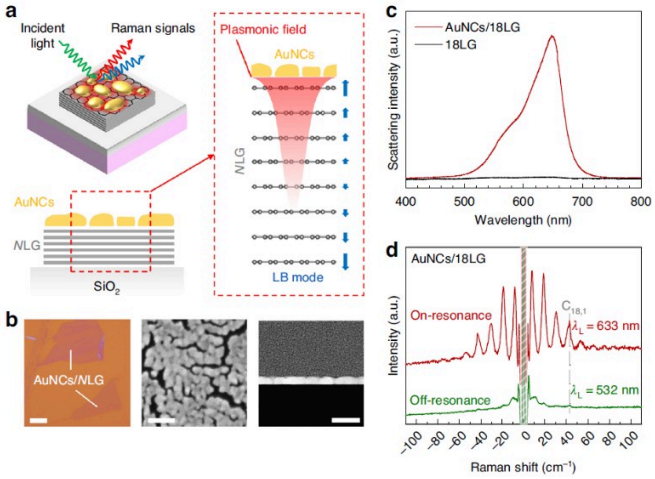

Fig. 1 Enhanced layer-breathing modes by PERS.

III. Results and Discussion

Experimental results show:

- upon resonant excitation of plasmonic cavities, a series of layer-number-dependent Raman features emerged below 130 cm^{-1}, which should be assigned as layer-breathing modes (Fig. 1).
- Strong interfacial coupling between Au/Ag nanocavities and two-dimensional materials, which modulated the interfacial polarizability modulation
- Strong agreement between simulated and measured spectra (Fig. 2)

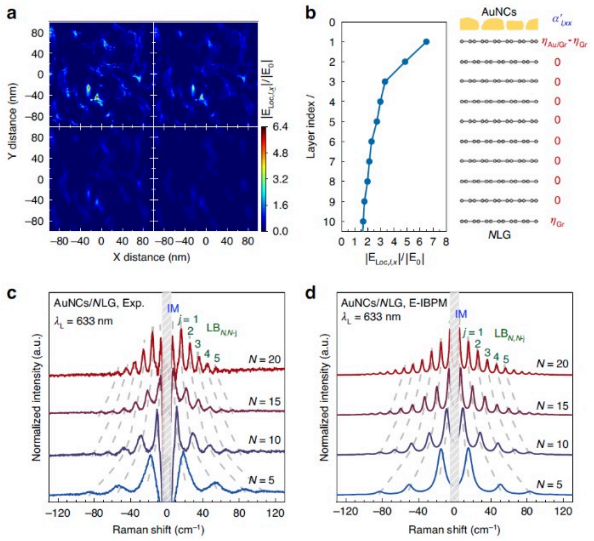

Fig. 2 Electric-field-modulated interlayer bond polarizability model for plasmon-enhanced LB modes in Au(Ag)NCs/NLG.

IV. Conclusion

We have developed a PERS approach using Au or Ag nanocavites to characterize LB modes in multilayer graphene, hBN and related heterostructures. This work opens avenues for precise characterization of interlayer interactions in emerging two-dimensional devices while providing fundamental insights into plasmon-phonon coupling phenomena.

***Abstract*— Chiral plasmonic Au nanoparticles are synthesized and demonstrated for chiral optical switching, chiral fluorescence emissions, circularly polarized organic light-emitting devices (CP-OLEDs), and photonic spin-Hall effect.**

***Keywords*— chiral plasmonic nanoparticles, circularly polarized light-emitting diodes, photonic spin-Hall effect, plasmon resonance, seed-mediated growth.**

Chirality is a fundamentally important concept in chemistry and physics. Chiral molecules exhibit chiroptical responses, which, however, are usually small. In this regard, the synthesis of plasmonic metal nanoparticles that possess chiral features on their surfaces has recently received much attention. Such chiral plasmonic nanoparticles exhibit much stronger chiroptical responses than molecules because of their larger sizes and localized surface plasmon resonance.

We have developed recipes for using seed-mediated growth to synthesize chiral Au nanoparticles in the presence of small peptide enantiomers. Different Au nanocrystals are employed as the starting seeds. The growth with Au nanodisks gives chiral Au nanotriskelions and helicoid Au nanocrystals. Halide ions are added to adjust the growth rates along different lattice directions of Au. The averaged scattering dissymmetry factors of the L- and D-nanotriskelions are as large as +0.57 and −0.49 at 650 nm, respectively. Moreover, the extinction dissymmetry factor of the chiral Au nanoparticles can be adjusted to change the sign using the chiral directing molecules of the same handedness. The growth with Au nanodecahedrons gives chiral Au nanorods, with five concave grooves inscribed on the side surface along the length axis. The length of the chiral Au nanorods can be varied by use of Au nanodecahedrons with different elongations.

We have further demonstrated the use of the chiral Au nanoparticles in chiral optical switching, chiral fluorescence emissions, circularly polarized organic light-emitting devices (CP-OLEDs), and photonic spin-Hall effect. The chiral optical switching device is fabricated by depositing the chiral nanoparticles randomly and densely on a substrate and coating them with an active electrochromic polymer layer that can be chemically and electrochemically switched between different redox states that have different dielectric functions. The chiral nano-emitters that preferentially emit left- or right-handed circularly polarized photons are prepared by coating mesostructured silica onto the individual chiral Au nanoparticles with fluorophores embedded in the silica shell. Efficient CP-OLEDs are realized through the assembly of chiral plasmonic Au nanoparticles and supramolecular aggregates. The chiral plasmonic nanoparticles serve as the chiral scaffold and chiral optical nanoantenna to modulate the circularly polarized absorption and emission of the supramolecular chromophores. The emissions of the OLEDs are dominated by either chiral excitons or chiral plasmons, dependning on the type of chiral plasmonic nanoparticle. The CP-OLED showing a high external quantum efficiency of 2.5% and a large dis-symmetry factor of 0.31 is achieved, as a result of multiscale chirality transfer, plasmonic enhancement, and the suppression of the overshoot effect. Previously reported CP-OLEDs generally exhibit an inverse relationship between the external quantum efficiency and the dis-symmetry factor. The CP-OLEDs fabricated in our work can achieve both high external quantum efficiencies and high dis-symmetry factors. The external quantum efficiencies of our devices are about two orders of magnitude higher than those of lanthanide-complex-based devices and the dis-symmetry factors are about two orders of magnitude larger than those of chiral cluster-based devices. When a chiral Au nanoparticle is attached on a silver nanowire, the linearly polarized incident light can be routed to the two ends of the nanowire. The direction of the routed light is determined by the handedness of the chiral nanoparticle.

Controllable Self-Assembly of Gold Nanoparticles with Concave Geometries

Limin Qi*

College of Chemistry and Molecular Engineering, Peking University, Beijing, China
*Corresponding author: liminqi@pku.edu.cn

***Abstract*— The nanoparticles with concave geometries emerge as unique nanoscale building blocks for the construction of nanoparticle assemblies with novel structures and unique photonic properties. This presentation summarizes our recent work on controllable self-assembly of concave gold nanoparticles, such as supercrystal engineering of gold nanoarrows and chiral self-assembly of gold nanodumbbells.**

***Keywords*— self-assembly of nanoparticles, concave nanoparticles, gold, nanoarrows, nanodumbbells.**

I. Introduction

Precise self-assembly of nanoparticles provides a facile and efficient bottom-up route towards ordered nanoparticle assemblies with novel properties and nanodevices with superior performance. In this regard, the plasmonic nanoparticles with concave geometries emerge as a unique kind of nanoscale building blocks for the construction of nanoparticle assemblies with novel structures and unique photonic properties.

II. Results and Discussion

First, shallowly concave gold nanoarrows (GNAs) with a delicately controlled concave-convex geometry are synthesized and employed for shape-directed self-assembly of a wealth of unprecedented, complex supercrystals. The concavity-enabled supercrystal engineering offers a promising route toward unconventional nanoparticle superstructures with expanded complexity and tunability in configuration.

Second, ligand-mediated self-assembly of gold nanoarrows into macroscopic monolayer films with tunable orientations is achieved at the oil-water interface, with the particle orientation readily modulated by adjusting the relative adsorbed amounts of the hydrophilic and hydrophobic ligands. After transferred onto a transparent polydimethylsiloxane substrate, the monolayer GNA films with type II orientation exhibits switchable color response toward the ethanol solvent.

Third, gold nanodumbbells (GNDs) are employed as achiral building blocks for controllable self-assembly into stable homochiral assemblies exhibiting strong chiroptical activity (Fig. 1). The formation of helically stacked side-by-side assemblies (SSAs) with a right handedness is triggered by introducing bovine serum albumin as the chiral additive. Remarkably, an asymmetry factor as high as 0.23 is obtained.

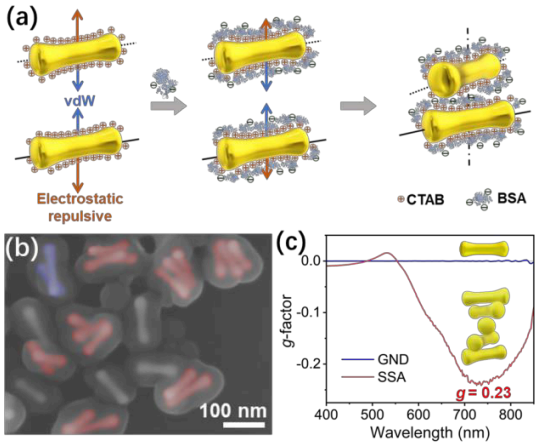

Fig. 1 Chiral self-assembly of gold nanodumbbells.

III. Conclusion

Controllable self-assembly of concave gold nanoparticles including supercrystal engineering of GNAs, interfacial self-assembly of GNAs, and chiral self-assembly of GNDs has been achieved. This work may advance the structural design of nanoscale plasmonic building blocks for supercrystal engineering and chiral assembly useful in nanophotonics.

Transition Metal–CO Bond: σ-bonding or π-bonding?

Zhen-Chao Dong*

Hefei National Research Center for Physical Sciences at the Microscale,
University of Science and Technology of China, China
*Corresponding author: zcdong@ustc.edu.cn

***Abstract*— By exploiting sub-nanometer resolved tip enhanced Raman spectroscopy (TERS), we identify the bonding type between transition metal (M) and CO molecule (namely, σ-donation or π-back donation) at the single-bond level through vibrational Stark effects under an external electric field, an issue theoretically well understood but experimentally very hard to achieve.**

***Keywords*— tip enhanced Raman spectroscopy, CO, coordinate bond, molecule-substrate interaction.**

Precise control over molecule-surface interactions is a cornerstone of surface chemistry, dictating the efficiency and selectivity of catalytic processes that underpin our industrial world. In particular, the interaction of carbon monoxide (CO) molecules with transition metals (M), which often serves as model catalytic systems, playes a pivotal role in facilitating chemical transformations such as carbonylation and reduction–oxidation reactions. Theoretically, based on the Dewar-Chatt-Duncanson model or Blyholder model (Fig. 1), the CO molecule can either serve as an acceptor to receive electrons from the metal atom through 2π*←d orbitals (known as the π back-donation, the classical regime called π bonding), or as a donor to give electrons to the metal atom through 5σ→d orbitals (known as the σ donation, the non-classical regime called σ bonding). Generally, the σ donation and the π back-donation would coexist and act synergistically. In the classical regime, π back-donation plays a more significant role and weakens the C−O bonding strength, while in the non-classical regime, the σ donation strengthens the C−O bond. Therefore, experimentally identifying these two bonding contributions is of fundamental importance, as it can not only determine and confirm the electronic structure of metal–-CO complexes, but also enable to gain insights into the mechanism that governs their catalytic reactivity and selectivity.

Various experimental approaches have been employed to investigate such a bonding interaction issue, including Raman, IR and single-crystal x-ray diffraction, largely performed on ensemble systems. However, experimental methods to unambiguously identify the bonding nature in this system is still out of reach. One natural and attractive approach is to chemically identify the bonding types of M−CO bonds at single-molecule single-bond scales, free of any ensemble averaging complication.

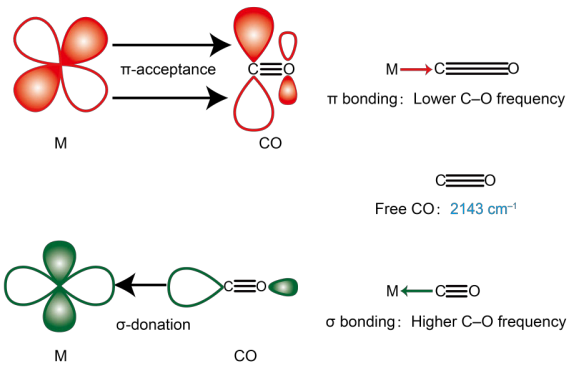

Fig. 1 Schematic representation of the σ donation and π back-donation.

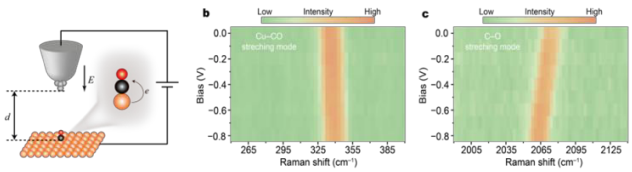

Fig. 2 Vibrational Stark effects in TERS.

In this work, by combining sub-nanometer resolved TERS [1-4] with vibrational Stark effects [5], we demonstrate a novel approach that can monitor the evolution of both the M−CO and C−O bond strengths through the shift of vibrational frequencies of these bonds in situ at the single-bond level (Fig. 2). Two model systems are selected, Cu-CO system for the classical regime and Ag-CO for the non-classical regime. By modulating the charge transfer between the transition metal and CO through the application of an electric field, the Cu−CO coordinate bond can be identified to be dominated by π back-donation while the Ag−CO bond is dominated by the σ donation due to their different evolution of the bonding strengths for the M−CO and C−O bonds along with the increase of electric fields.

***Abstract*— Chiral plasmonics has emerged as a frontier in nanophotonics, offering unprecedented opportunities to manipulate light at the nanoscale through handedness-dependent optical responses. However, unlocking its full potential demands precise synthetic control over chiral plasmonic nanostructures and rational strategies for dynamically tuning their optical properties.**

In recent years, we have initiated our research with the colloidal synthesis of intrinsically chiral plasmonic nanoparticles, including diverse morphologies such as chiral gold nanorods and Janus nanoparticles. Through systematic investigation, we have elucidated the growth mechanisms underlying chirality emergence and identified key synthetic parameters that govern morphological control. We further demonstrate how these nanostructures respond to external stimuli, including polymer encapsulation and shell engineering, to modulate their far-field and near-field chiroptical characteristics. These studies establish design principles for achieving dynamic switching, spectral tunability, and localized superchiral hotspot generation in plasmonic systems. On this basis, we demonstrate preliminary applications of these chiral plasmonic nanoparticles in circularly polarized luminescence, enantioselective sensing, and valleytronic devices. These explorations collectively advance chiral plasmonics toward practical implementation in next-generation photonic and optoelectronic technologies.

Plasmonic Control of Dark Excitons and Valley Coherence in TMDC Monolayers under Ambient Conditions

Lei Shao[1,*]

***Abstract*—We demonstrate the use of plasmonic nanocavities to enable control of dark excitons and valley coherence in monolayer WSe_2 under ambient conditions. With the help of a Au nanodisk-based nanocavity, the dark exciton emission is switched on with 22-fold enhancement and valley coherence is achieved through strong plasmon-exciton coupling.**

***Keywords*—transition metal dichalcogenides, dark excitons, valley coherence, plasmonic nanocavities.**

I. Results

Transition metal dichalcogenide (TMDC) monolayers are at the forefront of research in atomically thin optoelectronics and quantum technologies due to their direct bandgap and unique spin-valley locking properties. Harnessing their full potential requires the ability to control both long-lived, optically inactive (dark) excitons for quantum information processing and valley coherence for valleytronic applications. Traditionally, accessing these phenomena has necessitated complex photonic structures or extreme experimental conditions, such as cryogenic temperatures and high magnetic fields. Here, we introduce our recent results on using plasmonic nanostructures to overcome these limitations, enabling the control of both dark excitons and valley coherence in monolayer WSe_2 under ambient conditions. First, we demonstrate the switching-on of dark exciton emission using a simple, highly reproducible plasmonic nanodisk-on-mirror cavity. By sandwiching the WSe_2 monolayer within this structure and tuning the nanodisk diameter, we achieve a 22-fold enhancement in the dark-to-bright exciton emission ratio. This control is mediated by two orthogonal plasmon modes that generate strongly confined out-of-plane electric fields, coupling efficiently to the otherwise dark states. Second, we show that strong coupling between excitons and plasmons in a similar plasmonic architecture gives rise to distinct Rabi splitting in the polarization-resolved photoluminescence spectra. This strong coupling regime facilitates the addressing of valley coherence at room temperature within a sub-145 nm wide area, circumventing the need for bulky magnets or cryogenic cooling. Together, these findings establish that precisely engineered plasmonic nanocavities provide a versatile and practical platform for controlling the fundamental excitonic properties of TMDC monolayers. This work paves the way for the development of integrated nanophotonic and optoelectronic devices, including sources for quantum information processing and room-temperature valleytronic logic, by bringing the control of dark excitons and valley coherence from extreme conditions to readily accessible, chip-scale environments.

***Abstract*—Plasmonic catalysis offers new opportunities to improve photocatalytic activity and selectivity. By comparing carbon dioxide reduction and hydrogen peroxide synthesis systems, we identify charge-flow engineering as a common mechanism governing carrier utilization. These findings establish a general design strategy for efficient and selective solar-to-chemical conversion.**

***Keywords*—Plasmonic Catalysis, Charge-Flow Engineering, Morphology-Controlled Nanostructures, Solar-to-Chemical Conversion.**

I. Introduction

Solar-driven chemical conversion offers a promising route toward sustainable fuel and chemical production. However, the efficiency of conventional photocatalytic systems remains limited by rapid charge recombination, inefficient carrier utilization, and poor reaction selectivity. Plasmonic photocatalysis has emerged as a promising strategy to address these challenges[1].

Upon light irradiation, plasmonic nanostructures strongly interact with light through localized surface plasmon resonance (LSPR). LSPR can generate energetic charge carriers, localized electromagnetic fields, and photothermal effects that enhance catalytic reactions, attracting considerable attention in recent years[2,3].

Understanding how plasmonic structures influence charge-carrier behavior is essential for the rational design of efficient photocatalysts. In this work, two representative plasmonic systems are examined: morphology-dependent Au nanocrystals for CO_2 reduction and Au@TiO_2 core-shell structures for H_2O_2 synthesis. Although these systems involve different reactions, both reveal a common role of plasmonic excitation in regulating charge-carrier generation, transport, and utilization. Through a comparative analysis of these systems, charge-flow engineering is proposed as a general framework for controlling activity and selectivity in plasmonic catalysis.

II. Methods

2.1 Plasmon-assisted electrocatalytic CO_2 Reduction System

The first system consists of Au nanocrystals with controlled morphologies, including cubic (NC), rhombic dodecahedral (RD) and octahedral (OC) structures, as shown in Fig. 1(a). These nanocrystals expose different crystallographic facets and exhibit distinct plasmonic responses. Electrocatalytic CO_2 reduction performance was evaluated under both dark and illuminated conditions. Spectroscopic characterization together with numerical simulations was employed to investigate plasmonic behavior and charge-carrier dynamics[4].

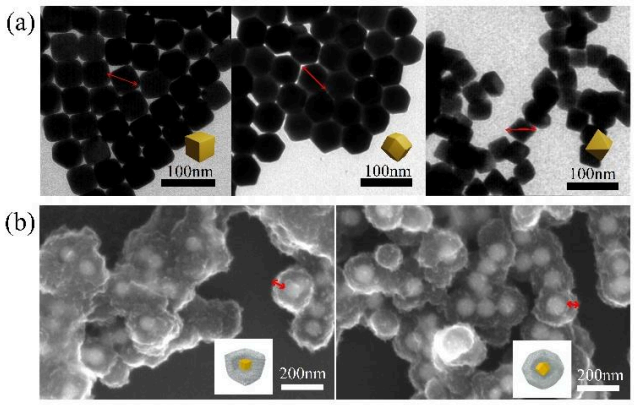

Fig. 1 Images of the plasmonic catalytic systems. (a) TEM images of morphology-controlled Au nanocrystals, including nanocubes (NC), rhombic dodecahedra (RD), and octahedra (OC), used for plasmon-assisted CO_2 reduction. (b) SEM image of Au@TiO_2 core–shell structures with NC and RD Au cores used for photocatalytic H_2O_2 synthesis.

2.2 Au@TiO_2 H_2O_2 Synthesis System

The second system consisted of Au@TiO_2 core-shell photocatalysts with morphology-controlled Au cores. Nanocubic and rhombic dodecahedral Au nanocrystals were encapsulated within porous anatase TiO_2 shells (NC@TiO_2 and RD@TiO_2), as depicted in Fig. 1(b). H_2O_2 production was quantified by iodometric analysis under full-spectrum irradiation and selected wavelength ranges. Electrochemical measurements, spectroscopic characterization, and electromagnetic simulations were performed to investigate the LSPR effect in carrier generation and transfer processes in Au@TiO_2 systems[5].

III. Results and Discussion

3.1 Morphology-Dependent Catalytic Performance

Both systems exhibit strong morphology-dependent photocatalytic performance.

In the CO_2 reduction system, Au nanocrystals showed distinct responses to light depending on their morphology. Under illumination, Au OCs exhibited approximately twofold higher CO Faradaic efficiency and threefold higher CO partial current density compared with dark conditions. Au NCs also showed noticeable performance enhancement under illumination, whereas Au RDs displayed little change. The observed enhancement could not be fully explained by conventional facet-dependent catalytic activity alone, indicating an additional contribution from plasmonic effects[4].

A similar morphology dependence was observed in the H_2O_2 synthesis system. NC@TiO_2 photocatalysts achieved substantially higher H_2O_2 production rates than their RD@TiO_2 counterparts. Moreover, H_2O_2 decomposition was more effectively suppressed in the NC@TiO_2 system, resulting in a significantly higher net H_2O_2 accumulation[5].

Although the two systems involve different catalyst architectures and reaction pathways, both exhibit a strong correlation between nanoparticle morphology and photocatalytic performance. These observations suggest that catalyst geometry influences photocatalytic behavior beyond conventional surface-structure effects and point toward a common plasmon-involved mechanism.

3.2 Photocarrier Dynamics as the Governing Factor

To understand the origin of the morphology-dependent catalytic behavior, mechanistic investigations including spectroscopy, numerical simulations, and electrochemical analyses were performed in the original studies. Although the experimental approaches differed between the two systems, both investigations consistently identified plasmon-induced charge-carrier dynamics as the key factor governing catalytic performance.

For plasmon-assisted electrocatalytic CO_2 reduction, the superior performance of Au OC was associated with stronger plasmonic excitation and more efficient utilization of photogenerated carriers. Electromagnetic simulations revealed enhanced electric-field distributions at low-coordinated surface sites, while atomistic simulations suggested morphology-dependent hot-carrier generation[4]. In contrast to conventional electrocatalytic systems, where catalytic activity is often governed by adsorption energetics on specific facets, plasmon-involved systems appear to be strongly influenced by low-coordinated sites. These findings indicate that plasmon-generated carriers actively participate in catalytic processes, allowing LSPR to modify the contributions of different active sites and activate the same material differently from conventional catalytic processes.

The Au@TiO_2 system provided further insight into the role of carrier transport. Spectroscopic analyses and simulations revealed that plasmon excitation in the Au core enhances charge separation across the Au-TiO_2 interface. Upon plasmon excitation, electrons generated within TiO_2 were preferentially transferred to Au sites, where oxygen reduction occurs, while plasmon-generated hot electrons mitigated hole-driven pathways responsible for H_2O_2 decomposition. As a result, plasmonic excitation simultaneously enhanced H_2O_2 formation and suppressed undesired product degradation. The stronger LSPR response of NC@TiO_2 further amplified these effects, leading to higher overall H_2O_2 yields[5].

Despite the differences in reaction chemistry, both systems reveal a common phenomenon in which plasmonic excitation influences charge-carrier behavior. Rather than simply increasing carrier populations, plasmonic nanostructures regulate the generation, transport, and utilization of photogenerated carriers. This ability to control charge-carrier flow provides a common explanation for the morphology-dependent catalytic behavior observed in both systems.

3.3 Design Principles and Future Perspectives

The common charge-flow control observed in both systems suggests that the primary advantage of plasmonic nanostructures lies in their ability to regulate carrier utilization during catalysis. In both CO_2 reduction and H_2O_2 synthesis, the observed performance improvements arise from more effective use of photogenerated carriers rather than merely increased carrier production. This perspective provides a useful framework for designing plasmonic photocatalysts with improved activity and selectivity.

Based on these observations, several design principles for plasmonic photocatalysts can be proposed. First, nanoparticle morphology should be carefully engineered to maximize localized plasmonic responses and promote favorable carrier distributions. The strong morphology dependence observed in both systems demonstrates that catalyst geometry directly influences photocatalytic performance through its impact on charge-carrier dynamics.

Second, catalyst architectures should be designed to facilitate directional charge transport and efficient carrier utilization. Rather than functioning solely as active catalytic components, plasmonic nanostructures can serve as regulators of charge flow, guiding charge-carriers toward desired reaction pathways while suppressing competing processes. This capability provides a unique opportunity to simultaneously improve catalytic activity and selectivity.

More broadly, plasmonic photocatalysis should be viewed as a platform for charge-flow engineering rather than solely light-harvesting enhancement. While plasmon excitation may not directly drive chemical reactions with high efficiency, it can strongly influence the transport and utilization of photogenerated carriers, thereby enhancing catalytic performance and controlling reaction pathways.

Despite the promise of plasmonic catalysis, the underlying

physical mechanisms remain incompletely understood. Key processes, including hot-carrier generation, interfacial charge transfer, and energy dissipation, occur on ultrafast timescales and nanometre length scales, making them challenging to observe directly. As a result, many fundamental questions regarding the relationship between plasmon excitation and catalytic activity remain unresolved[3].

Future studies should combine precisely engineered plasmonic nanostructures with advanced operando spectroscopic techniques, such as surface-enhanced Raman spectroscopy (SERS), surface-enhanced infrared absorption spectroscopy (SEIRAS), and ultrafast optical measurements[6,7]. In particular, self-assembled multilayer gold nanoparticle architectures with precisely controlled interparticle separations provide promising platforms for generating reproducible plasmonic hotspots and probing carrier dynamics under realistic reaction conditions[8]. Such approaches will enable direct observation of charge and energy transfer processes during catalysis and provide deeper insight into the mechanisms governing plasmon-mediated photocatalytic reactions. A more complete understanding of photocarrier generation, transport, and utilization will not only advance the fundamental understanding of plasmonic catalysis but also guide the rational design of highly efficient and selective light-driven systems for future energy conversion and chemical production[3,7].

IV. Conclusion

A comparative analysis of plasmon-assisted CO_2 reduction and plasmon-enhanced H_2O_2 synthesis reveals a common role of plasmonic excitation in regulating charge-carrier behavior. In both systems, LSPR influences the generation, transport, and utilization of photogenerated carriers, resulting in enhanced catalytic performance and selectivity. The strong morphology dependence observed across both systems further highlights the importance of charge-carrier dynamics in plasmonic catalysis.

These findings suggest that the role of LSPR extends beyond enhanced light harvesting, providing a means to control charge-carrier flow and reaction pathways. This perspective establishes charge-flow engineering as a promising strategy for the design of next-generation plasmonic catalysts.

Despite recent progress, a deeper understanding of hot-carrier generation, transfer, and dissipation remains necessary. Future operando and ultrafast spectroscopic studies will be crucial for revealing these processes and advancing the rational design of efficient light-driven catalytic systems.

***Abstract*—The rapidly evolving ability to harness quantum effects in various cavity quantum electrodynamics (cQED) architectures demands a rigorous theory for the investigation of inherently non-Hermitian systems. We present a quasinormal mode quantization scheme for electromagnetic resonators and demonstrate its capabilities for spatio-temporal studies and characterization of non-trivial cQED systems.**

***Keywords*— quasinormal modes, quantum electrodynamics, nanophotonics, plasmonics, magnonics.**

I. Introduction

Cavity-mediated control and enhancement of light-matter interaction has become a pervasive paradigm in modern quantum science and technology, enabling applications in quantum computation, memory and sensing, nano-lasing and quantum light sources. The rich nexus of nanotechnologies based on cQED systems stems from the vast diversity of architectures available to realize and harness quantum optical effects in evermore robust and reproducible ways, ranging from plasmonic systems able to confine light at deeply sub-wavelength scales and operate in an ultrafast temporal regime at ambient temperatures [1], through silicon-based photonic systems suitable for low-loss and scalable, on-chip operation [2], to magnonic systems able to elevate quantum effects to a macroscopic spatial scale [3].

In all these platforms, confined electromagnetic resonances can become inextricably intertwined with the excitonic or spin-related excitations of matter, giving rise to diverse light-matter dynamics whose richness and technological potential can only be truly unlocked with the aid of spatially and temporally resolved, fully quantum mechanical treatments. In particular, hybrid cQED platforms that are promising for nascent quantum device protocols often feature strongly coupled and dissipative resonances of photonic, plasmonic or magnonic character, giving rise to a panorama of polaritons, and where perturbative approaches for describing the dressing of matter by cavity electric and magnetic fields quickly become inadequate for the rigorous calculation of quantum optical figures of merit. Towards an improved understanding of both the near- and far-field properties of these systems, a unified theoretical framework is called for which captures the quantum properties of these myriad excitations, the coupling between them, as well as their interaction with embedded matter supporting electric and magnetic transition moments.

In this light, we present a quantum quasinormal mode (QNM) formalism for addressing problems in dissipative cQED [4], offering a unified, rigorous and practical simulation methodology for photonic, plasmonic and magnonic cavities interacting with quantum emitters (QEs) and spin qubits. We demonstrate its predictive power via the characterization of non-trivial, hybrid cavity systems and their interaction with QEs, paving the way towards a fully quantum mechanical description of phenomena such as quantum nanoplasmonic coherent perfect absorption [5], lasing in $\mathcal{PT}$-symmetric photonic systems, magnonic strong coupling and cavity-mediated spin-photon interfaces at the nanoscale.

II. Methods

a) Quasinormal modes: QNMs are used to describe the response of open and lossy, resonant electromagnetic systems and are defined as the eigensolutions of the macroscopic Maxwell's equations with complex frequencies:

$$\begin{pmatrix} 0 & -\mathrm{i}\mu^{-1}(\mathbf{r},\tilde{\omega}_n)\nabla\times \\ \mathrm{i}\varepsilon^{-1}(\mathbf{r},\tilde{\omega}_n)\nabla\times & 0 \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{H}}_n \\ \tilde{\mathbf{E}}_n \end{pmatrix} = \tilde{\omega}_n \begin{pmatrix} \tilde{\mathbf{H}}_n \\ \tilde{\mathbf{E}}_n \end{pmatrix} \tag{1}$$

They can be used to expand the electromagnetic field within the resonator for scattering or radiation problems. By leveraging perfectly matched layers (PMLs) and an auxiliary-field method for both numerical computations and analytical considerations, efficient finite-element-based QNM solvers have been implemented and simple analytical formulae for the excitation coefficients in the QNM expansion of the scattered electromagnetic field, $\mathbf{E}_{\mathrm{sca}} = \sum_n \alpha_n \tilde{\mathbf{E}}_n$, in both frequency and time domain have been derived [6] and applied for many different types of resonators [7]. By appropriately modeling the material parameters ε and μ, it is possible to describe photonic, plasmonic, magnonic or any kind of hybrid system. The QNM methodology thus provides a practical computational technique for solving scattering and radiation problems, while simultaneously allowing a much deeper physical insight into these processes as opposed to a brute-force numerical solution of Maxwell's equations in the frequency or time domain. In

the case of non-trivial backgrounds such as waveguides or substrates, the PML modes resulting from the introduction of a truncated, PML-transformed space also ensure the completeness of the set of modal solutions, which is otherwise not guaranteed by the QNMs alone.

b) Macroscopic QED and QNM quantization: Macroscopic QED provides a unified theory for the quantization of the electromagnetic field in the presence of arbitrary, 3D, dispersive and lossy, linear media characterized by the permittivity ε and permeability μ. The frequency components of the E-field operator satisfy the equation

$$\nabla \times \mu^{-1} \nabla \times \hat{\mathbf{E}}(\mathbf{r},\omega) - \varepsilon \frac{\omega^2}{c^2} \hat{\mathbf{E}}(\mathbf{r},\omega) = \mathrm{i}\mu_0 \omega \hat{\mathbf{j}}_{\mathrm{N}}(\mathbf{r},\omega) \ , \quad (2)$$

with an additional noise current density

$$\hat{\mathbf{j}}_{\mathrm{N}}(\mathbf{r},\omega) = \omega \sqrt{\frac{\hbar\varepsilon_0}{\pi}} \sqrt{\Im(\varepsilon(\mathbf{r},\omega))}\, \hat{\mathbf{f}}_{\mathrm{e}}(\mathbf{r},\omega) + \sqrt{\frac{\hbar}{\mu_0 \pi}} \nabla \times \left(\sqrt{-\Im(\mu^{-1}(\mathbf{r},\omega))}\, \hat{\mathbf{f}}_{\mathrm{m}}(\mathbf{r},\omega) \right) \ , \quad (3)$$

in accordance with the fluctuation-dissipation theorem and which ensures the preservation of the fundamental commutation relations. The bosonic operators $\hat{\mathbf{f}}_{\mathrm{e}}(\mathbf{r},\omega)$, $\hat{\mathbf{f}}_{\mathrm{m}}(\mathbf{r},\omega)$ correspond to the joint excitations of the electromagnetic-field-dressed media (polaritons) and diagonalize the Hamiltonian of the system. Utilizing the dyadic E-field Green's function of the system leads to an expansion of the E-field operator in terms of the continuum of bosonic modes:

$$\hat{\mathbf{E}}(\mathbf{r}) = \mathrm{i}\mu_0 \int_0^\infty \mathrm{d}\omega\, \omega \int \mathrm{d}^3 r\, G(\mathbf{r},\mathbf{r}',\omega) \hat{\mathbf{j}}_{\mathrm{N}}(\mathbf{r}',\omega) \ . \quad (4)$$

These formulae can be generalized for materials that exhibit amplification in certain spectral and spatial domains, in which creation and annihilation operators switch roles [8]. As the system is described by a very large continuum of bosonic modes in this formulation, an alternative treatment in terms of a small number of discrete modes is desirable. By incorporating PMLs into the quantum description and leveraging the QNM/PML mode expansion of the Green's function, such an alternative bosonic modal expansion of the E-field operator $\hat{\mathbf{E}}(\mathbf{r}) = \sum_n \hat{a}_n \tilde{\mathbf{E}}_n^{\mathrm{sym}}(\mathbf{r}) + \mathrm{h.c.}$ in terms of symmetrized QNMs $\tilde{\mathbf{E}}_n^{\mathrm{sym}}(\mathbf{r}) = P_{n'n}^{+\frac{1}{2}} \tilde{\mathbf{E}}_{n'}(\mathbf{r})$ can be derived. The temporal evolution of the modal operators is governed by Heisenberg-Langevin equations

$$\frac{\mathrm{d}\hat{a}_n}{\mathrm{d}t} = \frac{\mathrm{i}}{\hbar} \left[\hat{H}_{\mathrm{eff}}, \hat{a}_n \right] - \gamma_{nn'} \hat{a}_{n'} + \hat{F}_n(t) \ , \quad (5)$$

with some quantum noise term $\hat{F}_n(t)$. Practically, these equations can be solved approximately by solving the corresponding master equation [9] or by using the quantum cumulant expansion to obtain approximate truncated equations of the expectation values of the operators and their products. All quantities involved in these equations can be directly calculated from classical PML-based QNM computations and in the presence of amplification, the equations can be adjusted accordingly.

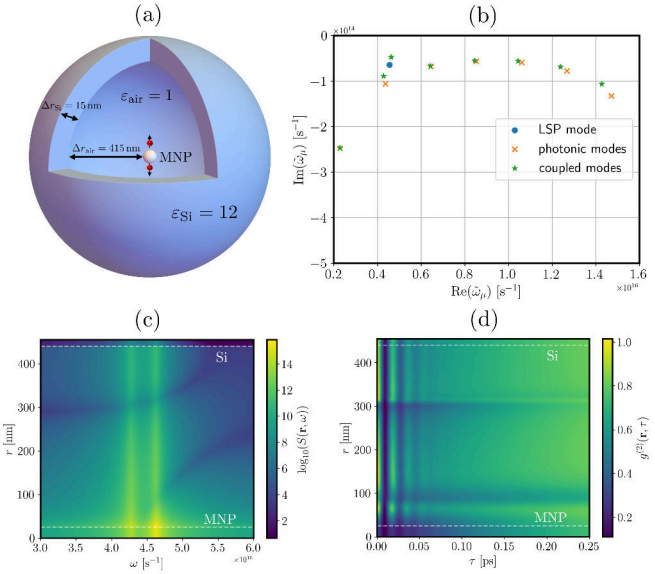

Fig. 1. Example metallodielectric cQED system. (a) Schematic of the hybrid system. (b) $\mathrm{TM}_{l=1}$ QNM frequencies of the system compared to the QNM frequencies of the bare dielectric cavity and the MNP. (c) Position-dependent, steady-state E-field spectrum $S(\mathbf{r},\omega)$ along the QE axis. (d) Position-dependent, steady-state second-order E-field coherence function $g^{(2)}(\mathbf{r},\tau)$ along the QE axis.

III. Results and Discussion

The presented quantum QNM theory can be used to rigorously investigate non-trivial cQED systems in a fully spatially and temporally resolved manner. To demonstrate the necessity of a more thorough investigation of such systems, we briefly discuss some results for a spherical, metallodielectric cavity consisting of a metal nanoparticle (MNP) (described by a Drude model $\varepsilon_{\mathrm{MNP}}(\omega) = \varepsilon_\infty[1 - \omega_{\mathrm{p}}^2/(\omega^2 - \omega_0^2 + \mathrm{i}\gamma\omega)]$ with the parameters typically used for the Drude pole of gold [7], $r_{\mathrm{MNP}} = 25\,\mathrm{nm}$), in the center of a hollow dielectric cavity ($\varepsilon_{\mathrm{air}} = 1$, $\Delta r_{\mathrm{air}} = 415\,\mathrm{nm}$) made out of a thin Si shell ($\varepsilon_{\mathrm{Si}} = 12$, $\Delta r_{\mathrm{Si}} = 15\,\mathrm{nm}$). The parameters are tuned so that a photonic mode of the cavity is strongly coupled to a localized surface plasmon mode (LSP) of the MNP, resulting in two hybrid modes in the QNM spectrum, as shown in Fig. 1(b). These QNMs were quantized and two quantum emitters (QEs) with radially oriented transition dipole moments $d = 30\,\mathrm{D}$, pure dephasing rates $\gamma_{\mathrm{d}} = 4 \times 10^{13}\,\mathrm{s}^{-1}$ and pumping rates $\gamma_{\mathrm{pump}} = 2 \times 10^{12}\,\mathrm{s}^{-1}$ were asymmetrically placed on opposite sides of the MNP ($r_{\mathrm{QE},1} = 32\,\mathrm{nm}$, $r_{\mathrm{QE},2} = 26\,\mathrm{nm}$) and tuned to the first and second hybrid QNM frequencies, respectively. In Fig. 1(c), the radially mapped, steady-state E-field spectrum (along the QE axis) was plotted. It is apparent that the form and the relative heights of the two QNM peaks are dependent on position. The consequences of the position-dependence become even clearer in the steady-state, second-order E-field coherence function in Fig. 1(d). Inside the MNP and in close proximity to its surface, we find $g^{(2)}(\mathbf{r},0) < 0.5$, corresponding to photon antibunching and the single-photon emission regime. Within the cavity, the $g^{(2)}(\mathbf{r},0)$ values are

modified due to multi-mode excitation and the hybridized photonic and LSP character of the modes, even reaching values of $g^{(2)}(\mathbf{r}, 0) > 1.0$, corresponding to photon bunching. This example illustrates that the experimentally accessible far-field quantities cannot be inferred directly from the dynamics of the modal operators, owing to their inherent position dependence within the cavity system. Instead, a near-field-to-far-field transformation is required to rigorously determine the emitted far-field characteristics from the internal dynamics. Analogous studies can be envisaged for cavity magnonic systems as well.

Such spatio-temporally resolved simulations of non-trivial cQED systems, which embrace diverse excitation types along with the rigorous calculation of near- and far-field properties, offer a deeper understanding of the relationships between them. Moreover, the proposed methodology facilitates optimized system design towards targeted performance metrics for quantum technological applications. Notably, architectures incorporating multiple excitation types enable platforms that are switchable across distinct quantum optical regimes, leveraging the spatial dispersion of key quantum optical figures of merit arising from the entanglement and coexistence of these excitations.

IV. Conclusion

We have presented a quantum QNM theory that enables spatio-temporally resolved studies of the dynamics of general magnetodielectric cQED systems. We demonstrate its capabilities with studies of hybrid systems in which different types of excitations lead to a spatial dispersion of typical quantum optical figures of merit.

Building the Innovation Pipeline: Leveraging Princeton Core Facilities and Statewide Resources for Photonics Commercialization

Alexander Norman
Princeton University, USA

***Abstract*— Princeton Materials Institute is the home to two large core facilities: the Micro/nanofabrication center (MNFC) and the Imaging and Analysis Center (IAC). Core facilities are used across the community to accelerate research and help steer ultimate product development. The broader innovation ecosystem in this area will also be highlighted.**

Azopolymer photomorphing as holographic lithography for reconfigurable structured surfaces

Marcella Salvatore[1] and Stefano Luigi Oscurato[1,*]

[1]Physics Department "E. Pancini", University of Naples Federico II, Complesso Universitario di Monte Sant'Angelo, via Cinthia, 80126, Naples, Italy.

*Corresponding author: stefanoluigi.oscurato@unina.it

***Abstract*— Azopolymers capture the inherent vectorial nature of the light in the form of reversible surface reliefs. Tailored intensity and polarization patterns directly map into operating surfaces, without requiring development or etching. We outline here the general phenomenology of azopolymer photomorphing and its potential routes for scalable photonic manufacturing.**

***Keywords*— holographic lithography, azopolymers, structured light, multiple degrees of freedom, diffractive optical elements.**

I. Introduction

Scalable fabrication remains a bottleneck for translating flat-optics concepts into accessible devices. Azopolymer offer a fundamentally different route to structured surfaces that fully leverages the spatio-temporal degrees of freedom of structured light, to propose an alternative lithographic approach based on direct, directional, and reversible material transport, rather than development and etching of conventional workflows. The material at the film surface moves following the local polarization direction and/or the local intensity gradient, originating a surface relief pattern that encodes the geometry of the vector light field (Fig. 1) [1].

Furthermore, wavefront, wavelength, time evolution of the optical field, and even the exposure history directly translate into the final surface morphology. The result are unique patterning capabilities that only require light to fabricate microstructured surfaces ranging from diffraction gratings and Fourier surfaces to anisotropic and chiral micropillars [2,3].

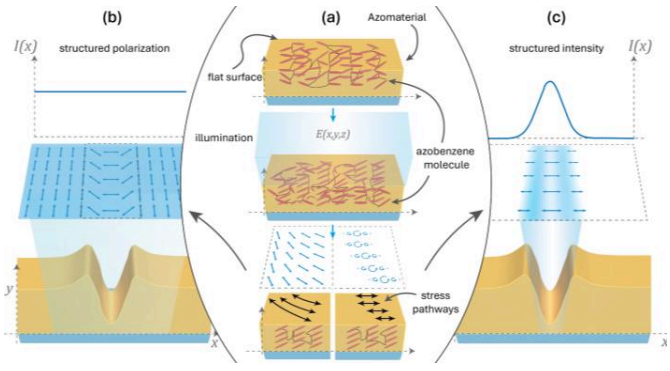

Fig. 1. All-optical vectorial holographic lithography in azopolymers.

II. Results and Discussion

We present the phenomenology of the light-induced mass transport of azobenzene-containing polymers (azopolymers) in several experimental configurations, moving from multi-beam interference to digital holographic configurations, up to tightly focused regimes, where the resolution is pushed down to the diffraction limit and the optical field acquires full 3D vectorial nature. We frame the capabilities of the azopolymer holographic lithography within our current shift toward the adoption of in-situ metrology and feedback during writing. Real-time, non-contact monitoring (e.g., holographic microscopy and diffractive models) can reconstruct evolving 3D topography without perturbing the surface, potentially enabling target morphologies or surface functionalities (e.g. diffraction efficiency) to be dynamically and automatically corrected in real-time.

III. Conclusion

Our work establishes a spatiotemporal strategy for on-demand, all-optical microfabrication and reprogramming of structured surfaces, where spatial and temporal degrees of freedom of structured light intermix to produce advanced patterning capabilities, to be directly exploited as flat optical elements or as reprogrammable templates for replication.

A Scalable Structural-Color Nanocavity Platform for Stain-Free Digital Pathology

Qizhe Chen[1], Qiaoqiang Gan[1, *]

[1]Materials Science and Applied Physics, Physical Science and Engineering Division, King Abdullah University of Science and Technology, Saudi Arabia
*Corresponding author: qiaoqiang.gan@kaust.edu.sa

***Abstract*— We introduce a scalable structural-color nanocavity platform for stain-free digital pathology. The planar nanocavities-on-silicon design avoids nanopatterning, enables wafer-scale manufacturing, and operates with standard optical microscopes. By minimizing system modification and cost, this platform supports large-scale deployment and AI-compatible histological imaging.**

***Keywords*— Structural color, Nanocavity platform, Stain-free pathology.**

I. Introduction

Pathology increasingly demands imaging technologies that are scalable, cost-effective, and compatible with existing clinical infrastructure. While advanced nanophotonic and label-free imaging techniques can provide rich contrast, their adoption is often limited by complex fabrication, expensive instrumentation, and substantial workflow disruption [1-2]. For broad clinical and industrial deployment, stain-free imaging platforms must balance optical functionality with manufacturability and system-level compatibility.

Structural-color nanocavities offer a promising route to achieve this balance. By encoding intrinsic tissue properties into visible color contrast, they enable stain-free visualization without reliance on chemical reagents or complex optical systems. In this work, we introduce a scalable structural-color nanocavity platform designed specifically for stain-free digital pathology, emphasizing simplicity, manufacturability, and seamless integration with existing imaging workflows.

II. Methods

The platform is based on planar nanocavities-on-silicon (NOS), formed by a single dielectric layer on a silicon substrate. This pattern-free architecture enables wafer-scale fabrication using established semiconductor processes. As illustrated in the workflow of Fig. 1a, tissue sections are directly mounted on the nanocavity slide, imaged using standard reflection-mode bright-field microscopy, and subsequently available for either visual assessment or downstream digital analysis. Structural-color imaging is performed without specialized illumination sources or major modifications to existing imaging instrumentation. The design prioritizes robustness, reproducibility, and seamless compatibility with standard digital pathology and AI-enabled analysis pipelines.

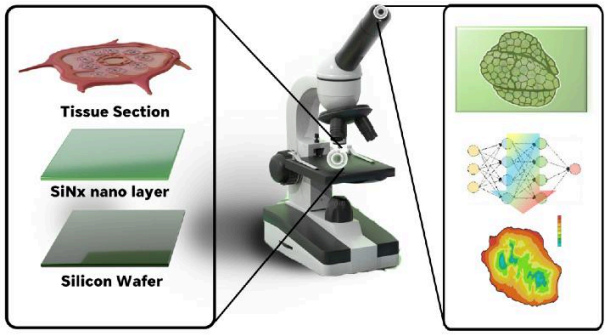

Fig. 1 Schematic of smart histological diagnosis on NOS slides.

III. Results and Discussion

Experimental results show:

- The structural-color nanocavity platform produces vivid, spatially resolved color contrast that translates intrinsic optical variations of tissue into diagnostically relevant visual information without staining. As shown in Fig. 2, its planar design ensures a uniform optical response across large areas and stable color contrast for tissue sections under routine imaging conditions.
-

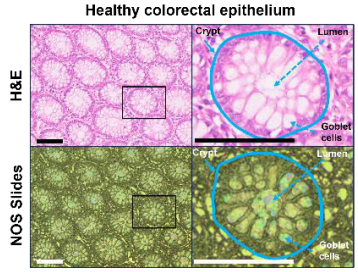

Fig. 2 Comparison of pathological serial sections of organs and tissues imaged using H&E staining and NOS slides, showing healthy colorectal epithelium with a zoomed-in epithelial cell.

- Compared with many advanced imaging modalities, the platform operates without substantial changes to optical hardware or imaging systems, significantly reducing system-level cost and deployment barriers. As demonstrated in Fig. 3, the resulting low manufacturing cost enables large-scale image acquisition, creating favorable conditions for downstream artificial-intelligence-based analysis and automated tissue assessment. These features position the platform as a practical bridge between nanophotonic innovation and real-world digital pathology.

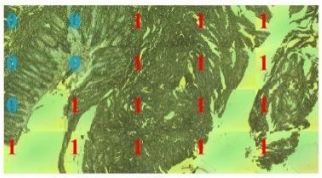

Fig. 3 Results of an AI classification model using the dataset from NOS slides.

IV. Conclusion

We have demonstrated a scalable structural-color nanocavity platform that enables stain-free digital pathology while addressing key barriers to commercialization. By combining planar nanocavity design, wafer-scale manufacturability, and compatibility with standard optical microscopes, this platform offers a realistic pathway for large-scale deployment and AI-enabled histological imaging. The approach illustrates how simplified nanophotonic architectures can accelerate translation from laboratory research to clinical and industrial applications.

***Abstract*— Subwavelength grating metamaterials have become a key tool in silicon photonics, enabling integrated optical devices with unprecedented performance. This invited talk reviews some of the main contributions made by the University of Málaga, in close collaboration with the National Research Council of Canada (NRC), to the development of this field. Particular emphasis will be placed on practical considerations in the design, fabrication, scaling, and qualification of these devices, as well as on how this line of research ultimately led to the creation of AGPhotonics, a university spin-off focused on integrated-photonics solutions for free-space optical wireless communications.**

***Keywords*— integrated photonics, silicon photonics, subwavelength gratings, metamaterials, optical antennas, free-space optical communications.**

Integrated photonics is rapidly emerging as a foundational technology for next-generation communications, sensing, signal processing, and AI-oriented computing hardware. Within this landscape, silicon photonics has become particularly attractive thanks to its scalability and compatibility with mature CMOS manufacturing techniques. One of the developments that most profoundly expanded its design space was the advent of subwavelength grating (SWG) metamaterials, which enabled precise lithographic control of effective index, dispersion, anisotropy, and radiation, converting periodic structures into essential building blocks for high-performance photonic integrated circuits [1].

This invited talk reviews the contributions that shaped our group's twenty-year trajectory in subwavelength grating integrated photonics [2]. From early SWG-based fiber-chip couplers [3] and dispersion-engineered broadband directional couplers [4], our work developed the theoretical, numerical, and technological basis needed to exploit periodic structures across their subwavelength, Bragg, and radiative regimes, while also clarifying practical issues such as substrate leakage in SWG waveguides through experimentally validated design rules [5]. This enabled a broad portfolio of high-performance devices, including ultra-broadband compact 3-dB/90° couplers based on anisotropy engineering [6], polarization-insensitive components in standard 220-nm SOI [7], narrowband and arbitrary-response Bragg filters [8], distributed Bragg deflectors for controlled on-chip beam shaping [9], and, more recently, directive, steerable integrated optical phased-array antennas for free-space optics [10].

Beyond the scientific and technological advances, this work also had a strong educational and technology-transfer impact. Over two decades, the group has trained numerous undergraduate, MSc, and PhD students, many of whom produced award-winning research, high-impact publications, and patents. This accumulated know-how in periodic integrated photonics, together with the sustained formation of talent, enabled the creation of AGPhotonics, a spin-off focused on integrated transceivers for future optical wireless communications [11].

Photonic Band Gap Robustness of Stealthy Hyperuniform Metamaterials

***Abstract*—We design, simulate, and fabricate stealthy hyperuniform metasurfaces of variably shaped silicon pillars for the mid-IR. Simulations reveal large photonic band-gaps (PBG) approximately 37% in width. Measurements show enhanced reflection regions around 950-1020 cm^{-1} corresponding to the PBG location for all geometries, confirming band-gap robustness to variations in pillar cross-section.**

***Keywords*— metamaterials, metasurfaces, disordered media, photonic gap, stealthy hyperuniform, fabrication, silicon, FTIR**

I. Introduction

Hyperuniform structures are metamaterials that exhibit an exotic state of matter [1], [2], [3] by blending crystal and liquid like characteristics. Characterizing these novel heterostructures using order metrics, such as pair correlation or structure factor, reveals long range order in inherently disordered media. For a point distribution to be *hyperuniform*, the structure factor $S(k)$ must vanish in the neighborhood of small k [1]:

$$\lim_{|k|\to 0} S(k) = 0 \tag{1}$$

Stealthy hyperuniform (SHU) structures are a special subclass of hyperuniformity; "Stealthiness" requires the structure factor $S(k)$ to vanish for a finite range of wavenumbers smaller than a critical wavenumber $k < K_c$. Studies have demonstrated SHU structures exhibiting crystal and liquid like behavior, such as photonic band gaps (PBGs) and spatial isotropy in the microwave [4] and mid-IR range [5]. Applications of hyperuniformity include silicon photonic waveguides [6], and hyperuniform THz quantum cascade lasers [7].

In this work, we design, simulate, fabricate, and characterize a SHU pattern of shaped pillars on a low doped silicon substrate to maximize transparency. The pattern is realized through a collective coordinate optimization algorithm with a targeted structure factor condition [8]. The generated SHU pattern forms a 30 X 30 μm square unit cell with periodic boundary conditions that can be tiled. We simulate the SHU structure as infinitely long semiconductor pillars embedded in air, and the transverse magnetic (TM) band diagram is computed along the irreducible Brillouin zone. Various regular geometric shaped pillars were generated to examine the robustness of the PBG size and location. Patterns of circles, triangles, squares and crosses were found to have large PBGs of widths about 37%, 37%, 40%, and 14%, and PBG center frequencies around 1065 cm^{-1}, 1065 cm^{-1}, 1165 cm^{-1}, and 1288 cm^{-1}, respectively.

II. Fabrication

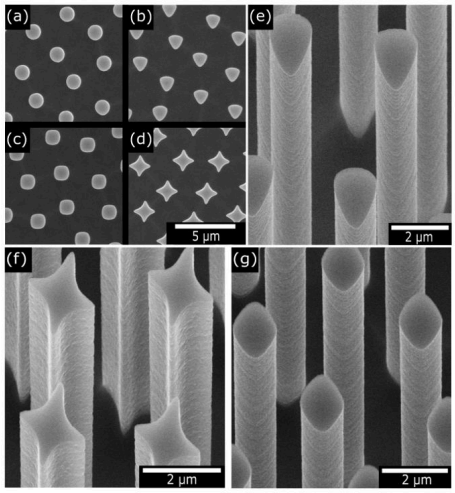

Fig. 1. Scanning Electron Microscopy (SEM) top view images of (a),(b),(c),(d) the shaped silicon pillars, and (e), (f), (g) the tilted view showing silicon pillars approximately 8.5 μm tall. Scalloping from the Bosch process is noticeable on the sidewalls.

Once the size and location of the PBG is confirmed via simulations, the SHU designs are then fabricated in two major steps; lithography and dry etch. The low doped silicon is spin coated with AZ 5214 image reversal photoresist for its thickness and feature resolution. The SHU pattern is then tiled to cover an area of approximately 1 cm^2, and the exposure conducted via direct write. An optimized recipe using this method of photolithography allows for writing of sub micrometer features necessary for our shaped pillars. The sample is then dry etched using the Bosch process using the photoresist

as a mask. Shown in Fig. 1 are top, and side view, electron microscopy images of the fabricated samples; sharper angles can be achieved by switching to electron beam lithography. The shaped silicon pillars were etched to approximately 8.5 μm deep and cleaned in piranha/HF solutions. Scalloping from the Bosch process is present on the sidewalls of all structures, however, these features are about 100 nm wide and do not interfere with IR spectrum measurements from the FTIR.

III. Characterization

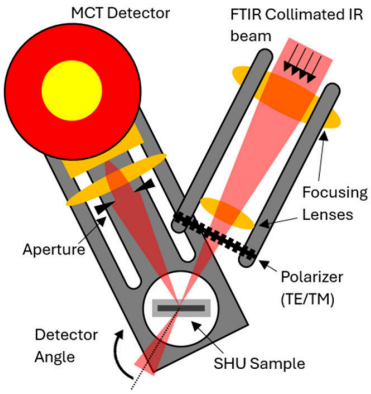

Fig. 2. Experimental setup for transmission and reflection spectra measurement for the SHU metasurfaces. Broadband IR light is TM polarized and focused onto the surface of the SHU structure. The sample and detector can freely rotate to measure various incidence angles.

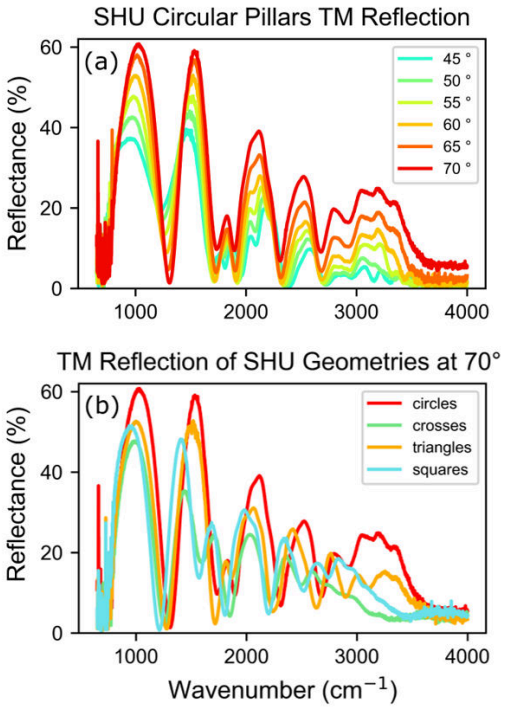

Fig. 3. FTIR TM spectra of (a) the circular pillars, and (b) the 70° reflection of all shapes. The circle spectra shows enhanced reflection with increasing incidence near 1020 cm^{-1} corresponding to the PBG from simulation at 1065 cm^{-1}. All geometrical shapes display an enhanced reflection region around 950-1020 cm^{-1}, and fringing associated with thin film interference from the metasurface.

The shaped pillar SHU samples are characterized by using a broadband IR light from a FTIR. Fig. 2 shows light passing through a polarizer and focused by ZnSe lenses onto the sample surface. The SHU sample and photodetector are both placed in independent rotational stages; allowing for fine adjustment of the incidence angle onto the metasurface. Fig. 3 (a) shows the TM reflection of the circular pattern SHU metasurface for various incidence angles (45°-70°) with an enhanced reflection region around 1020 cm^{-1}. This increased reflection corresponds closely to the simulated PBG around 1065 cm^{-1}, and is most notable with increasing incidence angles. Moreover, the oscillating peaks at 1020 cm^{-1}, 1530 cm^{-1}, 2120 cm^{-1}, ..., correspond to interference fringes from the SHU metasurface acting as a thin film on the bulk silicon substrate. Fig. 2 (b) shows the TM 70° incidence reflection of all four geometries, where an enhanced reflection region near 950-1020 cm^{-1} appears; confirming that SHU structures are indeed robust to changes in geometric shape.

IV. Applications and Conclusion

Studies have demonstrated that metamaterials with PBGs are capable of image differentiation [9], [10], Additionally, SHU metasurfaces function as tunable IR low pass filters by adjusting the target structure factor [5], [9]. In this study, we have simulated and realized a SHU metasurface and observed increased reflection associated with the designed PBG in all four geometries, cementing the fact that changes in the pillar geometry does not cause the PBG to shrink or be destroyed. SHU metasurface manufacturing can be scaled up via UV stepper photolithography, and large diameter automatic wafer processing to increase yield. Moreover, the robustness of the PBG to changes in geometry make it resilient to fabrication defects, such as sidewall roughness from dry etching.

This work was performed in part at the Micro/Nano Fabrication Center (MNFC), a core shared-use facility of the Princeton Materials Institute (PMI). Application focused meta-surface design: workflow, methods & examples

L. Penninck[1,*], C. Beckerleg[1], B. Robben[1]

[1]PlanOpSim NV, Gent, Belgium

*Corresponding author: lieven.penninck@planopsim.com

***Abstract*—Large volume metasurface applications are now a commercial reality. In this contribution we outline the engineering methods and workflows that enable design of metasurface products not demonstrators. This includes efficient design cycles, design-for-manufacture and system integration. Popularization of these methods will allow broad adaptation of metasurfaces in the optical industry.**

***Keywords*— metasurfaces, sensitivity analysis, design-for-manufacture.**

I. Introduction

Metasurface sensors are now applied in smartphone sensors. This marks a milestone for the metasurface field., that what once was an curious lab experiment is now a competitive mass market application. While many research groups have demonstrated metasurfaces for various applications on a lab scale. The know-how to develop metasurfaces for products and volume manufacturing is limited to a few specialized companies. The next step needed for a broad scale application of metasurface is for these methods to become known and available to the field as a whole.

II. Manufacturability

A critical concept is design-for-manufacture. Designing nanostructures, components not just for optimal performance in the idealized nominal situation but for robust performance given realistic manufacturing variability.

The field of electronics and photonic integrated circuits extensively used foundry provided design rules and process development kits (PDKs). Adhering to design rules ensures that a design meets the foundries processes. While PDKs ensure that structure are not only manufacturable but that their process has been optimized. An additional benefit is that designs made with the same PDK can share a lithograpy/imprint mask in a multi-project wafer (MPW). MPWs significantly reduce the prototyping cost making metasurface design accessible for more designers. First meta-atom PDKs have been released and integrated in commercial software tools [1].

In addition to process optimization, sensitivity and Monte Carlo analysis are needed to identify sensitive parameters and designs with higher tolerance to inevitable variability across wafers and between batches [2].

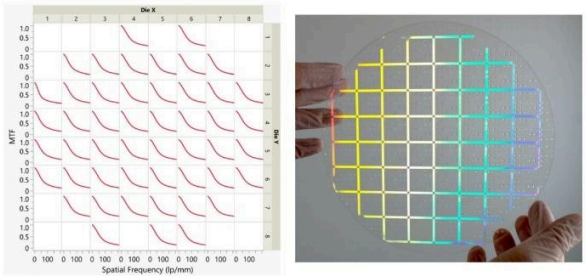

Fig. 1 MTF variability across dies in a wafer via PDK process. PDKs are integrated into design software [1].

III. System integration

Manufacturability is not limited to individual metasurfaces. Their integration and alignment with other sensors, lenses, and metasurfaces also can make or break product performance.

Integration methods for co-optimization of meta-surfaces have been developed. These allow combining traditional refractive and reflective designs with metasurfaces. These methods generally rely on continuous phase approximations. An important future development will be extending these methods to take into account higher order diffraction and stray light. As well as mitigating the system impact of nanostructure variability.

IV. Conclusion

Metasurfaces have reached the stage of mass manufacturing. Broad availability of design-for-manufacture methods and system design can enable a new range of applications for metasurfaces..

***Abstract*: Sol-gel chemistry combined to direct nanoimprint lithography was developed to elaborate robust metal-oxide meta-surfaces. This presentation shows that such a combination enables the facile production of various types of metasurfaces with materials specifically developed to cover a wide span of refractive index and an exceptional transparency.**

***Keywords* - Extreme refractive index (meta)materials, high transparency, direct NIL processing,**

Conventional top-down fabrication methods for metasurfaces are often cumbersome and expensive (both CapEx and production costs). Here, we showcase the use of Soft-Nano-Imprint-Lithography (soft-NIL) as a scalable, cost-effective, and CMOS-compatible method for directly imprinting sol-gel precursor resins into metasurfaces of metal oxides (e.g. SiO_2, TiO_2, VO_2, see Fig. 1). Photonic metasurfaces can be prepared with vertical aspect ratios up to 7, on diverse substrates such as glass, fused silica, sapphire, and silicon wafers. A precise adjustment of the chemical precursors and nano-imprint conditions ensure faithful replicas over large areas: the method is scalable up to 200 mm wafers, limited only by the plate-to-plate machinery employed. The resulting materials offer controlled, on-demand refractive indices ranging from 1.12 to 2.6@520 nm with near-zero extinction for passive photonic devices and extremely low haze. Various metasurface designs addressing diverse functionalities,[1-7] such as (i) light in- and out-coupling and transport for Augmented Reality and PICs using ultra high index materials, (ii) broadband and broad-angle anti-reflection coatings with high LIDT for high power laser optics, (iii) air-gap alternatives and cladding layers using ultra-low index materials, together with (iv) reconfigurable metasurfaces using the Metal to Insulator Transition of VO_2 metaatoms, have been developed and are discussed. This work highlights the potential of soft-NIL in advancing the field of optical metasurfaces and paves the way for their widespread applications in next-generation devices.

***Abstract*— Structured light from a spatial light modulator can programmably drive a real-time photomechanical response in azopolymer films. This new platform can print a variety of planar diffractive optics, including linear, circular and chirped gratings, dynamic diffractive elements, and structured color elements.**

***Keywords*— holographic, azopolymer, diffractive optical elements, microstructure, grating.**

I. Introduction

Spatially structured optical intensity or polarization drives a photomechanical response in azopolymer films, resulting in the formation of surface relief microstructures. The writing light is conventionally generated via multibeam laser interference, which is limited to fabricating structures of fixed period and orientation. Here we report that a spatial light modulator (SLM) configured as an intensity or polarization modulator is an alternative writing technique with several key advantages. The SLM can project structured light that is spatially addressable, enabling the facile fabrication of microscale planar optics in real-time and with no post-exposure chemical processing. Structures can be replicated immediately after exposure and in many cases can be dynamically reconfigured.

II. Experiment

Figure 1 shows the experimental setup. The laser is a 488 nm DPSS and the SLM is a liquid crystal on silicon, phase-only device.

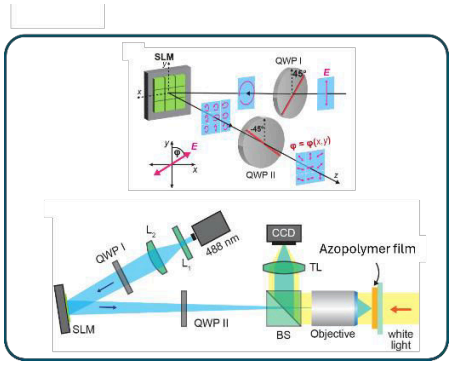

Fig. 1 SLM-based setup for dynamic photofabrication

III. Results and Discussion

When configured as a polarization modulator, the SLM maps grayscale images directly to the orientation of linearly polarized light on the film surface, resulting in a photomechanical stress that drives surface deformation. Single exposures of order 0.01 mm^2 in area can be stitched or raster-scanned for larger area structures. Structures such as linear gratings, sin-phase plates, and computer-generated holograms are readily implemented. First order diffraction efficiencies for typical holographic gratings are 33% at 633 nm. Currently, the lateral resolution is 600 nm, with z-resolution 2 nm.

One appealing application is in structured color. Here, the SLM is addressed to write spatially-multiplexed gratings with periodicities that generate RGB color-additive diffraction modes, with custom color generation based on grating area and amplitude.

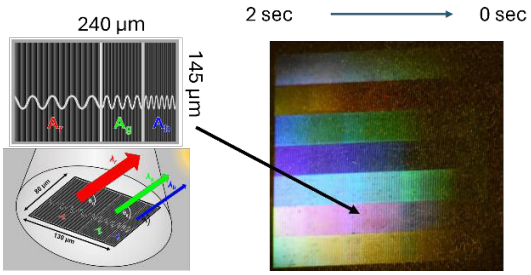

Fig. 2 100 x 100 array (right) of area-tuned RGB microgratings

***Abstract*— Plasmonic OLEDs, which utilize plasmonic effects to control light emission, demonstrate enhanced performance compared to traditional devices. Here, we present our recent results and discuss their potential applications in both current and future display technologies.**

***Keywords*— Plasmonics, OLED, displays, metasurface.**

I. Introduction

Organic light emitting devices (OLEDs) offer superior color saturation, unconventional form factors and reduced power consumption compared to conventional display architectures leading to their widespread adoption in displays. Plasmonic OLEDs further improve the properties of OLEDs by enhancing device stability, setting new limits on efficiency, and enabling tunable emission via device design. The decay rate enhancement caused by the coupling of excited states to the surface plasmon modes of metal contact enhances the device stability by minimizing the likelihood of destabilizing excited state interactions. Metallic structures with plasmonic material extracts energy from the surface plasmon mode and convert it to light, thereby enhancing the device efficiency, while providing the emission control needed for advanced display applications. Here, we present our recent results on plasmonic PHOLED research, highlighting emission tunability and device stability enhancements which may be leveraged for future display technologies.

***Abstract*—Manipulation of light below the diffraction limit in a two-dimensional plane is possible using patterned surfaces called metasurfaces. For light-emitting applications, metasurfaces can be coupled to semiconductor films to increase luminescence quantum-yield, rate, and directionality of photon emission. In this presentation, our research on improving light extraction efficiency and photostability of organic semiconductor thin films using plasmonic metasurfaces will be presented.**

***Keywords*—metasurface, light-emission, Purcell Effect, light-extraction, OLEDs**

I. Introduction

Plasmonic metasurfaces can be used to modify the light-extraction efficiency, emission rate and photostability of light-emitting materials placed with their near-field. In this presentation, we report on our investigations of interactions between plasmonic modes of the metasurface and the excitonic transitions of fluorescence and phosphorescent organic semiconductors used in blue organic light-emitting diode (OLEDs). Optimization of the Purcell effect enables greater photostability of the OLED emitter at the expense of quantum efficiency. However, the light-extraction ability of the metasurface can be used to compensate for non-radiative pathways introduced by the metasurface. The work is relevant to addressing the poor stability and low efficiency of blue OLED pixels using in portable display applications.

II. Methods

Silver nanoparticles are introduced at different device interfaces and within different layers from the anode to the cathode of blue OLEDs to combat the various optical losses that reduce light-extraction efficiency and to study the impact of changes in recombination rate on operational stability. We chose a blend of PFO:F8BT to study fluorescent OLEDs, and a blend of PVK: FIr6 to study blue phosphorescent OLEDs as a function of different nanoparticle additions. Studies of photostability used grating, nanoparticle and nanoporous silver metasurfaces fabricated by thermal dewetting and nanoimprint lithography. Additionally, for device studies, both colloidal silver nanoparticles and discrete thermally dewetted silver nanoparticles were integrated within OLED layers. We measured photoluminescence (PL) lifetime, PL quantum yield and PL stability of the emissive layers on the different silver metasurfaces and characterized the current-density, luminance, electroluminescence, and external quantum efficiency of the OLEDs to investigate how positioning of the plasmonic structures affects the efficiency and operational stability of the OLEDs.

III. Results and Discussion

Initial proof-of-concept studies of the use of silver metasurfaces to improve the photoluminescence stability of blue OLED phosphors show that the increased recombination rate improves the photostability of the phosphor due to the reduction in triplet quenching pathways [1]. The lifetime of phosphorescence is decreased significantly by nanoparticle-based plasmonic surfaces, which improves the photostability of the blue organometallic phosphor by up to a factor of 3.6. Other plasmonic surfaces are also tested and exhibit less significant photostability improvements due to a reduced spectral overlap of the plasmonic modes with the emitter and lower mode confinement. The use of plasmonic surfaces to improve phosphor photostability at blue wavelengths is distinct from other approaches because it involves modification to the local electromagnetic environment of the phosphor rather than modifications to the phosphor molecular structure or the emitting material composition.

In electroluminescent devices that integrate discrete silver nanoparticles into a bottom-emitting OLED device stack, we study several factors like quantum efficiency, PL lifetime and operational stability and find that although the silver nanoparticles can influence the radiative rate as well as the light outcoupling efficiency in OLEDs, they can also cause new photonic and electronic effects, particularly near the anode side

of the device, that need further study and optimization. In particular, we need a deeper understanding of the different mechanisms happening at the anode/hole-transport layer interface and the hole-transport layer/emissive layer interface to fully understand what needs to be done further increase Purcell enhancement, so as to improve the device stability [2]. Future work will focus on integrating the silver metasurfaces into top-emitting OLEDs, which are more amenable to the integration to metasurfaces into the back silver electrode. Additionally, the need for planarization layers and rapid nanofabrication to aid in the commercialization of metasurface-integrated OLEDs will be discussed.

IV. Conclusion

This work aims to contribute to solving the issue of low-performance blue OLEDs by improving the stability and efficiency of the devices, as well as achieving the "true blue" color that is required by the display industry, by manipulating interactions between plasmonic silver nanoparticles and metasurfaces, and OLED emissive layers.

Agentic Photonic Simulation with Tidy3D

Zongfu Yu and Yannick Augenstein

Flexcompute Inc.

zongfu@flexcompute.com

Abstract

The design and simulation of photonic devices traditionally demands deep domain expertise, manual scripting of simulation parameters, and iterative debugging — a workflow that creates steep barriers for new researchers and limits throughput even for experienced practitioners. In this work, we present an agentic framework for photonic simulation built on Tidy3D, a GPU-accelerated finite-difference time-domain (FDTD) platform, that leverages large language model (LLM) agents to automate the end-to-end simulation lifecycle. Our framework, powered by FlexAgent and the Model Context Protocol (MCP), transforms the conventional simulation workflow into a natural-language-driven, context-aware process in which an AI agent can autonomously construct electromagnetic models, configure simulation parameters, launch cloud-based GPU computations, and interpret results — all without requiring users to write a single line of code.

Central to our approach is the integration of physics-informed tool use within the agentic paradigm. Rather than relying on generic code generation, our agent is equipped with structured access to Tidy3D's full API surface, up-to-date documentation, and a 3D visualization interface through the MCP framework. This enables the agent to reason about electromagnetic simulation concepts — such as boundary conditions, mesh refinement, source placement, and monitor configuration — with domain-specific accuracy, substantially reducing the error rates commonly observed when general-purpose LLMs attempt simulation scripting. The agent can also iteratively refine simulations by analyzing intermediate outputs and adjusting parameters in a closed-loop fashion, mimicking the expert-level workflow of an experienced photonic engineer.

We demonstrate the capabilities of this agentic framework across a range of representative photonic devices, including waveguide couplers, grating structures, and metasurface elements, showing that the agent can reliably produce simulation setups that converge to physically meaningful results. We further discuss the implications of agentic simulation for accelerating photonic design cycles, democratizing access to high-fidelity electromagnetic modeling, and enabling new paradigms such as agent-driven inverse design and autonomous design-space exploration. Our results suggest that the combination of GPU-accelerated solvers with LLM-based agents represents a transformative step toward fully autonomous photonic design workflows.

Abstract- Inverse designed flat optics enable compact generation of long depth of focus laser beams for micromachining and structured light. We report multilevel diffractive lenses that maintain focused femtosecond spots over twenty millimeters, extend plasma channels to fifty five millimeters, and generate nondiffracting bottle beams over more than five centimeters.

Keywords- flat optics, inverse design, multilevel diffractive lens, beam shaping, micromachining, meta optics.

I. INTRODUCTION

Inverse designed multilevel diffractive lenses provide a compact route to three dimensional laser focus control with a single surface optical element. By optimizing the transmitted phase directly for a target axial intensity distribution, these flat optics can generate extended depth of focus, structured focal volumes, and application specific beam profiles that are difficult to realize with conventional refractive lenses. This direction is especially timely for the META community because recent rigorous comparisons at high numerical aperture show that conventional diffractive optics can remain highly competitive with, and in some cases outperform, metalenses when evaluated on equal footing [1-4].

II. METHODS

We use inverse design to determine the radial height profile of multilevel diffractive lenses for a prescribed three dimensional intensity distribution. The devices are fabricated by grayscale lithography as concentric multilevel structures. For bottle beam generation, a binary axicon first produces a Bessel input beam with suppressed sidelobes, which is then transformed by the multilevel diffractive lens. For femtosecond micromachining, the designed lens is illuminated by 800 nm pulses with 25 fs duration and pulse energies up to about 2 mJ [2,3].

III. RESULTS AND DISCUSSION

In this presentation, we will show several experimentally validated beam shaping regimes. First, a 1064 nm multilevel diffractive lens produced an extended depth of focus exceeding 15 mm with an approximately 32 μm focal width, while maintaining nearly constant beam size over propagation distances up to about 70 mm [1]. Second, for femtosecond pulses, a 10 mm diameter lens designed for a 200 mm working distance achieved an extended depth of focus of 20 mm, with focused spot sizes of about 24 to 35 μm across z = 18 to 22.5 cm and about 90% intensity transmission [2]. A second design provided an average spot size of about 60 μm over z = 27 to 37 cm [2].

In air, the same approach increased plasma channel length from 15 mm for a conventional lens to 55 mm for the flat optic, while laser marking on glass retained widths on the order of tens of microns over the extended focal region [2]. Third, when a Bessel beam illuminates the flat lens, the output becomes a sharply defined nondiffracting bottle beam with visibility about 0.86, period ranging from 0.2 to 1.36 mm, and propagation invariant behavior over more than 5 cm, reaching about 75 mm in our experiments [3]. Finally, recent high NA comparisons show that a Fresnel zone plate can reach 30 percent focusing efficiency at NA = 0.98, compared with 12 percent for a metalens of identical specification, reinforcing the performance relevance of carefully designed conventional diffractive optics within meta optics [4].

IV. CONCLUSION

These results position inverse designed diffractive flat optics as a practical platform for compact high performance laser beam shaping. The combination of long depth of focus, structured bottle beams, high transmission, and manufacturable multilevel profiles makes this approach promising for micromachining, filamentation, imaging, and broader meta optics applications.

Metaoptics metrology using a wave front sensor

Matthieu Ansquer, Nolan Chan, Benoit Wattellier

PHASICS, Parc Technologique, 91190 Saint Aubin, FRANCE
*Corresponding author: bw@phasics.com

***Abstract*— We present a solution for the metrology of metasurface optical properties based on wave front sensing. For this purpose, we use quadriwave lateral shearing interferometry, on which all PHASICS products are based. This commercial solution is easily integrated in academic laboratories for upstream studies but also in industrial metrology labs or in production lines.**

***Keywords*— metasurfaces, wave front sensing, quadriwave lateral shearing interferometer, singular beams, non-hermitian beams**

I. Introduction

Metasurfaces can be used to modulate the intensity and phase of a light beam. Polarization modulation is also often implemented with such optics. In theory, their behavior is well known but in real-life environments the optical function may differ from what is expected. Therefore, metrology of their transmittance is of great interest.

Errors on manufactured metasurfaces originate from their design (the theoritical optical function may not be perfect and often neglects coupling between meta-atoms), manufacturing technology (machines are limited in terms of spatial resolution or aspect ratio), manufacturing processes (exposure time calibration, mask alignment) and finally defects (punctual defects, incidents during manipulation).

At each step, metrology can help validating simulation models, understand technology and machine limits, tune exposure times, and other parameters, or detect manufacturing drifts. Finally, metrology is used for quality control of finished products.

Control means [1] include electron microscopy (SEM), which is very accurate but lengthy and can be destructive for the sample. People check the focusing quality of metalenses with intensity measurements in the focal volume. This is an indirect diagnosis and no feedback is usually possible with the design.

Optical transmittance measurement (intensity AND phase) is fast and applicable to any of the above requirements. It is often done with interferometers, which are limited in terms of available wavelengths and do not authorize multispectral characterization.

At PHASICS, we propose using a wave front sensor based on quadriwave lateral shearing interferometry (QLSI) [2] to characterize the transmittance of metasurfaces. It measures the optical ray directions which are proportional to the phase spatial derivatives. These are integrated to obtain the beam wave front (phase or equivalently optical path difference). This wave front sensor is compatible with any wavelength and unsensitive to polarization. The latter is important if one wants to check polarization sensitive MS such as Pancharatmann-Berry (PB) MS (see Fig. 1).

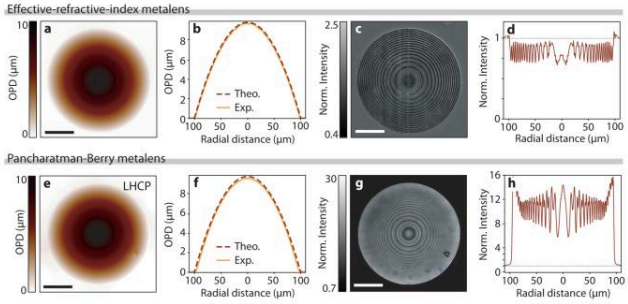

Fig. 1 – Examples of metasurface transmittance measurement with a QLSI of two metalenses using ERI or PB technologies. Extracted from [3]

II. Metrology for metasurface optimization

The set-up to measure the transmittance of any kind of metasurface is quite simple and easily implemented with a standard microscope. An optical source illuminates the metasurface with a plane wave (see Fig. 2). The MS is imaged onto the wave front sensor thanks to a microscope objective. If necessary, circular polarizers are placed before and/or after the sample. The transmittance is obtained by subtracting the wave front measured without the sample in the beam path to the wave front measured with the sample.

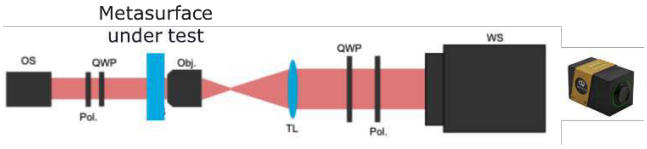

Fig. 2 – Experimental set-up to measure the transmittance of a metasurface in a microscope configuration. The Polarizer (Pol.)/Quarter wave plate (QWP) couples are used as circular polarizers for the characterization of PB MS. OS : optical source, namely a LED. Obj : microscope objective. TL : tube lens. WS : Wave Front Sensor.

Defects in the metasurface are easily and quickly observed without the need to use a scanning electron microscope (see Fig. 3). In this example, the thinnest pillars of an ERI metasurface were washed out during the development step. From the phase image, we could easily feedback with the manufacturing laboratory to further avoid this removal.

The transmittance can be decomposed into the transmission (the square of its modulus) and the phase-shift introduced by the MS optics. The transmission is used to assess the conversion or diffraction efficiency of a metasurface (see Fig. 4).

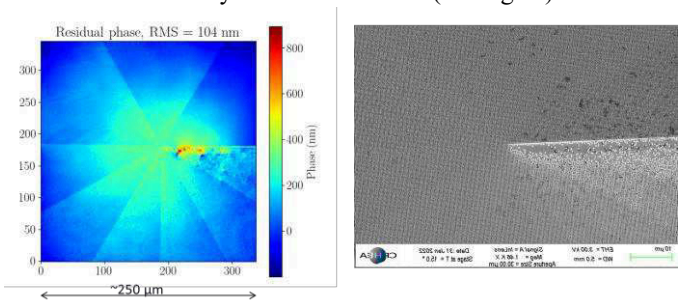

Fig. 3 – ERI metasurface defect as seen from the transmittance map (left) and a scanning electron microscope (right)

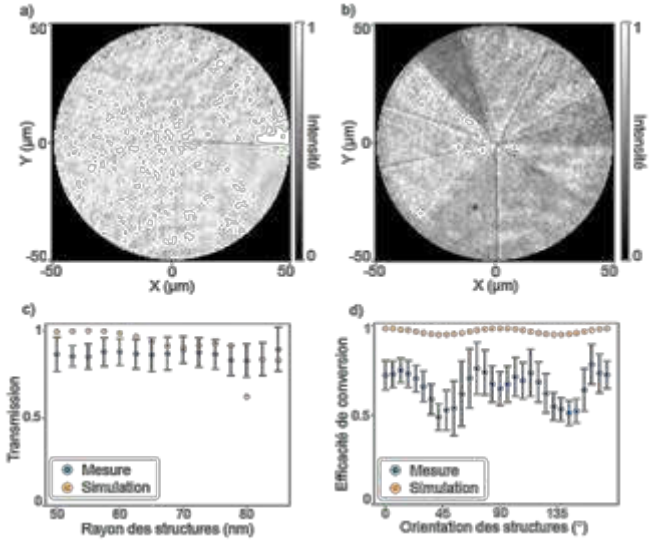

Fig. 4 – Efficiency study for an ERI (left) and PB (right) metasurfaces. The transmission is extracted from the intensity map and compared to the one obtained without a sample. For the ERI MS, we plot the transmission as a function of the pillar radius, which corresponds to the phase levels. For the MS, the phase variation is obtained by rotating a base pattern, generating a so-call geometrical phase. Due to coupling between different orientations, the conversion efficiency may be lower.

III. Singular and non-Hermitian metasurfaces

We got interested into the characterization of singular metasurfaces, which generate optical vortices for instance. Here the challenge is that the transmitted phase is not continuous and its derivatives are not a conservative vector field. Standard numerical integration algorithms cannot recover such functions. However, the information is still there and singularities are visible as peaks when one computes the curl of the derivatives [4,5].

Using this method, we were able to characterize MS generating beams containing multiple vortices (see Fig. 5) or a combination of irrotational and rotational patterns.

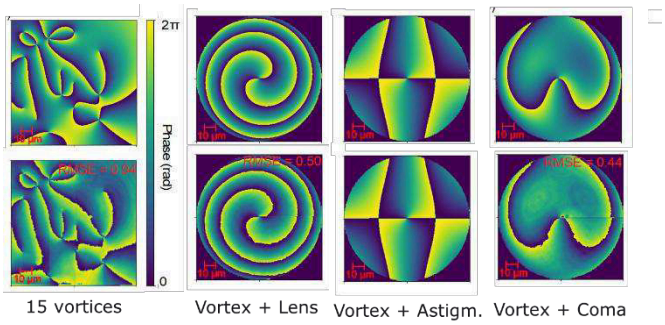

Fig. 5 – Examples of transmitted phase measurement of PB metasurfaces containing one of more singularities combined with other "irrotational" patterns

IV. Conclusion

In this presentation, we show how a wave front sensor is a powerful tool to characterize the transmission of any kind of metasurface. We focus on the use of QLSI, a wave front sensing technique well suited for this purpose thanks to its dense spatial resolution, low phase resolution (below 1 nm) and insensitivity to wavelength and polarization.

Mechanisms of noise immunity in quantum nonlinear and nonreciprocal dynamics

Nicholas Rivera[1]

[1]School of Applied and Engineering Physics, Cornell University, USA
*Corresponding author: nrivera@cornell.edu

***Abstract*— Noise immunity: observables weakly sensitive to dominant noise channels, can extend photonic devices to ultimate quantum limits of sensitivity and performance. We present a new mechanism of noise immunity based on nonlinear nonreciprocal Kerr lattices that directionally route injected noise, preserving squeezing via a non-Hermitian skin effect.**

***Keywords*— quantum noise, nonlinear optics, non-reciprocity, quantum optics**

I. Introduction

Noise often sets limits on the performance of photonic devices such as high-power lasers, quantum sources of light, and sensing and metrology systems. In this context, the existence of observables that are weakly sensitive (or insensitive) to the dominant noise sources, which we call *noise immunity*, is desirable. This is particularly important also in the context of intriguing effects such as chirality, non-Hermiticity, and non-reciprocity, that are known for adding fundamental noise which can preclude sensitive measurement applications.

II. Results

One approach to noise-immunity, which our group has been developing, is based on exploiting nonlinear multimode dynamics which generate anticorrelations between different modes that mutually cancel the effect of excess noise. For example, in [1], we demonstrate that intense femtosecond fields are converted into outputs with shot-noise-level (and below-shot-noise) intensity fluctuations despite large excess noise at the input, with reported overall noise reduction by a factor of ~30 while retaining extreme intensities (approaching 0.1 TW cm^{-2}). The mechanism is the creation of multimode quantum correlations by conservative nonlinear mixing (e.g., four-wave mixing), followed by *mode-selective filtering* that "down-selects" correlated degrees of freedom whose responses to dominant input-noise channels cancel in the measured observable. In a second approach [2], we show how combining programmable wavefront shaping (via a spatial light modulator) with *spatiotemporally* multimode Kerr dynamics can induce noise-immunity, steering a complex nonlinear system into output states whose intensity noise is dramatically reduced—down to the shot-noise level, even when the incident light carries very large excess fluctuations.

Motivated by these nonlinear-correlation routes to noise immunity, in this talk we highlight a new approach we have developed [3] based on nonlinear, nonreciprocal systems, where symmetry breaking manifests in the spatial transport of fluctuations. A nonreciprocal driven–dissipative lattice of Kerr resonators can route externally injected excess noise predominantly in one direction, thereby isolating a region of the device from excess noise such as intensity noise. In a representative example, injecting phase-insensitive excess noise into a central port degrades squeezing throughout a reciprocal chain, but in the nonreciprocal case the noise is funneled to one side and the other side remains essentially unaffected by the noise, preserving even a small amount of squeezing over a wide (~40 dB) range of injected noise levels. This behavior can be understood through the topology of an effective "noise Hamiltonian" and its associated non-Hermitian skin effect, which produces boundary-sensitive, edge-localized noise eigenmodes and strongly asymmetric steady-state noise profiles.

III. conclusions

Our results illustrate that by combining ideas in non-reciprocal systems with controlled nonlinearity, seemingly fundamental noise generation in non-reciprocal systems can be mitigated, potentially enabling the incorporation of these effects in practical photonic devices and sensors.

***Abstract*—We experimentally demonstrate two distinct spin redirection Berry phases in a single triangular Möbius microwave resonator. Fractional azimuthal mode numbers and frequency shifts relative to symmetric cavities confirm geometric phase accumulation linked to electromagnetic helicity.**

***Keywords*— Berry phase, Möbius resonator, microwave cavity, electromagnetic helicity, topological photonics.**

I. Introduction

The Berry phase, Π, is a geometric phase acquired during cyclic adiabatic evolution and appears across quantum and classical systems. In photonics, spin redirection Berry phases arise when polarised waves follow non-planar trajectories in momentum space [1]. Recent optical experiments [2] demonstrated a single Berry phase in rectangular dielectric Möbius resonators. Here, we extend this concept to microwave frequencies in a free-space resonator, using a triangular cross section electrically conducting boundary with D_3 symmetry. Unlike previous studies, this geometry supports two distinct Berry phases of equal magnitude but opposite sign within a single device. The resonator geometry supports electromagnetic modes with nonzero helicity, $\mathscr{H}$ [3], found to relate to the sign of Π, enabling direct observation of geometric phase accumulation through spectral measurements.

II. Methods

Three geometries were studied: asymmetric twisted Möbius resonators; untwisted toroidal resonators; and mirror-symmetric curved resonators, in which the cross section is twisted in one direction across π-radians and then twisted back the opposite direction for the remaining π-radians. These geometries are presented in Fig. 1 and are denoted by the nomenclature D^r_{sx}, where D_s specifies the s-fold dihedral symmetry of the resonator cross-section, r indicates the absolute number of full rotations of the cross-section in 2π-radians, and x identifies the global symmetry of the resonator, with A denoting mirror asymmetric Möbius-type geometries and S denoting mirror-symmetric. It can be shown that the two symmetric systems in Fig. 1 are topologically identical and therefore produce the identical resonant frequency spectra.

The twisted triangular resonator enforces a discrete rotational twist of integer multiples of $2\pi/3$ per circulation of the resonator. Finite element modelling was used to compute eigenfrequencies and field distributions for the lowest order Transverse Electric resonant mode family, $\mathrm{TE}_{1,0,n}$. The azimuthal mode number was extracted by counting surface current density antinodes over a complete loop. Twisted resonators require three windings for closure, leading to fractional mode numbers of the form: $n = \mathbb{Z} \pm 1/3$. Fractional values indicate accumulated Berry phase, a result of the $\mathrm{TE}_{1,0,n}$ modes' lack of rotational symmetry and hence exhibiting a $2\pi r/3$ phase offset with themselves after completing a full circuit of the resonator. Mirror symmetric geometries yield integer mode numbers only.

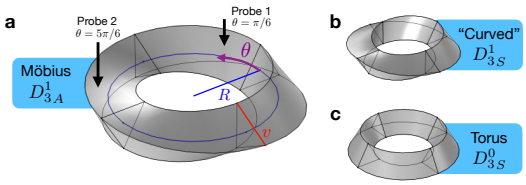

Fig. 1. Examples of the geometries considered; (a) the D^1_{3A} resonator, (b) the D^1_{3S} resonator and (c) the D^0_{3S} resonator. Shown are the free-space volume of the devices, with boundary conditions simulated as perfect electric conductors.

The Berry phase was extracted from measured frequency shifts between twisted and symmetric resonators. The phase is proportional to the frequency difference between $n = \pm 1/3$ modes in the former and $n = \mathbb{Z}$ modes in the latter. Separate internal eigenchannels corresponding to positive and negative electromagnetic helicity [3], which is proportional to the degree that electric and magnetic field vectors are parallel or anti-parallel, respectively, acquire distinct geometric phases, specifically $\Pi = \pm 2\pi/3$.

The D^1_{3S} and D^1_{3A} systems were then 3D-printed in aluminium and the frequency difference between resonant modes used to determine the experimentally confirm the simulated estimates of Berry phase in the Möbius resonators.

III. Results and Discussion

Simulated results confirm the appearance of fractional azimuthal mode numbers in the D^1_{3A} resonators, which are frequency shifted from their symmetric counterparts in opposite directions corresponding to the mode's electromagnetic

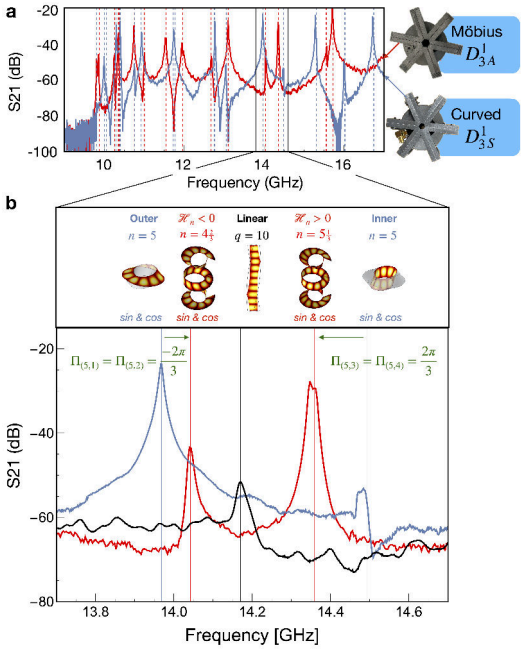

Fig. 2. (a) Experimental S_{21} transmission measurements of the D^1_{3S} (blue) and the D^1_{3A} (red) resonators. The gridlines, colour-coded to match the respective measurements, mark the simulated resonant frequencies of the $\mathrm{TE}_{1,0,n}$ modes for each resonator. These 3D-printed cavities are shown on the right.(b) A magnified view of the transmission spectra highlighting the $\mathrm{TE}_{1,0,5}$ mode of the D^1_{3S} resonator and the $\mathrm{TE}_{1,0,4\frac{2}{3}}$ and $\mathrm{TE}_{1,0,5\frac{1}{3}}$ modes of the D^1_{3A} resonator. For comparison, the transmission of a linear cavity with identical dimensions is also shown for the $\mathrm{TE}_{1,0,10}$ mode.

helicity, $\mathscr{H}_n$. Simulations are conducted for a much larger resonator with radius $R = 79.58$ mm as it gives access to a greater range of n before the onset of higher order modes, whilst a smaller $R = 23.67$ mm was also simulated to match the dimension of the 3D-printed cavities, chosen such that the device was printable.

The 3D-printed resonators demonstrate strong agreement with simulated results, as demonstrated in Fig. 2. The fractional modes appear spectrally between the split doublets of the symmetric resonator. Positive helicity modes shift upward in frequency, while negative helicity modes shift downward. These frequency shifts are directly linked to the Berry phase, which accounts for the adjustment needed to align the fractional $n = \mathbb{Z} \pm \frac{1}{3}$ modes in the D^1_{3A} resonator with the integer modes of the D^0_{3S} resonator. This relationship is expressed as [4]:

$$\Pi_n = \Delta \mathrm{f}_n \frac{4\pi^2 R}{c\sqrt{1 - \left(\frac{2c}{3v f^S_{(n,j)}}\right)^2}}, \tag{1}$$

where $\Delta \mathrm{f}_n$ denotes the frequency difference between companion modes in the two resonators, and c is the speed of light in vacuum.

Using (1), we can relate the difference in frequency spectra between symmetric and asymmetric resonators to the Berry phase for both experimental and simulated devices. In both

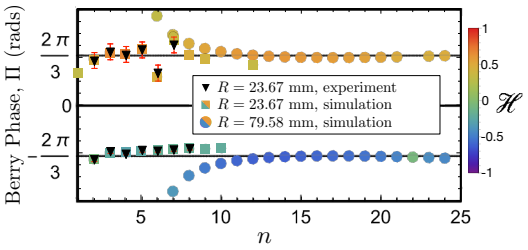

Fig. 3. Π_n as a function of n for the $\mathrm{TE}_{1,0,n}$ modes in the D^1_{3A} resonator for $R = 23.67$ mm (simulated and experimental) and $R = 79.58$ mm (simulated), with associated $\mathscr{H}_n$ depicted by colour. Asymptotic limits of $\pm 2\pi/3$ are shown as black lines. Error bars on the experimental results represent systematic errors.

cases, for both sizes of resonator, as the azimuthal number increases, the Berry phase asymptotically approaches $\pm 2\pi/3$, as demonstrated by Fig. 3. Simulations reveal that reversing the twist direction reverses the sign of the phase for the corresponding helicity, confirming its geometric origin.

The next mode family in these systems, the $\mathrm{TE}_{1,1,n}$ and $\mathrm{TM}_{1,1,n}$, have field profiles that share the rotational symmetry of the D_3 cross-section, and therefore meet up with themselves in-phase after one circulation of the cavity. As a result, these modes do not accumulate any Berry phase and no difference in resonant frequencies observed between the D^1_{3S} and D^1_{3A} resonators.

IV. Conclusion

We have demonstrated the first observation of two distinct Berry phases within a single triangular Möbius microwave resonator. Fractional azimuthal mode numbers and helicity-dependent frequency shifts confirm geometric phase accumulation of $+2\pi/3$ and $-2\pi/3$. This work extends geometric phase engineering to microwave cavity platforms and provides a route toward topologically robust photonic and quantum sensing devices.

Spin-selective Structural Phase Transitions in Chiral Crystals Driven by Chiral Phonon Condensation

Shun Asano*, Youichi Yanase

Department of Physics, Kyoto University, Japan
*Corresponding author: asano.shun.57x@st.kyoto-u.ac.jp

***Abstract*— We predict novel structural phase transitions unique to chiral crystals, where the renormalization of chiral phonon frequency by the electron-phonon coupling depends on their handedness. Consequently, soft mode encoding phonon angular momentum induces spin-selective Peierls gaps in the electronic band, entailing a helical spin density wave and chiral lattice distortion.**

***Keywords*— chiral crystal, Peierls transition, chiral phonon, helical spin density wave.**

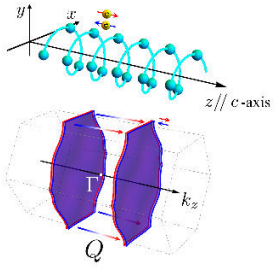
I. Introduction

Structural chirality manifests across material classes ranging from inorganic solids to molecular and biological architecture. Chiral materials have attracted interest due to their distinctive functionalities such as chirality-induced spin selectivity (CISS) and chiral phonons. In parallel, artificial strategies to engineer desirable chiral structures have advanced, with biological systems providing blueprints for elaborated chiral architectures.

However, existing design strategies are primarily chemical or symmetry-based, leaving open whether functionality can stabilize chiral structure and be active drivers of self-organization of materials. Addressing this question demands elucidating how structures and functional electronic or lattice responses mutually shape one another, ultimately determining ordering principles in chiral materials. Here, we address this issue by unveiling a spontaneous phase transition unique to chiral crystals with screw symmetry. Inspired by the Peierls transition [1], we predict a structural phase transition driven by condensation of chiral phonons, which we term chirality-induced spin-selective Peierls transition (CISSPT).

II. Methods

This presentation is based on our work in Ref [2]. In this work, we focus on the case where the parent phase is a chiral metal as shown in Figure 1, and we first formulate the electron–phonon couplings constrained by screw symmetry [3]. We thereby elucidate the handedness-selective softening of chiral phonons and the resultant phase transition by the qualitative calculation and theoretical analyses.



Element	Requirement		Consequences
Material Structure	Inversion ($\hat{\mathcal{P}}$)	✗	Existence of chiral phonon
	Mirror ($\hat{\mathcal{M}}$)	✗	
	Screw/ Helix ($\hat{\mathcal{S}}_{n,\zeta}$)	✓	Pseudo-angular momentum
Electronic States	Metallic/ Conductive		Fermi surface instability
	Nesting along c-axis		Softening of chiral phonon
Phase Control	External field	–	Spontaneous phase transition
	Thermal cooling	✓	

Fig1. (left) An illustration of the target material class in this work: chiral crystals with screw or helical structure and the well-nested electronic bands along c-axis in the Brillouin zone. (right) Minimal requirements and their physical consequences.

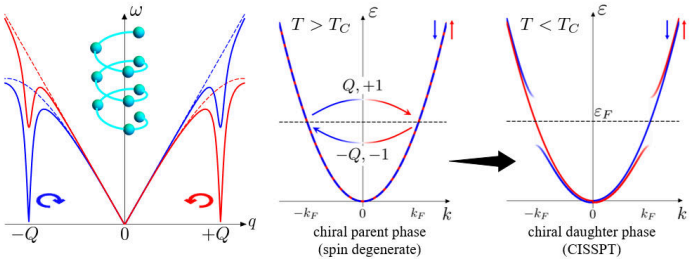


Fig.2 Schematic illustrations of the handedness-selective softening of chiral phonon and resultant spin-selective Peierls transition, in left-handed parent crystals.

III. Results and Discussion

When the high-temperature phase is chiral crystal, the phonon frequency is energetically splitting depending on circular polarization. Therefore, the renormalized frequencies of chiral phonons are handedness-selective, which reveals in the nesting vector involving not merely the linear momentum but also the phonon angular momentum. As a result, a spin-selective Peierls gap is introduced in the electronic band, accompanied by a helical spin density wave and a macroscopic chiral lattice distortion, regardless of whether the original band is spin-degenerate or not (Figure 2). Moreover, due to the coupling between the electronic and lattice sectors, the sliding mode carries mechanical phonon angular momentum and can be electrically actuated.

We have also identified minimal requirements to explore target material classes via symmetry and physical-property criteria. The CISSPT constitutes a family of the transverse Peierls transition which is recently experimentally recognized [4,5]. Furthermore, our mechanism—helical spin density waves stabilized by chiral lattice dynamics—offers a new possibility for the emergence of itinerant helimagnets in structurally chiral materials such as MnSi [6], providing an alternative to conventional scenarios.

IV. Conclusion

We have demonstrated a spontaneous structural phase transition unique to chiral crystals, driven by the mutual coupling between electrons and chiral phonons. While CISSPT is a fundamentally different phenomenon from CISS, our results unveil novel functionalities hosted by chiral materials. Leveraging functionality to shape structures introduces an additional axis for materials design principles, providing strategies for the synthesis and engineering of chiral materials.

From a broader perspective, we offer a novel perspective that bridges various viewpoints—from structure to function and from function to structure—within chirality research. Our findings may thus represent a key missing piece of the puzzle in chirality-driven phenomena in physics and beyond.

***Abstract*—We present a novel device based on a semiconductor quantum dot embedded in a photonic microcavity, which deterministically generate at gigahertz rate, strings of indistinguishable single photons in a Greenberger-Horn-Zeilinger (GHZ) multiphoton entangled state with entanglement length surpassing a dozen photons, providing valuable resources for quantum communication and computing.**

***Keywords*— quantum light sources, entangled multiphoton states.**

I. Introduction

Quantum technologies witness rapid contemporary developments transforming abstract scientific ideas and fundamental proof of principle demonstrations into systems of sufficient quality, enabling real applications in quantum information processing. Photonics quantum technologies, in particular, are playing pivotal role in these developments, since photons are quite robust, easy to detect, control and measure and thus to be used as flying quantum bits for carrying quantum information and distributing entanglement. The efforts invested in developing photonics-based quantum technologies stem also from the maturity of the relevant classical technologies. Most relevant to our work is the conceptual proof that a quantum light source of 3 entangled photons is sufficient for building a large-scale quantum computer using otherwise classical optical elements [1]

We present a novel device which deterministically generate at above a GHz rate, strings of entangled and indistinguishable single photons with entanglement robustness exceeding dozen photons. Our device is based on a semiconductor quantum dot embedded in an optical microcavity. The QD confines a spin, precessing in a very weak, externally applied magnetic field in Voigt configuration [2], [3]. The spin is resonantly excited periodically at an optimized rate of about 1.5 GHz, deterministically emitting a long string of single photons in a robust Greenberger- Horn-Zeilinger (GHZ) multi qubit entangled state [4].

The novelty in our device is in its natural spin echo, provided by the opposite precession-directions of the electron spin in the excited state before the photon emission and the hole spin in the ground state after the emission. The magnetic field independent optimized excitation rate is tuned to exactly nullify the acquired phase during both spin precessions.

II. Results

Our results can be summarized as follows:

- The optimized field independent excitation rate is 1.45 ± 0.01 GHz
- The maximal field dependent entanglement length achieved at external field of 50 milliTesla is 13 ± 1
- The field dependent indistinguishability between 2 sequential photons in the string at 50 milliTesla is 0.94 ± 0.02

These values are in good agreement with the model that we developed[5].

III. Conclusion

This deterministic, high-rate and robust quantum light source of more than a dozen of entangled photons, significantly reduces the overhead requirements for photonic measurement-based quantum computation [6] and communication [7], thereby bringing advanced photonic quantum technologies, closer to reality

Exponentially-enhanced sensing with a frequency-encoded bosonic Kitaev chain

Paul-Édouard Blanchard[1], Alexandre McDonald[2], and Philippe St-Jean[1,2,*]

[1]Department of Physics, Université de Montréal, Canada
[2] Institut quantique, Université de Sherbrooke, Canada
*Corresponding author: philippe.st-jean@umontreal.ca

***Abstract*—We experimentally realize a bosonic Kitaev chain by encoding the corresponding Hamiltonian in the resonant modes of a frequency comb. We harness the inherent nonreciprocal propagation of light in frequency space to detect a small microwave tone with a signal-to-noise ratio that scales exponentially with system size.**

***Keywords*— optical sensors, nonreciprocity, non-Hermitian physics, frequency combs.**

I. Introduction

The ability to optically detect faint perturbations through a noisy background underpins a wide range of important applications. Yet photonic systems, which are intrinsically open quantum systems, are unavoidably susceptible to environmental electromagnetic noise that couples into the apparatus. This unwanted noise mixes with the probe signal and ultimately degrades the signal-to-noise ratio (SNR) at the output.

Here we overcome this fundamental challenge by demonstrating a novel approach, based on a bosonic analogue of the Kitaev model, to realizing optical sensors in which environmental noise and input signal do not scale similarly with the system size, leading to an exponential enhancement of the signal-to-noise ratio.

II. BKC encoding in frequency space

A bosonic Kitaev chain (BKC) is described by the following lattice Hamiltonian with single-particle hopping (ω) and two-mode squeezing (Δ) processes (see Fig. 1a) :

$$H_{\mathrm{BKC}} = \sum_{n=1}^{N} \left[i\omega a_{n+1}^{\dagger} a_n + i\Delta a_{n+1}^{\dagger} a_n^{\dagger} + \mathrm{h.c.} \right]. \qquad (1)$$

The perturbation corresponds to a slight detuning of the last lattice site and the probe signal is weakly coupled to the first site and monitored with a homodyne detection [1].

This hamiltonian equivalently describes the chiral transport of the field's quadrature with $x_n = (a_n^{\dagger} + a_n)/\sqrt{2}$ and $x_n = i(a_n^{\dagger} - a_n)/\sqrt{2}$ respectively propagating to the left and right. In this equivalent picture, the perturbation now becomes a $x - p$ coupling term on the last site. We have encoded this chiral propagation using an electro-optic frequency comb where the nonreciprocal propagation is tailored through simultaneous phase and amplitude modulation (see Fig. 1b).

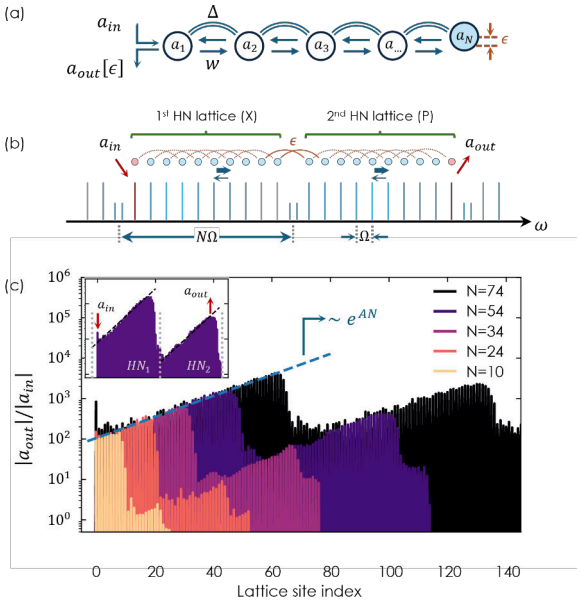

Fig. 1. (a) Bosonic Kitaev chain. (b) Encoding of a BKC in frequency space. (c) Exponential enhancement of the signal.

III. Results

Driving the frequency comb at the first resonant mode of one lattice allows measuring the transmitted light and extracting all its Fourier components through a heterodyne scheme. We observe an occupation of multiple combs as the perturbation couples neighbouring lattices (see Fig. 1c). The non-Hermitian skin effect in each lattice gives rise to an e^{2AN} scaling of the signal, whereas (not shown here) the noise scales as e^{AN} [2].

IV. Conclusion

We have observed an exponential scaling of the SNR in an optical sensor. This has potential applications in remote sensing, notably the optical readout of superconducting circuits.

Enhanced Microwave-to-Optical Quantum Transduction with Optomechanical Nanobeam Heterostructures

Akihiko Sekine[1,*], Ryo Murakami[1], Yoshiyasu Doi[1]

[1]Fujitsu Research, Fujitsu Limited, Kawasaki, Japan
*Corresponding author: akihiko.sekine@fujitsu.com

***Abstract*—Achieving a high transduction efficiency and a low added noise simultaneously is essential for the realization of quantum state transfer between distant superconducting qubits. We show theoretically that introducing optomechanical nanobeam heterostructures can improve the transduction efficiency and lower the added noise of the microwave-to-optical quantum transduction in optomechanical systems.**

***Keywords*—quantum transduction, quantum frequency conversion, optomechanical effect, nanobeam, quantum computing, superconducting qubit.**

I. Introduction

The quantum transduction, or equivalently quantum frequency conversion, between microwave and optical photons is an essential quantum technology for the realization of scalable quantum computers with superconducting qubits [1,2,3]. Due to the large frequency difference between microwave and optical ranges, the microwave-to-optical quantum transduction needs to be done via intermediate bosonic mode(s) or via nonlinear interaction process between photons. Theoretically, in the context of the quantum capacity, it has been known that the condition such that the transduction efficiency $\eta > 1/2$ and the added noise $N_{\mathrm{add}} \ll 1$ is required for quantum state transfer [3].

So far, the microwave-to-optical quantum transduction via the optomechanical effect, i.e., mediated by phonons, has attracted much attention as a promising method toward the practical quantum transduction including superconducting qubits [4]. However, achieving a high transduction efficiency of $\eta > 1/2$ and a low added noise of $N_{\mathrm{add}} \ll 1$ simultaneously still requires tremendous effects. It is well known that one of the ways for improving the transduction efficiency is to increase the optical input pump power. As a trade-off, however, there will be an increase in the environmental temperature, which can affect the nearby superconducting qubits.

II. Results

In this work, we show theoretically that introducing optomechanical nanobeam heterostructures can lead to a simultaneous improvement of the transduction efficiency η and lowering of the added noise N_{add} of the microwave-to-optical quantum transduction in optomechanical systems [5]. Such a heterostructure consists of N_{L} layers of an optomechanical crystal nanobeam and N_{L} layers of an insulator. We show that, in the ideal and simplest case where each nanobeam has the same geometrical structure, the electromechanical and optomechanical coupling strengths in the heterostructures are both enhanced by the factor $\sqrt{N_{\mathrm{L}}}$ compared to the single-layer case. As a result, the electromechanical and optomechanical cooperativities are also enhanced by the factor N_{L} compared to the single-layer case, giving rise to the enhanced microwave-to-optical transduction efficiency η. We also find that the added noise N_{add} in the heterostructures is suppressed by the factor $1/N_{\mathrm{L}}$ compared to the single-layer case. Our study opens up a new pathway for a high-efficiency and low-added-noise quantum transduction between microwave and optical photons.

***Abstract*—We theoretically investigate a cavity control of magnetic materials, including the Kondo effect in quantum impurities and heavy-fermion systems realized in two-dimensional materials. We show the possibility of enhancing Kondo effect and controlling quantum phases using vacuum fluctuations of quantized electromagnetic fields.**

***Keywords*— cavity QED, Kondo effect, 2D materials, strongly correlated systems**

I. Introduction

Cavity quantum electrodynamics (QED) provides a powerful platform to manipulate light-matter interactions that can effectively control electronic structure of materials at terahertz frequencies. In particular, vacuum fluctuations in cavity QED can offer a novel route to controlling quantum phases in a stable manner.

Such control has been mainly achieved through coupling electromagnetic fields to collective electronic excitations. However, using cavities based on van der Waals materials can provide a more precise control over the electromagnetic environment, enabling enhanced coupling between photons and electrons in two-dimensional systems at the level of single-electron excitations. This implies that the planar cavity consisting of van der Waals materials are particularly suitable for studying cavity-induced effects in two-dimensional correlated electron systems [1].

On the other hand, the interaction between localized magnetic moments and conduction electrons gives rise to the Kondo physics, a fundamental phenomenon in strongly correlated electron systems. At the low temperatures, the Kondo effect leads to the formation of a many-body singlet state, known as the Kondo singlet. In the Kondo lattice system, which consists of a periodic array of magnetic moments, the competition between the Kondo effect and magnetically ordered phases leads to quantum phase transitions and quantum criticality.

Recent advances in two-dimensional materials have enabled the realization of Kondo lattice physics in reduced dimensions. In particular, moiré-engineered structures provide effective realizations of two-dimensional Kondo lattice models with tunable parameters.

Motivated by these developments, we investigate how cavity QED can be employed to control Kondo physics in two-dimensional systems, ranging from impurity problems to Kondo lattice models (Fig. 1). Our study highlights van der Waals cavities as a versatile and well-matched platform for engineering quantum phases in strongly correlated two-dimensional materials.

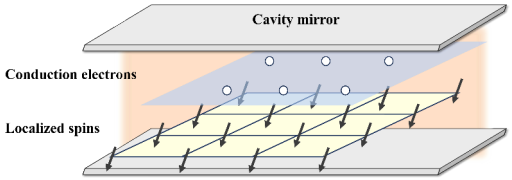

Fig. 1. Schematic of Kondo-lattice systems embedded in a cavity.

II. Methods

Our starting point is the Anderson model coupled to quantum electromagnetic fields in the Coulomb gauge represented as follows:

$$H = H_{\mathrm{PA}} + \sum_{\boldsymbol{k},\sigma} \frac{(\boldsymbol{p} + e\boldsymbol{A})^2}{2m} c^\dagger_{\boldsymbol{k}\sigma} c_{\boldsymbol{k}\sigma} + \sum_{\boldsymbol{q}} \hbar\omega_{\boldsymbol{q}} a^\dagger_{\boldsymbol{q}} a_{\boldsymbol{q}}, \quad (1)$$

where $c_{\boldsymbol{k}\sigma}$ is the annihilation operator for conduction electrons with momentum $\boldsymbol{k}$ and spin σ. H_{PA} is the standard Anderson model, which includes the hybridization between the localized and conduction electrons, the energy of the localized electrons, and the Coulomb interaction for the localized electrons. Here we consider that conduction electrons are affected by quantum electromagnetic fields. We consider the vector potential for multi-mode electromagnetic fields, given by

$$\boldsymbol{A} = \sum_{\boldsymbol{q}} A_{\boldsymbol{q}} (a^\dagger_{\boldsymbol{q}} + a_{\boldsymbol{q}}) \boldsymbol{e}_{\boldsymbol{q}}, \quad (2)$$

where $A_{\boldsymbol{q}}$ is proportional to $1/\sqrt{V_0}$, with V_0 being the mode volume of the cavity. $a_{\boldsymbol{q}}$ is the annihilation operators of bosonic mode with momentum $\boldsymbol{q}$ and frequency $\omega_{\boldsymbol{q}}$..

In the impurity problem, the single-impurity Anderson model coupled to a single-mode cavity photon provides a minimal setup for manipulating the Kondo state at the ground state level, owing to the broken translational symmetry introduced by the impurity. For this simplified model, we used a non-perturbative variational approach by applying a unitary transformation.

On the other hand, in the Kondo lattice model, where translational symmetry is preserved due to the periodic arrangement of local spins, more complex modes of electromagnetic fields are introduced to control the ground-state phase diagram. We analyze this model using controlled perturbative approaches and mean-field approximations.

III. Results and Discussion

We theoretically show the possibility of using cavity confinement to modify the electronic band structures through quantum electromagnetic fields. The characteristic energy scale of the Kondo effect is determined by a physical quantity called the Kondo temperature T_{K}. Variational calculations of the impurity system show that the Kondo state is enhanced by the cavity confinement [2]. Physically, this originates from an effective enhancement of the electron mass due to dressing by cavity photons. We also confirmed a similar mechanism by using the perturbative renormalization group analysis, which shows that the Kondo temperature is enhanced by the light-matter interaction g (Fig. 2).

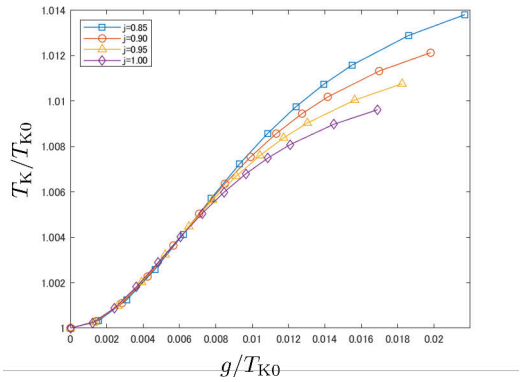

Fig. 2. Enhancement of Kondo temperature T_K as a function of light-matter coupling strength g.

In the two-dimensional Kondo lattice model incorporating interactions that mimic the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction, we demonstrate that the energies of both the Kondo-dominated (heavy-fermion) phase and the antiferromagnetic phase are lowered by the cavity-induced effects. Our analysis suggests that the antiferromagnetic phase can be stabilized more efficiently than the Kondo phase under cavity confinement.

IV. Conclusion

In conclusion, we have theoretically demonstrated that cavity QED can potentially provide an alternative and versatile tool for controlling Kondo physics in two-dimensional materials. By coupling correlated electron systems to quantum electromagnetic fields, both the impurity Kondo effect and quantum phases in Kondo lattice systems can be modified. Specifically, our results show that cavity-induced effects can enhance Kondo correlations and lower the energies of competing quantum phases, including the heavy-fermion and antiferromagnetic phases. These findings highlight the potential of cavity-based approaches for engineering quantum phases in strongly correlated systems and open new possibilities for stable control of quantum many-body states in low-dimensional materials.

***Abstract*—Axion electrodynamics describes the electromagnetic response of certain topological materials, including three-dimensional topological insulators and Weyl semimetals. Here we discuss the application to Weyl semimetals and a mechanical effect induced by the axion response in topological insulators.**

***Keywords*— axion, topological insulators, Weyl semimetals, plasmonics**

I. Introduction

Broadly, axion electrodynamics is a theory of electromagnetic interactions whose action contains the following term,

$$S_a = \frac{\alpha}{4\pi^2}\int dt \int d^3r a(t,\boldsymbol{r})\boldsymbol{E}\cdot\boldsymbol{B}, \tag{1}$$

where $\alpha = e^2/(\hbar c)$ is the fine structure constant, and $a(t,\boldsymbol{r})$ is the so-called axion scalar field [1]. Quite generally, the above contribution to the action modifies the Maxwell equations. For a nonzero uniform axion field inside a sample, the Maxwell equations are not modified, but the boundary conditions change, like for example in the case of topological insulators [2], [3].

Even within a static setting, electric fields may induce magnetic fields and vice-versa. As a result, a nonzero angular momentum of the electromagnetic field arises [3], [4].

II. Induced angular momentum in Weyl semimetals

Recently we have obtained that a Weyl semimetal with broken time-reversal (TR) symmetry features an angular momentum per unit area of the form [5],

$$\boldsymbol{L}_{\rm EM} = \frac{B_{\rm ap}^2 L\sqrt{\epsilon}}{8\pi g\coth\left(\frac{gL}{2\sqrt{\epsilon}}\right)}\left[\coth\left(\frac{gL}{\sqrt{\epsilon}}\right)-\frac{\sqrt{\epsilon}}{gL}\right]\hat{\boldsymbol{z}}, \tag{2}$$

in a system of thickness L. Here ϵ is the dielectric constant and $g = 2e^2b/\pi$ is related to the axion coupling, with e being the elementary electric charge and b the distance between the Weyl cones.

III. The Feynman paradox in axion insulators

The Feynman paradox highlights that static electromagnetic fields can store angular momentum. Recently, we have demonstrated [6] that axion electrodynamics in a spherical topological insulator provides a topological realization of this effect. Varying the distance of a nearby charged probe q induces Hall currents on the surface that convert electromagnetic angular momentum into mechanical rotation of the sphere, with a frequency derived from the topological response.

Large topological magneto-optical effect from atomic-scale skyrmion-like texture

Yoshihiro Okamura[1,*]

[1]Department of Applied Physics & Research Center for Advanced Science and Technology, University of Tokyo, Japan

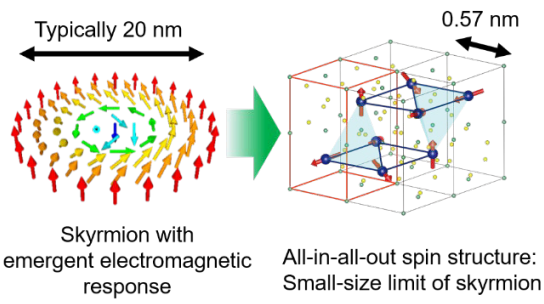
*Corresponding author: okamura @ap.t.u-tokyo.ac.jp

***Abstract*— We report the large spontaneous magneto-optical Kerr effect solely from scalar spin chirality of all-in-all-out state in quasi-two-dimensional triangular-lattice compound $CoNb_3S_6$. Over the entire measured energy region from 55 to 2000 meV, the topological effect dominates the optical response, whose figure of merit largely exceeds other magnets.**

***Keywords*— Skyrmion, topological magneto-optical effect, spin chirality.**

I. Introduction

Electrodynamics rooted in the topology and geometry of quantum states is a cornerstone of modern physics. When a conduction electron undergoes adiabatic transport through a topological spin texture, it acquires a nontrivial Berry phase that acts as an emergent electromagnetic vector potential, giving rise to novel quantum phenomena. In skyrmion magnets such as MnSi, the corresponding emergent magnetic field is typically predicted to reach several tens of tesla [1]. Nevertheless, the resulting electromagnetic responses do not markedly surpass those realized in archetypal ferromagnets. Recently, extensive materials exploration has uncovered the so-called all-in–all-out (AIAO) spin configuration, which breaks time-reversal symmetry while retaining an almost vanishing net magnetization [2]. The AIAO order can be viewed as the small-size limit of a magnetic skyrmion and inherently hosts much larger emergent fields (see figure). Such a state is therefore expected to produce gigantic topological electromagnetic responses, far exceeding those in conventional skyrmion magnets. Yet, this intriguing possibility remains largely unexplored.



II. Methods

We perform ultrabroadband spectroscopic measurement from 55 meV to 2000 meV and real-space imaging. Combined with numerical Kramers Kronig analysis, we obtain the Hall conductivity spectra down to zero frequency,

III. Results and Discussion

We observe a gigantic spontaneous magneto-optical Kerr effect (MOKE) arising solely from scalar spin chirality of the AIAO order in $CoNb_3S_6$. Ultra-broadband spectroscopy reveals that MOKE is overwhelmingly dominated by spin chirality, whose contribution is so large that any conventional magnetization-induced component is hardly visible. Spectral analysis further shows that the momentum-space Berry curvature generated by the AIAO structure governs the topological Hall responses including the optical regime. Remarkably, the figure of merit of this topological MOKE exceeds that of conventional magnets, including Mn_3Sn, by more than two orders of magnitude [3]. These results demonstrate exceptionally strong light–spin coupling mediated by Berry flux concentrated in the atomic-scale skyrmion-like texture, opening new avenues for antiferromagnetic spintronics and optospintronic applications.

IV. Conclusion

We have demonstrated the large topological MOKE induced by the intense Berry curvature arising from the atomic-scale skyrmion-like texture. Our findings demonstrate the spin-light coupling through the spin chirality, paving the way for future topological optospintronic devices.

Room-Temperature Orbital Angular Momentum Detection via Degree of Valley Polarization Tuning

Jiang Hao, Yan Zhang, Weibo Gao

Abstract

Excitons in transition metal dichalcogenides possess a valley degree of freedom, and tuning degree of valley polarization (DoP) is pivotal for advancing valleytronics, quantum communication, and quantum sensing. To date, most studies have focused on the influence of circularly polarized light on valley polarization, offering relatively limited tunability. Here, we report the interaction between the orbital angular momentum of twisted light (LG_0^l beam) with the valley degree of freedom in monolayer WSe_2. Through detecting the DoP of 1L-WSe_2 under the excitation of circularly polarized twisted light with different OAM number *l*, we find that the DoP of 1L-WSe_2 can be tuned directly by the OAM number *l*. The result shows that the DoP increases from 9% to 55% with the *l* changed from 0 to 10, and also increases from 9% to 58% when negative *l* changed from 0 to -10. This is consistent with the theoretical model we proposed for xxx. Leveraging this tunability, we fabricated 1L-MoS_2/1L-WSe_2 valleytronic transistor. For variations of OAM topological charge *l* from ±1 to ±10, the device exhibited a steadily increasing valley Hall voltage that enabled successful discrimination. This direct DoP-tuning scheme successfully enables on-chip OAM detection, offering a pathway towards high-capacity optical communication and quantum sensing.

Introduction

In monolayer transition metal dichalcogenide (TMDs), strong spin-orbit coupling and the time-reversal symmetry dictate the spin splitting to have opposite signs at the K and K' valleys in the Brillouin zone, which gives rise to an effective coupling between spin and valley pseudospin. An exciton, as a bound electron-hole pair, inherits the valley pseudospin as well (*1-3*). Meanwhile, the broken inversion symmetry in monolayer TMDs leads to a valley-dependent optical selection rule (*4*) (Fig. 1a). Excitons in the K valley couple to left-circularly polarized photons (σ^+), while excitons in K' valley couple to right-circularly polarized photons (σ^-), thus enabling the control of specific valley excitation through corresponding circularly polarized light (*5*). Therefore, it provides a promising platform for using the valley degree of freedom to carry and modulate information, known as valleytronics (*6, 7*).

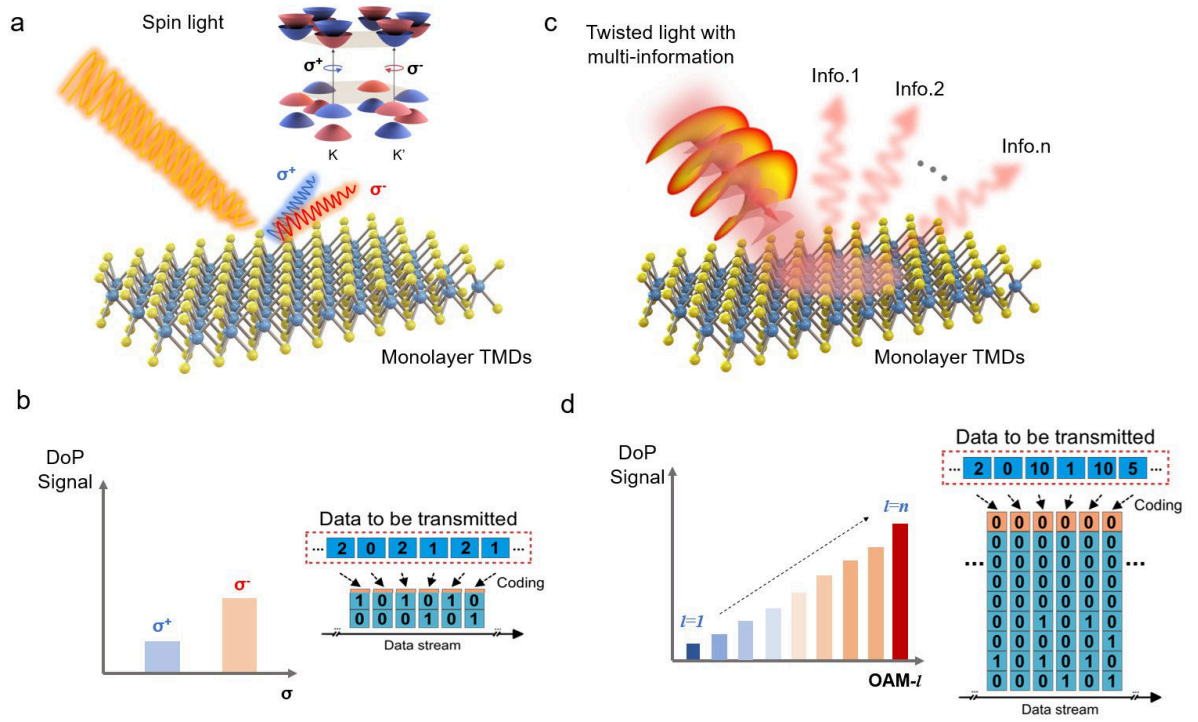

Figure 1. **Valley degrees of freedom carrying information. a**, Schematic of the band structure and optical selection rules in monolayer TMDs. Left-circularly (right-circularly) polarized light, σ^+ (σ^-), couples the valence and conduction bands at the K (K') valley. **b,** The degrees of freedom in DoP modulation by CPL and their applications. The modulation of DoP by CPL offers two degrees of freedom (σ±), which imposes limitations in encoding and communication. **c**, The combination of twisted light possessing boundless OAM $l\hbar$ per photon and the valley degrees of freedom makes monolayer TMDs a promising platform for information technologies. **d,** The degrees of freedom in DoP modulation by OAM and their applications. The modulation of DoP by OAM offers unlimited degrees of freedom (l = 1…n), showing great potential for encoding and communication.

In the experiment, circularly polarized light is used to preferentially excite just one valley (K or K'), which generates a difference in the population of the two valley excitons (*8, 9*). This degree of valley polarization (DoP), ρ, can be read out through measuring the circularly polarized components of the emitted photoluminescence (PL) intensity, which is expressed as $\rho = \left(I_{\sigma^+} - I_{\sigma^-}\right) / \left(I_{\sigma^+} + I_{\sigma^-}\right)$, where $I_{\sigma^{+(-)}}$ is the intensity of $\sigma^{+(-)}$-polarized emission. Accordingly, how to manipulate and tune the valley pseudospins, especially the DoP, is the key to realising practical valleytronic devices. Many efforts have been made to develop abilities to tune the DoP, such as applying an external magnetic field (*10, 11*), electrical field (*12-14*), and strain engineering (*15*). Nevertheless, all of them focus on the circular polarization degree of freedom (*16*), which exists in only two states $\sigma^{+(-)}$, thereby resulting in highly limited communication capacity (Fig. 1b). To increase the communication bandwidth, it is desirable to explore other degrees of freedom and make the DoP tuning rely on the light itself rather than the external control (*17*).

Twisted light (TL) exhibits this possibility. Apart from spin angular momentum (SAM), light can also carry orbital angular momentum (OAM), which is also referred to as twisted light. Whereas SAM of light decides its polarization state with only $\hbar$ or $-\hbar$ per photon, OAM of light involves its helical wavefront shape with a quantized but boundless value $l\hbar$ per photon

(*18, 19*), as shown in Fig. 1c, where *l* is the helical mode number. This unbounded OAM number *l* in twisted light apparently provides the possibility of carrying more information than nonstructured light carrying the SAM only (*20, 21*). Therefore, the successful manipulation of the DoP via OAM is expected to greatly expand the communication dimensionality, as shown in Fig. 1d. Up to now, many theoretical researches on the twisted light have exceptionally pushed its huge development (*18, 42*), as well as the theoretical (*38, 43-45*) and experimental (*36, 46-48*) twisted light matter interaction. However, the experimental investigation on twisted light interacting with DoP has not been systematically carried out, which is important to make TL-valleytronics realized.

Here, we report the interaction between the twisted light and the degree of valley polarization in monolayer WSe_2 (1L-WSe_2). The Laguerre-Gaussian (LG_p^l) beam, one of the typical twisted light, was used to excite the 1L-WSe_2. We find that the DoP of 1L-WSe_2 can be tuned directly by the OAM number *l*. The DoP increases from 9% to 55% with the *l* changed from 0 to 10, and also increases from 9% to 58% when negative *l* changed from 0 to -10. This phenomenon is associated with the out-of-pane magnetic field induced by twisted light, which directly affects the Zeeman splitting. Together with the transfer of momentum from photons with OAM to excitons, the intervalley electron-hole exchange interaction can be largely tuned. The realization of using twisted light to directly tune the degree of valley polarization in 1L-WSe_2, without any external field assisting, will certainly open a new avenue for valleytronics-based information technology. As an important validation and application, we designed and fabricated a 1L-MoS_2/1L-WSe_2 valleytronic transistor based on this mechanism. For variations of OAM topological charge *l* from ±1 to ±10, the device exhibited a steadily increasing valley Hall voltage that enabled successful discrimination, consistent with its tuning behavior to the valley DoP. This work proposes a method to directly tune the valley DoP using twisted light, without the need for any auxiliary external fields, and uniquely applies valleytronic devices to room-temperature OAM detection. The approach offers a pathway towards high-capacity optical communication, quantum sensing, and optical anti-counterfeiting.

Extraction of Circularly Polarized Single Photons from Linearly Polarized Emitters

Sarah Lindner[1,*], Peter Banzer[1]
[1] Department of Physics, University of Graz, Austria
*Corresponding author: sarah.lindner@uni-graz.at

***Abstract*—We target direct extraction of single photons with controlled circular polarization from linearly polarized emitters. We exploit the near-field features of linear dipole emitters to couple the emitters to waveguides, establishing a foundation for efficient, orientation-controlled extraction of circularly polarized single photons at the nanoscale applications.**

***Keywords*— single-photon emission, circular polarization, nanodiamonds, photonic integrated circuits.**

I. Introduction

The polarization state of single photons is a vital resource for quantum information encoding and secure communication protocols. Photonic integrated circuits (PICs) enhance quantum applications by enabling precise control over light-matter interactions through the manipulation of phase and polarization states. Solid-state emitters, such as defect centers in diamond, are ideal candidates for integration within these circuits, serving as the cornerstone for future on-chip light processing.

II. Methods

A key challenge for scalable quantum circuits is efficient, on-chip control of single-photon polarization, often relying on complex or inefficient external filtering. Our novel approach based on near-field coupling of quantum emitters and photonic integrated waveguide architectures will enable the direct on-chip extraction of circularly polarized single photons with defined handedness, significantly enhancing the integration and efficiency for quantum applications.

We aim to couple single photons from silicon-vacancy centers (SiV centers) in nanodiamonds to waveguide modes. We use the fact that linearly polarized dipoles feature partially circularly polarized near-fields. These non-zero near-field spin density components can be converted into circularly polarized waveguidemodes if waveguide and emitter are placed in close proximity. By positioning the SiV center on top of the intersection of waveguides which are tailored to match the near-field spin density distributions, we aim to extract circularly polarized single photons, emitted by a linear dipole-like single photon source, in different orientations propagating as waveguide modes along pre-defined directions (Fig. 1) [1].

III. Results and Discussion

Silicon-vacancy (SiV) centers in nanodiamonds serve as the ideal foundation for this architecture due to their robust and narrow-band fluorescence at room temperature [2], [3], paired with an almost fully linearly polarized zero-phonon line emission [4]. Their short lifetimes support high-rate quantum communication , while compatibility with pick-and-place techniques enables the precise spatial integration required for our waveguide design [5], [6]. FDTD simulations confirm that our cross-shaped geometry successfully exploits the longitudinal spin density of the evanescent field to convert linear dipole emission into circularly polarized light [1]. To maximize performance, we optimized the waveguide dimensions to match the specific spectral range of the SiV emission, ensuring efficient photon extraction.

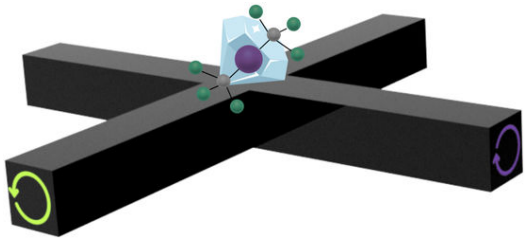

Fig. 1. Sketch of the proposed design for the waveguide structure with a nanodiamond hosting a SiV center positioned at the intersection of two orthogonally crossed waveguides.

IV. Conclusion

Our optimized waveguide geometry enables the direct extraction of circularly polarized single photons from solid-state emitters. By exploiting evanescent field characteristics, this architecture bridges the gap between linearly polarized quantum emitters and the requirements for integrated, polarization-encoded quantum applications.

Bulk-Edge Correspondence in Photonic Spacetime Insulators

João C. Serra[1,2,*], Rudin Kraja[3], Foster Sabatino[3], Alexander B. Khanikaev[3], Mário G. Silveirinha[1,2]

***Abstract*— Unlike general space-time crystals, periodic travelling-wave modulations possess a continuous translation symmetry and exhibit a truly insulating bulk response. This work analyzes the bulk-edge correspondence in such systems and reveals some unusual properties of the topological edge channels, such as a geometry-dependent Doppler effect and codirectional reflection mechanisms.**

***Keywords*— topological insulators, photonic crystals, time-variant modulations, bulk-edge correspondence.**

I. Introduction

Since their proposal in 1987, photonic crystals have revolutionised light-based technologies by allowing unprecedented control over the band structure and laid the foundations for future integrated platforms fully operated with light waves. In particular, two-dimensional periodic structures can be used as Bragg reflectors where light does not penetrate the bulk region but may propagate along the boundaries in the form of edge states. Notably, the net number of modes circulating in these edge-type channels is dictated by the bulk topology through the bulk-edge correspondence [1]. Edge waveguides are largely insensitive to path deformations and small fabrication defects.

The recent ability to control a system's response in time at an electrically small scale has opened an exciting degree of freedom to break Lorentz's reciprocity [2] and to explore exotic wave phenomena like temporal scattering [3]. For this reason, understanding how topology shapes the flow of light in time-variant systems is crucial to design compact waveguides that are simultaneously robust against deformations and exhibit frequency conversion mechanisms that may not conserve the wave's energy. Within this context, different topological aspects of systems periodically driven in time [4] and in space-time [5,6] have been discussed in the literature.

In this work, we argue that realistic Floquet-Bloch crystals do not behave as true insulators for light due to the unbounded photonic spectrum, and present travelling-wave modulations as a natural alternative. Additionally, we examine how trivial and nontrivial Chern phases in such platforms lead to unusual edge-like channels in moving-type boundaries.

II. Photonic Spacetime Insulators

Photonic insulators are platforms characterised by gaps in the spectral domain within which light cannot propagate. These spectral gaps, i.e., the absence of bulk modes for specific wavevectors and/or frequencies, are typically found in continuous systems with material dispersion or periodic man-made structures. Topological protection ensures that edge waves cannot be backscattered at the boundary between two inequivalent crystals. As space/time crystals conserve the wave's frequency/wavevector due to their invariance in time/space, their frequency/wavevector gaps make them true insulators only for spatial/temporal boundaries, respectively.

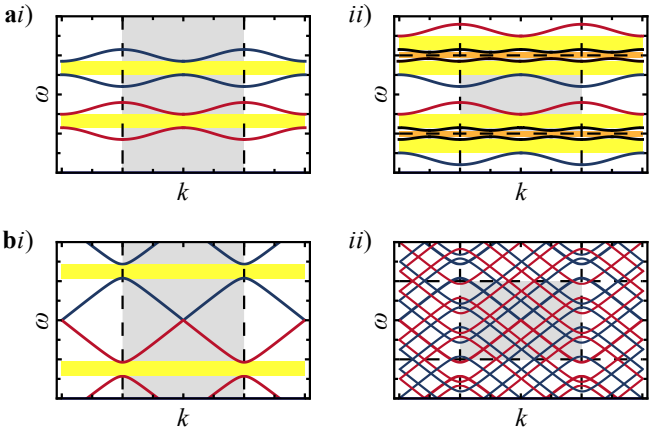

Fig. 1 Band structures for (a) a lattice of two-mode resonators and (b) a photonic crystal before (i) and after (ii) being periodically driven in time. The yellow strips represent the static frequency gaps, while the new Floquet gaps are coloured in orange.

Conventional space-time-variant insulators are engineered by periodically driving a crystalline structure in time [5,6]. Such Floquet-Bloch crystals lack a continuous time symmetry, but their discrete temporal translation symmetry conserves the Floquet frequency. This approach is suitable for systems with a bounded spectrum (e.g., a lattice of resonators), since the modulation frequency can be commensurable with the largest frequency of the bulk spectrum in the time-invariant case and open Floquet gaps [see Fig. 1a]. However, photonic space

crystals possess an infinite set of bands with a frequency accumulation point at infinity as illustrated in Fig. 1bi. Thus, due to the interaction of the different bands, the temporal modulation yields a very intricate dispersion without spectral gaps (Fig. 1bii).

To overcome this fundamental limitation, we introduced in Ref. [7] a new class of topological insulators characterised by periodic travelling-wave modulations of the material response $\bar{M} = \bar{M}(\mathbf{r} - \mathbf{v}t)$. Different from Floquet-Bloch insulators, these systems exhibit a continuous spacetime translation symmetry and conserve the Doppler-shifted frequency $\omega - \mathbf{v}\cdot\mathbf{k}$. Accordingly, the band structure in Fig. 2a presents spectral gaps within which the bulk region behaves as a true insulator since light cannot excite bulk modes.

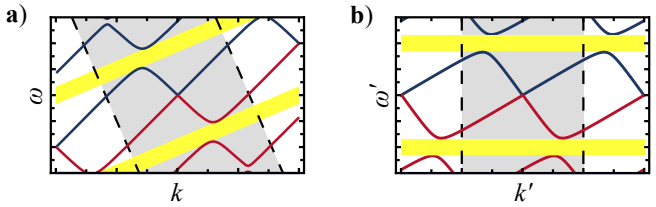

Fig. 2 Band structure in the laboratory frame (a) and in the comoving frame (b) for a photonic spacetime crystal with a travelling-wave modulation. The yellow strips highlight the spectral gaps.

These systems can be conveniently analysed in a reference frame

$$\begin{aligned} \mathbf{r}' &= \mathbf{r} - \mathbf{v}t, \\ t' &= t \end{aligned} \tag{1}$$

that moves with the synthetic velocity $\mathbf{v}$. In this Galilean comoving frame, the crystal becomes time-invariant and supports regular frequency gaps [see Fig. 2b] that can be topologically classified using conventional tools like the Green's function method [8]. Moreover, since the bulk-edge correspondence [1] is valid over static boundaries in this primed frame $(\mathbf{r}', t')$, it is only natural that the bulk topology ensures the existence of robust edge-type channels over boundaries that follow the travelling-wave perturbation in the original laboratory frame $(\mathbf{r}, t)$.

III. Bulk-Edge Correspondence

To better understand this novel bulk-edge correspondence, we consider the two-dimensional spacetime crystal represented in Fig. 3a with a synthetic velocity $\mathbf{v}$ inside the plane of propagation $x0y$. It comprises a honeycomb lattice of red rods isorefractive with vacuum and a green ring with a broken inversion symmetry characterised by the inhomogeneous refractive index

$$n_{\mathrm{G}}^2(\varphi) = 1 + \delta\cos(\varphi), \tag{2}$$

where φ denotes the angular coordinate around the ring's centre. In-plane travelling-wave modulations of this central inclusion implement a rotating vector field $\mathbf{A}'$ in the comoving frame for photons with a transverse electric polarisation $\mathbf{E}' \sim \hat{\mathbf{z}}$ that is analogous to the magnetic vector potential for electrons [9]. Notably, this photonic angular momentum bias $\langle \nabla' \times \mathbf{A}' \rangle \cdot \hat{\mathbf{z}} \sim \delta \mathbf{v} \cdot \hat{\mathbf{y}}$ splits the Dirac cones of the honeycomb lattice and opens a spectral gap [see Fig. 3b] characterised by the topological Chern $\mathcal{C}_{\mathrm{gap}}$ phase diagram shown in Fig. 3c.

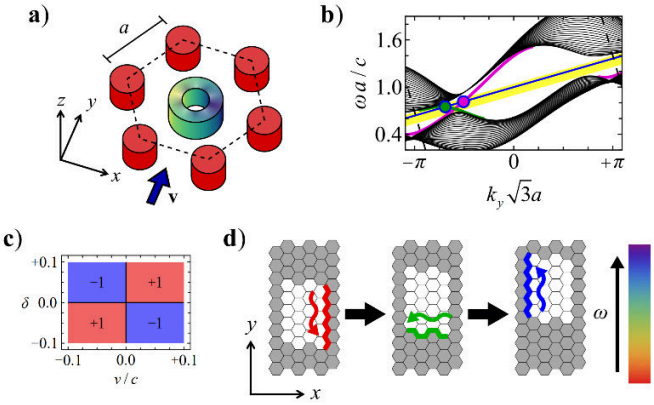

Fig. 3 (a) Unit cell of the spacetime Chern insulator with an in-plane travelling-wave modulation. (b) Band structure in the laboratory frame for the Chern insulator enclosed by two zigzag boundaries parallel to the synthetic velocity $\mathbf{v} = v\hat{\mathbf{y}}$: bulk modes are represented by black curves, while the green and purple solutions denote edge states localised near different boundaries. (c) Chern phase diagram. (d) Qualitative representation of a topological edge state propagating inside a spacetime cavity: the oscillation frequency varies along the propagation path due to a geometry-dependent Doppler effect.

To characterise the edge dispersion over moving opaque boundaries, we developed a simplified tight-binding description. Specifically, we considered zigzag terminations parallel to the modulation velocity $\mathbf{v} = v\hat{\mathbf{y}}$ and armchair terminations with the orthogonal orientation. In both scenarios, we found $\mathcal{C}_{\mathrm{gap}}$ unidirectional clockwise edge states that cross the spectral gap [see Fig. 3b for the zigzag termination], in agreement with the conventional bulk-edge correspondence in the comoving frame.

Remarkably, due to the conservation of the spectral parameter $\omega' = \omega - \mathbf{v}\cdot\mathbf{k}$, one may control the oscillation frequency ω in the laboratory frame of these edge modes by tailoring the shape of the moving frontier. For instance, in the spacetime cavity represented in Fig. 3d, the edge state experiences a Doppler effect determined by the local orientation of its cycloid-like path. This exotic behaviour may find applications in compact frequency conversion devices resilient against backscattering interference.

It is worth noting that the direction of propagation of these boundary modes does not need to coincide in the comoving and laboratory frames. Indeed, the velocities of edge states in the two frames differ by a relativistic velocity addition determined by the modulation velocity. For this reason, topologically trivial systems may exhibit unidirectional

channels in the laboratory frame for sufficiently fast (but subluminal) modulations. In the comoving frame the edge channels remain bidirectional, as required by the bulk-edge correspondence. At the conference, we will show that such edge-type waveguides exhibit a spacetime scattering mechanism, where light is constantly being "reflected" into the same direction.

IV. Conclusion

In summary, unlike tight-binding models, the unbounded spectrum of realistic photonic systems poses fundamental restrictions on the topology of space-time-variant platforms. To circumvent this challenge, we propose travelling-wave modulations as a simple and powerful scheme to achieve genuine insulation in topological systems. The proposed periodic structures can host topological Chern phases that control the flow of light over moving-like boundaries through a well-defined bulk-edge correspondence in a comoving frame. Finally, we argued that these novel topological channels may exhibit unusual properties in the laboratory frame, such as a geometry-dependent Doppler effect and codirectional reflection mechanisms.

Time-Varying Metamaterials for Synthetic Motion

Satoshi Tomita
Institute for Excellence in Higher Education, and Department of Physics, Tohoku University, Sendai, Japan
tomita@tohoku.ac.jp

***Abstract*—We demonstrate time-varying magnetic metamaterials at GHz frequencies using ferromagnetic permalloy ($Ni_{80}Fe_{20}$). The experimental results are reproduced via numerical simulation, verifying that frequency conversion observed is caused by time modulation of magnetic permeability. The present study opens a door to magnetoelectric metamaterials with synthetic motion for probing quantum vacuum effects.**

***Keywords*— time-varying metamaterials, magnetoelectric effects, moving media, quantum vacuum effects.**

I. Introduction

Metamaterials are man-made structured materials exhibiting intriguing optical properties unavailable in natural materials. The most typical examples are metamaterials for negative refractive indices and for invisible cloaks. These are referred to as space-varying metamaterials because of the spatially modulated refractive indices.

Very recently, a new paradigm for light generation and steering using metamaterials has emerged – time-varying metamaterials, in which refractive indices are temporally modulated. Time-varying metamaterials bring about exotic phenomena, for example, time refraction, time reflection, and analogue of a continuous time crystal as well as promising applications to frequency converters, nonreciprocal devices, and antireflection temporal coatings. Furthermore, time-varying metamaterials mimic magnetoelectric interaction in equivalent moving media [1].

In particular, the space-time modulation of both electric permittivity (ε) and magnetic permeability (μ) is indispensable for investigating Fresnel drag for light in the synthetically moving media. However, experimental demonstration of time modulation in μ is still lacking [2], [3] while time-varying ε has been achieved. Therefore, time-varying μ metamaterials are highly desired.

II. Methods

We prepare magnetic metamaterials including a ferromagnetic-metal (permalloy (Py), Ni80Fe20) layer together with modulation and carrier lines. Temporal modulation of μ is realized by altering an effective magnetic field for ferromagnetic resonance of the Py layer using time-periodic Oersted magnetic field generated by modulation microwaves of frequency $f_{\rm m}$. Output carrier microwaves of $f_{\rm c}$ = 4.0 GHz are measured under $\mu_0 H_{\rm dc}$ = 24.4 mT at various $f_{\rm m}$.

III. Results and Discussion

Figure 1 shows experimetal results [4]. We observe frequency up- and down-conversions of the carrier microwave of $f_{\rm c}$ = 4.0 GHz, which are caused by the temporal μ modulation with $f_{\rm m}$. These experimental results are reproduced via numerical calculation, verifying that the frequency conversion is traced back to time-varying μ. Moreover, numerical calculation indicates that the nonlinear magnetization dynamics and microwave response through nonlinear susceptibility are keys of the predominant frequency up-conversion observed in the experiments.

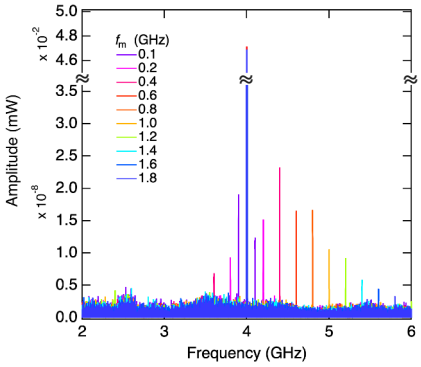

Fig. 1. Output carrier microwaves spectra of $f_{\rm c}$ = 4.0 GHz under $\mu_0 H_{\rm dc}$ = 24.4 mT at various modulation frequency $f_{\rm m}$..

IV. Conclusion

We demonstrate time-varying μ metamaterials at GHz frequencies using ferromagnetic Py. The present study opens a door to magnetoelectric metamaterials with synthetic motion [5], [6], [7] for probing quantum vacuum effects, for example, dynamical Casimir effects.

***Abstract*—This talk presents nanophotonic inverse design methods, ranging from physics-guided diffusion models to time-domain adjoint optimization. We demonstrate broadband metalenses, multi-functional AR waveguide couplers, and angle-robust CMOS color routers. Emphasis is placed on scalable, fabrication-aware optimization methods for nanophotonic inverse design.**
***Keywords*— Metasurface, Inverse Design, Diffusion Model, Time-Domain Adjoint Optimization.**

I. Introduction

Inverse design has emerged as a pivotal approach in nanophotonics, enabling the discovery of freeform device geometries that can achieve performance far beyond traditional intuitive designs. Modern optical systems demand multi-functional components, for example, metasurface lenses that operate across broad bandwidths, or couplers that perform simultaneous display and imaging tasks, which greatly expands the design parameter space. Adjoint-based topology optimization [1] provides efficient gradients to navigate these high-dimensional spaces, but it often requires cumbersome filtering to enforce fabrication constraints and can stagnate in suboptimal local minima. Conversely, data-driven strategies (e.g., generative models and reinforcement learning) explore vast design spaces but typically require prohibitive training data or simulation budgets. Additionally, designing for multiple objectives or broadband operation has been challenging: frequency-domain methods require separate simulations for each wavelength, while naive time-domain approaches blur multi-band goals into a single response. In this talk, we demonstrate recent advances [1], [2], [3], [4], [5] that address these challenges by tightly integrating physics into machine-learning models and extending adjoint optimization into the time domain. We summarize two methodological innovations, a physics-guided diffusion model and a multi-objective time-domain adjoint technique, and demonstrate their impact on complex nanophotonic devices for augmented reality and imaging sensors.

II. Methods

Physics-Guided Diffusion Models [3]: We developed an inverse design framework that embeds first-principles physics into a generative diffusion model, yielding a fabrication-aware and simulation-efficient optimization tool. In our approach (dubbed AdjointDiffusion), a diffusion neural network is first trained on a library of manufacturable device patterns, and during generation its iterative denoising process is guided by adjoint electromagnetic gradients. At each step, the physics-based gradient nudges the design toward higher performance (greater figure-of-merit) while inherently respecting fabrication constraints. This closed-loop integration of adjoint feedback allows the algorithm to avoid the complex binarization filters that brute-force optimizers require, directly producing physically realizable nanostructures. Notably, the diffusion-driven optimizer achieved 15% higher performance at equal simulation cost compared to state-of-the-art gradient-based methods, or required only about one-third the simulations to reach the same performance. It also showed a three-orders-of-magnitude reduction in required simulations versus purely data-driven generative approaches, highlighting the benefit of physics guidance. By eliminating tedious parameter tuning and reducing computational overhead, the physics-informed diffusion model offers a powerful new paradigm for photonic inverse design.

Multi-Objective Time-Domain Adjoint Optimization [4], [2]: To efficiently handle broadband and multi-criteria design targets, we extended adjoint optimization into the time domain with novel spectral control techniques. Traditional frequency-domain adjoint methods become computationally expensive when optimizing multiple wavelengths or functions, as they require independent gradient computations for each frequency or objective. Our approach leverages finite-difference time-domain (FDTD) simulation of the device to capture a wide bandwidth in a single simulation, then isolates individual objective responses via temporal signal processing. In one strategy, we apply temporal convolution filtering to the recorded fields, using band-pass filters to extract frequency-specific gradients from a single time-domain simulation. By invoking the convolution theorem, this method yields band-selective adjoint gradients without needing separate simulations for each spectral band, thus restoring the efficiency advantage of

time-domain optimization for multi-band problems. In another complementary strategy, we introduce dynamic pulse shaping during iterative optimization: the incident pulse (or other waveform parameters) is adaptively adjusted in each iteration to emphasize underperforming wavelength ranges, balancing broadband efficiency and uniformity. These enhancements enable true multi-objective optimization in one framework, as demonstrated by our designs of complex photonic components that meet several performance goals simultaneously. For example, using a convolution-enabled time-domain adjoint, we inverse-designed a wavelength demultiplexer with over 90% efficiency at each output channel, achieving this in a fraction of the runtime required by conventional multi-frequency optimizations. Likewise, dynamic pulse shaping was key to our achromatic metalens design, discussed below, enabling simultaneous improvements in efficiency and spectral consistency across the visible spectrum. Together, these time-domain adjoint innovations dramatically broaden the scope of inverse design, making it feasible to optimize broadband, multi-functional nanophotonic devices without incurring multiplicative simulation costs.

III. Conclusion

In this talk, we demonstrate that combining advanced optimization algorithms with physical-domain knowledge can substantially improve the design of multifunctional nanophotonic devices. Physics-guided diffusion models allow us to traverse the enormous solution space of topology optimization with unprecedented efficiency, yielding manufacturable designs that were previously impractical to discover. Time-domain adjoint methods equipped with spectral filtering and adaptive sources restore computational tractability for broadband, multi-objective problems, enabling devices that operate over wide frequency and angular ranges simultaneously. The application case studies, from AR waveguide couplers and wide-FOV color routers to high-efficiency achromatic metalenses, demonstrate the real-world impact of these methodologies in enabling compact optical systems with performance near theoretical limits. Looking forward, several open challenges and opportunities remain. Integrating the strengths of generative models and adjoint optimization (for example, by using hybrid approaches that refine AI-generated designs through adjoint fine-tuning) is a promising way to further improve design quality and reduce costs. Scaling these inverse design techniques to fully three-dimensional, large-area metastructures while accounting for fabrication imperfections and tolerances will be crucial for practical deployment. Additionally, expanding the design frameworks to incorporate active or nonlinear materials could unlock dynamically reconfigurable photonics optimized via similar principles. By addressing these challenges, the community can continue to push the frontier of optical device functionality. This talk will conclude by discussing how the presented innovations in physics-aware inverse design can be extended to meet future needs, and by identifying the key avenues where theory, computation, and fabrication must converge to realize the next generation of nanophotonic technologies.

***Abstract*— A mathematical framework for quantization of the electromagnetic fields emitted by single dipole radiators is presented. The theory predicts directionality of photon emission probability and light-induced electromagnetic wave collapse, which will be tested using an experimental setup currently under development.**

***Keywords*— spontaneous emission, stimulated emission, photon emission probability, angular dependence of photon emission.**

I. Introduction

The advent of single-molecule fluorescence imaging techniques [1, 2] has made it necessary to relate photon emission statistics to the orientation of the emitting dipoles. While classical electrodynamics (ED) does predict a dependence of the dipole radiation pattern on the polar angle, the standard approach to the quantization of the free electromagnetic field [3] has not revealed any such dependence. In this presentation, we first outline a recently proposed theoretical framework [4] for a classical ED derivation of the electromagnetic fields of single dipoles and their subsequent quantization [5], and then present the design and preliminary results of an experimental setup for testing the angular dependence of the photon emission probability predicted by the aforementioned theoretical work.

II. Methods

In the first successful attempt to quantize the electromagnetic field, Dirac considered a "free field" arising from the vector potential only. When traced back to the source of the field and potentials – a transition dipole –, Dirac's approximation turns out to be equivalent [5] to a zero-order small dipole approximation in which the scalar potentials related to the opposite ends of the emitting dipole cancel each other out exactly. Using the general quantization protocol introduced by Heisenberg, Dirac expanded the vector potential into a series of plane waves with arbitrary amplitudes and replaced the latter with quantum mechanical creation and annihilation operators, which obey usual commutation relations. This approach has been essential for understanding quantum optics with free electromagnetic fields and led to numerous practical applications. In the recent generalization of Dirac's approach by one of us [5], contributions to the electric field of velocity-dependent terms in the scalar potential, neglected in the standard approach, also have been incorporated. These led to the following Hamiltonian ($\hat{H}$) and electromagnetic momentum ($\hat{G}$) operators and their eigenvalues:

$$\hat{H} = \sum_k \hbar\omega_k \sin^2\varkappa_k \left(\hat{N}_k + \frac{1}{2}\right) \rightarrow E = \sum_{\vec{k}} \hbar\omega_k \sin^2\varkappa_k \left(n_k + \frac{1}{2}\right), \quad (1)$$

$$\hat{G} = \sum_k \hbar\,\vec{k}\ \sin^2\varkappa_k \left(\hat{N}_k + \frac{1}{2}\right) \rightarrow \vec{G} = \sum_k \hbar\,\vec{k}\ \sin^2\varkappa_k \left(n_k + \frac{1}{2}\right), \quad (2)$$

where the other symbols have their usual meaning. The additional trigonometric function depends on the angle, $\varkappa_k$, between the mode vector $\vec{k}$ and the direction of the emitting dipole for each field mode and indicates that spontaneous emission is maximal for directions perpendicular to the emitting dipole and zero along its direction, in agreement with classical electromagnetism. This is the first testable experimental prediction of the theory.

When used to describe single-radiator emission stimulated by collimated single photons, this approach gives the eigenvalues of the Hamiltonian ($\hat{H}_{SE}$) and momentum ($\hat{G}_{SE}$) operators and their eigenvalues:

$$\hat{H}_{SE} = 2\hbar\omega_s \sin^2\varkappa_{kS} \left(\hat{N}_{kS} + \frac{1}{2}\right) \rightarrow E_{SE} = 2\hbar\omega_S \sin^2\varkappa_{kS} \left(1 + \frac{1}{2}\right), \quad (3)$$

$$\hat{G}_{SE} = 2\hbar\vec{k}_s \sin^2\varkappa_{kS} \left(\hat{N}_{kS} + \frac{1}{2}\right) \rightarrow \overrightarrow{G_{SE}} = 2\hbar\vec{k}_S \sin^2\varkappa_{kS} \left(1 + \frac{1}{2}\right). \quad (4)$$

The last equations indicate that (**i**) the dipole and stimulating fields carry away, in the direction of propagation of the stimulating field (given by angle $\varkappa_{kS}$), all the energy and momentum which, when compared to Eqns. (1) and (2) are equivalent to those of two photons plus twice the vacuum, and that (**ii**) the stimulating field *collapses the electromagnetic radiation* emitted by the dipole into a single mode.

Experimental tests of these predictions may include defocused imaging of single fluorescent molecules, which allows for determination of transition dipole orientation [6], as well as cavity QED experiments with Rydberg atoms or fluorescent molecule monolayers [7, 8], in which the emitters

have differing orientation angles relative to cavity walls.

In my lab, an experimental setup is being developed to determine the emission probability of fluorescent molecules whose dipole orientation is optically selected by choosing the linear polarization orientation of the excitation light, while emission is detected in a direction perpendicular to the optical axis of the excitation. The setup (Fig. 1) consists of a tunable Ti:Sapphire laser (680-1040 nm) for two-photon excitation of the sample, two optical micro-spectroscopes (OptiMiS) [9] with optical axes perpendicular to one another, and a computer-controlled half-wave plate for selective excitation of the molecules whose transition dipoles are oriented under a set angle ($\varkappa_k$) relative to the horizontal OptiMiS optic axis. The sample consists of fluorescent (mEGFP) molecules whose rotational diffusion was reduced by fusion to a large macromolecule (that increased total molecular size) and suspension in a viscous 50/50 glycerol/water mixture.

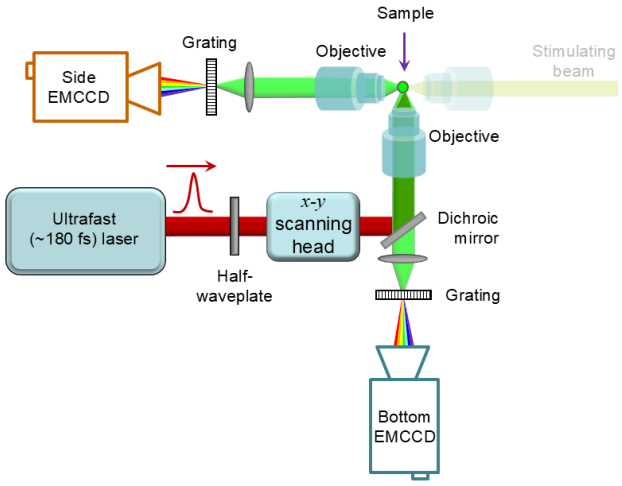

Fig. 1 Experimental setup for testing photon emission probability on the dipole orientation angle which is optically selected through polarization control.

III. Results and Discussion

The preliminary results shown in Fig. 2 show agreement with the $\sin^2 \varkappa_k$ prediction for the case of spontaneous emission. The intensity does not vanish at its minimum both because (1) rotational diffusion of the excited molecules causes rapid thermalization of the orientations of the transition dipoles, and (2) the relatively large numerical aperture objective (NA=0.5) integrates emission over a wide range of angles. These measurements will be refined by testing the effects of microscope objectives with various numerical apertures, further increasing the viscosity of the medium (e.g., by immobilization of the fluorophores within gels), and extending the study to investigate the dependence of the stimulated emission photon probability on the angular orientation of the transition dipoles. In addition, we will probe for the existence of an anticorrelation between the spontaneous emission rate detected by the Bottom EMCCD (as a function of the stimulation angle $\varkappa_{kS}$) and the stimulated emission rate detected by the Side EMCCD; observing such an anticorrelation would support stimulated wave collapse.

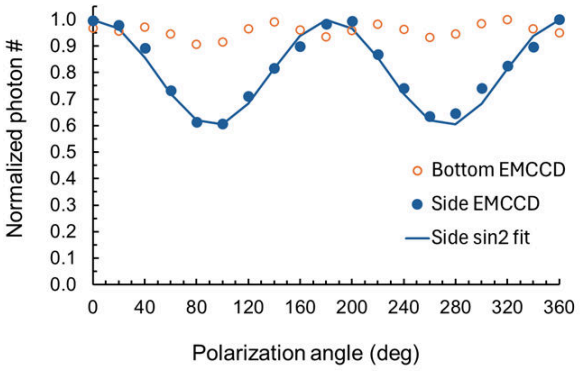

Fig. 2 Preliminary results on spontaneous emission from fluorescent molecules whose transition dipole is optically selected using the experimental setup shown in Fig 1.

IV. Conclusion

The proposed theoretical approach may lead to a better understanding of the processes accompanying radiation emission from excited atoms and molecules in the presence and absence of vacuum fluctuations or stimulating light [10]. It also opens a path for rigorous yet intuitive interpretations of the results of single molecular dipole imaging experiments [6] and quantum mechanics experiments with single photons [11].

***Abstract*— We demonstrate ultrastrong coupling between highly subwavelength THz resonators and high quality, HBN encapsulated single and bilayer graphene. The presence of gates allows the study of coupling strength as a function of carrier density and , in the case of bilayer, bandgap tuned in the 0-7 THz range.**

***Keywords*— van der Waals, terahertz, near field, strong coupling, cavity driven**

I. Introduction

Strong light-matter coupling has been recently successfully explored in the GHz and THz range with on-chip platforms, where metallic resonators with small cavity volumes are combined with high electron density materials to exploit the collective enhancement of the coupling **Ω**. New and intriguing quantum optical phenomena have been predicted in the ultrastrong coupling regime, when the coupling strength **Ω** becomes comparable to the unperturbed frequency of the system ω [1], [2]. The use of extremely small cavity volumes ($V/\lambda^3 \simeq 10^{-6}$), attainable with circuit-like resonators, has allowed the study of ultrastrong light-matter coupling at THz frequencies[3], [4], [5] While sub-wavelength localization of terahertz fields can be efficiently achieved using micro-structured metallic resonators, conventional approaches rely on metamaterials of repeating resonators placed atop the material of interest.[4] [6] This method is incompatible with exfoliated 2D materials, which are usually limited to in-plane dimensions of just a few microns, and with the study of few-electron systems requiring an active mode surface of a few micrometer squared.

II. Results and Discussion

We will discuss experimental results where a *single strongly subwavelength resonator* is coupled to a single graphene flake and, in a second experiment, to a dual-gated Bernal stacked bilayer graphene.

In the first experiment, we use the Landau polariton platform that has been extensively exploited to investigate the physics of ultrastrong light-matter coupling both in optical and transport experiments [4], [7]. We employ a system of immersion lenses [8] to spectroscopically investigate a graphene flake encapsulated in hexagonal Boron Nitride and embedded in single resonator operating at 1.2 THz. The resonator features an electrical gate in order to modulate the graphene's electron density ρ_{2deg} and, as a consequence, the Rabi frequency **Ω**. The normalized coupling ratio **Ω**/ ω scales with the expected fourth root of the density reaching a maximum value of 0.3, well within the ultrastrong coupling range.

In the second experiment, we couple a Bernal stacked bilayer graphene (BLG) to a bow-tie antenna resonator, operating at 2.3 THz. The presence of a dual gate system allows to independently tune the carrier density and the displacement field, with which we tune the BLG gap in the range 1-6 THz[9]. The immersion lens assembly allows the measurement of the field-tunable bandgap of bilayer graphene as a function of the displacement field. With such a setting we demonstrate that terahertz cavity photons can mediate attractive interactions in a tunable van der Waals material and reorganize a continuum of electron–hole transitions into an exciton-like state [10] [11]. Spectral measurements in the 1- 6 THz range reveals an anticrossing behavior of such an exciton-like state, and the estimated coupling strength, $\eta = \Omega/\omega \approx 0.43$, which places our system well into the ultrastrong coupling regime.

MEQED and Bianisotropy

Eugene Kamenetskii*

School of Electrical and Computer Engineering, Ben Gurion University of the Negev, Israel
*Corresponding author: kmntsk@bgu.ac.il

***Abstract*— Near field bianisotropy and chirality are associated with violations of local P and T symmetry and the problem of cross polarization coupling energy – the ME energy. The quantum behavior of bianisotropic metamaterials arises from quantum effects in ME meta atoms. These fundamental challenges lead to the development of ME quantum electrodynamics (MEQED).**

***Keywords*— metamaterials, magnetoelectric energy, symmetry breakings, quantum electrodynamics.**

The interplay between light and matter is fundamentally shaped by concepts such as bianisotropy and chirality. It is assumed that due to the cross-coupling dyadics in constitutive relations, magnetoelectric (ME) interactions in bianisotropic media occur. The problem of local bianistropy and local chirality (in other words, near-field bianistropy and near-field chirality) is the problem of cross-polarization coupling energy – the ME energy. This mesoscopic problem of quasi-static oscillations contradicts classical electrodynamics. The intense near-fields – ME near fields – are enantioselective fields. The additional (with respect to macroscopic Maxwell equations) coupling introduces fundamental challenges that have led to the development of ME quantum electrodynamics (MEQED). MEQED is an extension of standard QED that describes the quantum behavior of light-matter systems characterized by strong ME coupling. It provides a theoretical framework for studying systems where spatial inversion P and temporal reversal symmetries T are broken, often using engineered meta-atoms to observe these effects in subwavelength regions. MEQED advances the study of ME interactions into the quantum realm, treating coupled electric and magnetic responses not just as material parameters, but as fundamental quantized excitations in structured materials and the nearby vacuum.

Quantum Noise Spectroscopy of Chiral Quantum States

***Abstract*— We explore critical dynamics in the presence of competing ferromagnetic and antiferromagnetic interactions with all-optical spin-based quantum sensing protocols in variable temperature and variable magnetic-field environments.**

***Keywords*— quantum sensing, quantum noise spectroscopy, chiral quantum materials.**

I. Introduction

We recently used all-optical relaxometry measurements with a scanning nitrogen vacancy (NV) center probe to measure the spin fluctuations in a magnetic thin film near criticality[1]. This approach proved to be a valuable tool for extracting the universality class for the thin film in question, but scanning NV probes are challenging to deploy in low temperature, high-magnetic field environments, as field components orthogonal to the NV spin axis can suppress the spin contrast. Spin defects in hexagonal boron nitride (hBN) like the boron vacancy (V_B^-) are aligned out-of-plane and exhibit no loss of contrast in out-of-plane fields of up to 7 T[2,3]. Here, we use 2D spin-based quantum sensors for quantum noise spectroscopy of chiral quantum materials.

II. Methods

We initially focus on $LuMn_6Sn_6$, an antiferromagnetic material with a rich phase diagram of field-induced phases, including a canted antiferromagnetic phase that exhibits an anomalous Hall effect[4]. In order to better understand the interplay between magnetic phases in $LuMn_6Sn_6$, we leverage all-optical quantum noise spectroscopies of V_B^- spin defects in an exfoliated hBN flake transferred onto a bulk $LuMn_6Sn_6$ crystal. Measurements are performed at 2-300K and 0-7 T. Initial measurements have focused on the spin fluctuations near a phase transition between collinear and incommensurate spiral antiferromagnetic phases, but we are now extending to lower temperatures and higher fields in order to explore spin-interactions in additional commensurate antiferromagnetic phases, and a transverse conical spiral phase that may exhibit the topological Hall effect with associated scalar spin chirality.

III. Results and Discussion

The results shown in Fig. 1 highlight the measured spin noise near one phase transition in $LuMn_6Sn_6$ acquired at zero field and near room temperature. While conventional pulse sequences for measuring spin lifetime and spin coherence time can be applied at small magnetic fields, it becomes very challenging to deliver pi pulses in cryogenic environments at fields greater than 0.7T as the relevant frequencies exceed 20GHz. Thus, we use all-optical relaxometry schemes to extend these spectroscopies to fields of up to 7T.

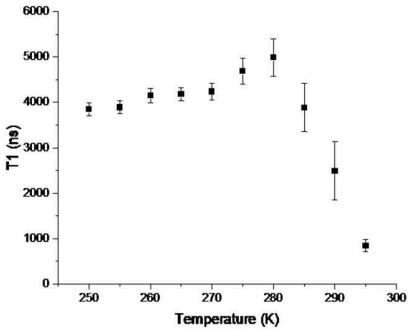

Fig. 1: Initial quantum noise spectroscopy of a phase transition between collinear and incommensurate spiral antiferromagnetic phases in $LuMn_6Sn_6$.

IV. Conclusion

All optical quantum noise spectroscopies of chiral quantum materials offer key understanding of critical spin dynamics and may help to unlock new understanding of chiral interactions in condensed matter.

***Abstract*—We present a comprehensive modal analysis of single-phase and multi-phase vanadium dioxide nanoparticles using in-situ high-resolution electron energy loss spectroscopy. In addition to identifying individual plasmonic modes and bulk losses as a function of nanoparticle size, our focus is on capturing the dynamic nanoscale optical response throughout the metal-insulator transition.**

***Keywords*—vanadium dioxide, insulator-metal transition, tunable devices, EELS.**

I. Introduction

Vanadium dioxide (VO_2) has been identified as a promising phase-changing material for use in tunable plasmonic devices due to its insulator-metal phase transition, which occurs at a convenient temperature of around 67 °C [1]. It was shown that VO_2 is biocompatible [2] and that its metallic phase supports near-infrared plasmonic resonances [3]. These findings open a way to design a temperature-driven plasmonic biosensor. However, localized surface plasmon resonances have been so far investigated in detail only in VO_2 nanostructure arrays using optical microscopy techniques, which did not provide comprehensive information about individual plasmonic modes and their tunability. In our recent studies of individual VO_2 nanoparticles using transmission electron microscopy techniques [4], [5], the transition and hysteresis were also probed by tracking plasmonic resonances that appear when VO_2 undergoes a transition from an insulator to a metal. Despite being able to link those results directly to optical properties, these plasmonic resonances and their modes have been discussed sparsely. Here, we present a spatial modal analysis of excitations within individual VO_2 nanoparticles in both the low-temperature insulating and high-temperature metallic phases using in-situ scanning transmission electron microscopy (STEM) with high-resolution electron energy-loss spectroscopy (EELS) [6].

II. Methods

VO_2 nanoparticles were manufactured on a heating chip (Protochips) with a 30 nm thick silicon nitride membrane in a two-step process introduced in [2]. STEM EELS measurements were performed on a TEM FEI Titan equipped with a monochromator, a GIF Quantum spectrometer for EELS, and an in-situ Fusion Select system (Protochips) for heating experiments at CEITEC Nano and on the Nion aberration-corrected high energy resolution monochromated EELS-STEM (HERMES^{TM}) equipped with a prototype Nion spectrometer possessing a Hamamatsu ORCA high-speed CMOS detector and an in-situ Fusion Select system (Protochips) for heating experiments at Oak Ridge National Laboratory.

Fig. 1. Tuning of the dipole plasmon mode in a vanadium dioxide nanoparticle via partial insulator-metal transition. The schematic depiction of the thermally tunable NP followed by measured EEL spectra for the fully dielectric state, four transition states, and the fully metallic state of the nanoparticle. HAADF STEM image with marked area for the EEL spectra integration and EEL maps (1.0–1.5 eV) of a partially switched NP at different temperatures. The green arrows indicate the approximate size of the metallic part (brighter area).

III. Results and Discussion

We have studied an ensemble of VO_2 nanoparticles of hemispherical shape using STEM-EELS in order to experimentally resolve the dipole plasmon peak, in addition to potentially higher-order and breathing plasmonic modes and

bulk losses. As a result, we introduce a full modal analysis of both insulating and metallic VO_2 NPs with an experimental observation of the energy of the dipole plasmon mode and its other parameters (amplitude and quality factor) as a function of the size of the metallic VO_2 NPs. The energy tunability of the dipole mode reads $0.1\,\mathrm{eV}$ for the size of NPs from 50 to $220\,\mathrm{nm}$. The quality factor of the VO_2 resonances was found to be significantly lower than that of traditional plasmonic materials, with values ranging from 1 to 1.5.

Furthermore, we have focused on transitional states within the insulator-to-metal transition. The tuning of the dipole plasmon mode in a $120\,\mathrm{nm}$ VO_2 nanoparticle via partial insulator-metal transition is shown in Figure 1. One can clearly see that it represents a system that can be switched on and off and tuned to the extent of $0.18\,\mathrm{eV}$. As a result, the dynamics of the phase transition facilitated the specific particle's ability to establish a correlation between the local temperature and the relative switched volume. This correlation was achieved by employing the dipole plasmon mode in the metallic region as the linking variable, with the peak position serving as the indicator.

IV. Conclusion

To summarize, we have introduced a comprehensive modal analysis of single-phase and multi-phase vanadium dioxide nanoparticles using in-situ high-resolution electron energy loss spectroscopy. We have shown that an individual vanadium dioxide nanoparticle represents a nanophotonic system that can be gradually switched on and off in terms of the emergence of near-infrared plasmonic absorption. The switching is accompanied by a gradual spectral shift of the absorption peak. It is envisioned that this phenomenon can be generalized to larger nanostructures with a higher aspect ratio, thereby introducing a wider tunability of the system, which is essential for functional nanodevices based on vanadium dioxide.

***Abstract*— Gold nanoparticles (GNP) are widely used in many fields, such chemistry and nanomedicine. Recently, scattering correlation spectroscopy (SCS) is one of the most used techniques for GNP surface and biomolecules interaction characterization. The SCS correlation curve is very sensitive to Parameters such as molecules orientation, binding affinity and cooperativity regarding the GNP surface.**

***Keywords*— Gold nanoparticles, biomolecules, correlation spectroscopy, biosensors, Superoxyde Dismutase (SOD).**

I. Introduction

In recent years, aptamer-based biosensors (aptasensors) have emerged as powerful alternatives to antibody-based detection systems due to their high affinity, strong specificity, chemical stability, and cost-effectiveness. Aptamers are short, single-stranded nucleic acid sequences, which enables them to fold into unique three-dimensional structures capable of binding molecular targets with high selectivity [1]. Although a broad body of literature addresses aptamer-based biosensors for various analytes, there are relatively few reports specifically describing the application of aptamers for SOD detection. Among them, studies have demonstrated the conjugation of SOD-specific aptamers on metallic nanoparticles to enable sensitive protein recognition via optical or SERS-based readouts, with detection limits in the nanomolar to picomolar range [2].

Scattering Correlation Spectroscopy (SCS) has emerged as a sensitive analytical technique for characterizing the dynamic and structural properties of nanoscale systems, particularly gold nanoparticles (GNP) in colloidal solutions. Unlike traditional light-scattering methods, SCS analyzes the temporal fluctuations of scattered intensity within a confined optical volume, enabling the determination of particle diffusion coefficients, hydrodynamic radii, and concentration without the need for external labels. This confocal autocorrelation approach, analogous in concept to fluorescence correlation spectroscopy, exploits the statistical analysis of intensity fluctuations to extract detailed information about particle motion and interaction dynamics over time.

In recent years, SCS has been increasingly applied to the study of GNP, whose morphology, surface chemistry, and interaction with biological molecules critically influence their behavior in sensing, biomedical, and catalytic applications. Djaker and co-workers have significantly contributed to this field by demonstrating the utility of SCS for distinguishing subtle differences in nanoparticle shapes and surface functionalities. They employed SCS to measure hydrodynamic sizes and biomolecules interactions of various GNPs, highlighting enhanced sensitivity to structural features such as surface branches and anisotropy in gold nanoflowers and nanourchins [3,4].

In this work, we present an SOD biosensor based on GNP-aptamer by using SCS. The results shows that this technique can provide many information such as binding affinity constant, binding cooperativity and number of interacted molecules on GNP.

II. Methods

SCS was previously described by the authors [3,4]. The set-up is based on an inverted microscope (Nikon) with an excitation wavelength at 633nm (He-Ne laser, Thorlabs) and an excitation power of 10 µW. A water immersion objective (Olympus, 40, NA = 1.2) was used for both excitation and collection signal. The confocal volume is selected by a 50µm pinhole and recorded by two avalanche photodetectors (PerkinElmer). The cross-correlation was performed by a correlator (ALV-7004). SCS curves were obtained by averaging at minimum five runs, each of 60 s duration.

III. Results and Discussion

Fig. 1 shows the extinction spectra of GNS before and after aptamer grafting and incubation with SOD1 (10 µM) at saturation. The results show that the LSPR maximum wavelength of pegylated GNS is around 533 nm with a FWHM around 30 nm, which reveals a good monodispersity of the

nanoparticles as already demonstrated by the authors.

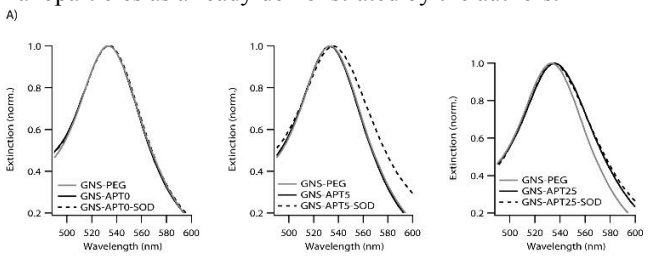

Fig. 1 Normalized extinction spectra of GNP before and after interaction with SOD (A).

In general, the aptamer and SOD grafting at the GNS surface leads to a red-shift of the LSPR position and an increase of the FWHM of the extinction spectrum. By considering the error bars, the LSPR red-shift and FWHM variations are not visible in each case, especially in the case of GNS-APT0 (without thymine-spacer). While, for GNS-APT25, the FWHM increases gradually. For all GNS-APT, the functionalization with SOD1 gives a higher LSPR and a larger FWHM, which demonstrates the SOD-APT interaction. This interaction is also revealed by DLS and zeta-potential measurement. The synthesized pegylated GNS have a hydrodynamic size about (78±6) nm and a ζ-potential of (-47±5) mV. The functionalization with the different aptamers and after interaction with SOD1 proteins (10 μM) gave generally a higher hydrodynamic size and ζ-potential. In the case of GNS-APT0, without thymine spacer, the hydrodynamic size decreases after interaction with SOD1, which reveals that the aptamers orientation and immobilization in GNS-APT0 is different than the GNS functionalized with thymine-spacer aptamers. Note that, the hydrodynamic radius doesn't reflect only the size of the particle but also its shape and surface chemistry, which affect its mobility in the solvent. This mobility seems to be different in the presence or not of the thymine-spacer. The error-bars given by the DLS method are too large to make a precise observation in this case, so that, the aim of this work is to use the scattering correlation spectroscopy as a powerful tool to precisely measure the variations of the hydrodynamic size at different SOD1 concentrations and to see the effect of the different thymine-spacer lengths on SOD1 sensing.

Fig 3 shows normalized SCS curves of gold nanoparticles at each step of functionalization. Pegylated gold nanoparticles showed a diffusion time of 9.85 ms corresponding to a hydrodynamic radius of 38.3 nm (hydrodynamic size of 76.6 nm). After interaction with the aptamer (without thymine spacer, GNS-APT0), the diffusion time increased to 11.4 ms corresponding to a hydrodynamic radius of 45.0 nm (hydrodynamic size of 90.0 nm), this gave an increase of the hydrodynamic radius of about 6.7 nm due to the aptamer (0T) interaction (typical size for an aptamer of 72 bases).

Hydrodynamic radius R_H calculated from SCS curves of gold nanoparticles after interaction with different concentrations of SOD (dots).

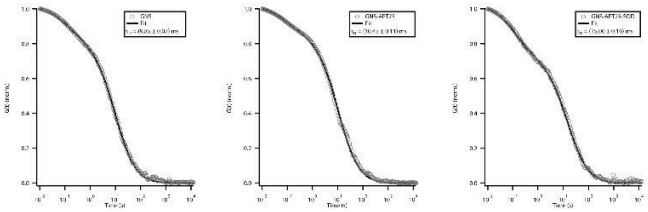

Fig. 3 Normalized cross-correlation curves (grey circles) and their fits (solid lines) of gold nanoparticles before and after interaction with SOD.

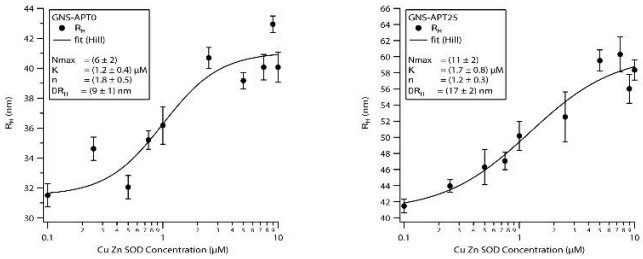

Fig. 4 GNP hydrodynamic radius after interaction with different concentrations of SOD (dots). The curves were fitted (solid lines) by using Hill equation.

IV. Conclusion

In this work, we have demonstrated an aptamer-GNP biosensor for SOD detection based on correlation spectroscopy. The SCS technique enables highly precise quantitative analysis, providing an exceptional level of accuracy in nanoparticle characterization. It is the only method capable of determining the exact number of molecules bound to a single nanoparticle. This study was performed using only microliter sample volumes and picomolar nanoparticle concentrations, making it both highly sensitive and resource-efficient.

***Abstract*— Surface enhanced Raman spectroscopy is employed to probe intracellular pH and local chemical microenvironments using plasmonic gold nanostructures functionalized with pH sensitive Raman reporters. Systematic comparison of reporter molecules and nanoparticle architectures reveals how cellular environment nanoparticle morphology and reporter chemistry jointly determine sensor response inside living cells.**

***Keywords*— surface enhanced Raman spectroscopy, intracellular pH, gold nanoparticles, nanopopcorn, cellular microenvironment.**

I. Introduction

Intracellular pH is a key regulator of cellular processes including metabolism protein activity endocytosis and cell fate decisions. While average cytosolic pH is relatively well characterized much less is known about local pH heterogeneity at the nanoscale and its dynamic changes within organelles. Conventional fluorescence based probes face limitations related to photobleaching spectral overlap and restricted multiplexing. Surface enhanced Raman spectroscopy offers molecular specificity high photostability and the ability to probe highly localized environments near plasmonic nanostructures.

II. Methods

Gold nanoparticles with controlled morphology including spherical particles and anisotropic nanopopcorn structures were synthesized using seeded growth approaches. Nanoparticles were functionalized with thiolated pH sensitive Raman reporters including mercaptobenzoic acid mercaptopyridine and aminothiophenol derivatives. SERS calibration curves were established in buffer solutions and cell culture media over physiologically relevant pH ranges. Nanoparticle uptake intracellular localization and biocompatibility were assessed using transmission electron microscopy confocal microscopy and viability assays. Intracellular SERS measurements were performed in living cells to extract local pH information.

III. Results and Discussion

Distinct Raman reporters exhibit different pH sensitivities dynamic ranges and stability depending on their chemical structure and orientation on the gold surface. Nanopopcorn architectures provide enhanced electromagnetic hot spots leading to increased SERS signal and improved intracellular detectability compared to spherical nanoparticles. Calibration curves obtained in buffer solutions differ substantially from those measured in cell culture media and inside cells highlighting the influence of protein corona formation ionic strength and confinement effects. The results demonstrate that intracellular SERS based pH sensing reflects not only proton concentration but also the complex physicochemical microenvironment surrounding the nanosensor.

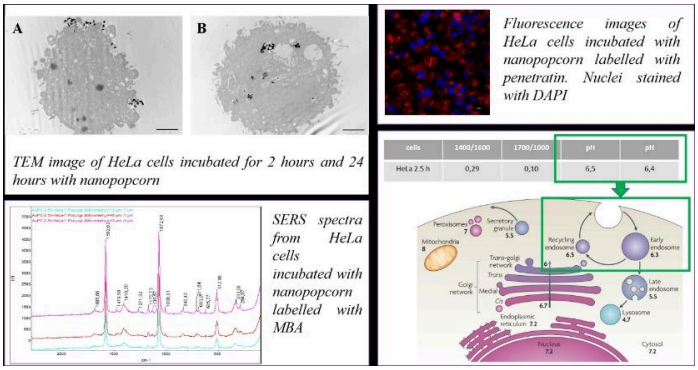

Fig. 1 Multi-Technical Approach for Intracellular pH Measurements: Integration of SERS, Fluorescence, and TEM.

IV. Conclusion

This study demonstrates that SERS based nanosensors enable probing of intracellular microenvironments with high chemical specificity. Understanding how nanoparticle morphology reporter chemistry and cellular context affect sensor response is essential for reliable intracellular pH measurements. These insights provide a framework for designing next generation SERS probes for studying dynamic processes inside living cells.

***Abstract*—**

Colorimetric sensors based on a color change in the presence of an analyte represent one of the most extensively investigated applications of plasmonic nanoparticles, particularly gold nanoparticles. In a colloidal system of surface-functionalized gold nanoparticles, aggregation can occur upon interaction with an analyte, producing a spectral shift that can be quantitatively analyzed by UV–visible spectroscopy [1,2] and qualitatively detected by the naked eye.

A similar behavior has been observed in silver nanoparticles and, more recently, in rhodium nanoparticles [3], although their plasmonic and physicochemical properties make these materials generally less attractive for this specific application.

In this contribution, we discuss the potential of these three types of plasmonic nanomaterials and highlight the still unexplored opportunities they may offer to the field of plasmonic colorimetric sensing.

***Abstract*—This work reports a low-power hybrid plasmonic platform for nanoscale analyte transport and trapping aimed at plasmonic biosensing applications. The platform integrates asymmetric nanoantenna arrays that enable rectified Brownian transport under modulated illumination with plasmonic bowtie electrodes that provide frequency controlled dielectrophoretic trapping and release, enabling spatially resolved analyte delivery.**

***Keywords*— plasmonics, dielectrophoresis, optical trapping, nanoparticle transport, biosensing**

I. Introduction

Efficient manipulation of nanoscale analytes is a key requirement for plasmonic sensing and lab on chip technologies. Conventional optical trapping techniques typically rely on high optical intensities [1], which can induce heating, photodamage, and degradation of sensitive biological samples. These limitations motivate the development of alternative low power strategies capable of enhancing analyte localization and transport without compromising sample integrity.

In this work, two complementary plasmonic approaches are investigated to address analyte manipulation across different spatial regimes. First, plasmonic Brownian ratchets based on asymmetric nanoantenna arrays are employed to generate directed, long range transport of nanoparticles under temporally modulated illumination. Second, hybrid plasmo dielectrophoretic traps combine localized plasmonic field enhancement with electrically driven dielectrophoretic forces to achieve stable, frequency dependent trapping and controlled release. Together, these systems provide versatile routes for analyte delivery and confinement in integrated plasmonic platforms.

II. Methods

Plasmonic nanostructures were investigated using finite-element frequency-domain simulations performed in COMSOL Multiphysics to model their electromagnetic response under optical (RF module) and electrical (AC/DC module) excitations. Simulations were used to calculate near-field distributions, optical forces, trapping potentials, and electric-field gradients generated by asymmetric nanoantenna geometries. For the plasmonic Brownian ratchet structures, a range of asymmetric gold nanoantenna unit-cell geometries was examined to assess how structural asymmetry influenced the optical force landscape along a defined transport axis. For the dielectrophoretic structures, bowtie-shaped nanoantennas integrated with in-plane electrodes were examined to evaluate optical near-field confinement and electrically induced field gradients relevant for dielectrophoretic manipulation. In all cases, the nanostructures were modelled as 40 nm high gold features fabricated on a quartz substrate with a 5 nm chromium adhesion layer and immersed in water.

Optical forces acting on dielectric nanoparticles were calculated using the Maxwell stress tensor (MST) formalism:

$$\mathbf{T} = \frac{1}{2}\mathrm{Re}\left[\varepsilon_0\varepsilon\left(\mathbf{E}\mathbf{E}^* - \frac{1}{2}|\mathbf{E}|^2\mathbf{I}\right) + \mu_0\mu\left(\mathbf{H}\mathbf{H}^* - \frac{1}{2}|\mathbf{H}|^2\mathbf{I}\right)\right], \tag{1}$$

The force acting on the analyte particle was then obtained by integrating $\mathbf{T}$ over a closed surface enclosing the particle. Trapping potentials were obtained by spatial integration of the force along the transport axis.

Arrays were fabricated by electron-beam lithography followed by metal deposition (Cr/Au) and lift-off (Fig. 1(a) and (Fig. 2(b)). Experiments were carried out on an inverted microscope (Nikon Eclipse Ti2) equipped with a 40× objective and an sCMOS camera. Nanoparticles were illuminated using dark-field or angled bright-field white-light illumination (Fig. 1(d)). Optical excitation was provided by a normally incident continuous-wave laser at 980 nm. For ratcheting experiments, directional transport was induced by periodically modulating the laser intensity using a mechanical chopper with a 50% duty cycle. Videos were acquired for subsequent trajectory analysis. Particle positions were extracted frame-by-frame to obtain (x, y, t) trajectories for large ensembles. Tracks were filtered by minimum duration, and net displacements were computed over defined time windows. Mean particle velocities were obtained from linear fits of displacement versus time. Trap stiffness was estimated using equipartition-based analysis.

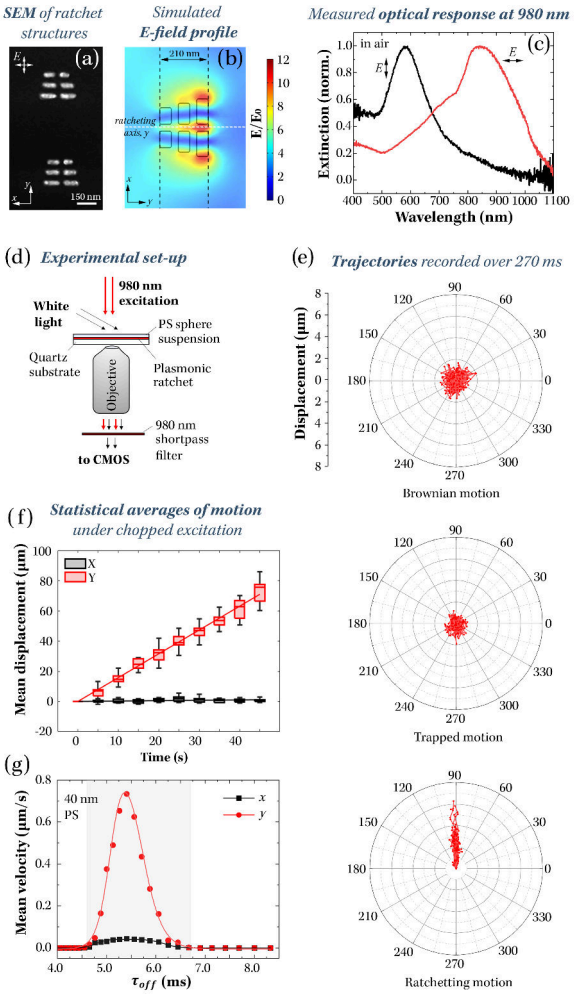

Fig. 1. Plasmonic Brownian ratchet structures and nanoparticle transport under temporally modulated excitation. (a) SEM image of an asymmetric plasmonic ratchet unit cell; arrows indicate the excitation polarization and ratchet axis. (b) Simulated near-field intensity profile under 980 nm illumination, showing an asymmetric optical potential along the transport direction. (c) Measured extinction spectra for orthogonal polarizations, confirming resonant excitation near 980 nm. (d) Schematic of the experimental configuration for particle tracking above the ratchet arrays. (e) Representative particle trajectories recorded over 270 ms in the absence of optical excitation (top), under continuous-wave illumination (middle), and under temporally modulated illumination (bottom). (f) Mean particle displacement as a function of time under chopped excitation, showing directed motion along the ratchet axis. (g) Mean particle velocity as a function of modulation off-time for 40 nm polystyrene particles, exhibiting a finite operating window for rectified transport.

For dielectrophoretic experiments, bowtie-electrode antenna arrays were mounted on a custom holder providing electrical contacts. An alternating-current voltage generated by a function generator (Agilent 33120A) was applied across the integrated electrodes, with frequencies swept in the kilohertz to megahertz range at fixed peak-to-peak voltage to switch between positive and negative dielectrophoretic regimes. Trapping and release dynamics were recorded optically. Particle accumulation at individual bowtie sites was quantified by integrating scattering intensity over regions of interest around the antennas and normalizing by background signals measured in adjacent regions.

III. Results and Discussion

Nanoparticle trajectories above the plasmonic Brownian ratchet arrays exhibited distinct regimes depending on the optical excitation used (Fig. 1(e)). In the absence of the 980 nm illumination, particle motion was consistent with free Brownian diffusion, while continuous-wave illumination resulted in localization at optical potential minima without net transport. When the excitation was temporally modulated, Brownian motion was rectified, producing net particle displacement along the direction defined by the ratchet asymmetry, with trajectories extending over several tens of micrometers during the recorded 40 ms time window (Fig. 1(f)).

Statistical analysis of large particle ensembles revealed that the rectified transport depended on the modulation parameters (Fig. 1(g)). For 40 nm polystyrene particles, directed motion was observed only within a finite range of modulation frequencies, consistent with diffusion times set by the ratchet unit-cell dimensions and the asymmetry of the potential established within. Outside of this regime, rectified transport diminished when the modulation off-time was either shorter than the characteristic diffusion time between adjacent potential minima or sufficiently long that particles explored multiple unit cells before re-trapping, resulting in negligible net displacement.

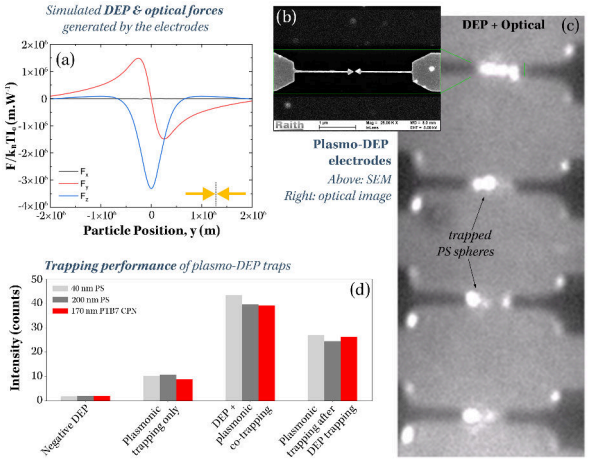

Fig. 2. Plasmonic bowtie-electrode antennas for dielectrophoretic trapping and optical confinement. (a) Simulated dielectrophoretic and optical force components acting on a nanoparticle along the bowtie axis under combined electrical and optical excitation. (b) SEM image of a bowtie-electrode antenna with integrated in-plane electrodes. (c) Optical image showing nanoparticle accumulation at the bowtie gap under simultaneous dielectrophoretic and optical excitation. (d) Trapping performance quantified by scattering intensity for different particle sizes and materials under negative DEP, optical trapping only, combined DEP and optical co-trapping, and optical trapping following DEP pre-concentration.

Dielectrophoretic manipulation using plasmonic bowtie-electrode antennas exhibited a distinct frequency-dependent response. When an AC voltage was applied across the integrated electrodes, nanoparticles accumulated above the bowtie gaps

under conditions corresponding to positive dielectrophoresis. Increasing the excitation frequency resulted in a transition to particle repulsion, defining a well-resolved crossover between trapping and release (Fig. 2(c)). For 40 nm polystyrene particles, this crossover occurred in the megahertz range, consistent with the frequency dependence of the Clausius–Mossotti factor of the particle–medium system. Concurrent optical excitation at 980 nm enhanced particle confinement at the bowtie gaps by increasing local field gradients at the plasmonic hotspot, while the sign of the dielectrophoretic force remained governed by the electrical excitation. Quantitative analysis of scattering intensity confirmed increased particle accumulation under combined optical and electrical excitation compared to electrical excitation alone (Fig. 2(d)).

IV. Conclusion

Plasmonic Brownian ratchet arrays were shown to rectify Brownian motion and drive directional nanoparticle transport under temporally modulated optical excitation. For 40 nm particles, net displacements over tens of micrometers and mean transport velocities of up to $\sim$2–3 μm s^{-1} were achieved at incident intensities below 1 kW cm^{-2}, well below those typically required for conventional optical trapping [2]. The transport was governed by the relation between the modulation off-time and the particle diffusion time between adjacent potential minima, defining a finite operating regime for rectification.

Plasmonic bowtie-electrode antennas enabled localized nanoparticle manipulation through frequency-dependent dielectrophoresis. Application of an alternating-current voltage produced reversible switching between trapping and release, with confinement occurring at the bowtie gaps below a well-defined crossover frequency in the megahertz range for 40 nm particles. Optical excitation at 980 nm enhanced confinement through increased near-field gradients, while the sign of the dielectrophoretic force remained controlled by the electrical excitation.

Together, these results demonstrate low-power plasmonic approaches for nanoparticle transport and localization operating over distinct spatial and temporal regimes relevant to micro- and nanoscale analyte manipulation.

Fluorescence-based chiral sensing with silicon metasurfaces

Tom T.C. Sistermans[1], Artemijs Krimovs[2], Robert Pal[2], Alberto G. Curto[1*]

***Abstract*— Chiral molecules with opposite handedness can have strongly differing biological properties. Identifying chirality is, however, limited by low sensitivity, restricting detection to high concentrations and large sample volumes. To overcome this, we propose a silicon nanophotonics-based sensing technique to enhance the sensitivity of chiral molecular detection.**

***Keywords*— metasurface, chirality, sensing, nanophotonics.**

Detecting the handedness of chiral molecules is essential in biochemistry, as the biological behavior of proteins, amino acids, and carbohydrates can differ dramatically between enantiomers. Circularly polarized light is commonly used to distinguish enantiomers by their differential absorption of left- and right-handed circularly polarized light, a technique known as circular dichroism (CD). However, this transmission-based technique relies on detecting small absorption differences, which becomes challenging at low concentrations where the overall absorption is negligible. Consequently, the weak signal becomes buried in background noise, severely limiting sensitivity and requiring high molecular concentrations and long measurement times. These limitations make conventional CD unsuitable for critical applications such as the early detection of protein aggregates associated with various diseases.

Using circularly polarized luminescence (CPL), some of the limitations of CD can be bypassed. The luminescence is shifted in wavelength, allowing separation from the excitation beam and strongly reducing background noise. The chirality is now detected by analyzing the circular polarization of the luminescence. Nonetheless, CPL contrasts are typically small because fluorescence is weak and the polarization asymmetry is low. To address this, we employ a metasurface composed of an array of silicon nanodisks, which act as optical resonators to enhance light–matter interaction [1-3]. The periodic arrangement introduces collective resonances that further enhance fields and scattering [4]. In addition, the resonators can increase the radiative decay rate via the Purcell effect and improve emission directionality, enabling more efficient detection. Together, these mechanisms can substantially boost the detected fluorescence intensity.

For chiral discrimination, the emission polarization properties are equally critical. High-index dielectric nanodisks allow tuning of electric and magnetic resonances to control the local optical chirality density, potentially enabling super-chiral near fields to enhance the CPL.

The metasurface is fabricated by electron-beam lithography from crystalline silicon, providing high refractive-index contrast and low optical losses in the visible range. Deposited on a glass substrate, the structures are compatible with transmission-mode measurements in our custom-built polarization microscope. The setup integrates dual single-photon counting detectors and dual photoelastic modulators to enable full Stokes polarimetry of the photoluminescence, allowing reliable CPL quantification with a spatial resolution of a few micrometers.
To evaluate performance, we deposit a chiral lanthanide complex embedded in a PMMA layer on the metasurface. Depending on the nanodisk radius, the fluorescence intensity increases by up to 2.5 times compared to the bare thin film. Importantly, by carefully tuning the electric and magnetic resonances of the silicon disks, this enhancement is achieved while largely preserving the emitters' intrinsic circular polarization. This combination of simultaneous enhancement of fluorescence while preserving circular polarization is a key advantage over other enhancement approaches and highlights the strength of high-index dielectric metasurfaces for chiral sensing. Overall, the metasurface more than doubles the total CPL sensitivity, demonstrating that silicon nanophotonics can substantially boost fluorescence-based chiral readout.

***Abstract*— Solar conversion to heat in building interiors causes significant energy use through air-conditioning, contributing massively to global CO_2 emission. A smart windows solutions based on plasmonics makes use of environmental sensing to dynamically modulate near infrared light entry as a function of solar intensity.**

***Keywords*— Thermoplasmonics, dynamic blocking, NIR**

INTRODUCTION

Plasmonic metamaterials provide multiple functional applications including sensing and photo-thermal conversion. These two capabilities can be combined to provide a smart nanoscale material solution for windows applications.

I. METHODS

Nanofabrication of plasmonic nanostructures via self-assembly approaches such as colloidal lithographies open for applications were larger areas of plasmonic materials are required. Here we developed Hole mask Colloidal Lithography (HCL) for the fabrication of nanoscale rings of arbitrary materials [1-2]. Silver nanorings arrays on glass were characterized spectroscopically and by FDTD then integrated into double-glazed window designs where small amounts of solvents were injected into the interior cavity of the windows to build a responsive system where the plasmon resonance shifted in response to the intensity of light shone on it. The complete window was tested under natural solar illumination and showed dynamic response as the sun intensity changed across a day[3].

II. RESULTS AND DISCUSSION

Silver nanoring arrays with major plasmon resonance around 950nm showed light blocking in the near infrared by absorption of photons. For windows without solvent in the interior space the NIR blocking effect reduced the temperature of black objects behind the window by up to 4 degrees C. By placing solvent in the interior space a thin solvent layer formed on the plasmon arrays shifting the plasmon resonance 80-100nm to longer wavelength through refractive index effects. Solvent covered plasmonic surfaces showed photothermal conversion and bulk heating and evaporation of the solvent which in turn shift the plasmon resonance to shorter wavelength. When integrated into a double-glazed window the effect was reversible so that turning off the illumination and subsequent cooling lead to resonance shift to longer wavelength. The combined system was a dynamically responding photothermal switch which reduced NIR transmission as light intensity increased. Solar testing dynamic response where NIR transparency was controlled by the solar intensity over the course of the day.

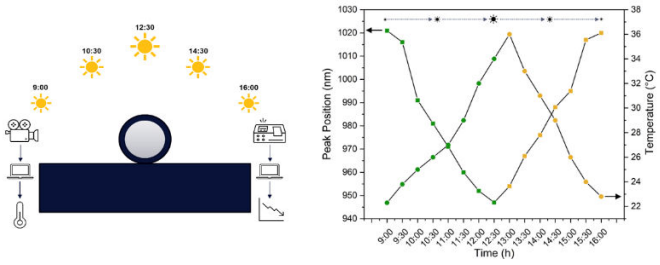

Figure1 Left: Schematic of solar illumination during the day. Right: Glass temperature and plasmon peak position shift in response to altered solar intensity. Reproduced from [3]

III. CONCLUSION

Plasmonic materials integrated into windows can utilize environmental sensing and photothermal conversion to provide passive technology for dynamic solar blocking while retaining visible transparency.

***Abstract*- Solar photothermal desalination is limited by latent heat. We demonstrate resonant heat transfer that recycles condensation heat back to the feed when counterflows are dynamically matched. With nanophotonic or plasmonic absorbers for high light to heat conversion, resonance increases fresh water output and enables off grid desalination.**

***Keywords*- solar desalination, resonant energy transfer, photothermal, plasmonics, heat recovery.**

I. Introduction

Sunlight is an abundant electromagnetic energy source for decentralized thermal desalination when efficiently absorbed and converted into localized heat[1]. However, evaporation is intrinsically energy intensive, so practical systems must recover and reuse latent heat while remaining scalable and resistant to fouling[2].

II. Methods

We couple photothermal evaporation modules with countercurrent heat exchange so that condensation heat is circulated back to preheat the feed. Resonant Energy Transfer (RET) occurs when the interacting flow rates satisfy a resonance condition that maximizes internal heat circulation, analogous to coupled oscillators[3]. RET can be implemented in membrane distillation and in membrane free humidification dehumidification architectures, with dynamic flow control under variable solar input.

III. Results and Discussion

Key results include:

- Up to five-fold increase in collected distillate in a photothermal membrane system at the RET resonance condition by matching feed and distillate flows[4].
- Membrane free architecture extends RET to humidification dehumidification, predicting weeklong productivity gains of about 77 percent and average gained output ratio near 1.9 at seawater salinity under realistic solar profiles[5]
- Broadband nanophotonic and plasmonic absorbers localize solar heating at the evaporation interface, improving scalability and enabling compact off grid modules (Refs. 1 and 5).

IV. Conclusion

Resonant heat transfer provides a unifying physics framework for optimizing solar thermal desalination beyond component level absorber design. By combining engineered electromagnetic absorption with flow tuned heat recovery, RET enables higher efficiency, continuous production under time varying sunlight, and architectures that avoid fragile membranes.

Abstract— Optical interfaces for deep brain regions are enabling new opportunities for multimodal investigation of neural activity. Here we present a multifunctional tapered optical fiber platform that integrates plasmonic nanostructures and microelectronic elements on a non-planar implantable waveguide. By exploiting radiative and evanescent field components along the taper surface, we achieve enhanced light–matter interaction for highly sensitive surface-enhanced Raman spectroscopy of neurotransmitters such as dopamine and serotonin. The engineered plasmonic structures also enable localized photothermal stimulation through wavelength-selective excitation. In parallel, a custom two-photon lithography approach allows the integration of active and passive electronic components for extracellular recording and sensing. This hybrid photonic–electronic system provides an integrated and versatile tool for multimodal neural interfacing.

***Keywords*— plasmonics, neurophotonics, implantable photonic devices, neural interfaces, hybrid photonic-electronic systems, nanophotonics**

I. Introduction

The adoption of optical methods for accessing deep brain regions has empowered the neurophotonics community to explore new frontiers in photonic interfaces with the mammalian brain [1]. These advances enhance optical control and monitoring of neural activity while integrating multiple functionalities —such as electrophysiological and neurochemical detection—within a single device.

In this presentation we describe our tapered optical fibers technology, capable of providing multifunctional photonic interaction with the brain tissue [2,3,4]. This is achieved by the integration of plasmonic nanostructures on the wide surface area of the implantable waveguide together with passive and active electronic elements.

II. Results and Discussion

Our approach exploits the coexistence of radiative and evanescent field on the wide surface of the narrowing waveguide to enhance the coupling between the electromagnetic field and photonic structures fabrication on the taper. We have investigated multiple methods to overcome the challenge of fabricating nanophotonic structures on the non-planar highly-curve implantable waveguide, including focused ion beam milling, repeated dewetting, wet-chemical overgrowth and sputtering deposition [5,6,7,8]. This enabled to achieve very low detection limit with surface-enahnced Raman spectroscopy for neurotransmitter molecules, including serotonin and dopamine. In addition to sensing capabilities, the implemented plasmonic nanostructures design allows to generate local heat with a simple wavelength switch, resulting in all-photonic integrated multifunctionality for neural interfaces.

Together with nanoparticles, the same implantable system can host microelectronic elements, fabricated with a custom approach to two-photon lithography [9]. We have indeed developed a method to adapt planar microfabrication to the non-planar tapered surface, achieving the integration of active and passive electronic elements. These can provide extracellular recording of neural activity, temperature sensing as well as neurochemical detection.

III. Conclusion

In conclusion, we will present a hybrid photonic–electronic approach expanding the functional capabilities of implantable

devices and represents a promising step toward fully integrated, multimodal tools for neuroscience research and future neurotechnological applications.

***Abstract*— Disordered plasmonic metasurfaces provide scalable alternatives to lithographic nanophotonics, creating dense hotspots and robust structural colors. We overview rapid wafer-scale electrostatic nanoparticle assembly and highlight imaging-oriented functions including imaging-based molecular sensing, optical security authentication, and emerging opportunities toward label-free bioimaging.**

***Keywords*— disordered plasmonics, plasmonic metasurface, scalable assembly, imaging, sensing**

I. Introduction

Disorder has emerged as a practical design degree of freedom in plasmonics because it relaxes nanofabrication constraints and can spontaneously produce dense electromagnetic hotspots. In this work, we present a wafer-scale, rapid electrostatic assembly strategy to construct disordered plasmonic metasurfaces within minutes [1]. By integrating colloidal nanoparticle coatings with metal–dielectric mirrors, the platform provides (i) reproducible far-field structural colors and (ii) strong near-field enhancement. We then summarize how these features can be exploited for imaging-oriented functions, including imaging-based molecular sensing [2], optical secure identification [3], and recent directions toward label-free cellular contrast enhancement.

II. Methods

Disordered plasmonic metasurfaces are fabricated by electrostatically assembling colloidal metal nanoparticles onto dielectric-spaced metallic mirrors (Fig. 1), forming a nanoparticle-on-mirror architecture. A proton-assisted process accelerates adsorption in aqueous media and enables rapid, uniform, and surface-selective coating over wafer-scale substrates [1]. Optical hotspots are formed both in interparticle nanogaps and between nanoparticles and the underlying mirror, providing strong local field confinement that is advantageous for sensing and imaging modalities.

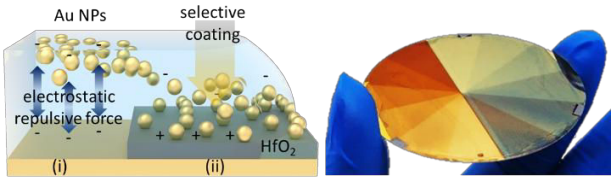

Fig. 1 Disordered plasmonic metasurface fabricated via rapid electrostatic assembly.

III. Results and Discussion

Representative results and applications include:

- Rapid wafer-scale fabrication: Proton-assisted electrostatic assembly yields uniform nanoparticle-on-mirror constructs with consistent structural colors, enabling lithography-free, scalable production [1].
- Imaging-based molecular sensing: Droplet-array projection imaging translates physicochemical properties (e.g., refractive index and surface tension changes) into intuitive optical signatures (color/size features), enabling binding-free taste visualization [2].
- Secure optical identification: The metasurfaces can maintain uniform far-field colors while exhibiting unclonable, stochastic scattering fingerprints, enabling robust authentication and anti-counterfeiting [3].
- Toward label-free cellular contrast: The disordered metasurfaces suggest a route to enhance optical contrast associated with refractive-index variations in biological samples, offering an emerging direction for imaging applications.

IV. Conclusion

Disordered plasmonic metasurfaces enabled by rapid electrostatic assembly provide a scalable route from nanoscale light confinement to system-level imaging functions. By combining wafer-scale manufacturability, uniform structural color, and strong near-field enhancement, this platform supports low-cost sensing and imaging concepts as well as optical security labels. Beyond established demonstrations, the approach also motivates future extensions toward compact,

label-free imaging components.

***Abstract*— Light-activated vaterite–silver nanoparticle metamaterials enable precise, localized ROS production for photodynamic therapy. Silver plasmonic effects extend visible-light absorption (400–700 nm), enhancing oxygen activation under mild irradiation, while the porous vaterite host stabilizes and uniformly distributes AgNPs, ensuring controlled radical generation and biocompatibility.**

***Keywords*— metamaterials, reactive oxygen species, silver nanoparticles, vaterite cargo.**

I. Introduction

Reactive oxygen species (ROS) are chemically reactive molecules containing oxygen that induce oxidative stress, damaging cellular components such as DNA, proteins, and lipids. This property makes ROS powerful therapeutic agents for selectively eliminating diseased cells or pathogens in cancer therapy, antimicrobial treatments, and wound healing. Photodynamic therapy (PDT) utilizes light-activated photosensitizers to produce ROS precisely at the target site, demonstrating remarkable success in treating early-stage cancers with minimal side effects. [1]. However, conventional photosensitizers suffer from low stability, unpredictable degradation in biological environments, and limited tissue penetration due to UV activation requirements. Nanotechnology addresses these challenges by enabling stimuli-responsive nanoparticles that generate ROS only under specific triggers like visible light, which offers deeper tissue penetration and reduced photodamage to healthy tissues.

Vaterite, a metastable polycrystalline form of $CaCO_3$, serves as an ideal carrier due to its biocompatibility, high porosity, biodegradability, and pH sensitivity. These properties enable controlled drug release and surface functionalization with plasmonic silver nanoparticles. Vaterite-AgNP metamaterials integrate plasmonic enhancement through localized surface plasmon resonance (LSPR), shifting activation to therapeutic visible wavelengths (400-700 nm). The porous vaterite matrix prevents nanoparticle aggregation while enabling tunable loading for reproducible dosing. This platform combines plasmonic "optical antenna" effect amplifying local electromagnetic fields for enhanced ROS production with SERS capability for molecular fingerprinting and biosensing (10^4-10^6 enhancement). This multifunctional system enables Raman-guided cell differentiation followed by selective light-activated cell death, bridging diagnostics and therapy in precision nanomedicine.

II. Methods

Vaterite microparticles were synthesized via controlled co-precipitation of $CaCl_2$ and Na_2CO_3 in ethylene glycol:water mixture and stabilized in ethanol. PVP-capped AgNPs were prepared by chemical reduction of $AgNO_3$ with $NaBH_4$. Composites with different loading cycles were formed by iterative impregnation of vaterite suspension with AgNP colloid, followed by ultrasonication, vortexing, and centrifugation [2]. Loading efficiency was quantified from supernatant UV-Vis spectra (SPR ~440 nm). Samples were characterized by SEM/EDS, FTIR spectroscopy, and ROS generation via fluorescence and absorbance probes (Fig. 1a,b).

The general catalytic efficiency of ROS generation was performed using the L-ascorbic acid (LAA) reaction leading the direct oxidation of LAA following the decreasing its absorbance in UV region. The diving deeper study of detection specific ROS types (hydroxyl radicals - ·OH, singlet oxygen radicals - $^1O_2$) was performed using selective fluorescence and absorbance probes, which showed qualify and quantify ROS types of generation rates (Fig. 2a,b,c.) [3].

III. Results and Discussion

• FTIR, SEM and EDS confirmed the successful injection of 2-6 nm in diameter AgNPs into vaterites pores (fig. 2a.). Broadband absorption verifies intra-particle AgNP distribution. UV-Vis analysis revealed broadband absorption for Ag-vaterite hybrids confirming intra-particle AgNP distribution, while supernatant spectra quantified loading efficiencies: VAg1 (LE=28%), VAg2 (47%), VAg3 (62%), VAg4 (74%), VAg5 (85%) based on 440 nm plasmon peak depletion. ROS generation, measured by 7-hydroxycoumarin (7HC) fluorescence (λex. 350 nm, λem. 440 nm), showed strong dependence on AgNP loading and irradiation dose: increasing the AgNPs concentration within vaterite increases the ROS

generation efficacy, but prolonged irradiation negatively effects on it

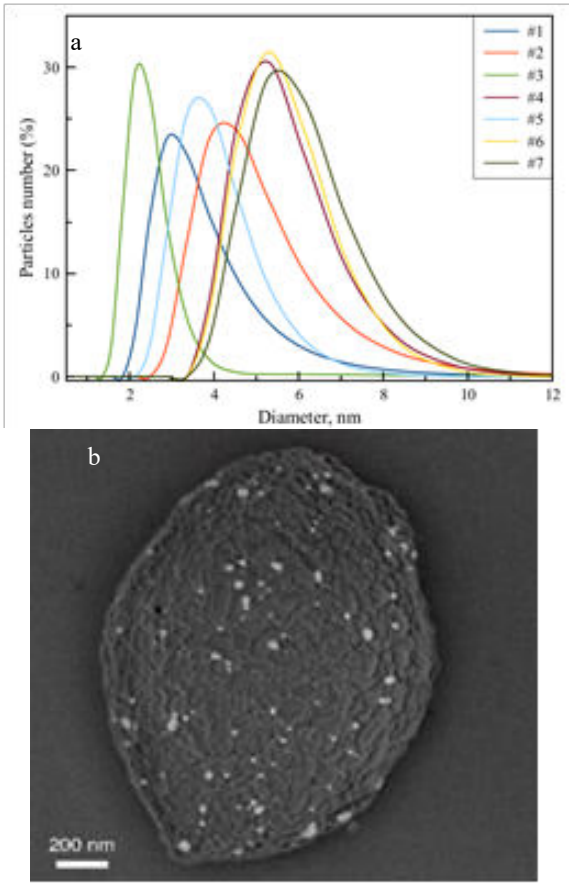

Fig 1. (a) AgNPs sizes measures via DLS; (b) SEM image of silvered vaterite.VAg

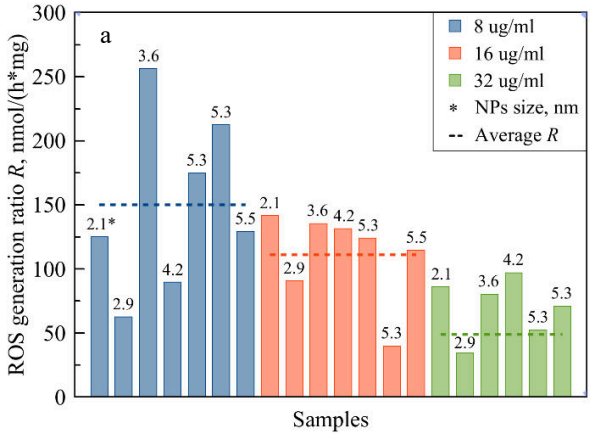

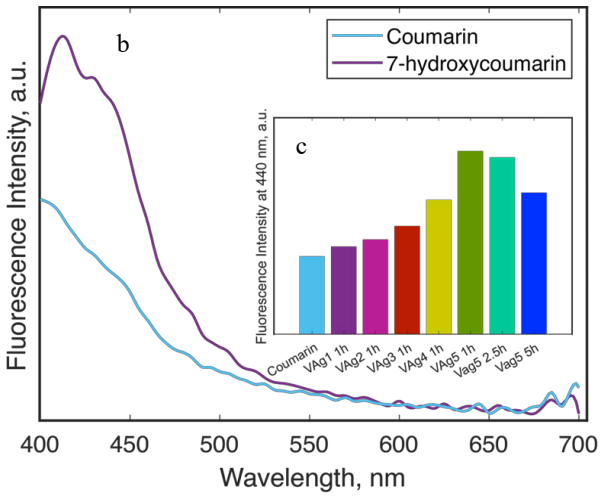

Fig 2. (a) General ROS generation efficacy by various AgNPs sizes; (b) Hydroxyl radicals generation by silvered vaterite and (c) the effect of AgNPs concentration and prolonged irradiation on hydroxyl radicals formation.

IV. Conclusion

Vaterite-AgNP metamaterials deliver efficient, visible-light ROS generation with proven biocompatibility, tunable loading (28–85% LE), and superior antimicrobial performance. The platform shows potential for antibacterial action, compatibility with cellular models, and applicability in targeted therapy, accelerated wound healing, and photocatalytic purification of water and air, while remaining technologically scalable and compatible with widely used optical diagnostic methods.

***Keywords*: Chip-scale, Mercury-free, Cathodoluminescence, Cold field-emission, Broadband UV emission, 9-log reduction**

Summary:
We report free-electron-driven, compact, chip-scale, mercury-free ultraviolet (UV) light sources enabled by cathodoluminescence and cold field-emission.[1] The devices deliver spectrally engineered broadband emission spanning the UVC, UVB, and UVA regions, with peak intensity precisely aligned near the DNA absorption maximum (~262 nm). Owing to strong spectral overlap with germicidal effectiveness curves, the UV chip provides, to our knowledge, the first single-source chip-scale platform capable of achieving log-9 microbial reduction — a performance level traditionally requiring multiple discrete emitters.[2]

Experimental validation demonstrates a 9-log reduction of *Escherichia coli* within 6 minutes at a delivered dose of ~45 mJ/cm², enabled by synergistic activation of DNA damage, protein oxidation, membrane disruption, and oxidative stress pathways.[2] Beyond germicidal efficacy, the devices offer decisive practical advantages, including intrinsically mercury-free operation, compact architecture, and instant ON/OFF capability. Long-term stability testing confirms robust operation up to ~2000 hours, while thermal characterization across –20 °C to 80 °C demonstrates consistent optical output and strong environmental tolerance. The sources operate at ≈4% efficiency with optical power ≥20 mW, underscoring their viability for energy-efficient deep-UV generation.[1]

Unlike conventional UV technologies limited by material constraints, efficiency droop, thermal management requirements, or bulky vacuum hardware, our approach employs high-integrity vacuum microcavities integrating ZnO nanostructured cold cathodes and spectrally tuned high-efficiency phosphor anodes, enabling stable, energy-efficient free-electron-driven UV generation without active thermal management.[3] The demonstrated performance establishes chip-scale cathodoluminescent UV sources as a scalable, high-impact platform for disinfection, food safety, healthcare, environmental monitoring, and advanced sterilization applications.

***Abstract*—We report a biological FRET platform based on engineered bacteria enabling direct spectro temporal mapping of donor and acceptor dynamics. By tuning protein spacing and coupling to different plasmonic systems, we modulate energy transfer efficiency and excited state kinetics, establishing a route toward plasmon assisted biointegrated optical sensing.**

***Keywords*— FRET, plasmonic systems, fluorescent proteins, biosensing.**

I. Introduction

Fluorescence Resonant Energy Transfer in the Förster regime is a widely studied photodynamic process based on a non-radiative dipole-dipole interaction between an excited donor molecule and a ground-state acceptor molecule [1]. Due to its strong dependence on the distance and relative orientation of the interacting dipoles, as well as the electromagnetic properties of the surrounding environment, FRET has emerged as a powerful tool for biosensing applications. While FRET inhibition can be achieved by increasing the donor-acceptor distance, its enhancement can be realized through interaction with resonant photonic environments, such as plasmonic structures or optical cavities [2].

In this work we report on the electromagnetic interaction between multi-resonant plasmonic systems and a biological FRET platform. By tailoring plasmonic resonances to match the absorption and/or emission spectra of the donor-acceptor pair (DAP), we aim to selectively modulate the acceptor fluorescence, enabling precise control over FRET efficiency [3]. Beyond fundamental insights into energy transfer mechanisms, this approach holds great potential for developing highly sensitive biosensors. Compared to conventional sensing platforms, plasmon-assisted FRET offers superior specificity, rapid response, and the ability to detect biomarkers at ultralow concentrations, making it a promising candidate for next-generation diagnostic tools.

II. Methods

We engineered Escherichia coli (*E. coli*) bacteria to express a fusion protein composed of enhanced cyan fluorescent protein (eCFP) as donor and enhanced yellow fluorescent protein (eYFP) as acceptor.

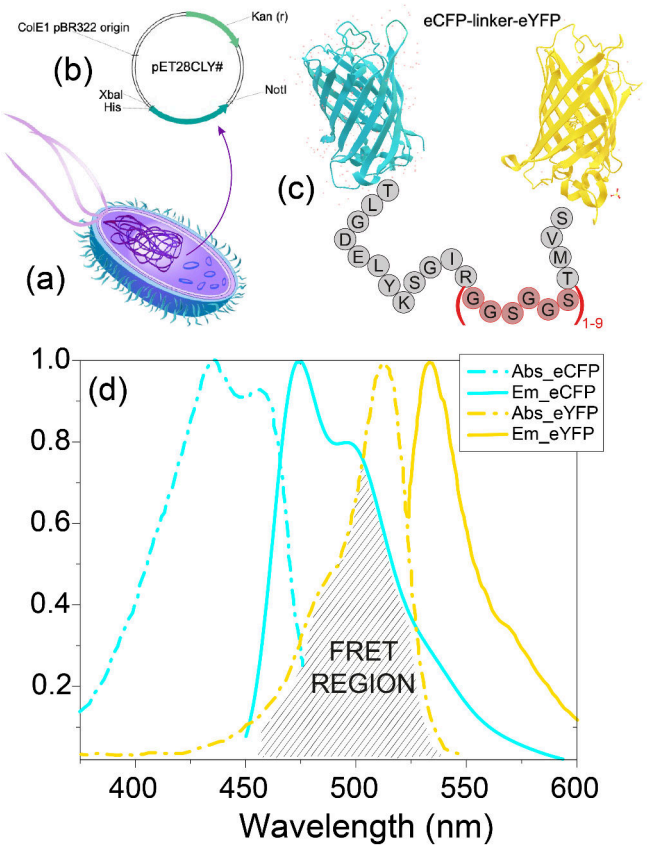

Fig. 1. Schematic representation of the biological FRET system: (a) sketch of the bacterium (*E. coli*); (b) vector map of pET28-CLY#, indicating the open reading frame of fusion protein between the Xba I and Not I sites, antibiotic resistance gene (Kan(r)), and its origin of replication; (c) sketch of fusion protein: eCFP-peptide-eYFP. (d) Absorption (dashed) and emission (solid) curves both for donor (cyan) and acceptor (yellow).

The two fluorophores are connected by a peptide linker

with variable length, depending on the number of (GGSGGS) repeats, ranging from 1 to 9 (see highlighted red area in Figure 1c). The resulting fusion proteins are indicated as CLY#, where # represents the number of (GGSGGS) repeats. In this study, the optical properties of bacterial strains expressing CLY1, CLY3, CLY6, and CLY9 have been investigated. Absorption (dashed) and emission (solid) curves both for donor (cyan) and acceptor (yellow) are reported in Figure 1d, including the FRET region. Excitation at 405 nm selectively pumps eCFP while avoiding direct excitation of eYFP. This configuration ensures that acceptor emission arises predominantly from FRET. Time wavelength resolved photoluminescence was measured using a streak camera system, providing two dimensional intensity maps $I(t, \lambda)$. This approach enables simultaneous extraction of donor bi-exponential decay components and acceptor population dynamics. FRET bacteria were mixed with 50 nm gold nanoparticles supporting a plasmon resonance centered near 530 nm, overlapping mainly with the acceptor emission band. This configuration allows investigation of Purcell enhanced donor emission and metal enhanced fluorescence effects. Two other plasmonic structures have been investigated to enable a controlled manipulation of the local density of optical states (LDOS), offering a direct route to modulate spontaneous emission rates, non-radiative channels, and energy transfer efficiency. This demonstrates how morphology, emitter–metal distance, and spectral overlap determine the balance between emission enhancement, quenching, and energy transfer.

III. Results and Discussion

Steady state spectra show two emission bands corresponding to eCFP and eYFP. The ratio between acceptor and donor emission decreases monotonically with linker length, confirming reduced FRET efficiency at larger separations. Streak camera maps (see Figure 2a and 2b referred to CLY3 and CLY6, respectively) reveal a clear temporal delay between donor emission maximum and acceptor emission maximum (see black dashed curves on the colored maps). This delay increases systematically from CLY1 to CLY9, providing a direct visualization of excited state energy transfer (see the sigmoidal behavior reported in the curves of Figure 2c). Bi-exponential analysis of donor decay allows extraction of FRET efficiency and estimation of donor acceptor distance, in excellent agreement with nominal linker lengths.

Unlike conventional time correlated single photon counting, this approach directly resolves acceptor build up dynamics, offering experimental access to excited state reaction signatures described by Joseph R. Lakowicz [1].

When coupled to 50 nm gold nanoparticles, two distinct regimes emerge. For intermediate spacing (CLY6), donor lifetime shortens and donor emission increases, consistent with Purcell enhanced radiative decay. This additional channel competes with FRET, slightly reducing transfer efficiency while simultaneously boosting acceptor fluorescence through metal enhanced fluorescence.

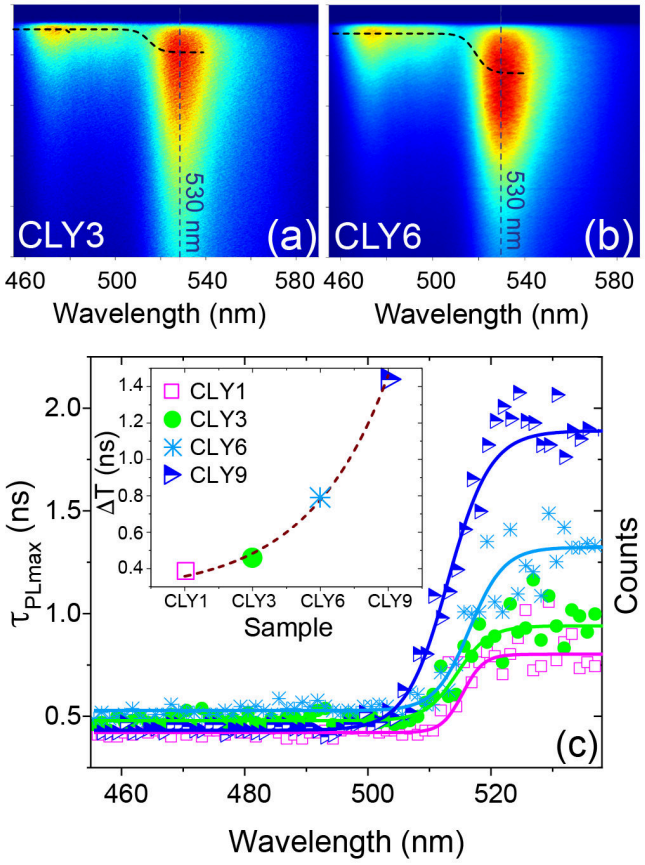

Fig. 2. Time/wavelength maps for (a) CLY3 and (b) CLY6 system. (c) Wavelength/delay-time graph showing the time points at which the emission maxima were recorded for each wavelength within the investigation range, for the CLY1 and CLY2 systems. The inset shows the Δt calculated for each biological FRET system.

For large spacing (CLY9), where intrinsic FRET is weak, plasmon induced radiative pathways dominate. The donor lifetime increases and FRET contribution is suppressed, demonstrating that plasmonic environments can either enhance or inhibit biological energy transfer depending on the initial coupling regime.

These results prove that FRET in intact bacteria can be externally engineered without protein extraction or membrane disruption, bridging nanophotonics and living systems.

IV. Conclusion

We demonstrated a living bacterial FRET platform enabling direct spectro-temporal visualization of donor-acceptor coupling. Controlled linker length allows quantitative distance extraction, while plasmonic structures modulate decay pathways through Purcell and metal enhanced fluorescence effects. This work establishes a foundation for plasmon assisted bio-integrated sensing and engineered nano-bio energy transfer systems.

***Abstract*— We present a low-cost SERS-based sensing platform for the detection and discrimination of Shiga toxins in clinical and food-related matrices. The approach enables label-free toxin typing with clinically relevant sensitivity and shows potential for translational applications ranging from patient diagnostics to food safety monitoring.**

***Keywords*— Nanoparticles, Shiga toxin, SERS, Clinical diagnostics, Food safety.**

I. Introduction

Shiga toxin–producing Escherichia coli (STEC) represents a major threat to public health, causing severe gastrointestinal infections that may progress to life-threatening complications such as hemolytic uremic syndrome (HUS). Among STEC virulence factors, Shiga toxins (Stxs) play a central role in disease severity, with Stx2 being strongly associated with an increased risk of systemic complications. Beyond the clinical setting, STEC infections are closely linked to food contamination, making food safety a critical component of Shiga toxin surveillance. Conventional detection methods, including culture-based assays, immunoassays, and RT-PCR, offer high sensitivity and specificity but rely on specialized laboratories and relatively long turnaround times. These constraints limit their suitability for rapid decision-making in both clinical diagnostics and food monitoring, where fast screening tools are essential to enable prompt intervention and outbreak prevention.

Surface-enhanced Raman spectroscopy (SERS) has emerged as a powerful bioanalytical technique, combining molecular fingerprinting with ultra-high sensitivity and enabling label-free detection of biomolecules. SERS can offer strong signal enhancement through simple and low-cost fabrication strategies, making it particularly attractive for real-life applications. Nevertheless, the direct detection and discrimination of Stxs by SERS, especially in complex biological and food-related matrices, remains largely unexplored.

In this context, we present a SERS-based sensing platform based on low-cost gold nanoparticle substrates for the detection and discrimination of Stxs. Building on a validated clinical proof of concept, we outline ongoing translational studies. These include the application of the platform to fecal samples for rapid toxin typing in a broader patient cohort and its extension to food safety, through the analysis of enriched media obtained from STEC-contaminated food matrices. By integrating clinical and food-related applications within a single SERS-based framework, this work highlights the potential of SERS to address urgent challenges in infectious disease detection.

II. Methods

SERS substrates were fabricated using a bottom-up approach based on the self-assembly of gold nanoparticles into plasmonic monolayers on silicon supports. This strategy enables the production of low-cost, reproducible substrates suitable for real-life applications.

In the clinical proof of concept, the platform was validated using human serum samples, where Stxs were selectively

captured on the SERS substrates through antibody-based functionalization and physical adsorption. Spectral data were analyzed using PCA to discriminate between samples containing Stx1, Stx2, and cleaved Stx2. The SERS-based classification was compared with RT-PCR results obtained for the same samples.

Ongoing investigations aim to extend the SERS platform to more complex matrices, including fecal samples and food-related environments. For fecal samples, supervised learning approaches are being explored to train classification models that can discriminate between toxin profiles and large spectral datasets. In the food safety context, preliminary experiments were performed on enriched media obtained from food matrices contaminated with Stx2-producing *E. coli* to assess sensitivity and feasibility. These studies are currently under development.

III. Results and Discussion

The SERS-based platform was first validated using human serum samples spiked with Shiga toxins. As shown in Figure 1a, the SERS fingerprints of Stx1, Stx2a, and cleaved Stx2a exhibit distinct spectral features that remain detectable despite the complexity of the serum matrix, demonstrating the capability of the substrates to preserve toxin-specific vibrational signatures.

Multivariate analysis was employed to evaluate toxin discrimination. PCA of SERS spectra acquired from antibody-functionalized substrates enabled the separation of Stx1, Stx2a, and cleaved Stx2a (Figure 1b), indicating that subtle spectral differences can be effectively captured through data-driven approaches for accurate toxin typing.

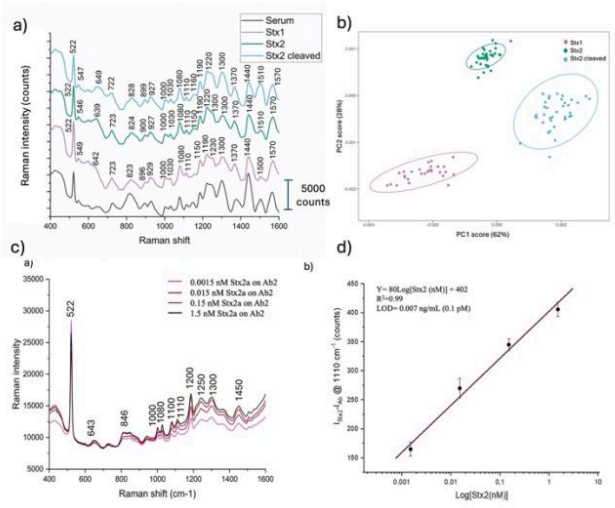

Figure 1. Results obtained in human serum. a) Fingerprint of the three Stxs in serum and serum itself; b) PCA discriminating the three toxins in serum on antibody; c) Stx2 on antibody spectra at increasing concentrations; d) calibration curve for LOD of Stx2.

Sensor sensitivity was assessed by measuring Stx2a at increasing concentrations. A progressive reduction in Raman intensity was observed while maintaining characteristic spectral features (Figure 1c). Quantitative analysis revealed a linear response on a semi-logarithmic scale (Figure 1d), allowing the estimation of a limit of detection of 0.007 ng/mL (0.1 pM), within the clinically relevant range.

In addition to controlled spiking experiments, the platform was evaluated in a blinded proof-of-concept study using sera from HUS patients with STEC infection confirmed by RT-PCR. PCA analysis of spectra acquired with toxin-specific antibodies showed overlap between clinical samples and their corresponding spiked controls in early-collected sera, indicating the presence of Stx2 and, where expected, Stx1 at low concentrations. These results demonstrate the ability of the SERS-based approach to detect and discriminate Shiga toxins directly in real patient-derived matrices despite inter-individual serum variability.

Building on these validated results, ongoing studies aim to extend the SERS-based approach to more complex and application-oriented matrices. In the clinical context, current efforts focus on fecal samples, where increased matrix complexity and variability require the acquisition of large spectral datasets and the implementation of supervised learning strategies to enable robust toxin classification. In parallel, preliminary investigations in the food safety domain explore the detection of Stx2 in enriched media derived from artificially contaminated food matrices. These studies are intended to assess feasibility across different foods and to define appropriate data analysis strategies for reliable screening applications.

IV. Conclusion

Overall, this work demonstrates the potential of SERS combined with data-driven analysis to support rapid and flexible Shiga toxin monitoring across clinical and food-related contexts.

Acknowledgments

The authors gratefully acknowledge the support for this work from the European Union - NextGenerationEU Call PRIN2022 Development of a plasmonic nanobiosensor for the rapid diagnosis of Shiga toxin-producing E. coli human infections at the point of care - SENSOSTEC (CUP B53D23019990006).

***Abstract*— We demonstrate a Surface Plasmon Resonance biosensor chip, based on organic optoelectronics and a biofunctionalized nanoplasmonic grating, capable of being used as a reusable, semi-automated and semi-quantitative screening test for sulfonamide antibiotics in milk and neonicotinoid-class insecticides in soil, at concentrations down to the maximum residue levels.**

***Keywords*— Surface Plasmon Resonance, plasmonic biosensors, organic photonics, food safety, environmental sensing, photonic chips.**

I. Introduction

Miniaturized optical plasmonic-based sensors are demonstrating the largest potential for Lab-on-a-chip systems to perform label-free sensitive, quantitative, and fast sensing for healthcare and environmental monitoring. While complete miniaturization of Surface Plasmon Resonance (SPR) biosensors integrating on the same chip an organic light source/light detector and a plasmonic sensing surface has been fully assessed, [1] main challenges for real world applications are still related to biofunctionalization and regeneration issues, and to automatized data analysis, which both correlate with sensor's specificity, reusability and reliability. We addressed those issues in our SPR biosensor chip, demonstrating semi-quantitative detection, below 10 ppb, of small-molecular contaminants in real matrices. Targets selected from crops and agrifood production chains included sulfonamide-class antibiotics in milk and neonicotinoid-class insecticides in soil.[2]

II. Methods

The full characterization of the SPR biosensor chip is carried out. The antibody-based competitive immunoassays, including cross-reactivity and optimization of regeneration protocols of the sensing surface, are developed through benchmark instrumentation. Simple sample preparation protocols include filtration, centrifugation, and dilution. Optimization of the SPR biosensor chip response to antibody injections in absence or presence of competition from targets is carried out, and matrix effects for real sample measurements are evaluated. Finally, an algorithm for automatic analytical signal extrapolation from SPR sensorgrams is implemented, with experimental feedback.

III. Results and Discussion

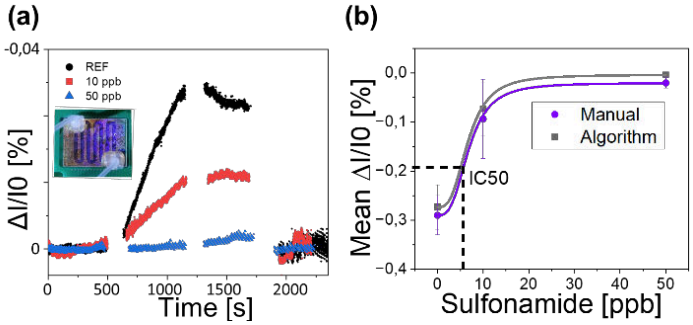

Fig. 1 (a) SPR sensograms from the proposed miniaturized SPR biosensor for injections of 0, 10 or 50 ppb of a sulfonamide-class antibiotic. Inset: picture of the sensor chip. (b) Dose-response curves extrapolated from the manual or algorithm-based analysis.

Experimental results show:

- Sensograms (Fig. 1a) and dose-response curves (Fig. 1b) matching with competitive immunoassay mechanisms
- Effective regeneration of the biofunctionalized sensing surface, which allows running triplicates
- Strong agreement between manual and algorithm-based data analysis (Fig. 1b)
- Half-maximal Inhibitory Concentration (IC50) below 10 ppb for both small-molecular target contaminants.

IV. Conclusion

We have demonstrated a new SPR biosensor chip with multiplex and semi-quantitative analytical capability of detecting small-molecular contaminants in real matrices, which can be applied in the future by operators in the crops and agrifood production value chains at the point of need.

***Abstract*— Plasmonic nanomaterials, metasurfaces and integrated photonic circuits enable compact biosensing platforms. Recent advances in waveguide-integrated sensors, plasmonic nanoarrays and metasurface-based architectures are discussed, highlighting their potential for lab-on-chip diagnostics and sensing applications in environmental monitoring, food safety and biomedical analysis.**

***Keywords*— plasmonics, biosensing, SERS, metasurfaces, integrated photonics, lab-on-chip sensing.**

I. Introduction

The development of compact optical biosensors is attracting increasing interest as rapid analytical tools become essential for environmental monitoring, food safety and biomedical diagnostics. Nanophotonics and plasmonics are playing a key role in this technological evolution, enabling highly sensitive detection mechanisms through enhanced light–matter interaction [1], [2].

Plasmonic nanostructures support surface plasmon resonances that confine electromagnetic fields at subwavelength scales, generating intense localized fields that enhance optical sensing mechanisms and spectroscopic signals [3–5]. Such properties make plasmonic nanomaterials highly attractive for biosensing applications.

Among the techniques benefiting from plasmonic enhancement, Raman spectroscopy has received considerable attention due to its ability to provide molecular fingerprints of chemical and biological species. In particular, surface-enhanced Raman spectroscopy (SERS) enables dramatic amplification of Raman signals through the localized electromagnetic fields generated by plasmonic nanostructures [6–8]. Recent advances have demonstrated flexible SERS sensors based on plasmonic nanoparticles capable of detecting biological toxins at extremely low concentrations, with limits of detection in the picomolar range [9]. Such technologies open new perspectives for rapid detection of pathogens and contaminants in environmental monitoring and food safety.

In parallel with plasmonic sensing technologies, integrated photonics provides compact platforms for guiding and manipulating optical signals. Optical waveguides enable precise control of light propagation in miniaturized systems and allow multiple optical functions on the same chip [10].

The integration of plasmonic nanostructures with photonic waveguides therefore represents a promising strategy for the development of compact sensing devices for environmental monitoring, food safety, and biomedical sensing [11–14]. Hybrid plasmonic–photonic architectures can exploit both the field enhancement provided by metallic nanostructures and the scalability of photonic integration.

Photonic waveguides can be implemented using a wide variety of material platforms, including dielectric, polymeric, and hybrid systems, enabling operation across a broad spectral range from the visible to the infrared. Among these approaches, ion-exchanged glass waveguides, polymer-based structures such as SU-8, and liquid-crystal-integrated photonic devices have attracted considerable attention for sensing and integrated photonics applications [15–19].

This work reviews some recent developments in integrated photonic biosensors, plasmonic nanoarrays and metasurface-based sensing platforms. Perspectives toward future photonic sensing systems capable of integrating optical signal processing functionalities are also discussed.

II. Integrated Photonic Biosensing Platforms

Integrated optical waveguide sensors represent an important class of compact biosensing devices. These sensors exploit the interaction between the evanescent field of a guided optical mode and the surrounding medium, enabling detection of refractive index variations or optical absorption changes associated with biomolecular binding events [20], [21], [22].

Compared with conventional free-space optical systems, waveguide-based sensors provide several advantages. They ensure stable optical alignment, reduced system complexity and

compatibility with microfabrication technologies, making them suitable for portable diagnostic devices and lab-on-chip platforms.

Recent developments have demonstrated integrated sensing architectures in which both the interaction region and the detection module are fabricated on the same substrate. In these devices, light propagates through an optical waveguide and interacts with the analyte through the evanescent field, while the resulting optical variations are detected by integrated photodiodes.

Integrated biosensors based on this principle have been demonstrated for several applications including biochemical sensing and beverage quality monitoring [23], [24]. These platforms highlight the potential of integrated photonics for developing compact and cost-effective sensing technologies suitable for real-world environments.

III. Plasmonic Nanoarrays for Enhanced Light–Matter Interaction

The sensitivity of integrated photonic sensors can be significantly improved by incorporating plasmonic nanostructures. Metallic nanoarrays placed near optical waveguides interact with the evanescent field of guided light and produce strong electromagnetic field localization.

Periodic arrays of plasmonic nanostructures such as nanocylinders or nanogratings can efficiently couple guided optical modes to radiated fields. Numerical studies have shown that waveguide-fed plasmonic nanoarrays can produce highly directional scattering patterns and enhanced optical emission signals [25]. These effects are particularly relevant for spectroscopic sensing applications where enhanced scattering and field localization improve light–analyte interaction. Further improvements in the coupling between waveguides and plasmonic nanostructures can be obtained by introducing intermediate optical layers. Transparent conductive materials acting as optical buffer layers can enhance the interaction between guided modes and metallic nanoarrays, leading to improved scattering efficiency [26].

These hybrid structures illustrate how nanomaterials can be integrated with photonic waveguides to develop highly sensitive optical sensing platforms.

IV. Plasmonic Metasurfaces for Advanced Biosensing Applications

Beyond periodic nanoarrays, plasmonic metasurfaces offer additional possibilities for engineering the optical response of nanostructured materials. Metasurfaces consist of planar arrays of subwavelength resonators capable of tailoring amplitude, phase and polarization of light with high precision [27–29].

In biosensing applications, metasurfaces can be designed to enhance specific optical interactions with analytes. Metasurface geometries can generate strong polarization-dependent responses or concentrate electromagnetic fields in selected regions of the structure [30]. Planar plasmonic metamaterials composed of engineered nanostructures have demonstrated strong optical activity and circular dichroism in the visible spectral range [31–34]. These effects can be exploited to enhance optical detection of chiral molecules and improve the sensitivity of spectroscopic sensing techniques.

The integration of metasurfaces with optical waveguides therefore represents a promising direction for future biosensing platforms, combining plasmonic field enhancement with the signal routing capabilities of photonic integrated circuits.

V. From Plasmonic Sensing to Quantum Plasmonics and Photonic Information Processing

Recent research has explored the integration of quantum nanoplasmonics with biosensing technologies. In such systems, plasmon–polariton modes strongly interact with quantum emitters, enabling coupling effects that enhance sensing sensitivity. Quantum plasmonic immunoassays based on plasmonic cavities can produce characteristic spectral signatures for ultrasensitive detection [35]. Nanoplasmonic waveguides supporting slow-wave plasmon–polariton modes have also been proposed as platforms for collective quantum dynamics of spatially separated quantum emitters [36].

While plasmonic nanostructures enhance light–matter interactions with analytes, integrated photonic circuits provide compact platforms for guiding and manipulating light. Reconfigurable photonic elements capable of dynamically controlling light propagation enable programmable interferometric architectures and adaptive sensing configurations [37].

Photonic circuits can also implement optical information processing through all-optical logic elements. Optical logic gates based on semiconductor optical amplifiers have been proposed as building blocks for photonic computing architectures performing logical operations entirely in the optical domain [38].

The convergence of plasmonic sensing, nanophotonic integration and photonic information processing may therefore enable intelligent lab-on-chip systems capable of combining analyte detection with real-time optical signal analysis.

VI. Conclusions

Plasmonic nanomaterials, metasurfaces and integrated photonic circuits are rapidly converging toward a new generation of compact optical sensing technologies. Plasmonic nanostructures provide strong electromagnetic field enhancement, while metasurfaces enable advanced control of the optical response of nanostructured materials. When integrated with photonic waveguides, these elements allow the development of compact sensing platforms capable of guiding and manipulating optical signals.

Future developments are expected to further integrate plasmonic nanostructures, metasurfaces and photonic information processing elements within the same platform, enabling intelligent sensing devices capable of combining

enhanced detection, spectroscopy and on-chip signal processing. Such hybrid technologies hold strong potential for future diagnostic systems addressing challenges in environmental monitoring, food safety and biomedical sensing.

DNA identification using surface-enhanced Raman spectroscopy and surface plasmon resonance

Andrzej Kudelski*

Faculty of Chemistry, University of Warsaw, Poland
*Corresponding author: akudel@chem.uw.edu.pl

***Abstract*— Surface plasmon resonance and surface-enhanced Raman scattering spectroscopy are promising methods for detection of specific DNA fragments. Example applications of these two techniques in DNA analysis is presented. Sensitivity of both methods in the identification of six the most popular in Poland variants of *BRCA1* gene mutations is compared.**

***Keywords*— surface plasmon resonance, surface-enhanced Raman scattering, SPR, SERS, DNA.**

I. Introduction

The deoxyribonucleic acid (DNA) is the carrier of genetic information for all living organisms. Detection of DNA which is characteristic of a given organism allows, for example, for identification of various dangerous microorganisms or for detection of counterfeit food products. Detection of mutations of DNA is also very important in medical diagnostics. Therefore, developing sensitive, fast and precise methods for detection of specific DNA fragments is very important.

II. Methods

Surface-enhanced Raman scattering (SERS) and surface plasmon resonance (SPR) sensors for identifying various fragments of DNA were constructed and tested. Both sensors were based on a selective hybridization of the target DNA with capture DNA immobilized on various plasmonic substrates (see Figure 1).

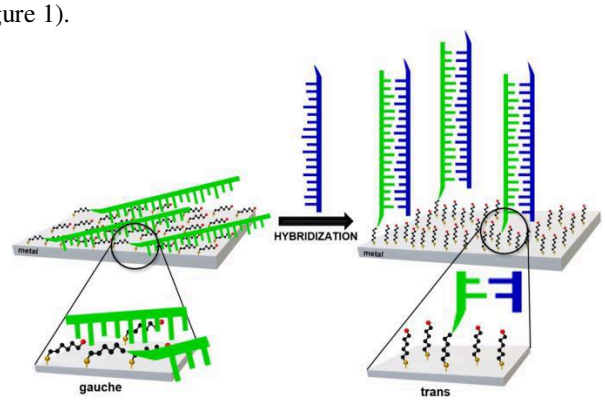

Fig. 1. Scheme of the SERS DNA sensor based on DNA hybridization-induced rearrangement of the alkanethiol chains (alkanethiolate linking moiety of single stranded DNA and 6–mercaptohexan–1–ol). Reprinted from ref. [1]. CC BY-NC-ND license.

The SPR sensor relied on the shape of the SPR sensorgrams, whereas the intensity of the Raman band at about 715–735 cm^{-1} (this band is mainly due to the superimposition of the band due to the ν(C–S) vibration of the alkanethiol chain in the *trans* conformation and the band due to the breathing vibration of adenine [2]) was the analytical signal for the SERS sensors.

III. Results and Discussion

The constructed SERS and SPR DNA biosensors are characterized by a low detection limit at a level of $fg \cdot \mu L^{-1}$, a wide analytical range, and high selectivity [2]. For the first time, the sensitivity of SERS and SPR methods was compared when hybridizing DNA chains that had not been labeled before hybridization [2].

IV. Conclusion

SPR and SERS techniques have great potential in DNA analysis (including detection of gene mutations). Our results indicate that SPR and SERS methods are much more sensitive at detecting mutations in clinical samples than standard genetic methods such as PCR-HRM. For different DNA sequences, either the SPR or the SERS sensor displayed greater detection sensitivity, which means that the selection of the optimal sensor type depends on the sequence of the target DNA.

Thermal management of plasmonic nanoparticles using 2D materials for single-molecule biosensing

Peter Zijlstra[1,*]

[1]Eindhoven University of Technology, Eindhoven, The Netherlands
*Corresponding author: p.zijlstra@tue.nl

***Abstract* — Plasmonic structures are widely used for biomolecular detection, down to the single-molecule level. However, non-radiative decay of surface plasmon resonances causes photothermal heating which mitigates real-world applications in sensing and beyond. Conventional cooling strategies fail at these scales due to limited heat transport and high interfacial thermal resistance, motivating the integration of advanced materials for thermal management. I will discuss simulations and experiments on the use of hexagonal boron nitride (hBN) thin flakes as a new class of nanoscale heat spreaders to efficiently mitigate plasmonic heating of single gold structures in aqueous environments.**

***Keywords*— single-particle spectroscopy, 2d materials, nanoscale thermometry, biosensing**

I. Introduction

In this presentation I will show our recent work on biomolecular sensing using single plasmonic particles. I will discuss the mechanisms by which plasmon-enhanced fluorescence can be employed for single-molecule biosensing at picomolar levels [1] and in complex biological fluids [2].

I will then discuss strategies to mitigate optical heating [3,4]. Although plasmonic effects enable enhanced optical functionalities, the associated temperature rise can degrade performance in heat sensitive applications such as biosensing, nanophotonics, and microelectronics. Conventional cooling strategies fail at these scales due to limited heat transport and high interfacial thermal resistance, motivating the integration of advanced materials for thermal management. I will discuss the use of hexagonal boron nitride (hBN) thin flakes as nanoscale heat spreaders to mitigate plasmonic heating of gold nanospheres surrounded by water. Using finite-element simulations, we quantify the influence of hBN thickness, in-plane thermal conductivity, and interfacial thermal conductance on cooling efficiency. Complementary experiments employ cross-grating wavefront microscopy (CGM) for nanothermometry to map temperature distributions around optically heated gold nanoparticles and quantify the cooling effect of hBN flakes. Our results reveal a strong thickness dependence, where heat dissipation in thin flakes is limited by the heat capacity of hBN and in thick flakes by interfacial thermal conductance. We obtain a reduction in the steady-state temperature rise by up to ~60 % compared to glass by including hBN. In addition, the presence of two main heat dissipation pathways emerges: a direct one from the nanoparticle to the hBN and an indirect one from the particle via water to the hBN. This combined simulation–experiment framework offers a versatile approach to improve thermal management in plasmonic systems and beyond, establishing design guidelines for integrating 2D materials into thermally sensitive platforms such as biosensors, integrated circuits, and energy conversion.

*Corresponding author: k.r.rusimova@bath.ac.uk

***Abstract*— We investigate how probe proximity modifies interfacial electronic structure in single-molecule junctions on Si(111)-(7×7). Building on equilibrium interface-state measurements and controlled single-molecule reactivity, we integrate optical and electronic probes to examine how hybridized junction states influence energy redistribution and competing reaction pathways at room temperature.**

***Keywords*— STM-induced luminescence, single molecule junctions, atomic manipulation.**

Understanding how atomic-scale contacts influence molecular electronic structure is crucial for molecular and quantum devices, as well as nanoscale chemical control. The proximity of a probe can fundamentally alter junction electronic structure through structural relaxation, orbital hybridization, and emergent interface states, which in turn can govern transport and reaction dynamics [1]. While scanning probe studies have long highlighted these phenomena, direct experimental observation of interface states at equilibrium - and their impact on reaction selectivity - remains largely unexplored.

In our recent investigations, we identified equilibrium electronic states emerging from molecule-surface proximity that act as precursors to covalent bonding. These states are robust across different local environments and do not depend on specific orbital symmetries or probe-induced effects. Computational modelling links the formation of these interface states to subtle nuclear motion preceding bond formation or desorption, revealing a direct connection between evolving electronic structure and nascent reaction pathways.

We further observed that single-molecule excitations can lead to competing reaction outcomes [2], with branching ratios that depend on the energy delivered to the system rather than simple geometric considerations. This demonstrates the potential to control reaction selectivity through the local electronic environment, offering a pathway toward targeted single-molecule reactivity.

Building on these findings, we have begun combining simultaneous optical and electronic measurements to correlate the emergence of interface states with energy redistribution and reaction probabilities [3]. This approach provides a new window into how equilibrium junction states govern energy flow and selectivity in single-molecule reactions, establishing a conceptual framework for state-engineered control of chemical outcomes.

Plasmonic nanofibers for neurochemical monitoring

Jean-Francois Masson[1,*], Maryam Hojjat Jodaylami[1], Ailsa Geddis[1]

[1]Department of Chemistry, Université de Montréal, Canada
*Corresponding author: jf.masson@umontreal.ca

***Abstract*— The use of plasmonic optical fibers allows to design sensors for many neurochemicals and neuroproteins. These fibers combine enhancement from the fiber acting as an optical element (resonator and microlens) and from the plasmonic materials. The presentation will show their application for the detection of neuroproteins and neurotransmitters**

***Keywords*— Plasmonic sensing, nanomaterials, metamaterials, neurochemistry.**

I. Introduction

Plasmonic nanomaterials offer a suite of opportunities for the design of nanosensors for proteins and other metabolites. In this presentation, we will focus on plasmonic nanofibers harvesting the sensitivity benefits of optoplasmonic architectures for the detection of brain protein S100b in animal models.

II. Neuroproteins

The quantification of proteins involved in the complex neurobiochemistry of the brain remains a frontier in analytical sensing. The challenge is even greater if the monitoring of proteins requires high spatial resolution and minimal invasiveness to be compatible with monitoring directly in the brain of a living organism. We have developed an optical fiber-based surface-enhanced Raman scattering (SERS) nanoendocope for the quantitative detection of S100β, an astrocytic protein, with high regiospecificity and minimal invasiveness. The concentration of S100β protein released in specific regions of mouse brain slices was measured under various stimulation conditions, including N-methyl-D-aspartate, electrical, and optogenetic stimulation. SERS nanoendoscopes were also used to investigate the in vivo release of S100β protein in the brainstem and the primary somatosensory cortex of mouse models following the rhythmic jaw movements induced by optogenetic stimulation of the cortical masticatory area and the tactile stimulation of the hindlimb, respectively. This presentation will show the ability of SERS nanoendoscopes for ex vivo and in vivo quantification of proteins in the complex biological matrix of the brain, which is important for understanding the molecular mechanisms underlying neuronal activity and brain function.

III. Neurochemistry

For neurotransmitters, unfunctionalized Au nanoraspberries or gold nanostars were synthesized and immobilized on a pulled fiber functionalized with a block copolymer. The sensors were tested for sensing neurochemicals and a convolutional neural network (CNN) was trained for spectral classification. Dynamic SERS will be shown to detect neurotransmitters secreted upon neuronal stimulation and in the presence of therapeutic compounds. Different levels of neurotransmitters were seen for cultured neurons from different regions of mouse brain tissue.

IV. Conclusion

We will show the use of plasmonic fibers for the detection of various chemicals and biochemicals important for neuroscience studies.

***Abstract*— Self-assembly Plasmonic nanostructures provide a scalable bottom-up approach for engineering surfaces with controlled localized surface plasmon resonances. Techniques such as nanosphere lithography and hierarchical sphere assembly enable ordered arrays and dense nanogaps, generating intense and reproducible electromagnetic hot spots for SERS and biosensing applications.**

***Keywords*— Plasmonics, Self-assembly, SERS, Nanosphere lithography, Biosensing**

I. Introduction

Self-assembly is a promising technique for creating SERS-active surfaces, characterized by technological simplicity, scalability and cost-effectiveness. Self-assembled nanosphere-based architectures have been extensively studied due to their formation of homogeneous and reproducible ordered matrices. However, these systems have limitations due to their uniform morphology and low dimensionality, which limit the localization of the electromagnetic field and accessibility to hot spots. To address these challenges, new self-assembled platforms based on hierarchical nanostructures have been developed. Specifically, colloidal plasmonic arrays (CPAs) with binary hierarchical designs offer improved multiscale roughness [1]. These systems increase the density of accessible hot spots and optimize light–matter interactions, while maintaining the scalability and low-cost advantages inherent in self-assembly methods. On the other hand, nanopillar-based structures represent an alternative due to their three-dimensional architecture and larger surface area. This study will also present preliminary results on the fabrication of self-assembled structures based on nanopillars.

II. Methods

The fabricated planar SERS substrates were carefully characterized to evaluate both their structural and sensing performance. In particular, the morphology of the nanostructures was analyzed using microscopy SEM and AFM. Subsequently, Raman measurements were performed to evaluate SERS activity in terms of increased signal intensity and to identify the presence and distribution of electromagnetic hot spots in the substrate.

III. Results and Conclusion

Self-assembly enables planar SERS substrates ranging from highly ordered nanosphere arrays to structurally complex architectures, realized through different bottom-up strategies. Numerical and experimental results, supported by SEM, AFM and Raman measurements, confirm improved Raman signals compared to simpler configurations, highlighting the potential for further optimization and improved fabrication strategies.

***Abstract*—A silver plasmonic SERS nanostructure is presented for the recognition of pesticides in water. Fingerprint spectra of fipronil, imidacloprid, and thiram are acquired and analyzed using principal component analysis, enabling clear label-free discrimination and demonstrating the potential of the platform for water quality monitoring.**

***Keywords*— Silver nanostructure, pesticide, SERS, PCA, sensing, electron beam lithography.**

I. Introduction

The widespread use of pesticides in agriculture has led to increasing contamination of surface and groundwater, raising serious concerns for environmental safety and human health [1,2]. Insecticides such as fipronil and imidacloprid, as well as fungicides like thiram, are among the most frequently detected compounds in aquatic environments, even at trace concentrations. Prolonged exposure to these substances has been associated with toxic and ecotoxic effects, making their rapid and reliable detection in water a critical challenge.

Conventional analytical techniques, including gas and liquid chromatography coupled with mass spectrometry, provide high sensitivity and selectivity but often require complex sample preparation, expensive instrumentation, and laboratory-based analysis. In this context, Surface-Enhanced Raman Spectroscopy (SERS) has emerged as a powerful alternative, offering molecular fingerprint specificity, label-free detection, and the potential for rapid analysis [2,3]. The effectiveness of SERS strongly depends on the design of the plasmonic substrate, particularly its ability to generate intense and reproducible electromagnetic hot spots.

In this work, we present an engineered silver plasmonic SERS nanostructure used for efficient and sensitive pesticide recognition in water. By combining SERS measurements with principal component analysis (PCA), we demonstrate the ability to distinguish between different classes of pesticides based on their vibrational fingerprints.

II. Methods

The SERS substrate consists of a periodic array of nanocavities fabricated on a silver thin film using a top-down electron beam lithography process. Each unit cell is formed by three equilateral triangles with a side length of 200 nm, arranged such that their midpoints lie on the vertices of a virtual equilateral triangle with a side length of 230 nm. The overall patterned area has dimensions of approximately 450 × 430 μm². This geometry was designed to promote strong localized surface plasmon resonances and a high density of electromagnetic hot spots.

Three pesticides were investigated: fipronil, imidacloprid (both insecticides), and thiram (a fungicide). All analytes were prepared in water and deposited onto identical silver nanostructured substrates by direct adsorption. SERS measurements were performed under identical experimental conditions to ensure spectral reproducibility. For each pesticide, multiple spectra using a laser wavelength of 785 nm were acquired and averaged. PCA was applied to the normalized SERS spectra to extract the most relevant spectral features and enable multivariate discrimination.

III. Results and Discussion

The average, normalized SERS spectra of fipronil, imidacloprid, and thiram are reported in Figure 1a. Each pesticide exhibits a characteristic vibrational fingerprint associated with its molecular structure. While some Raman bands partially overlap, clear differences in peak positions and relative intensities can be observed, particularly between the insecticides and the fungicide.

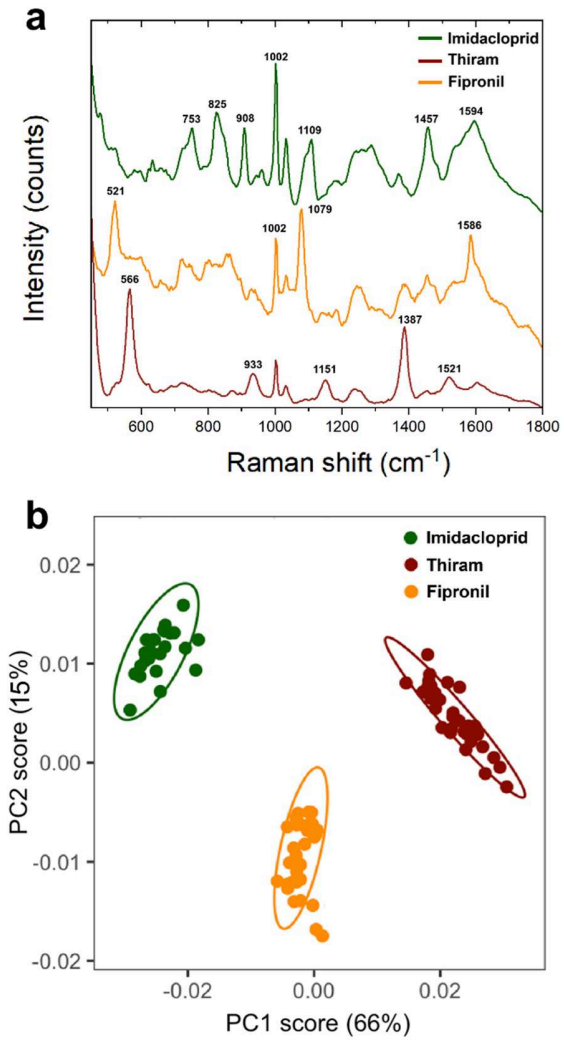

Fig. 1 SERS recognition of pesticides: a) average normalized SERS spectra of imidacloprid (green line), thiram (red line), and fipronil (yellow line); b) PCA analysis associated with the SERS measurements of the imidacloprid (green points), thiram (red points), and fipronil (yellow points).

To enhance analyte discrimination and objectively assess spectral differences, PCA was applied to the SERS datasets. The PCA score plot shown in Figure 1b reveals a clear separation of the three pesticides into distinct clusters. Fipronil, imidacloprid, and thiram occupy well-defined regions in the PC1–PC2 space, indicating that the SERS nanostructure provides sufficient sensitivity to capture subtle chemical differences.

The successful separation can be attributed to the variance explained by the first two principal components, with PC1 accounting for 15% and PC2 for 66% of the total variance. Together, they explain more than 80% of the overall variance, a commonly accepted threshold for reliable analyte discrimination. These results demonstrate that the combination of a silver plasmonic SERS nanostructure and PCA enables robust, label-free recognition of pesticides in water.

IV. Conclusion

A silver plasmonic SERS nanostructure has been demonstrated as an effective platform for pesticide recognition in water. The combination of SERS fingerprinting and principal component analysis enables clear discrimination between fipronil, imidacloprid, and thiram without the use of labels or selective probes. This approach shows strong potential for rapid and reliable water quality monitoring and environmental sensing applications.

***Abstract*— We present low-cost flexible SERS platforms for label-free detection of *Escherichia coli* and *rotavirus* in wastewater. The platforms combine high plasmonic performance with mechanical conformability and system integrability, enabling portable and on-site pathogen monitoring. The approach offers a scalable alternative to rigid and highly engineered sensors for environmental surveillance applications.**

***Keywords*— SERS, gold nanoparticles, paper tape, wastewater monitoring, pathogens biosensing.**

I. Introduction

Bacterial and viral contamination of water represents a major concern for public health and environmental safety. Among fecal indicators, *Escherichia coli* is one of the most widely used markers of microbiological water quality, as pathogenic strains can cause severe gastrointestinal diseases and serious clinical complications. Similarly, Rotavirus is a leading cause of acute gastroenteritis worldwide and is frequently detected in wastewater due to its high environmental stability and resistance to conventional treatment processes. [1-4]

Conventional detection techniques, including culture-based methods, PCR, ELISA, and sequencing, provide high specificity but rely on complex laboratory workflows, expensive instrumentation, and long analysis times, limiting their applicability for rapid and decentralized environmental monitoring. [5]

Surface-Enhanced Raman Scattering (SERS) has emerged as a powerful label-free technique for pathogen detection, offering high sensitivity, molecular specificity, and minimal sample preparation. Most SERS platforms are based on rigid substrates, such as silicon or glass, which are costly, fragile, and poorly suited for in-field applications. In this context, flexible SERS substrates represent a promising alternative, enabling mechanical conformability, low fabrication costs, and straightforward integration into portable sensing systems for real-world environmental surveillance. [6-8]

II. Methods

Flexible SERS substrates were fabricated through bottom-up self-assembly of gold nanostructures onto commercial adhesive paper tape, forming a plasmonically active and mechanically compliant platform [9]. The fabrication relies on simple and scalable procedures, avoiding complex lithographic steps and costly cleanroom technologies. Wastewater samples were spiked with inactivated *Escherichia coli* and Rotavirus. SERS measurements were performed directly on the contaminated samples without labeling or extensive preprocessing. The collected spectra were analyzed using multivariate statistical methods, including Principal Component Analysis (PCA), to enable pathogen discrimination.

III. Results and Discussion

The developed SERS substrate exhibited an enhancement factor on the order of 10^7 and enabled the acquisition of reproducible Raman fingerprints of both bacterial and viral targets in wastewater. Distinct spectral features associated with inactivated *Escherichia coli* and inactivated Rotavirus allowed their reliable differentiation despite the complexity of the environmental matrix [10–11], as shown in Fig. 1. Compared to conventional rigid and engineered SERS substrates, the proposed platform offers advantages in terms of cost-effectiveness, scalability, and ease of system integration. Its mechanical conformability supports coupling with portable optical systems and in-field devices while preserving sensing performance. For inactivated *Escherichia coli*, a detection limit of 26 CFU/mL in water was achieved. Compared to existing flexible SERS substrates, the sensor demonstrates competitive sensitivity together with straightforward fabrication and

suitability for on-site environmental monitoring [12–13].

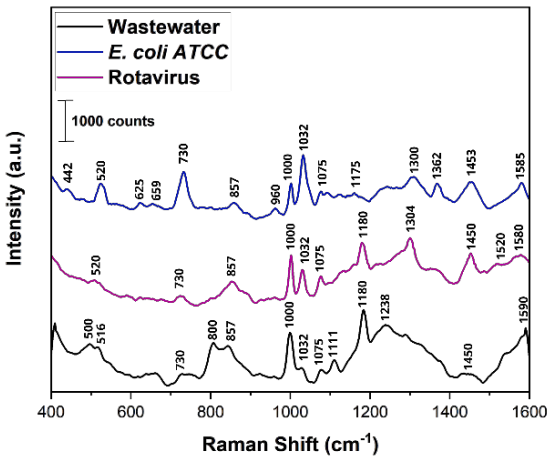

Fig. 1 SERS spectral fingerprints of inactivated *Escherichia coli* (10^8 CFU/mL) and Rotavirus (10^5 $TCID_{50}$/mL) in wastewater acquired using the flexible paper tape SERS sensor. Each spectrum is the average of acquisitions collected at different points of the same droplet.

IV. Conclusion

This study shows the potential of low-cost flexible SERS platforms for real-world monitoring of pathogenic microorganisms in wastewater. By combining very good sensing performance with mechanical conformability and easy system integration, these substrates provide a practical and scalable solution for on-site surveillance, representing a valid alternative to rigid and laboratory-based biosensing technologies.

***Abstract*— We describe a platform that optimizes coupling between guided modes in multimode fibers and photonic structures on the facet, eighter metalenses or plasmonic nanoparticles. Using wavefront shaping, we control light propagation to enhance imaging, SERS, and thermoplasmonic heating, demonstrating the potential of compact fiber-based probes for minimally invasive biological interfacing.**

***Keywords*— plasmonics, endoscopes, wavefront shaping, SERS, thermal heating, metalenses**

I. Introduction

Plasmonic platforms offer versatile routes to enhance light–matter interactions, enabling both advanced sensing modalities and highly localized photothermal effects across a range of applications.[1], [2] Although translating these concepts into in vivo environments remains challenging, they offer compelling opportunities for minimally invasive optical interfacing with neural tissue. On the other hand, dielectric metalenses have the potential to revolutionize endoscopy, enabling complex shaping of the wavefront at the output of optical fibers. A key requirement for unlocking full potential of this approach is the ability to tailor the excitation conditions both in the near and in the far-field. In this context, wavefront-shaping techniques offer a promising route to improve the coupling between guided modes and the integrated photonics structures.

II. Methods

Our approach entails the integration of plasmonic and dielectric photonic structures on flat multimode fibers (MMFs), exploiting different fabrication strategies. For the fabrication of plasmonic surfaces of the fiber facet, we employed solid-state dewetting, enabling high-throughput formation of nano-islands with diameters of approximately 50 nm and gaps of 20 nm. While MMFs represent a promising substrate thanks to the small cross-section to sustained mode ratio, they also entail a challenge due to the scrambling of light into a speckle pattern.[3] To enhance the performance of our probes, we have implemented a wavefront shaping method that allows controlling the coupling between guided modes in MMFs and plasmonic resonances both in the near field and the far field of metallic nanostructures fabricated on the distal fiber facet.[4] A phase-modulation algorithm tailors key excitation parameters, controlling spatial confinement on the plasmonic facet and the angular distribution in the far field (kx, ky).

Another promising direction is to combine wavefront-shaping algorithms with dielectric metalenses fabricated on the multimode fiber facet. The integration of the metalens can be achieved through two-photon lithography, which allows direct printing on the MMF.

Together, these two approaches could overcome the intrinsic limitations of multimode optical fibers.

III. Results and Discussion

We will describe how wavefront shaping can successfully control the near and far field emitted from MMFs decorated with plasmonic structures or with metalenses. Moreover, by functionalizing the nanostructures with benzenethiol molecules, spatially resolved SERS can be achieved. Dewetted nanoparticles are also able to detect neurotransmitters dispersed in aqueous solutions.

The use of metalenses allows improved resolution in the near field and expanded angular control over the far field.

Lastly, plasmonic heating can be also explored, opening the possibility to employ fiber-based endoscopes not only for diagnostic purposes but also for thermal treatments.

IV. Conclusion

In conclusion, combining MMFs with plasmonic structures or metalenses with wavefront-shaping strategies has the potential to achieve precise control over light–matter

interactions, enabling both sensitive optical readout, improved imaging capabilities, and localized photothermal functionality within compact endoscopic platforms.

Topological Bound States in the Continuum in Photonic Crystal Slabs for Label-Free Biosensing

Karen Caicedo[1], Silvia Romano[1], Gianluigi Zito[1], Ivo Rendina[1] and Vito Mocella[1,*]

[1]Institute of Applied Sciences and Intelligent Systems (ISASI), National Research Council (CNR), Naples, Italy

*Corresponding author: vito.mocella@cnr.it

***Abstract*— We report the first experimental observation of broadband bound states in the continuum (BICs) in simple photonic crystal slabs: continuous lines of vanishing radiation loss extending over approximately 15 nm along high-symmetry directions. This new class of high-Q states opens transformative perspectives for label-free sensing, including biodiagnostics and food safety applications.**

***Keywords*- bound states in the continuum, broadband BIC, photonic crystal slabs, biosensing, food safety, ochratoxin A.**

I. Introduction

Bound states in the continuum (BICs) are localized photonic modes embedded in the radiation continuum that exhibit theoretically infinite quality factors and giant field enhancement [1]. In photonic crystal slabs (PhCS), BICs have been conventionally realized at isolated points in momentum space, typically at the high-symmetry point. Our group has exploited these isolated BICs to develop a powerful sensing platform in silicon nitride PhCS, demonstrating record-level detection of ochratoxin A for food safety [3] and selective trace-detection of cancer biomarkers for clinical diagnostics [5,6]. However, isolated BICs inherently limit the operational bandwidth available for sensing. Here, we present a fundamentally new result: broadband BICs, i.e. continuous lines of BICs extending along high-symmetry directions in momentum space, can be realized in simple, vertically asymmetric PhC slabs. Unlike isolated BICs, broadband BICs maintain vanishing radiative losses over an extended spectral range, offering a paradigm shift for high-Q photonic devices with direct implications for enhanced, multiplexed biosensing.

II. Methods

We fabricate silicon nitride photonic crystal slabs on silicon and characterize them using Photonic Angle-Resolved Transmission Spectroscopy (PARTS), a far-field technique that maps the full dispersion surfaces with angular accuracy of 3 x 10^{-4} rad and spectral resolution of 0.2 nm. PARTS enables the precise identification of symmetry-protected and accidental BICs, Friedrich–Wintgen BICs arising from avoided band crossings, and - crucially - broadband BICs that appear as continuous lines of vanishing radiative linewidth along the high-symmetry direction. The underlying topological structure is revealed by tracking polarization vortices and C-points carrying well-defined topological charges. A non-Hermitian two-level Hamiltonian model predicts that broadband BICs emerge when a frequency-degenerate and radiatively balanced doublet of modes interferes destructively along a mirror line. Vertical asymmetry of the slab is essential: it forces both modes to radiate into the same physical channels, enabling the interferometric cancellation that converts ordinary isolated BICs into a continuous BIC line.

III. Results and Discussion

Using PARTS, we achieve the first direct experimental observation of broadband BICs in simple PhC: continuous lines of vanishing radiation loss spanning approximately 15 nm in wavelength along the high-symmetry direction, in excellent agreement with the non-Hermitian theoretical model and full numerical simulations. The Q-factor diverges as the BIC line is approached from any direction in momentum space, confirming the genuine BIC character of the extended dark state. This result fundamentally expands the BIC paradigm from isolated points to continuous lines in a minimal, technologically relevant platform. The implications for sensing are far-reaching. Our group has already demonstrated that isolated BICs in the same silicon nitride PhCS platform deliver record-level performance: trace detection of ochratoxin A (OTA) with a limit of detection of 2.3 pg/mL for food safety [3], selective detection of cancer biomarkers such as TGF-beta [5], and resolution of protein binding kinetics for clinical diagnostics [6]. Broadband BICs are expected to substantially enhance these capabilities by extending the high-Q interaction region over a wider spectral window, enabling simultaneous multi-analyte detection and more robust signal acquisition in complex biological matrices.

IV. Conclusion

We present the first experimental demonstration of broadband BICs in a photonic crystal slabs, a discovery that extends the BIC concept from isolated points to continuous high-Q lines in momentum space. Combined with the already

proven sensing capabilities of our silicon nitride BIC platform - including record detection of ochratoxin A and cancer biomarkers - broadband BICs open a clear pathway toward next-generation integrated, multiplexed lab-on-chip devices with broadband sensitivity for biodiagnostics, environmental monitoring, and food safety.

Flowthrough Raman readout in plasmonic nanopores for sequencing applications

Francesco De Angelis

Istituto Italiano di Tecnologia, Via Morego 30, 16163, Genova, Italy

*Corresponding author: francesco.deangelis@iit.it

***Abstract*— Inspired by nanopore sequencing, we developed a Raman sequential readout strategy based on plasmonic nanopores. Molecules are delivered electrophoretically while real-time Raman spectra are recorded. We identified four DNA nucleotides and multiple amino acids at single-monomer level, achieving 89% nucleotide discrimination accuracy and angstrom-scale spatial resolution, corresponding to only 4 nucleotides.**

***Keywords*— plasmonic nanopores, sequencing, Raman, SPAD camera.**

I. Introduction

Surface-Enhanced Raman Scattering has been studied for decades as a recognition technique due to its high sensitivity and discriminative power, particularly in biological applications. Inspired by nanopore sequencing technology, we developed a plasmonic device capable of operating in a flow-through configuration to detect individual molecules as they pass through the plasmonic hotspot [1-5]. Among different kinds of nanopores, a scalable device consists of permeable plasmonic films [2], through which single molecules are sequentially delivered via electrophoresis, while Raman spectra are recorded in real time. A very effective light matter coupling, combined with the ultrasmall size of plasmonic spots enabled to access spatial and temporal scales compatible with polymer sequencing, namely few angstroms and few µs [1-2].

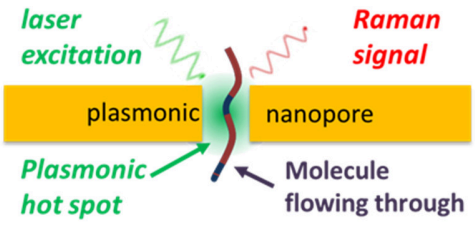

Fig. 1: Scheme representing the concept of Raman sequential readout in nanopores. SPAD camera and effective plasmonic nanopore enables sequential readout at a speed comparable to the translocation time of molecular subunits such as nucleotides in DNA or Amino Acids in protein.

II. Methods

The key point of the presented approach is based on innovative plasmonic membranes and solid state nanopores, combined with latest generation SPAD camera [1-2].

III. Results and Discussion

We successfully captured the Raman spectra of the four DNA nucleotides as well as multiple amino acids at a frame rate fast enough to detect the translocation of individual monomers. Leveraging SPAD cameras, we achieved an acquisition time of just 10 microseconds, maintaining a continuous frame rate of 100 kHz. By analyzing the sequential Raman spectra, it becomes possible to determine the precise sequence of the polymeric molecule, whether it be DNA, RNA, or proteins. For nucleotides we achieved a discrimination accuracy of 89% at single molecule level. Also, we demonstrated a spatial resolution on the order of a few angstroms, suggesting clear potential for Raman based identification and sequencing of nucleic acids (DNA/RNA) and proteins including post translational and transcriptional modifications.

IV. Conclusion

We demonstrated a spatial resolution comparable to single units in biopolymers, suggesting clear potential for Raman based identification and sequencing of nucleic acids (DNA/RNA) and proteins including post translational and transcriptional modifications.

Communicating and Computing with Microwave Networks

Matteo Nerini[1,*], Bruno Clerckx[1]

[1]Department of Electrical and Electronic Engineering, Imperial College London, UK
*Corresponding author: m.nerini20@imperial.ac.uk

***Abstract*—Future wireless systems will communicate and process extremely high-dimensional signals under stringent latency constraints. As antenna arrays scale toward massive and gigantic multiple-input multiple-output (MIMO), conventional digital signal processing becomes prohibitive, motivating paradigm shifts where both communication and computation are partially offloaded from the digital to the analog domain.**

***Keywords*— Beyond-diagonal reconfigurable intelligent surface (BD-RIS), microwave linear analog computer (MiLAC).**

Reconfigurable intelligent surfaces (RIS) were introduced to make the wireless channel programmable by adjusting the reflection or transmission properties of a surface (see Fig. 1(a)) [1]. Conventional RIS architectures are typically restricted to diagonal scattering matrices, meaning that each surface element independently applies a tunable phase to the incident wave. While attractive for their simplicity, such diagonal constraints limit the channel shaping capabilities. Beyond-diagonal RISs (BD-RISs) overcome this limitation by enabling controlled coupling among surface elements through tunable interconnections [2]. A BD-RIS is a microwave network whose scattering matrix is fully programmable and not limited to being diagonal. This additional freedom allows the surface not only to reflect energy individually at each element, but also to reflect the energy absorbed by an element from other elements, enhancing the impact on the wireless channel [3].

While the microwave networks used in BD-RIS are used to shape the wireless channels, they can also be exploited to perform computations (see Fig. 1(b)). Microwave (linear) networks used for computations have been denoted as microwave linear analog computers (MiLACs) [4]. In a MiLAC, the multiport microwave network is reconfigured such that its response implements a desired transformation. By programming their admittance matrix, MiLACs can realize operations such as matrix–vector multiplication, matrix inversion, linear minimum mean square error (LMMSE) estimation, and least squares estimator directly in the analog domain. For example, matrix inversion, LMMSE, and the least squares estimator can be computed with a complexity growing with the square of the matrix size rather than the cube.

The relevance of MiLAC becomes particularly evident in gigantic MIMO systems, where electromagnetic (EM) signals at hundreds or thousands of antennas must be jointly processed. The least squares estimator is commonly used in MIMO communications to perform zero-forcing beamforming. Therefore, a MiLAC can be used to efficiently precode

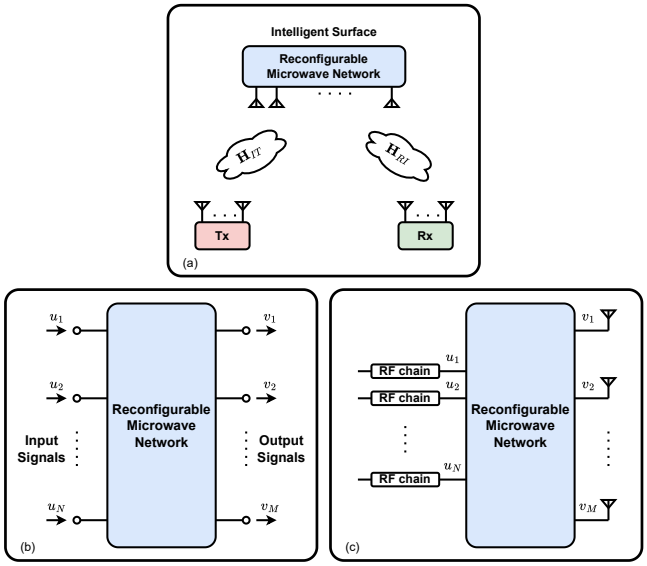

Fig. 1. (a) a reconfigurable microwave network implementing an intelligent surface to improve the wireless channel, (b) a reconfigurable microwave network processing EM signals in the analog domain, and (c) a transmitter with a reconfigurable microwave network that processes the transmitted symbols.

symbols intended for multiple users in a gigantic MIMO base station (see Fig. 1(c)) [5], offering several benefits in terms of hardware and computational complexity.

***Abstract*—Reconfigurable microwave systems, including contemporary examples involving programmable metasurfaces (e.g., dynamic metasurface antennas, reconfigurable intelligent surfaces), can be abstracted in terms of a multiport-network representation. This abstraction enables a universal framework for formulating the model, experimentally estimating its parameters to avoid model-reality mismatch, and leveraging the model for optimization and determining fundamental bounds. In addition, the model structure reveals fundamental insights into principles for maximizing wave-domain flexibility. Altogether, this universal wave-control framework for reconfigurable microwave systems paves the way to a prototype-aware electromagnetic information theory for programmable wave systems.**

***Keywords*—electromagnetic information theory, multiport-network theory, programmable metasurface.**

I. Introduction

Programmable metasurfaces such as dynamic metasurface antennas (DMAs) and reconfigurable intelligent surfaces (RISs) are technological enablers for the next generation of systems in wireless communications, sensing, and wave-domain computing. Despite many theoretical studies and some antenna-level experiments, system-level experimental demonstrations remain challenging. The fundamental crux is the availability of an accurate forward model mapping the configuration of the tunable parameters to the resulting transfer function. On the one hand, intricate electromagnetic coupling effects intertwine the effects of the tunable parameters. On the other hand, due to fabrication inaccuracies and/or unknown system details, the model parameters are generally neither known in closed form nor accessible via numerical simulation.

Because tunable lumped elements are the predominant mechanism for reconfigurability in programmable metasurfaces, a universal representation in terms of multiport network theory exists. Techniques developed for estimating its parameters, as well as leveraging it for optimization, and determining fundamental bounds are thus broadly applicable.

II. Results

To minimize model-reality mismatch, the model parameters should be estimated experimentally. However, they cannot be measured directly because the tunable lumped elements are not connectorized and too numerous. Various techniques enable the estimation of a set of proxy model parameters that accurately map the chosen configuration to the physically observable scattering parameters [1], [2], [3], [4], [5]. However, ambiguities in these proxy parameters are usually inevitable, unless the loads have specific and known characteristics [6], [7], [8]. Fortunately, these ambiguities do not influence model-based optimization and bounding.

Once a calibrated forward model is available, standard techniques for discrete optimization (e.g., genetic algorithm, coordinate descent, etc.) can be used for model-based optimization of the prototype's configuration. In addition, we can derive fundamental bounds on achievable functionalities with a given prototype [9], [10], [11]. Such bounds can inform us, for instance, about the quality of our optimization outcomes.

Finally, we can explore principles for designing reconfigurable wave systems with maximal wave-domain flexibility. In particular, the model structure reveals benefits of strong mutual coupling between tunable elements. The latter is typically treated as a vexing nuisance to be mitigated, instead of reaping it as a resource for maximizing wave-domain flexibility [12], [13].

III. Conclusion

We review recent efforts toward establishing a universal wave-control framework for reconfigurable microwave systems.

***Abstract*—We introduce a bio-inspired generative model that serves as a parametrization of photonic metasurfaces. This approach, inspired by morphogenesis, has proved successful in the microwave range. This framework utilizes reaction-diffusion patterns to self-organize dielectric structures. We demonstrate a functional 50 µm silicon lens operating at λ = 1550 nm.**

***Keywords*— metasurfaces, self-organization, reaction-diffusion.**

I. Introduction

Metasurfaces have emerged as a powerful paradigm for wavefront manipulation, yet their synthesis relies on the juxtaposition of discrete unit cells. This method often fails at synthesizing metasurfaces with large phase gradients. Our decentralized synthesis framework inspired by morphogenesis addresses this limitation [1], [2], generating structures that adapt to the constraints of photonic metasurface fabrication through the use of non-uniform unit cells.

II. Generative Model and Mapping

Our approach utilizes the Gray-Scott reaction-diffusion model, which mimics chemical pattern formation. The evolution of species u and v is governed by:

$$\frac{\partial u}{\partial t} = D_u(x)\nabla^2 u - uv^2 + F(1-u) \quad (1)$$

$$\frac{\partial v}{\partial t} = D_v(x)\nabla^2 v + uv^2 - (F+k)v \quad (2)$$

with feed rate $F = 0.04$, kill rate $k = 0.0605$, and a fixed diffusion ratio $D_v = 0.5\,D_u$, parameters chosen to support pattern self-organization. The diffusion coefficient $D_u(x)$ acts as the local control parameter for the pattern's period, while a binarization threshold σ applied to the concentration of v adjusts the fill factor (silicon/air ratio). To link geometries to electromagnetic responses, we compute the transmission of a database of periodic supercells. A path is identified in the (D_u, σ) generative space that maximizes transmission while providing 2π phase coverage. This defines a mapping function Φ encompassing the complex relationship between the generative parameters and the electromagnetic response.

III. Lens Synthesis and Results

We synthesize a metalens with a holographic approach, combining an incident plane wave and a spherical wave to maximize constructive interference at a focal point. The target local transmission is translated into a spatial distribution of generative parameters via the inverse mapping Φ^{-1}, allowing for the growth of a self-organized structure following local rules in a few seconds (Fig. 1).

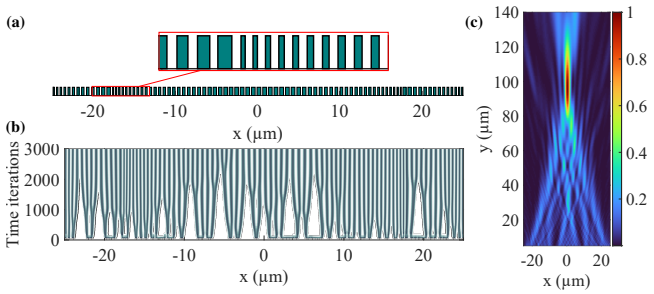

Fig. 1. (a) Generated metalens. (b) Generative growth of the lens where Φ^{-1} translates the target transmission into growth dynamics $D_u(x)$. High concentration of v results in pillar formation, later binarized by $\sigma(x)$. (c) Simulated electromagnetic field intensity showing lens behavior.

The resulting metasurface and focused field (Fig. 1) demonstrate the capability of the proposed method. The structure evolves seamlessly, avoiding the abrupt discontinuities inherent to unit-cell discretization. Full-wave simulations confirm the formation of a sharp focal spot, validating that the bio-inspired approach successfully meets the trade-off between scattering efficiency and phase control in a non-uniform, self-organized metalens. This method bridges local generative computations to large-scale structures. Future works will extend this method to the synthesis of two-dimensional, polarization-constrained metalenses.

Analysis and Simulation of Intrinsic Response Time of Time-Varying Metasurfaces

Sheng Lei[1], Alex M. H. Wong[1,2,*]

***Abstract*— We investigate the causes of time delays for varactor-driven meta-atoms. Particularly, through theory, simulation and experiment, we study the electromagnetic response time of the meta-atom given fast switching signals. Our results pave way to designing fast time-varying metasurfaces whose modulation approaches or exceeds the frequency of the illumination wave.**

***Keywords*—Intrinsic response time, time-varying metasurface, frequency conversion**

I. Introduction

Time-varying metasurfaces are two-dimensional artificial active structures whose electromagnetic properties can be modulated in real time by external signals. It exhibits extraordinary capabilities to freely control electromagnetic waves in both the spatial and temporal domains, with a low profile and high efficiency [1]. Over the past few years, time-varying metasurfaces have been applied to harmonic wave control [2], time-varying orbital angular momentum (OAM) wave generation [3], nonreciprocal communication [4], and Doppler cloaking [5], demonstrating their potential. However, the performance of existing time-varying metasurfaces is constrained by their modulation speeds, which are typically much slower than their design frequencies, resulting in a narrow harmonic frequency conversion range, limited nonreciprocal performance, and slowly varying OAM waves. For a realistic meta-atom, there are three main limitations on its modulation speed, including the control network, the switching element, and the electromagnetic response of its structure. While the former two limitations can be overcome with advanced electronics and component technology, the intrinsic response time remains a fundamental limitation on meta-atom design. To overcome this constraint, we conduct a comprehensive investigation of the intrinsic response time and its influence on the performance of time-varying metasurfaces. In this work, we investigate the response speed of time-varying meta-atoms inside a rectangular waveguide. An equivalent circuit analysis is performed to find the cause of the intrinsic response time, which is further validated by finite-difference time-domain (FDTD) simulations. To visualize the effect of the intrinsic response time on the performance of the time-varying metasurface, frequency conversion experiments are conducted using the fabricated waveguide model.

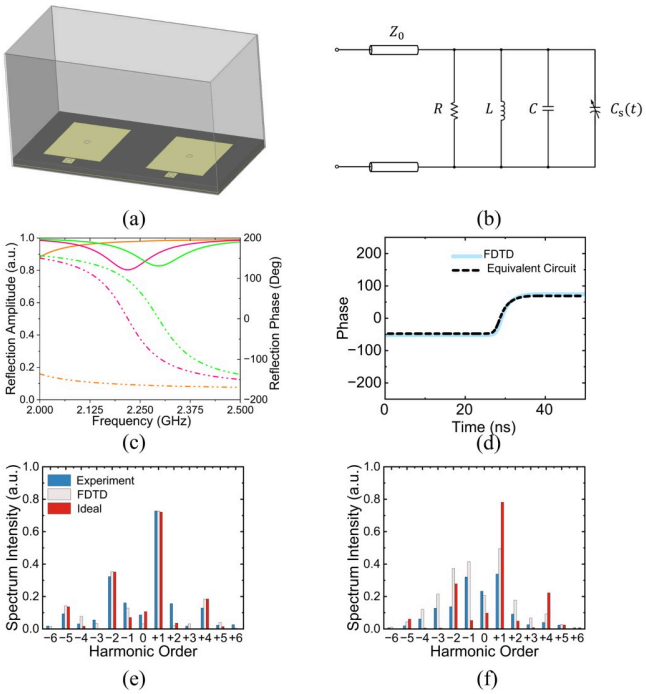

Fig. 1 (a) Schematic of the proposed waveguide model associated with time-varying meta-atoms. (b) Equivalent circuit of the waveguide model. (c) Reflection coefficients of the waveguide model under different reverse-bias voltages. (d) The equivalent circuit analysis and FDTD simulation results for the intrinsic phase response time. (e-f) The reflected wave spectrum from the FDTD simulation, experimental results, and the ideal case with modulation speeds of (e) 10 MHz and (f) 120 MHz.

II. Methods

Fig. 1(a) shows the structure of the waveguide model. The meta-atom comprises a radiation patch and a varactor diode for tunability. The wave propagating along the waveguide will be reflected and modulated by the meta-atom. Therefore, as shown in Fig. 1(b), the equivalent circuit of the waveguide structure can be modelled as a terminated transmission line. The meta-atoms studied here is similar to the type we used in two previous works [3, 6]. can be divided into two parts. The radiation patch can be modelled as a parallel RLC circuit, and the varactor can be regarded as a time-varying capacitance in parallel with the

radiation patch. By changing the reverse-bias voltage applied to the varactor, the capacitance of the varactor can be changed accordingly, which further leads to the variation of the meta-atom's property. As shown in Fig. 1(c), the structure has three states whose reflection coefficients have nearly unit amplitudes and a 120° phase difference. By analyzing the voltage and circuit relationship of the equivalent circuit model, we find that the response times required by the meta-atom to change within these three states are limited by a coefficient

$$\tau = -\frac{2RZ_0(C+C_s)}{R+Z_0} \approx -2Z_0(C+C_s) \quad (1)$$

Therefore, it can be clearly observed that the intrinsic response time of this meta-atom is induced by charging the equivalent capacitor. Furthermore, to validate the equivalent-circuit analysis results, we also conduct full-wave FDTD simulations of the time-varying meta-atom. The varactors are modelled as time-varying lumped elements whose capacitance is updated at each time step based on the applied modulation signal. As shown in Fig. 1(d), it is obvious that the phase of the reflected wave requires some time to gradually change from the previous state to the target state, even with an ideal modulation signal. Additionally, the FDTD simulation results agree well with the equivalent circuit analysis results.

III. Results and Discussion

Finally, we fabricate the waveguide model and perform several frequency-conversion experiments to demonstrate the limitation imposed by the intrinsic response time. The modulation signal is provided by an arbitrary waveform generator, which is a periodic signal that equally contains the aforementioned three states. A spectrum analyzer is used to capture and analyze the reflected wave from the time-varying meta-atoms at different modulation frequencies. As shown in Fig. 1(e), at a low modulation speed, the response time is negligible. Therefore, both the simulation and experimental results exhibit a frequency spectrum similar to that of the ideal case, in which we assume the meta-atom's property changes instantaneously with the modulation signal, so the +1st and -2nd harmonics dominate the spectrum. However, as shown in Fig. 1(f), when the modulation speed is sufficiently high, the intrinsic response time will destroy the modulation, resulting in a nonideal frequency spectrum. Therefore, to further improve performance and overcome the limitations of time-varying metasurfaces, the intrinsic response time should be considered a significant parameter in the design of time-varying meta-atoms, which can be analyzed and simulated using the aforementioned methods.

IV. Conclusion

In this work, we have proposed an equivalent circuit analysis method and an FDTD simulation method to determine the intrinsic response time of meta-atoms to transition between states. Using a waveguide model, we experimentally demonstrated the existence of the intrinsic response time and its limitation on the time-varying metasurface's performance via frequency conversion experiments. The proposed method can simulate the intrinsic response time of an arbitrary meta-atom, enabling the design of time-varying metasurfaces with a short response time and a fast modulation speed. Besides, our method enables ultrafast modulations that may exceed the incident frequency, such as parametric amplification and oscillation, providing a powerful tool to explore the limits and expand the potential of time-varying metasurfaces.

Transformer-based Neural Network Enabled Subpixel-Resolution in Wide-Field Meta-Microscope

Shanshan Hu, Tao Li*

School of Physics, College of Engineering and Applied Sciences, Nanjing University, China
*Corresponding author: taoli@nju.edu.cn

***Abstract*— We propose and experimentally demonstrate a synergistic computational imaging framework that integrates a compact metalens microscope with a transformer-based neural network, which enables wide-field and subpixel resolution imaging without added optical complexity, illustrating a scalable and cost-effective approach to miniaturized and intelligent microscopy.**

***Keywords*— metalens, deep learning, microscope, subpixel-resolution, wide-field imaging.**

I. Introduction

Metalenses have revolutionized ultracompact imaging systems, benefiting from their ultra-thin, lightweight, and flat design that facilitates assembly onto image sensors. While the integration of metalens and sensor eliminents the bulky optical elements, the resolution remains limited by pixel-induced undersampling, and a fundamental trade-off exists between resolution and field of view (FOV). These challenges are especially pronounced in microscopy, motivating the development of innovative strategies for compact microscopy systems.

II. Methods

We have proposed a computational imaging strategy that utilizes a unit-magnification meta-microscope equipped with a transformer-based neural network, overcoming the inherent sensor pixel size limitation through data-driven reconstruction. To bridge the gap between simulation and experimental implementation, the first experimental dataset of metalens-acquired thyroid pathological sections images was constructed. The Hybrid Attention Transformer model was employed to reconstruct high-resolution images by learning the mapping from unit-magnification and three-fold magnification imaging. After training, the model demonstrates computational subpixel-resolution reconstruction, producing high-fidelity, high-resolution images from a single-frame input.

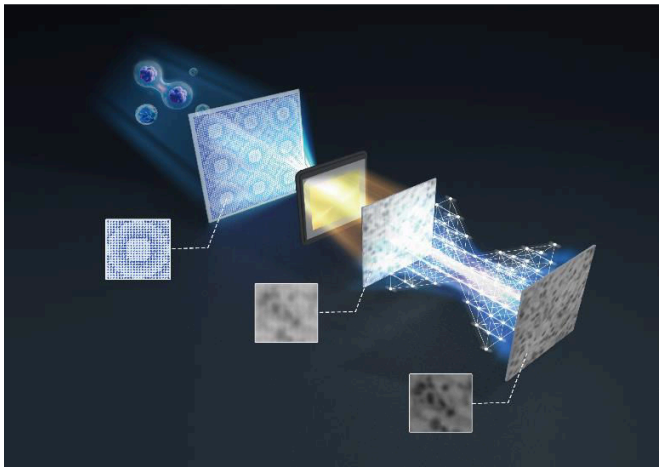

Fig. 1 Schematic diagram of the proposed intelligent meta-microscope

III. Results and Discussion

The trained model enables rapid (~0.2s for 110 μm × 110 μm FOV), high-fidelity (structural similarity up to 91%) reconstruction from single-frame inputs, achieving 3× spatial sampling density and computational subpixel-resolution (close to 0.87 μm, pixel size is 1.67 μm). A cross-tissue generalization experiment also showed that the model maintained good performance on other tissues with similar morphology.

We further incorporate the metalens array-based integrated microscope with the trained model, achieving wide-field (4 mm × 6 mm) and high-resolution (comparable with the Olympus 10×/0.25NA objective) imaging, providing a FOV approximately 14.5 times that of the Olympus objective with similar resolution.

IV. Conclusion

We have demonstrated a synergistic computational imaging scheme that provides wide-field, subpixel resolution imaging without added optical complexity via a metalens-transformer design, demonstrate experimentally validated performance on real thyroid pathology sections with reasonable cross-tissue generalizability, and feature a compact, low-cost configuration suitable for portable diagnostic applications.

We demonstrate this for a metasurface adapting to a beam with unkown angle of incidence.**

***Keywords*— metamaterials, machine learning, adaptive metasurfaces.**

Tunable metasurfaces are ultrathin engineered surfaces made of subwavelength ”meta-atoms” that can precisely control light (or other waves) in terms of phase, amplitude, polarization, and direction [1]. By incorporating active materials or external controls such as electrical bias, heat, mechanical strain, or optical pumping, they enable tunable and reconfigurable functions such as beam steering, adaptive lenses, and programmable holography [1–3]. However, when a metasurface has to adapt to the environment, one needs a way to reconfigure the tunable elements in response to a changing environment. This not only requires calculating the state of the environment, but also an inverse design step during every update.

Inverse design of a metasurface is a rather slow process that normally requires multiple full-wave simulations. Recently, machine-learning has been used to achieve inverse design of metasurfaces [4]. Although it requires time to generate training data from simulations, once trained, neural networks can generate metasurface designs fast, with typical inference times of the order of milliseconds.

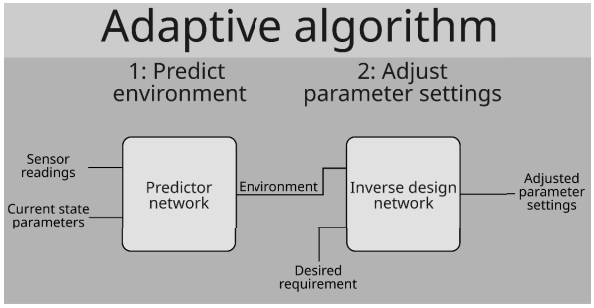

Fig. 1: Overview of the adaptive algorithm. The first step of the algorithm is a *predictor network* that predicts the environment, which is subsequently used in the second step by an *inverse-design network* in order to adjust the tunable element in order to correctly adapt to the environment.

In this contribution, we will present a machine-learning-based algorithm to adapt a tunable metasurface to the environment. Such an algorithm needs two components: a detection component, which takes physical quantities in the metasurface as input (e.g., a current in a capacitor) and uses that information to predict the environment, and an action component, which performs an inverse design of the metasurface under the condition of the current environment.

To achieve this, we implement the adaptive algorithm using two neural networks [4], as illustrated in Fig. 1. First, the detection step is performed by a predictor network that predicts the state of the environment from the current state of the metasurface, obtained from sensor readings from the metasurface (e.g., current through a capacitor) and the settings the tunable parameters. Second, the action step is performed by an inverse design network that does inverse design, i.e., calculates the tunable elements’ values (e.g., capacitances) from a desired output state (e.g., reflectance), but with the predicted environment as an extension of its input.

The neural networks are trained on a data set that is constructed from full-wave simulations of a meta-atom proposed in Ref. [3]. These simulations are carried out for random input values of the angle of incidence and the capacitor values. This allows us to train a forward network that maps the capacitances of the metasurface onto the reflection phase. Constructing both the predictor and inverse design networks are two ill-posed problems [4], which, however, can be solved using a so-called tandem network. We use our pre-trained forward network and freeze it, meaning we no longer change its weights. The predictor and inverse design networks are then connected separately to the input of a forward network, where the objective function of the forward model is to reproduce the original inputs to the respective neural network. After training, the forward networks can be removed.

Finally, we show the performance of the entire adaptive algorithm in Fig. 1 by running an experiment where we randomly change the angle of incidence of the incident beam and let the adaptive algorithm adjust the tuneable parameter on the meta-atom, such that the reflection phase stays constant.

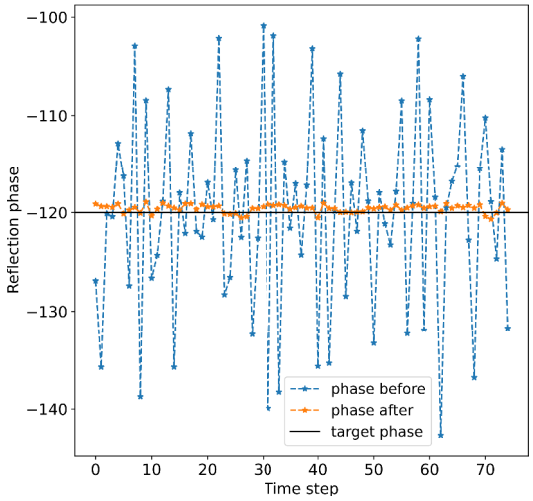

Fig. 2: Results from the experiment, from both before and after the correction from the adaptive algorithm. The adaptive metasurface is able to adjust its tunable parameter to maintain a constant -120 degrees phase output for 75 random angles of incidence

The result is shown in Fig. 2. In every time step, the angle of incidence is changed between between 20 and 40 degrees. This causes the reflection phase to alter significantly (blue line). However, after correction of the capacitances by the adaptive algorithm, the reflection phase is almost constant around our target phase (orange line). The inference times of the adaptive algorithm are of the order of milliseconds, which allows for an update frequency of the order of kilohertz, which makes it useful for application in communications systems, holograms, and other optical applications where the system needs to be corrected for changes in the environment.

Our work paves the way for adaptive metasurfaces that change in response of environments of increasing complexity. This is due to the flexibility neural network design and the rapid detection of the environment and the rapid inverse design by machine learning.

***Abstract*—We demonstrate the generation of attosecond skyrmion pulse trains via high harmonic generation driven by an infrared femtosecond vector beam carrying fractional orbital angular momentum. Consecutive far-field harmonics around 70 eV exhibit skyrmion polarization textures whose coherent superposition yields ∼500-attosecond pulses, enabling new avenues for ultrafast control, imaging, and spectroscopy.**

***Keywords*— skyrmion, structured light, attosecond science**

Skyrmions are topological field distributions in which a spatial domain maps onto a complete spherical parameter space. Such configurations have been observed across a broad range of physical platforms, including magnetic systems and structured optical fields [1]. Optical skyrmions emerge in beams whose transverse profiles contain the full set of paraxial polarization states. These fields therefore map a planar region onto the entire Poincaré sphere, where each point represents a distinct polarization state. Their potential impact is currently being investigated in complex media, topological materials, and advanced imaging schemes [1]. However, the generation of skyrmion pulses in the attosecond regime has not yet been demonstrated, with previous realizations restricted to continuous-wave illumination or long optical pulses.

The generation of attosecond pulses has been established for over two decades through high harmonic generation (HHG) in gases, where an intense infrared (IR) laser drives the emission of a plateau of high-frequency phase-locked harmonics with comparable amplitudes. The coherent superposition of selected harmonics yields attosecond pulse trains. In contrast, spatial structuring of high-energy radiation has only become feasible recently, owing to the inefficiency of conventional optical elements at extreme energies. Most approaches therefore focus on engineering the spatial profile of the driver to control the structure of the generated harmonics, enabling extreme-ultraviolet (EUV) structured beams such as attosecond vortices [2] or EUV vector beams [3].

Designing a driving field capable of producing a desired topological structure in the attosecond regime is nontrivial. In particular, HHG efficiency rapidly deteriorates with increasing polarization ellipticity, preventing a straightforward translation of optical skyrmions into the harmonic spectrum. A scheme based on a bichromatic structured driver has been proposed to induce skyrmion patterns at the gas-jet plane, where the skyrmion topology varies across consecutive harmonics [4]. Consequently, this approach does not deliver a phase-locked harmonic comb with similar skyrmion textures, which is a prerequisite for synthesizing attosecond pulses with a temporally robust skyrmion structure. Here, we show that HHG driven by a tailored linearly polarized vector beam produces a phase-locked plateau of consecutive harmonics that exhibit nearly identical skyrmion textures in the far field. Their coherent addition therefore results in attosecond skyrmion pulse trains.

Figure 1(a) illustrates the proposed scheme, where a linearly polarized IR vector driving beam interacts with a gas jet to produce an attosecond skyrmion pulse train. The local polarization state is encoded using a color representation corresponding to points on the Poincaré sphere (Fig. 1(b)). The left- and right-circular polarization (LCP and RCP) driver components carry fractional orbital angular momenta $\ell_{l,r} = -65/132$ and $67/132$, respectively, as depicted in Fig. 1(a). The choice of these parameters follows from a simplified model (see Ref. [5] for more details). The driver can be realized experimentally using metasurfaces or spatial light modulators.

We use the structured driving field in numerical HHG simulations in an argon gas jet. Our model combines a single-atom quantum response, within the strong-field approximation, with an electromagnetic propagation scheme that accounts for macroscopic phase matching and yields the far-field harmonic distribution. The driving pulse has a central wavelength of 1.2 μm, a full width at half maximum (FWHM) duration of 11.5 fs, and a peak intensity of 1.19×10^{14} W/cm^2. By applying realistic Al and Zr filters with thicknesses of 0.2 μm and 0.3 μm, respectively, we isolate five consecutive harmonics around 70 eV. The unfiltered spectrum and the selected window (purple shaded region) are shown in Fig. 2(a). The far-field spatial profiles of these five harmonics exhibit nearly identical skyrmion textures within an annular region of 0.19 mrad radius. The far-field intensity and polarization distribution for the central harmonic are displayed in Fig. 2(b).

The coherent superposition of the harmonics produces an attosecond pulse train with individual pulse durations of approximately 500 attoseconds (FWHM). The Skyrme number N_S characterizes the topology of the skyrmion by quantifying how many times the polarization texture maps the Poincaré

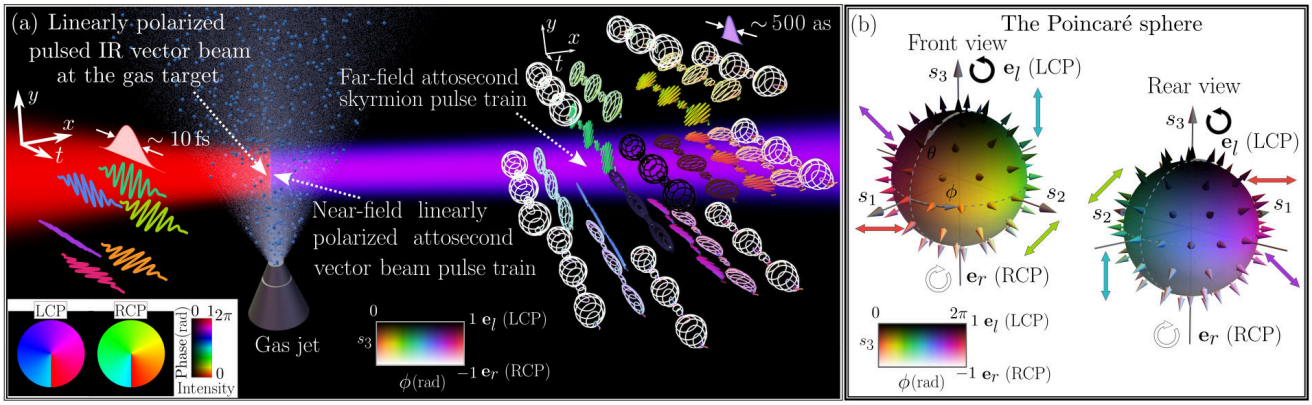

Fig. 1. (a) Illustration of attosecond EUV skyrmion pulse train generation by HHG driven by a linearly polarized femtosecond vector beam. The local polarization state of both the driver and the emitted attosecond field is represented by a color code corresponding to points on the Poincaré sphere. The driving beam consists of left- and right-circular polarization (LCP and RCP, respectively) components carrying fractional orbital angular momentum. (b) Representation of paraxial polarization states on the Poincaré sphere, where each polarization ellipse maps to a single point. The color map is defined by the azimuthal angle ϕ (twice the ellipse orientation) and the s_3 coordinate, which encodes ellipticity and handedness.

sphere [1]. Evaluated at different instants during the central pulse and within the same 0.19 mrad contour (Fig. 2(c)), N_S remains remarkably stable in time, reaching a maximum value of $N_S = 1.000$ with fluctuations limited to $\Delta N_S = 0.009$. Figure 2(d) displays the real electric-field distribution of the most intense pulse in the synthesized train, revealing a well-defined skyrmion texture that persists in time.

To sum up, we presented an experimentally viable route for generating attosecond skyrmion pulses whose topological properties are preserved in time. Such pulses open new pathways for encoding topological information into photoelectron angular and spin distributions [6], for simultaneously probing structural and anisotropic material responses in high-resolution EUV imaging [7], and for enabling ultrafast probing of magnetic helicoidal dichroism [8].

***Abstract*—A spectral localizer methodology for diagnosing topology in Floquet insulators will be presented. This approach leverages local topological markers to probe topology in periodically driven lattice systems without time-reversal symmetry. Quantitative bounds on the range of topological protection can be proved.**

***Keywords*— Floquet insulator, local Chern number**

I. Summary

A well-known challenge in periodically driven (Floquet) systems is the characterization of Chern topology and its relationship to topologically protected chiral states. In the anomalous insulator regime, the presence of gapless edge states in both the zero and π gaps results in trivial Chern numbers, defying the typical intuition of Chern insulators.

In [1] we developed a spectral localizer technique for diagnosing topology in periodically driven waveguide systems. A local Chern number, defined in terms of the Floquet Hamiltonian, directly characterizes the presence of chiral edge states without having to resort to a bulk-edge correspondence. To test the method, we apply it to the Floquet tight-binding model given in [2]. The Floquet localizer is able to correctly identify space-energy values that support topologically protected states.

An additional benefit of the spectral localizer framework is the ability to derive quantitative bounds on topological states. That is, when the instantaneous Hamiltonian is perturbed, a sufficient condition for guaranteeing the topological state is derived. Said differently, how much disorder can be tolerated before we lose our topological state? A set of bounds in terms of the Floquet Hamiltonian and the instantaneous Hamiltonian are obtained.

***Abstract*— Here, we investigate experimental parameters for synthesizing engineered $PtTe_2$ microribbon arrays, enabling precise control of surface plasmon polariton excitation. This design selectively enhances mid-infrared polarization-sensitive photocurrent, with spectral tunability via ribbon array geometry**

***Keywords*— Dirac semimetal, MIR, Surface Plasmon Polaritons, $PtTe_2$, topological Schottky junction.**

I. Introduction

Platinum ditelluride ($PtTe_2$) is a type-II topological Dirac semimetal allowing for broadband optical absorption within its tilted Dirac cones. Given its robust topological nature persisting up to room temperature, $PtTe_2$ represents an ideal candidate for uncooled Mid-infrared (MIR) photodetection.[1] Moreover, the high carrier mobility and low scattering rate of Dirac semimetal results in a very low loss for surface plasmon polaritons (SPPs) propagation in these materials in comparison to the normal metals and make them suitable for application in optical devices. [2]

II. Methods

Large area $PtTe_2$ microribbons array are synthetized in a two-step process consisting of sputtering deposition of few nm thick Pt microribbons (typically in a range of 4 – 8 nm) and subsequent tellurization at 400 – 450 °C in a tubular furnace. [3] By combining the Pt deposition with maskless optical lithography, arbitrarily patterned $PtTe_2$ microstructures are then fabricated over large areas (~cm^2). The main advantage of this growth technique is the material homogeneity, which is a critical requirement for scalable integration in any device configuration. Material characterization is carried out by Raman spectroscopy, atomic force microscopy, X-ray photoelectron spectroscopies and FTIR absorbance and reflectance. Electrical characterizations are carried out with magneto-transport measurements, and under illumination with optical excitation in the MIR range.

III. Results and Discussion

Experimental results show that when the $PtTe_2$ microribbons are directly in contact with a n-type Si substrate a topological Schottky junctions (TSJ) is formed. The TSJ tested under MIR laser illumination (9 μm wavelength) shows photocurrent response with responsivity up to 10^{-4} A/W and a detectivity of 10^4 Jones. More importantly, we observed a polarization-sensitive response of the TSJ driven by the selective excitation of the SPP resonances at both the $PtTe_2$/air and $PtTe_2$/substrate interfaces.

IV. Conclusion

We have realized $PtTe_2$ microribbon arrays on doped silicon as a versatile platform that addresses multiple critical challenges in MIR photodetection: achieving room-temperature operation, enabling polarization sensitivity, and providing tunable spectral response through geometric design. The fundamental insights gained from this investigation of SPP-mediated photodetection mechanisms are expected to inspire new directions in topological photonics and advance the development of next-generation infrared sensing technologies

***Abstract*—We demonstrate that combining a topological insulator layer with an active metamaterial substrate strongly enhances the magnetic field induced by an electric point source. Optimized substrate parameters increase the response by over four orders of magnitude and extend the magnetic field into free space.**

***Keywords*—topological insulators, metamaterials, magnetic field enhancement, hybrid layered structures.**

I. Introduction

Topological insulators are materials with insulating bulk states and conductive surfaces. Their electromagnetic response includes coupling between electric and magnetic fields. A well-known example is that an electric charge near a topological insulator surface induces a weak magnetic field response [1].

In practice, this magnetic signal is extremely small, typically in the pT range. This limits experimental detection and reduces the potential for device applications. Enhancing this response is therefore important for both fundamental studies and engineering use.

In this work, we propose a hybrid platform where a topological insulator layer is placed on an active metamaterial substrate [2]. We show that the substrate can be designed to strongly amplify the induced magnetic field.

II. Methods

We model a layered structure consisting of free space, a finite-thickness topological insulator film, and an infinitely thick substrate. A static electric point source is positioned above the top surface.

The electromagnetic fields are obtained using the constitutive relations of topological insulators, which include a magneto-electric coupling term. We solve the resulting boundary value problem using a Hankel transform approach, which is efficient for cylindrical symmetry.

The substrate is treated as either a conventional insulator or an active metamaterial with tunable effective permittivity and permeability. We perform parameter sweeps to identify conditions that maximize the magnetic field response in free space.

III. Results and Discussion

Our simulations show that conventional dielectric substrates produce only weak induced magnetic fields, which decay rapidly away from the topological insulator surface.

In contrast, active metamaterial substrates can generate resonant enhancement when their effective permittivity and permeability take specific negative values. Under optimized conditions, the induced magnetic field increases by more than four orders of magnitude, reaching the mT range.

The enhanced field is strongest at the interface between the topological insulator and metamaterial substrate, and it extends into free space over a much larger distance than in standard configurations.

We also find that thicker topological insulator layers broaden the enhancement region, making the design more tolerant to substrate variations.

IV. Conclusion

We have demonstrated that topological insulator metamaterial hybrid structures provide a practical route to amplify the static magnetic response induced by electric charges. By selecting suitable metamaterial substrate parameters, the magnetic field enhancement can exceed four orders of magnitude and become accessible for experimental detection. This approach opens new opportunities for magnetic sensing, spintronic devices, and engineered platforms for studying topological electromagnetic phenomena.

***Abstract* — High-order harmonic generation (HHG) in solids—the frequency up-conversion of an optical signal—is governed by symmetries. Here, we demonstrate frequency up-conversion in the 6.4 (even-order)–9.7 (odd-order) THz frequency range. This results from bulk centro-symmetry (odd states) and symmetry breaking in the topological surface states (odd and even).**

***Keywords*— metamaterials, terahertz, harmonic generation**

INTRODUCTION

Optical nonlinearity in the terahertz (THz) range represents a key technology to access high frequency spectral windows that are usually difficult to cover using conventional solid state laser technologies.

Over the past decade, the non-linear optical properties of graphene have been extensively investigated, and a wide range of related applications demonstrated, ranging from optical modulators [1] to saturable absorbers [2]. High harmonic generation (HHG) – the frequency up-conversion of an optical signal – in materials systems is governed by symmetries. This effect has been exploited in graphene [3], where HHG has been demonstrated, albeit only at odd multiples of the driving frequency owing to its inherent centro-symmetry. In topological insulators (TIs), unconventional HHG has been predicted [4], supported by the bulk and topological surface states, which are usually difficult to distinguish, relying on the ultrafast intraband dynamics, and the inversion symmetry-breaking even-order nonlinearity in the topological phase.

Here, we exploit innovative technological approaches in large area topological insulator metamaterials and heterostructures to device high efficient non-linear micro-devices, optically pumped by quantum cascade lasers (QCLs) delivering 2W optical power, and electrically-driven integrated plasmonic lasers comprising integrated QCL heterostructures, targeting HHG in the technologically relevant *Reststrahlen* gap (6-12 THz) at both odd or even orders, via symmetry breaking [5], [6], [7].

This talk will provide future perspectives in the fascinating field of topological photonics and non-linear THz photonics.

***Abstract*— Graphene and topological insulators have in common that photoexcitation with virtually any wavelength, including gigahertz (GHz) and terahertz (THz) light, can lead to highly efficient carrier heating. This carrier heat can be exploited to create novel metamaterial devices with applications in terahertz nonlinear photonics and terahertz photodetection for quality inspection.**

***Keywords*— metamaterials, terahertz, graphene, topological insulators**

I. Introduction

The THz region of the electromagnetic spectrum is still lacking behind in terms of available techniques for the creation, detection and conversion of radiation, compared to the regimes on either side of the THz spectrum. For lower frequencies, electronic techniques are effective, while for higher frequencies, optical techniques provide solutions. While the THz regime has thus far strongly relied on optoelectronic techniques, strategies exploiting electronic heat in quantum materials, in particular graphene and topological insulators, are highly promising.

The electronic heat that is generated in graphene and topological insulators is the result of efficient electron-electron thermalization after photoexcitation and their relatively low carrier densities [1]. Importantly, electronic heating occurs both after interband excitation and intraband excitation, and therefore also for light with low photon energy, such as GHz and THz radiation. By designing suitable (metamaterial) devices, it is possible to exploit electronic heat for different GHz/THz applications, as we will show here. In particular, we will discuss i) efficient nonlinear conversion of (sub-)THz light using metamaterials that consist of graphene or a topological insulator, combined with a metallic grating for field enhancement; ii) highly sensitive detection of (sub-)THz light using graphene-metal-antenna metamaterials.

II. Methods

For part (i) on THz nonlinear photonics, our approach consists of shining (sub-)THz multicycle pulses onto graphene- and topological-insulator-based metamaterials and detecting upconverted signals, such as harmonics up to the 9th harmonic, using electro-optic sampling. This up-conversion is the result of the ultrafast heating-cooling dynamics of electronic heat.

For part (ii) on THz photodetection, we use continuous wave (sub-)THz light sources to shine light onto graphene-based metamaterial photodetector devices and measuring the directly generated photocurrent via the photo-thermoelectric effect.

III. Results and Discussion

For part (i), notable results have been the observation of highly efficient THz harmonic generation in graphene-grating metamaterials [2] and almost a milliwatt of output power from a topological-insulator-grating metamaterial [3].

For part (ii), we have very recent results [4] that demonstrate that graphene-based THz detectors can function as an integrated detector-interferometer that allows for the coherent detection of (sub-)THz light, with applications in quality control and wireless communication.

IV. Conclusion

These results demonstrate that exploiting electronic heat in graphene- and topological-insulator-based metamaterials indeed forms a promising alternative to conventional, purely optoelectronic approaches.

Exceptional points can enable lower-Q modes to lase first

J. Kullig[1], Q. Zhong[2,3], J. Wiersig[1], and R. El-Ganainy[2]

Abstract

Laser systems are commonly expected to lase first in the cavity mode with the highest quality factor Q under uniform pumping. We show that this intuitive rule can fail in the presence of non-Hermitian degeneracies known as exceptional points (EPs). As the pump strength increases, two initially lower-Q modes may coalesce at an EP, after which one of the resulting hybrid modes exhibits a faster increase in modal gain and reaches the lasing threshold before a competing higher-Q mode. We illustrate this mechanism using a coupled-cavity toy model and confirm it in a uniformly pumped polygonal microcavity. These results reveal a previously overlooked pathway for lasing mode selection in non-Hermitian laser systems.

Introduction— Laser systems are essential in many modern technologies. Although laser implementations vary widely in materials and cavity geometries, their operation generally follows a simple principle: under uniform gain, the cavity mode with the highest quality factor Q is expected to reach the lasing threshold first.

Because lasers inherently involve both gain and loss, they naturally form non-Hermitian systems. Recent advances in non-Hermitian photonics have revealed a variety of counter-intuitive effects in laser dynamics, including gain-induced suppression of lasing and the closely related phenomenon of loss-induced lasing [1, 2].

Despite these developments, one fundamental rule of lasing mode selection has remained largely unquestioned: under uniform pumping and weakly dispersive gain, the mode with the highest Q factor and the largest modal gain increase rate is expected to reach threshold first as the pump power increases. In this work [3], however, we demonstrate a mechanism that violates this rule. Specifically, we show that in certain systems two initially lower-Q modes can coalesce at an exceptional point (EP) [4] as the pump is increased from zero. Beyond the EP, one of the resulting hybrid modes acquires a larger gain increase rate and ultimately reaches the lasing threshold before the initially dominant higher-Q mode.

We illustrate the underlying mechanism using two complementary approaches. First, we analyze a simplified model in which coupled-mode theory provides physical insight into the effect. We then demonstrate the phenomenon in a single uniformly pumped cavity by solving the full-wave Maxwell equations.

Conclusion— Exceptional points below threshold can fundamentally modify laser mode competition. The usual rule that the highest-Q mode lases first can fail because EP-induced mode coalescence changes the gain evolution of competing modes. These results show that non-Hermitian degeneracies must be taken into account when predicting lasing order in multimode systems.

***Abstract*— This study explores directional solidification to fabricate bulk metamaterials and topological-insulator-based eutectic heterostructures. By engineering complex interfaces, these self-organized composites exhibit unique light-matter interactions, offering promising avenues for advancements in ultrafast photonics and energy-efficient optoelectronics.**

***Keywords*— Directional solidification; Bulk metamaterials; Topological insulators; Eutectic heterostructures; Ultrafast photonics; Crystal growth.**

Directional solidification provides a versatile route for fabrication of bulk metamaterials and photonic composites with engineered electromagnetic properties. In this work, we present recent advances in self-organized eutectic structures and nanoparticle-doped composites designed for plasmonic, photonic, and topological functionalities.

Particular attention is devoted to topological-insulator-based heterostructures integrated with self-assembled metamaterial-like architectures. We demonstrate that directionally solidified eutectic systems combining topological insulators with semiconducting and magnetic phases exhibit distinctive light-matter interactions arising from their complex lateral heterostructures and high density of interfaces. These materials provide a versatile platform for studying optical and ultrafast carrier dynamics, including terahertz emission, interface-driven photocurrent generation, and polarization-dependent electromagnetic responses.

These results highlight the potential of crystal-growth-based metamaterial platforms for applications in ultrafast photonics, sensing, and energy-efficient optoelectronic devices.

Topological Metamaterials Driven Study of the Dielectric Response of the Cancerous Biological Tissue

Tatjana Gric[1,*]

[1] Department of Electronic Systems, Vilnius Gediminas Technical University, Vilnius, Lithuania

*Corresponding author: tatjana.gric@vilniustech.lt

***Abstract*— Cancerous tissues are treated as the disordered anisotropic media. The classical Maxwell-Garnett technique is utilized to evaluate an effective medium of the sample with no needs of human intervention. In this relation, the presented technique allows for the creation of the phantom tissue models for the usage in clinical applications.**

***Keywords*— metamaterials, cancer, effective medium theory.**

I. Introduction

This work aims to refine fundamental ideas used in electrodynamics and some optical problems and to apply them for biological systems. We aim to correct a common practice if effective medium models for biological systems. An analytical approach to calculate the macroscopic complex dielectric properties of materials is possible due to the effective medium theory models. The former is performed by employing the dielectric properties of their constituents and their volume fractions [1]. It is well-known that early cancer detection is of substantial importance to increase the chances of survival. To address this grand societal challenges, this work aims at introducing a paradigm shift in the study of the dielectric response of the cancerous biological tissues.

II. Methods

Effective medium theories stand for as a perfect toll aiming to identify an effective dielectric function for a composite material taking into account the dielectric function of its components and their geometrical distribution [2]. Let us now assume that inclusions are embedded into the host medium. Moreover, the implants are prepared by utilizing different materials with permittivities ε_n (n=1, 2, … , N). Then Maxwell-Garnett equation is generalized as

$$\frac{\varepsilon_{MG}-\varepsilon_h}{\varepsilon_{MG}+2\varepsilon_h}=\sum_{n=1}^{N} f_n \frac{\varepsilon_n-\varepsilon_h}{\varepsilon_n+2\varepsilon_h}, \qquad (1)$$

where f_n is the volume fraction of the n-th component.

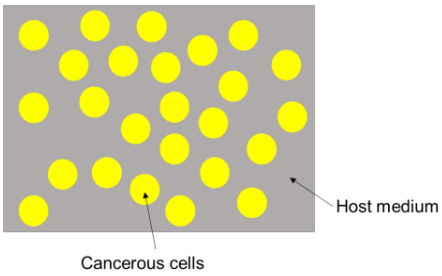

Fig. 1 Biological tissue with the embedded cancerous cells.

III. Results and Discussion

The phantom tissue models are created based on the topological metamaterial formalism methodology. It is assumed, that brain (grey matter) forms the host medium and cancerous cells are implanted in it. Following the former approach one may construct an anisotropic metamaterial (Fig. 1) with the host material being grey matter of the brain and the nanocylinders embedded in it possessing permittivity of the cancerous cells.

IV. Conclusion

It was concluded that cancerous tissues can be treated from the perspectives of the highly disordered topological metamaterial medium. In this relation, effective permittivity of the biological tissue under consideration can be considered. The presented approach may serve as a perfect tool aiming to create phantom tissue models for the clinical applications.

***Abstract*— We present an algorithm-driven strategy to automatically design metasurfaces for functionally multiplexed light manipulation. Our metasurface design pipeline comprises iterative optimization steps, integrating gradient-based optimization or heuristic algorithms enhanced by machine learning models. This approach has been experimentally validated using multi-channel holograms, focusing lenses, and wavelength routers.**

***Keywords*— Machine Learning, optimization algorithms, metasurface, multiplexed functions.**

I. Introduction

Recently, with the aid of intelligent algorithms, the nanophotonic community has witnessed tremendous development in the design, measurement and application of nanophotonic devices and systems. The core impetus is the prevalence of inverse design methods, which convert a design problem into an optimization problem, and solve it with various algorithms automatically[1-3].

II. Methods

In this talk, we conceptually propose and experimentally demonstrate an end-to-end design pipeline with embedded statistical machine learning models for automatic design of metasurfaces. Instead of a two-step design routine including designing each meta-atom through a parameter sweep and then arrange them periodically, we resort to statistical machine learning as the bridge that directly links the structural parameters of each single meta-atom and the target metasurface performance. The machine learning model is composed of several probabilistic inverse retrieving models and a deterministic predicting model, which accurately capture and faithfully reproduce the statistical features of the high-dimensional joint distribution of meta-atom structures and their optical responses. Consequently, instead of artificially decoupling the complex optical response into independent sub-targets, a system-level multi-object optimization can be implemented to fully exploit the design space to push the design capacity to its physical limit. Under this design scheme, we experimentally demonstrated several design examples of metasurfaces including multi-channel holograms, wavelength-multiplexed light focusing and optical wavelength router.

III. Results and Discussion

Experimental results show:

- Through algorithm-driven optimization, multifunctional metasurface holograms achieve generation of up to 8 independent holographic images using combinations of 4 wavelengths and 2 polarizations (Fig 1).
- Algorithm-optimized wavelength routers deliver a 50% energy utilization efficiency, significantly surpassing the 25% theoretical upper bound of traditional 2×2 filter-array architectures (Fig 2).
-

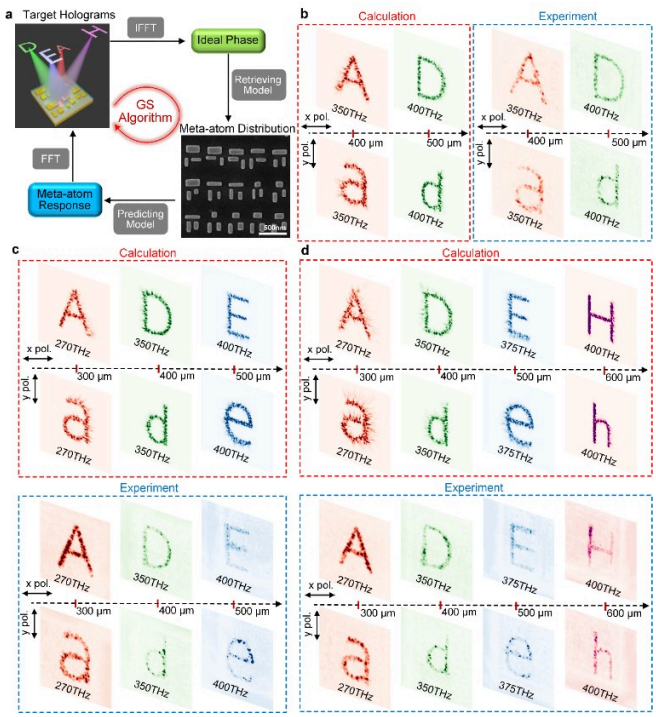

Figure 1 Embedding the statistical learning model in GS algorithm for multifunctional metasurface holograms.

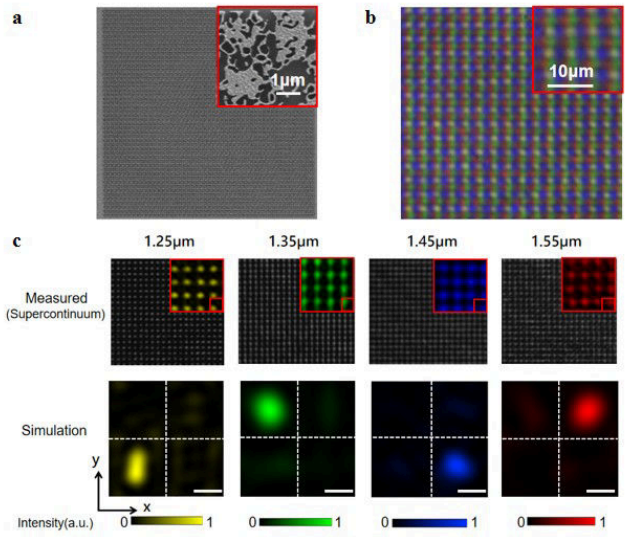

Figure 2 Focal-plane characterization of a four-wavelength router device

IV. Conclusion

We have demonstrated multi-channel holograms, focusing lenses, and wavelength routers using algorithm-driven metasurface design.

Adjoint-Based Characterization of Anisotropic and Bianisotropic Metamaterials Guided by Group Theory

Edgar Bustamante[1,*] Denis Ridzal[1] , Ihab Fathy El-Kady[1]

[1]Sandia National Laboratories, USA
*Corresponding author: ebustam@sandia.gov

***Abstract*— Group theory and adjoint optimization are combined to characterize anisotropic and bianisotropic metamaterials. Using MIRaGE, a target constitutive tensor is mapped to compatible metamaterial symmetries. Adjoint optimization is then used to determine the effective tensor values of a homogenized material model whose effective electromagnetic response approximates an explicitly modeled metamaterial unit cell.**

***Keywords*— adjoint optimization, anisotropy, bianisotropy, group theory, homogenization, metamaterials.**

I. Introduction

Metamaterials are engineered materials whose electromagnetic properties arise from the arrangement of subwavelength structures rather than from the intrinsic properties of the base materials alone. Depending on the symmetry of the unit cell, their effective response may require anisotropic permittivity and permeability tensors, as well as bianisotropic magnetoelectric coupling terms. Accurately characterizing this response enables homogenized simulations of periodic devices without explicitly meshing the detailed subwavelength metamaterial structures. Conventional S-parameter retrieval methods that use reflection and transmission data are useful for extracting homogenized effective parameters [1], but a full tensorial constitutive description requires identifying which parameters are physically admissible and which independent excitations are needed to determine them [2]. This presentation considers a workflow that combines group-theory constraints with adjoint-based parameter extraction.

II. Symmetry Constrained Constitutive Model

Multiscale inverse rapid group-theory for engineered-metamaterials (MIRaGE) maps prescribed constitutive tensor forms to compatible metamaterial symmetry groups [3]. Once the entries of the effective permittivity, permeability, and magnetoelectric coupling tensors are selected, compatible symmetry groups are identified. This step determines which tensor components are allowed by symmetry [4]. The resulting symmetry-constrained tensor form is then used in an adjoint-based parameter extraction procedure, where electromagnetic simulation data are used to recover numerical values for the independent tensor components.

III. Adjoint Parameter Extraction

The resolved metamaterial geometry is first simulated for a set of incident angles, polarizations, and frequencies chosen to test the independent tensor components. These simulations provide the reference electromagnetic response used in the parameter extraction. In the homogenized model, the metamaterial is replaced by a homogeneous block occupying the same region, with its constitutive tensors constrained by MIRaGE. The independent anisotropic or bianisotropic tensor entries are then treated as the unknowns in the adjoint-based optimization.

The objective function measures the mismatch between the resolved and homogenized responses over the selected excitations. Forward simulations are used to evaluate this mismatch, while the corresponding adjoint simulations provide gradients with respect to the active constitutive parameters [5]. The optimization updates the effective tensor values rather than the unit-cell geometry, producing a homogenized anisotropic or bianisotropic material model that best matches the metamaterial response while preserving the symmetry constraints.

IV. Discussion And Outlook

This work combines group-theory-based symmetry classification with numerical extraction of effective material tensors. MIRaGE is used to reduce the number of tensor components that need to be fitted and to enforce symmetry constraints. Adjoint sensitivities are then used to fit the material response across multiple excitations simultaneously. The presentation will discuss how the excitations are chosen, which response quantities are used in the fitting, and how the extracted tensors are validated by comparing full-wave simulations of the resolved metamaterial with simulations of the homogenized model. The goal is to obtain effective tensor descriptions that can make metamaterial analysis faster while preserving the relevant electromagnetic response.

***Abstract*— Scaling photonic inverse design from isolated components to deployable systems requires optimization frameworks that capture multi-block interactions, enforce foundry manufacturability, and remain computationally tractable at large design scale. I will describe a co-optimized inverse design methodology that leads to performance improvements, and highlight inverse designs in foundry photonic systems.**

***Keywords*— photonic inverse design, silicon photonics, foundry-photonics.**

SUMMARY

Scaling photonic inverse design from isolated components to deployable systems requires optimization frameworks that capture multi-block interactions, enforce foundry manufacturability, and remain computationally tractable at large design scales. I will describe a co-optimized inverse-design methodology that treats a photonic system as a coupled optimization problem, jointly optimizing multiple subsystems under shared constraints and system-level figures of merit, while co-designing around pre-existing foundry-qualified building blocks. As a representative demonstration, I present a co-optimized inverse-designed WDM in which the wavelength-routing element is optimized together with Bragg filters, rather than cascading independently optimized blocks. Finally, I show how foundry photonics enables these inverse-designed components to transition rapidly into scalable photonic solutions, supporting system-level demonstrations that highlight a practical path to manufacturable, high-yield photonic systems.

***Abstract*—Reconstructive spectrometers are devices that combine complex scattering with inference. We argue that their reconstruction error is governed by Fisher information, and can be expressed via the spectral correlation length, mean transmittance, and the number of frequency and measurement channels. This numerically-validated theory also predicts the conditions for superresolution.**

***Keywords*—enhanced spectroscopy, disorder**

I. Introduction

Spectrometers are devices that decompose light into its spectral constituents for analysis. Traditional designs—dispersive spectrometers and interferometric spectrometers—benefit from increased device size, and so face limits in miniaturization. An emerging family of spectrometers, called reconstructive spectrometers [1], [2], [3], [4], [5], may be able to overcome such limits. Broadly speaking, they encode the input light into a complex interference pattern, which is used to infer the spectrum via prior knowledge (e.g., a one-time calibration). Although we have a sound understanding of the limitations of conventional spectrometers (e.g., the pixel-limited spectral resolution of a dispersive spectrometer scales inversely with the optical path length), the physical determinants of performance for reconstructive spectrometers remain unclear.

Recently [6], we have developed a broadly-applicable figure of merit for the performance of reconstructive spectrometers. Under the assumptions that (i) the spectrum is inferred from light intensity measurements on a fixed set of output channels; (ii) each intensity measurement is subject to independent Gaussian noise; and (iii) there are no additional relevant priors about the spectrum (e.g., sparsity), the theory of Fisher information [7] states that the reconstruction error is bounded below by $\sigma_\epsilon^2 \,\mathrm{Tr}[(\mathbf{A}^T\mathbf{A})^+]$, where σ_ϵ is the noise level, $\mathbf{A}$ is the normalized spectral transmission matrix, and $(\cdots)^+$ denotes the Moore–Penrose pseudoinverse. Using empirically-grounded features of generic $\mathbf{A}$ matrices [8], [9], we derive the noise-induced reconstruction error and effective resolution in terms of the spectral correlation length Γ_{corr}, the average transmittance, and the number of frequency and measurement channels. These results clarify the necessary conditions for a reconstructive spectrometer to achieve "super-resolution" below the scale set by Γ_{corr}. We have also validated the theory using random matrix theory (RMT) simulations and full-wave simulations.

II. Theory

A schematic of a reconstructive spectrometer is shown in Fig. 1(a). Light enters an input port (0), is scattered, and partly exits through output ports 1 to M. The scattering matrix is $\mathbf{S}(\omega)$. We sample N equally-spaced frequencies $\{\omega_n\}$, hence defining the $M \times N$ spectral transmission matrix $\mathbf{A}$, where $A_{mn} = |S_{m0}(\omega_n)|^2 \in \mathbb{R}_0^+$. For input spectrum $\mathbf{x}$, we assume the output intensities are $\mathbf{y} = \mathbf{A}\mathbf{x} + \boldsymbol{\epsilon}$ (i.e., additive Gaussian noise $\boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}, \sigma_\epsilon^2 \mathbf{1}_M)$). By the Cramér–Rao lower bound [7], the estimator variance is bounded below by

$$\sigma_\epsilon^2 \,\mathrm{Tr}(\mathbf{G}^+), \quad \mathbf{G} = \mathbf{A}^T\mathbf{A}. \tag{1}$$

We analyze this bound under a set of broadly-applicable physical constraints, including speckle statistics typical of chaotic scattering media, with Lorentzian correlations. In the under-determined regime $M < N$, we obtain [6]

$$\mathbb{E}\left[\,\mathrm{Tr}(\mathbf{G}^+)\,\right] \approx \frac{MN}{|M-N|}\frac{\tilde{J}(a)}{T_0^2}, \tag{2}$$

$$\tilde{J}(a) = \frac{2\sinh\left(\sqrt{2}\frac{M}{N}\pi a\right)}{\pi a^2}\tan^{-1}\left[\tanh\left(\frac{\pi a}{2}\right)\right]. \tag{3}$$

where $a \equiv \Gamma_{\mathrm{corr}}/\Delta\omega$ is the normalized correlation length.

From this result, we can proceed to derive various performance characteristics of the spectrometer. For instance, Fig. 1(b) shows the results of numerical simulations based on random matrix theory (RMT)—specifically, the Mahaux-Weidenmüller model of a scatterer [10]. We plot the effective resolution $\Delta\omega_{\mathrm{min}}$, defined as the minimum frequency spacing to keep the reconstruction mean squared error (MSE) below a stated threshold, versus the outcoupling constant γ of the RMT model. The theory predicts, and the numerical results confirm, that it is possible for a reconstructive spectrometer to achieve "superresolution" regime where $\Delta\omega_{\mathrm{min}}$ is smaller than the spectral correlation length Γ_{corr}.

We have also validated our theory against finite-difference time-domain (FDTD) simulations of an exemplary reconstructive spectrometer [3], shown in Fig. 1(c). The resulting plot of $\mathrm{Tr}[\mathbf{G}^+]$ versus cavity size L is shown in Fig. 1(d): the simulation results (stars) agree well with the predictions from

Fig. 1. (a) Schematic of a reconstructive spectrometer with M output ports. (b) Effective resolution $\Delta\omega_{\text{min}}$ versus coupling strength γ (orange dots), obtained from a Mahaux-Weidenmüller random matrix theory (RMT) model [10] with 500 cavity modes, using $M = 50$, $N = 100$ and averaging over 200 samples per data point. The effective resolution is defined as the minimum frequency spacing to keep the reconstruction MSE below a threshold $\delta_{\text{th}}^2 = 4 \times 10^{-4}$. Over a range of γ, the device exhibits super-resolution ($\Delta\omega_{\text{min}} < \Gamma_{\text{corr}}$. (c) Schematic of an on-chip reconstructive spectrometer with a $L \times L$ scattering region. (d) Reconstruction error metric $\text{Tr}[\mathbf{G}^+]$ versus L. The results obtained directly from the simulated $\mathbf{A}$ matrices (blue stars) are close to the theoretical predictions (blue line). The minimum of the latter matches the optimal cavity size L_{opt} derived by combining the theory with diffusive scattering scaling laws (vertical dashes).

our theory (solid line). By combining the scaling laws of diffusive transport [11], we can also predict the optimal cavity size, which closely matches the numerical minimum (vertical dashes).

III. Conclusions

The performance of a reconstructive spectrometer is largely determined by the variance bound $\text{Tr}[\mathbf{G}^+]$, derived from its spectral transmission matrix. When noise is present but non-dominant, this quantity accurately describes the noise-induced error for not only pseudoinverse-based reconstruction, but also inference using a neural network, implying that the criterion is reasonably algorithm-independent. We have derived expressions for $\text{Tr}[\mathbf{G}^+]$, and hence the effective frequency resolution, in terms of physically meaningful variables: the spectral correlation length Γ_{corr}, mean transmittance T_0, the number of intensity measurement channels, etc. The theory yields successful predictions for both RMT models and a full-wave simulation of an on-chip device. The tests confirm that Γ_{corr} is not the sole determinant of performance for a reconstructive spectrometer; notably, T_0 also plays a role and can lead to a trade-off.

***Abstract*—Deep learning surrogate models can accelerate modeling of electromagnetic devices by several orders of magnitude, but usually require very large amounts of training data. We show that neural networks can be made more data efficient by utilizing symmetries of Maxwell's equations.**

***Keywords*— machine learning, symmetries, scattering, metasurfaces, diffraction gratings, inverse design.**

I. Introduction

Physics-informed machine learning has recently gathered significant attention in the field of artificial electromagnetic materials. While traditional neural networks are applicable to a wide range of problems, they typically require very large amounts of data to train, generalize poorly, and make predictions that are not consistent with the governing physics [1]. Physics-informed machine learning aims to alleviate these issues by incorporating prior knowledge about the physics into neural network architecture or training procedure. Previous works in physics-informed machine learning for artificial electromagnetic materials have primarily focused on feature engineering, building algebraic expressions into the neural network architecture, or adding extra loss functions to promote consistency with governing physical laws [2].

In this contribution, we propose symmetries as a new direction in physics-informed machine learning for electromagnetic scattering. Our approach is applicable to any supervised learning problem where the label is a set of parameters $\mathbf{d}$ describing a material distribution in space (ε, μ), and the target is a set of scattering parameters S describing the relation between the amplitudes $\mathbf{s}^+$ and $\mathbf{s}^-$ of incoming and outgoing electromagnetic waves through $\mathbf{s}^- = S\mathbf{s}^+$. The training data for such problems is typically generated by a numerical simulator, here represented by a function $F : \mathbf{d} \mapsto S$. The simulator can calculate the scattering parameters of any design but is expensive to evaluate. However, given a sample $(\mathbf{d}, S)$, the scattering parameters $\hat{S}$ of a new design $\hat{\mathbf{d}}$ can often be inferred from symmetry without any additional evaluations of F, as illustrated in Fig. 1. In the language of group theory, F is said to be an *equivariant map*, commuting with the action $\triangleright$ of the transformation g, i.e.,

$$F(g \triangleright \mathbf{d}) = g \triangleright F(\mathbf{d}),$$

where the action is defined such that $g \triangleright \mathbf{d} = \hat{\mathbf{d}}$ and $g \triangleright F(\mathbf{d}) = g \triangleright S = \hat{S}$. This equivariance is not automatically respected by standard neural networks, and can therefore be exploited to improve data efficiency.

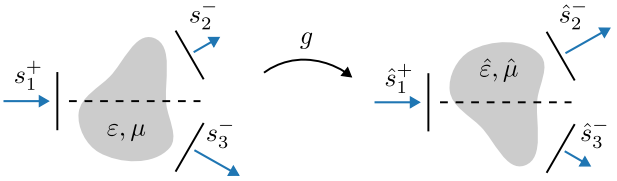

Fig. 1. Reflecting the electromagnetic geometry on the left yields the new geometry on the right. The scattering parameters of the new geometry can be inferred from the scattering parameters of the original geometry without any additional simulations.

II. Method

The most straight-forward way to exploit the equivariance of F is to use it to generate more training samples, a strategy referred to as data augmentation. A more sophisticated approach is to construct the neural network such that it has the same symmetry as F. This is possible using openly available software libraries for equivariant deep learning [3, 4].

We compare these two methods on a dataset of 24 000 randomly generated one-dimensional diffraction gratings. In this case, the goal is to predict the scattering parameters

$$S = \begin{pmatrix} S_{-1} \\ S_0 \\ S_{+1} \end{pmatrix}$$

from a binary vector $\mathbf{d} = (d_1, d_2, \ldots, d_{32})$ describing the geometry of the grating as shown in Fig. 2(a). Translating the grating by a distance t corresponds to a cyclic permutation of the design vector and transforms the scattering parameters as

$$t \triangleright S = \begin{pmatrix} e^{\frac{2\pi i t}{a}} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & e^{-\frac{2\pi i t}{a}} \end{pmatrix} \begin{pmatrix} S_{-1} \\ S_0 \\ S_{+1} \end{pmatrix}, \tag{1}$$

where a is the lattice parameter. Mirroring the grating reverses the order of the design vector and transforms the scattering matrix as

$$m \triangleright S = \begin{pmatrix} 0 & 0 & -1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{pmatrix} \begin{pmatrix} S_{-1} \\ S_0 \\ S_{+1} \end{pmatrix}.$$

These actions on the scattering parameters have to be calculated analytically for each new problem. We have derived a systematic procedure for this purpose that is applicable to a wide range of geometries and transformations.

Fig. 2. Diffraction grating example. (a) Illustration of the unit cell, parameterized by a vector of zeros and ones. (b) The action of translation and mirroring on the grating geometry. (c) Test error as a function of the number of training samples for five models trained to predict the scattering parameters of the grating. (d) Illustration of the model-predicted paths of S_{-1} through the complex plane as the grating in the top-right is translated through its periodicity. Markers (circle, diamond, square, cross) correspond to the un-translated grating, black dashed lines are the ground-truth path.

III. Results and Discussion

We compare three different neural networks architectures on the grating dataset. The first is a standard multilayer perceptron (MLP), the second a standard convolutional neural network that partially satisfies translation equivariance (CNN), and the third is a carefully constructed CNN with a custom readout layer that ensures exact equivariance to both translations and reflections (ECNN). We also train MLPs and CNNs with data augmentation (MLP-A and CNN-A).

The test error of all models as a function of the number of training samples is shown in Fig. 2(c). Applying data augmentation to the MLP and CNN yields an improvement in test loss that corresponds to increasing the dataset size by a factor of approximately 20. The ECNN preforms even better than the models using augmentation, especially for large dataset sizes. This improvement is partially due to the equivariant model converging faster during training, which is favoured by our fixed-epoch evaluation scheme.

To test the translation equivariance of the models, we select a sample grating $\mathbf{d}$, generate the set of all possible translated versions of this grating, and feed this set through the neural networks. The resulting predictions of S_{-1} are plotted in Fig. 2(d), together with S_{-1} from the ground-truth simulator. According to the transformation rule (1), translating the grating adds a complex phase to S_{-1}, meaning that S_{-1} should trace out a circle in the complex plane. This symmetry is respected by the exactly equivariant ECNN, but not by the MLP or CNN, even when trained with augmentation. This highlights another benefit of building equivariance directly into the model architecture.

IV. Conclusion

In conclusion, we have shown that symmetries in the underlying physics can be exploited to improve data efficiency in deep learning for electromagnetic scattering parameter prediction through data augmentation and equivariant neural networks. This approach is applicable to a wide range of problems and can be combined with other physics-informed techniques. Although only spatial symmetries and basic neural network architectures were used in the example shown here, the same methods could be applied to more exotic symmetries and advanced architectures using tools from geometric deep learning [5]. We hope this work will spark an interest in equivariant deep learning in the field of metamaterials and enable more data efficient and consistent surrogate models for a wide range of applications.

***Abstract*— Optical phased arrays (OPA) are promising solid-state integrated photonic technologies for compact beam steering targeting free-space optical telecommunication and sensing applications. In this work we present an inverse design framework to optimize correction silicon nitride meta optics to straighten the curved OPA radiation pattern and expand the field of view coverage.**

***Keywords*— inverse design, OPAs, beam correction, meta optics**

I. Introduction

Optical phased arrays (OPA) are compact solid-state photonic integrated devices that enable large angle beam steering without moving parts, with enormous potential for applications such as free space optical telecommunication and LIDAR sensing. OPAs consist of arrays of optical emitters with fixed spacing between them [1]. By introducing a phase difference between consecutive emitters, using integrated phase shifters, the wavefront normal, or beam direction, can be electronically steered. A two-dimensional beam steering OPA photonic integrated circuit (PIC) has been demonstrated with large azimuthal 180° field of view (FoV), combining a slab output grating as a single emitter, allowing the elevation angle, or second axis, to be altered by tuning the laser wavelength [2]. Here, however, the output grating pitch, beam direction, and varying wavelength, result in a curved radiation field of view that lead to coverage blind spots, as illustrated in Figure 1. A new fully integrated blue spectrum 2D OPA transceiver PIC module based on a similar architecture is under development, targeting underwater optical wireless communications. To correct the curved FoV and eliminate blind spots, a novel corrective meta optics will be integrated at the package level, enabling optical links to be established between two or more transceivers without rotating the modules.

In this work, we present a versatile inverse design framework to optimize beam shaping metasurfaces, or corrective meta optics, and demonstrate its application in designing corrective silicon nitride meta optics targeting blue light OPAs.

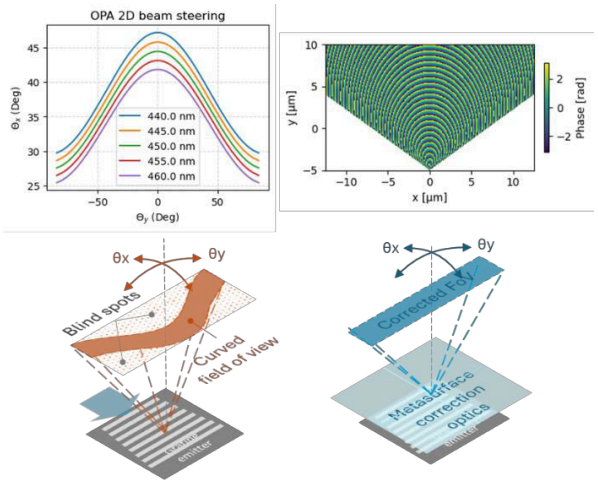

Figure 1 – Top: Expected directions (left) and vectorial field phase (right) of the radiation pattern of the blue light OPA. Illustration of the curved field of view and coverage blind spots(center); and straightened field of view by the meta surface correction optics (right).

II. Methods

The inverse design method for optimization of corrective meta optics is implemented into the open-source Python library pyMOE [3], which was recently expanded to include accurate and efficient Bluestein, and non-paraxial Scalable Angular Spectrum Method propagators, with automatic differentiation enabled by the JAX machine learning package [4]. A model of the OPA emitter was developed to describe its output vectorial field and its spatial distribution incident on the metasurface (see Figure 1 top right), dependent on the grating dimensions, laser wavelength, and tuning phase. Taking these input vectorial fields and the target desired output radiation pattern (e.g. regular FoV), the phase distribution of the metasurface is iteratively optimized.

III. Results and Discussion

We employed the developed method to optimize beam shaping metasurfaces towards arbitrary non-paraxial far field distributions, from distorted input fields, such as the curved

large angle OPA radiation pattern. The figures of merit are defined as the smallest orthogonal deviations of the far field pattern from an ideal azimuth cut, when sweeping the OPA phase, or from the elevation cut, when sweeping the laser wavelength, reducing the cross-dependence between steering inputs. We introduce boundaries to the optimization to discourage solutions outside fabrication feasibility of silicon nitride blue-light metasurfaces, such as too small critical dimensions, low transmission amplitudes, or sub-2π phase modulation ranges.

IV. Conclusion

We have demonstrated that inverse design can provide correction optics for large field of view beam steering of OPAs in wavelengths compatible with underwater communications. The reported designs are suitable for fabrication using nanofabrication techniques, specifically e-beam lithography, with the meta optics device being integrated at the package level with the OPA PIC.

Engineering van der Waals Materials for Quantum Optical Emission

Shengxi Huang

Department of Electrical and Computer Engineering & Department of Materials Science and NanoEngineering, Rice University, Houston, TX 77005

shengxi.huang@rice.edu

Abstract: We report new atomic engineering approaches on van der Waals materials to generate high quality single photon emitters. Our approaches include atomic substitution through plasma treatment, in-situ doping, and manipulating layer thickness and polarization. Such approaches have led to single photon emission with high purity, high brightness, and high stability.

Key words: single photon purity, Debye-Waller factor, atomic substitution, transition metal dichalcogenide, hexagonal boron nitride

Designer van der Waals (vdW) materials offers enormous opportunities to tune material properties for various applications. Isolated, optically-active defects generated in vdW materials could lead to single photon emission. 2D vdW materials as host materials for single photon emission hold various advantages, such as high optical extraction efficiency from the atomically-thin layered materials, and readiness to integrate with on-chip photonic and electronic devices. However, single photon emission from 2D vdW materials typically suffers from low purity and lack of controllability, due to the sensitivity of these atomically-thin materials to external dielectric environments, surface defects and adsorbents, and strains and wrinkles introduced during material processing. This talk introduces our recent efforts to improve the single photon purity and controllability in vdW materials. We developed novel defect structures that can overcome several current issues, and explored their electronic structure and tunability in optical emission. Through a combination of approaches, including strain engineering, heterostacking, employing optical selection rules for excitation and detection, optimization of material synthesis and handling, we were able to achieve high purity (> 98%) for single photons emitted from 2D transition metal dichalcogenides (TMDs) at cryogenic temperature and in hBN at room temperature. This work provides deep insights into the electronic, spin, and valley properties of TMDs and hBN. It also paves the way towards the

application of 2D vdW materials for quantum optical applications. The materials engineering approaches developed here can be applied to the optimization of other optical and quantum materials.

***Abstract*—I will present a framework to study the topology of coupled metallic nanoresonantors arranged in a Su-Schrieffer-Heeger geometry embedded in a dielectric. To correctly account for Ohmic losses, we use a non-Hermitian description allowing us to uncover boundary states, and compare our results to existing literature and full-wave numerics.**

***Keywords*— plasmonics, topology, non-Hermitian physics.**

Plasmonics is the study of the interaction between light and free electrons at metal-dielectric interfaces at a nanoscale level. In this context, we are interested in coupled metallic nanoresonators, MNRs, embedded in a dielectric material. Such MNRs can be used to construct metasurfaces for, e.g., sensing applications. Topology provides a route towards novel functionalities to the already rich physics of these structures. To analyze and design the topological properties of these systems, we employ a non-Hermitian treatment to accurately account for Ohmic losses.

In my talk, I will present a framework to analyze the topology of coupled MNRs. In particular, the properties of the coupled MNRs are encoded in the solutions of a non-Hermitian eigenvalue problem. Using this method, we analyze a plasmonic analogue of the Su-Schrieffer-Heeger chain, and compare our results with the existing literature and full-wave numerics.

Integrated Nonlinear Photonics for Compact Terahertz and Quantum Devices

Shima Rajabali[1,2,*]

[1]Quantum and Computer Engineering Department, Delft University of Technology
[2]School of John A. Paulson School of Engineering and Applied Sciences, Harvard University, USA
*Corresponding author: s.rajabali@tudelft.nl

***Abstract*— In this talk, I will highlight our recent advancement in realizing terahertz photonic devices and electro-optic quantum transducers on a nonlinear integrated photonic platform.**

***Keywords*— nonlinear optics, integrated photonics, terahertz, thin film lithium niobate, electro optic.**

SUMMARY

Real-world use of terahertz communications and broadband terahertz spectroscopy requires compact, energy-efficient devices capable of high-speed performance and high sensitivity. Integrated photonics offers a promising chip-scale platform for addressing these needs [1]. Among emerging technologies, thin-film lithium niobate (TFLN) stands out as an ideal wafer-scale solution for high-speed devices and systems [2,3]. Its strong optical nonlinearity, broad transparency window, low propagation loss, high electro-optic coefficient, and wide modulation bandwidth make it particularly well-suited for optical-to-terahertz transduction and the development of compact THz devices. However, researchers are actively working to overcome challenges such as integrating active components and minimizing device footprints, further advancing the capabilities of the TFLN platform.

In this talk, I will showcase the recent development of hybrid photonic-THz TFLN chips for compact THz resonators [4], broadband integrated generation/detection up to multi-THz bandwidths [4,5], frequency combs with millimeter wave Spacing [6], and dual-tone source for compact THz transmitters [7]. Current challenges, and future opportunities in integrated nonlinear photonic devices for optical-terahertz applications will be discussed to explore how integration and miniaturization can enable complex terahertz photonic functionalities on a single chip.

Beyond classical use cases, I will also present the potential of TFLN platform for quantum networks, including on-chip microwave-to-optical transduction [8, 9] and other nonlinear functions [10].

This work introduces a novel approach for realizing a tunable nanoscale source of polarization-entangled photon pairs in the near-infrared, using orthogonal GaAs nanowires. Photon pairs arise from type-0 spontaneous parametric down-conversion (SPDC) and the quantum state is adjustable via pump polarization, enabling a continuous transition from entangled to separable states.

***Keywords*— SPDC, GaAs nanowires, polarization-entanglement, quantum nanophotonics.**

As fundamental building blocks of quantum technologies, entangled photon-pair sources enable applications such as quantum communication and quantum imaging [1,2]. Spontaneous parametric down-conversion (SPDC) has been the prevalent process to generate polarization entanglement. While the use of bulk non-centrosymmetric crystals in most of the realizations prevents chip-scale integration, emerging nanoscale platforms provide a route to miniaturization. Among them, GaAs nanowires (NWs) stand out as a new promising solution for quantum application at the nanoscale. GaAs NWs not only exhibit an intrinsically large second-order nonlinear susceptibility $\chi^{(2)}$, reaching values as high as 370 pm/V [3], but also offer significant advantages over conventional top-down fabrication techniques thanks to their bottom-up growth. In particular, they exhibit a high crystalline quality with minimal defects, and their diameter and length can be precisely controlled through the adjustment of growth parameters.

Here, we show that we can exploit the emission of photon pairs from GaAs NWs via type-0 SPDC [4] to generate polarization entangled states, by pumping two orthogonal GaAs NWs with a linearly polarized laser. In type-0 SPDC, the pump, signal, and idler photons all share the same polarization. Rotating the pump polarization then enables to tune the quantum state from separable to entangled [5].

I. Methods

The schematic of the tunable nanosource of polarization-entangled is shown in Fig. 1, together with the SEM image shown in the inset. It consists of two orthogonal Zinc Blende GaAs NWs (≈ 400 nm diameter, ≈ 5 µm long), grown in the (111) direction and laid on a transparent SiO_2 substrate. The two nanowires are pumped at the same time by a continuous-wave (cw) linearly polarized laser at 778 nm, with a power of 12 mW.

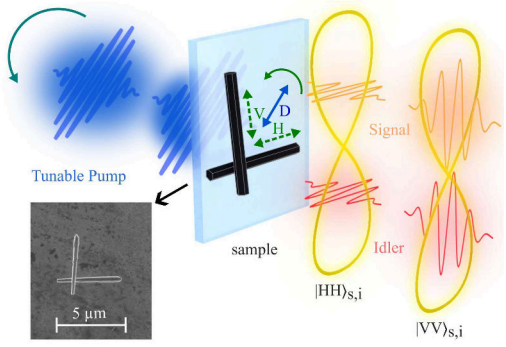

Fig. 1 : Schematic of the tunable nanosource of polarization-entangled photons from orthogonal GaAs nanowires (NWs) and SEM image of the GaAs NWs.

The pump polarization can be rotated to be aligned with either one of the NWs (referred as horizontal H or vertical V pump

polarizations), or at ±45° of the NWs' axis (referred as diagonal D and antidiagonal A pump polarizations). The quantum state is then measured as a function of the pump polarization by performing quantum state tomography and the density matrices are retrieved via the maximum likelihood estimation method [6].

II. Results and Discussion

The real parts of the experimental density matrices are plotted in Fig. 2, as a function of the pump polarization. When the pump is aligned at ±45° of the nanowires long axis, two entangled Bell's states are generated with $|\Psi^{D,A}\rangle = \frac{1}{\sqrt{2}}(|HH\rangle \mp |VV\rangle)$ (Fig. 2a,b) with high fidelities reaching 90% for both cases. However, when the pump is aligned along the long axis of one NW, the photon pair is generated exclusively by that NW. In this configuration, the quantum state is either $|\Psi^{H}\rangle = |HH\rangle$ for H-polarized pumping (Fig. 2c), or $|\Psi^{V}\rangle = |VV\rangle$ for V-polarized pumping (Fig. 2d), with fidelities reaching 88% and 89% respectively.

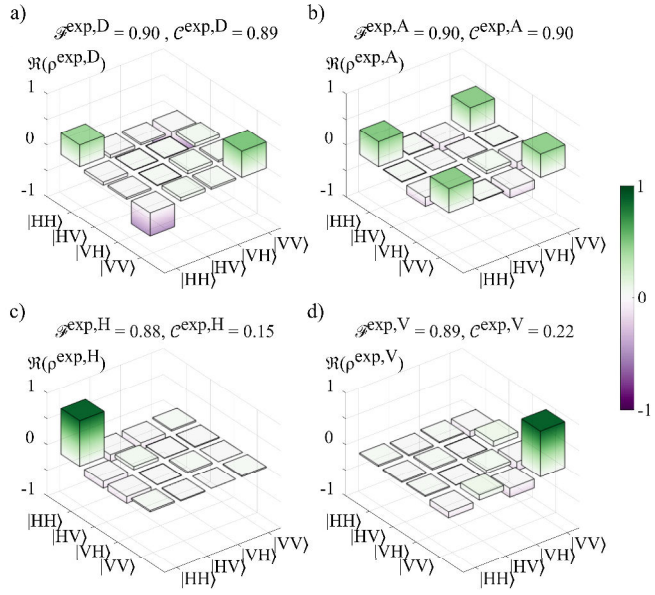

Fig. 2 : Real parts of the experimental density matrices ρ^{exp} for a) diagonal (D), b) antidiagonal (A), c) horizontal (H) and d) vertical (V) pump polarizations.

The degree of entanglement can be evaluated by computing the concurrence C as a figure of merit [7], ranging from 0 (for fully separable states) to 1 (for fully entangled states). Here, we obtained an experimental concurrence of 0.15 and 0.22 for H and V pump polarizations respectively. Conversely, the concurrence reaches 0.89 and 0.90 for D and A pump polarization respectively. These experimental results confirm that changing the polarization of the pump enables to tune the degree of polarization entanglement without post selection or without any additional optical components.

III. Conclusion

In this work, we have demonstrated a tunable nanosource of polarization entangled photons from bottom-up GaAs nanowires via spontaneous parametric down-conversion. Rotating the pump polarization enables to tune the degree of entanglement of the state, from separable to entangled, without the need of additional optical components. Besides its versatility, it is among the most compact polarization-entangled photon pair sources ever obtained.

***Abstract*— Tunable lasers are essential for optical communication, spectroscopy, and precision sensing. Many tunable laser systems rely on mechanical components, limiting speed and stability. Here, we demonstrate an external cavity semiconductor laser capable of achieving ultrafast frequency and amplitude modulation within a compact footprint without any moving parts.**

***Keywords*— external cavity lasers, metasurfaces, electro-optics.**

I. Introduction

Tunable single-mode lasers are essential in applications such as spectroscopy, metrology, ranging and communications. Since their invention in the mid-1960s, external cavity diode laser (ECDL) designs have evolved significantly, often improving wavelength tunability and spectral purity. Among the simplest and most widely used is the Littrow configuration, where light emitted from an anti-reflection (AR) coated laser diode facet is collimated and directed onto a diffraction grating. The first-order diffracted beam is reflected back into the diode to provide optical feedback. This configuration depends on mechanical tuning for wavelength adjustments, limiting speed and tuning range. To overcome this, electro-optic modulators have been inserted into the laser's cavity, but their bulk footprint limited the development of compact laser diodes [1].

II. Methods

In this work, we integrate a compact, frequency-selective electro-optic metasurface into the cavity as its external mirror (Fig. 1), replacing both the bulk EO crystal and the diffraction grating. The electro-optic metasurface is made from an array of interdigitated electrodes covered by a layer of electro-optic polymer JRD1 and supports guided-mode resonances [2] which occur when the diffraction angles from the gold stripes coincide with the total internal reflection angle of the polymer slab. The metasurface is electro-optically active and the refractive index of the entire external mirror can be tuned electro-optically through the Pockels effect.

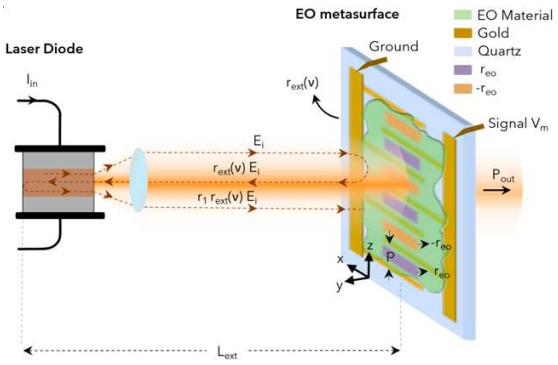

Fig. 1 Concept of metasurface-controlled external cavity tunable laser.

III. Results and Discussion

By opting for a resonant electro-optic metasurface as the external mirror, we simultaneously achieve single-mode and voltage-tunable frequency response. We demonstrate linear frequency tuning rates of up to 180 THz/s, with frequency excursions reaching 110 MHz under a 10 V peak RF drive, clearly surpassing rates attainable through piezoelectric actuation. When biasing the laser close to its threshold, our method also provides intensity modulation, exceeding 100% modulation efficiency at a peak RF voltage of 4 V.

IV. Conclusion

We have demonstrated a high-speed tunable external cavity laser in the telecom C-band, enabled by a single ultrathin electro-optic metasurface employed as the external cavity mirror. Further cavity [3,4] and resonance designs [5,6,7] can be considered in the future to improve the frequency excursion and stability of the devices proposed here.

***Abstract*—We present our work on maximizing the nonlinearity in CdO at its ENZ frequency to enhance the phase shift occuring due to the effective optical Kerr-effect tracing the ultimate goal of mid-IR single photon detection at room temperature. We discuss the nonlinear refractive index response to wavelength and angular tuning.**

***Keywords*— single photons, mid-infrared, optical Kerr effect, epsilon-near-zero material, nonlinear refractive index.**

I. Introduction

The generation and detection of single photons is a crucial part of the progress in quantum technology. The detection of light in the atmospheric transmission window in the mid-infrared (mid-IR) plays a crucial role in a variety of research fields such as materials characterization[1], quantum communication[2], and medical imaging[3]. Within this frequency regime, however, single photon detection has so far only been realized with cryogenic temperatures around 1K [4,5] due to the lower energy of mid-IR photons. Detector operation at room temperature comes at the cost of increased thermal background noise and a limited detector sensitivity as well as increased absorption and scattering.

We here present our scheme to circumvent these problems in a setup exploiting the benefits of cross-phase modulation. Our approach as shown in Fig. 1 is based on the effective optical Kerr-effect: A mid-IR signal beam travelling through a highly nonlinear medium can induce a phase shift in a second probe beam that is travelling through the medium simultaneously [6]. This phase shift is proportional to the signal beam photon population. A material with stronger nonlinearity leads to an increased phase shift induced by each photon and is thus highly desirable for mid-IR detection.

We use the well-established z-scan technique [7] to measure the nonlinearity of CdO at its epsilon-near-zero (ENZ) frequency. At the ENZ frequency, the complex dielectric permittivity ε is close to zero, leading to a maximized shift Δn in the nonlinear refractive index n_2:

$$\Delta n = \frac{\Delta \varepsilon}{2\sqrt{\varepsilon}}$$

.

We will discuss the influence of different parameters on the nonlinear refractive index, starting with the excitation wavelength. By changing the thickness of the CdO layer, we can actively tune the response of the nonlinear refractive index as the influence of the ENZ character owned by our sample changes. This will be further analyzed with angular sample rotation measurements, where we will discuss the influence of the ENZ condition vs. active coupling to ENZ modes.

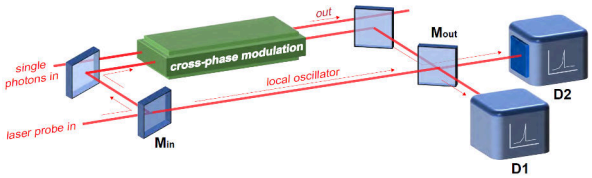

Fig. 1. Schematic of the single photon detection scheme. A laser beam at a probe frequency ω_{probe} is split into two beams, one at lower intensity guided through a strongly nonlinear medium and and a second higher intensity local-oscillator beam propagating in free space. Due to the effective optical Kerr effect, the electric field of a mid-IR signal travelling through the nonlinear medium simultaneously with the probe induces a phase shift in the probe beam. This phase shift is proportional to the signal beam photon population. The phase-shifted probe beam is then recombined with the local-oscillator beam in a Mach-Zehnder configuration, and the intensity difference recorded by the balanced detector is related to the phase shift induced on the probe beam by the signal beam.

***Abstract*— We demonstrate 800-fold enhancement of the second-order nonlinear response of hexagonal boron nitride (hBN) monolayers by a mid-IR phonon. This enables rapid imaging of the usually invisible monolayers with sum-frequency generation microscopy, revealing their crystal orientation. Furthermore, we characterize the nonlinear response of buried hBN interfaces with artificial stacking.**

***Keywords*— sum-frequency generation, hexagonal boron nitride, mid-infrared, 2D materials, nonlinear.**

I. Introduction

Hexagonal boron nitride (hBN) is an important material for infrared nanophotonics, quantum light emission and van der Waals heterostructures. The second-order nonlinear optical response of hBN is however typically much lower than that of other 2D materials, such as transition metal dichalcogenides, because the material has no optical resonances across the VIS and near-IR spectral ranges. This limits the applicability of hBN for nonlinear nanophotonics and makes monolayers optically almost invisible.

II. Methods

We employ phase-resolved sum-frequency generation (SFG) microscopy combining mid-IR and VIS femtosecond laser pulses to characterize the second-order nonlinear optical response of hBN.[1] The microscope provides combined spatial, spectral and crystallographic information, as described in previous works.[2-3]

hBN monolayers were grown by chemical vapor deposition (CVD) and subsequently transferred to a transparent fused silica substrate.[1,4] Thicker hBN slabs (~5-10 nm) were folded resulting in near-180° twist angles to realize stacking configurations with sliding ferroelectricity.[5]

III. Results and Discussion

We observe a strong enhancement of the nonlinear optical response when matching the mid-IR laser wavelength with the transverse optical (TO) phonon of CVD-grown hBN monolayers (Fig. 1b). The measured second-order nonlinear susceptibility exhibits a pronounced resonance at the TO phonon frequency with imaginary part $\chi^{(2)}_{\mathrm{eff}}(\omega_{\mathrm{TO}}) = 1.9 \cdot 10^{-19}\ \mathrm{m^2/V}$, which corresponds to an exceptionally large bulk susceptibility of $\chi^{(2)}_{\mathrm{eff}}(\omega_{\mathrm{TO}}) = 580\ \mathrm{pm/V}$ when assuming a thickness of 0.33 nm of the hBN monolayer. This is much larger than the off-resonant susceptibility $\chi^{(2)}_{\mathrm{eff}}(\omega_{\mathrm{VIS}}) \approx 20\ \mathrm{pm/V}$ and makes SFG of hBN monolayers equally efficient as second-harmonic generation in transition metal dichalcogenide monolayers. The TO phonon resonance therefore causes an ~800-fold enhancement of the SFG intensity.

The enhanced SFG response makes it possible to record nonlinear images of hBN across large 100×100 μm² sample areas in less than 1 s, enabling rapid screening of usually optically invisible monolayers. Furthermore, the polarization selection rules of SFG enable us to determine the full crystal orientation of the hBN monolayers. We analyze SFG images for various azimuthal sample orientations and obtain an image of the crystal orientation from a Fourier analysis of the rotation dependent signal (Fig. 1c). Comparison to DFT calculations reveals that the CVD-grown hBN monolayer flakes have nitrogen terminated zigzag edges, which could so far only be probed locally with atomic resolution microscopy techniques.

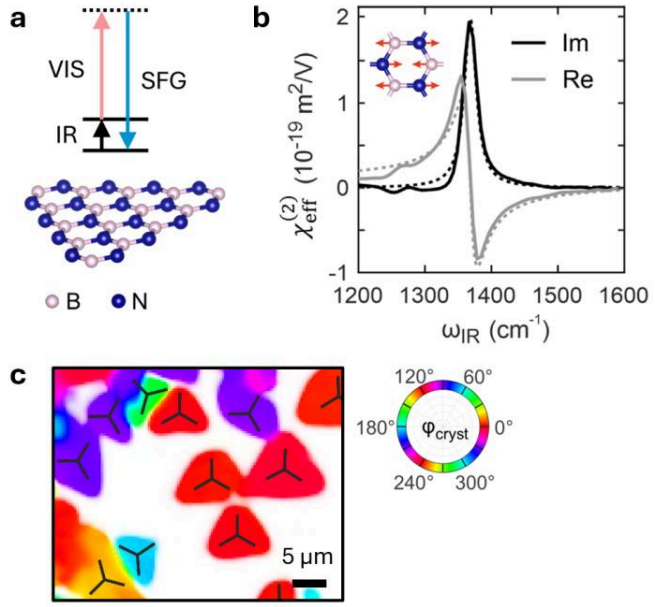

Fig. 1 SFG Spectro-Microscopy of hBN. (a) Scheme of SFG from fs mid-IR and VIS laser pulses (top) and crystal structure of hBN monolayer (bottom). (b) Spectrum of second-order nonlinear susceptibility enhanced by phonon resonance, with experimental data (solid) and fit (dashed). (c) Crystal orientation of hBN monolayers from phase-resolved nonlinear images. Colors show angles between B-N arm-chair directions (black lines) and *x* axis. Figure panels adapted from Ref. 1, Wiley-VCH, published under a Creative Commons Attribution (CC BY) license.

The second-order nonlinear response of hBN can be tailored by stacking and twisting several hBN layers. We find that CVD-grown hBN bi- and few-layers exhibit non-standard stacking configurations with an increased SFG signal. Furthermore, we characterize the SFG response of thin exfoliated hBN slabs that were stacked with near-180° twist angles. Kelvin probe force microscopy (KPFM) measurements reveal the formation of domains with out-of-plane static dipoles, a phenomenon known as sliding ferroelectricity.[5] SFG spectro-microscopy enables selective microscopy and spectroscopy of these buried interfaces, which break inversion symmetry. We observe a modified nonlinear optical response that depends on the twist angle. Furthermore, preliminary data reveal spectral shifts and broadening of the nonlinear phonon-spectra, which could arise from to the formation of domains walls with large uniaxial strain.

IV. Conclusion

We showed that the second-order nonlinear optical response of hBN is strongly enhanced by a phonon resonance in the mid-IR, which enables rapid imaging the usually optically invisible monolayers. Furthermore, we show that the nonlinear response can be tuned by artificial stacking and twisting of hBN. This enables efficient spectral conversion of mid-IR to visible light on the nanoscale and opens a toolbox for nonlinear mid-IR nanophotonics.

***Abstract*—We introduce wave mixing cathodoluminescence, combining visible light and focused electron beams to probe low-frequency excitations with nanoscale resolution. Calculations for a retinal-coated silver nanorod show that far-infrared vibrational fingerprints are up-converted to visible sidebands, enabling electron microscopy in electron microscopes without low-frequency detectors.**

***Keywords*— wave-mixing cathodoluminescence, electron-light wave mixing, sum- and difference-frequency generation, low-frequency excitations, nanoscale spectroscopy, cathodoluminescence, vibrational mode detection.**

I. Introduction

Nonlinear optics describes processes whose description requires going beyond the linear response of a given system. A particularly important example of such processes is wave mixing, whereby two or more input waves combine in nonlinear materials to generate output waves with new frequencies, with widespread applications in communication, imaging, sensing, and quantum optics. However, such applications are hindered by challenges like complex experimental setups, low nonlinear susceptibilities, and limited frequency generation, which cap the nonlinear conversion efficiency. While nonlinear processes are traditionally driven by intense laser fields, we present electron beams as an alternative source for wave mixing. Specifically, we introduce Wave-Mixing Cathodoluminescence (WMCL), in which a specimen is simultaneously illuminated by monochromatic visible light and a focused electron beam. We leverage the broadband and highly localized nature of the electron field to probe low-frequency excitations with nanoscale resolution.

II. Methods

We model wave-mixing cathodoluminescence (WMCL) by combining the self-consistent linear fields generated by a monochromatic optical pump and a swift electron beam with the second-order nonlinear response of the specimen. For a pump field $\mathbf{E}_{\rm pump}(\mathbf{r})\mathrm{e}^{-\mathrm{i}\omega_{\rm pump}t}$ and a frequency-resolved electron field $\mathbf{E}_{\rm electron}(\mathbf{r},\omega)$, the nonlinear polarization density at the emitted frequency $\omega_{\rm WM}$ is written as [1]

$$\mathbf{P}^{\nu}_{\rm WMCL}(\mathbf{r},\omega_{\rm WM}) = \chi^{(2)} : \mathbf{E}_{\rm pump}(\mathbf{r})\mathbf{E}_{\rm electron}(\mathbf{r},\omega), \quad (1)$$

where $\chi^{(2)}$ is the position- and frequency-dependent second-order susceptibility tensor corresponding to the three different WMCL channels under consideration, indexed by ν, with the appropriate frequency arguments [2]. The emitted field is then obtained from the electromagnetic Green tensor,

$$\mathbf{E}^{\nu}_{\rm WM}(\mathbf{r},\omega_{\rm WM}) = \int_V d^3\mathbf{r}'\, \mathcal{G}(\mathbf{r},\mathbf{r}',\omega_{\rm WM})\cdot\mathbf{P}^{\nu}_{\rm WMCL}(\mathbf{r}',\omega_{\rm WM}), \quad (2)$$

where V denotes the nonlinear material volume. From here, we obtain the far-field WMCL amplitude

$$\mathbf{f}^{\nu}_{\rm WM}(\Omega_{\hat{\mathbf{r}}}) = \int_V d^3\mathbf{r}'\, g(\Omega_{\hat{\mathbf{r}}},\mathbf{r}',\omega_{\rm WM})\cdot\mathbf{P}^{\nu}_{\rm WM}(\mathbf{r}',\omega_{\rm WM}) \quad (3)$$

where $\Omega_{\hat{\mathbf{r}}}$ denotes the emission direction $\hat{\mathbf{r}}$, and we implicitly defined the far-field Green tensor as $\mathcal{G}(\mathbf{r},\mathbf{r}',\omega_{\rm WM}) \approx g(\Omega_{\hat{\mathbf{r}}},\mathbf{r}',\omega_{\rm WM})\mathrm{e}^{\mathrm{i}k_{\rm WM}r}/r$. The far-field kernel is obtained from reciprocity by calculating the self-consistent near field produced inside the structure by plane-wave illumination incident from the opposite emission direction, following the procedure described in Methods of Ref. [2].

We start by addressing the case of small cavities (compared with all relevant wavelengths), which can be treated analytically in the electrostatic limit. The optical and electron fields inside the particle are uniform and approximately given by the external fields at the sphere center times a factor $3/(\epsilon+2)$ evaluated at the frequencies $\omega_{\rm pump}$ and ω, respectively. We use a Drude–Lorentz permittivity given by $\epsilon(\omega) = 1 + f\omega_{\rm r}^2/[\omega_{\rm r}^2 - \omega(\omega+\mathrm{i}\eta)]$, where f is a dimensionless factor, $\omega_{\rm r}$ is an intrinsic resonance frequency, and η is an inelastic damping rate. We calculate the corresponding output frequency emission rate out in a generic Drude metal spherical cavity for all different allowed outcomes of SFG and DFG in this limit and find that it is boosted when the incident light and/or electron beam resonates with the natural modes supported by the cavity, following $\omega_0 = \omega_{\rm r}\sqrt{1+f/3}$.

We extend the study to a retinal-coated silver nanorod, for which we calculate the optical and electron-induced fields with an axisymmetric boundary-element method [3]. Since silver is a centrosymmetric material, its second-order nonlinear response only arises from the nanorod surface, and is quantified by a nonlinear surface susceptibility $\chi^{(2)}$ for which we

Fig. 1. **Probing low-energy excitations through WMCL. (a)** Scheme of the structure under consideration, consisting of a silver nanorod (length $L = 100$ nm, radius $a = 10$ nm) coated by a retinal layer (thickness t). The structure is irradiated by a light plane wave of frequency $\omega_{\rm pump}$ and polarization along the rod. The electron moves with a velocity $v = 0.45\,c$ and passes at a distance $b = 3$ nm from one end of the coated rod. SFG and DFG produce output photon energies $\omega_{\rm WM} = \omega_{\rm pump} \pm \omega$ through the second-order susceptibility $\chi^{(2)}_{\perp\perp\perp}(\omega_{\rm pump}, \pm\omega, \omega_{\rm WM})$ at the silver surface. **(b)** CL spectra for bare ($t = 0$) and coated ($t = 5$ nm) silver nanorods under the geometry depicted in (a). **(c)** Normalized probability of SFG and DFG photon emission as a function of electron energy change. We plot the quantity $\mathcal{R}(\omega)/\xi^2$ for bare and retinal-coated nanorods, with $\mathcal{R}(\omega) = \Gamma_{\rm SFG/DFG}(\omega_{\rm WM})/\Gamma_{\rm CL}(\omega_{\rm WM})$, $\omega = \pm(\omega_{\rm WM} - \omega_{\rm pump})$, and $\xi^2 = \left|\chi^{(2)}_{\perp\perp\perp} E_{\rm pump}\right|^2/A$ combining the surface area of the nanorod $A = 2\pi a L$ and the incident light-field amplitude $E_{\rm pump}$. The upper horizontal scale indicates the output photon energy for the retinal-coated nanorod (blue curve), with the bare-nanorod counterpart (green curve) shifted by $+184.5$ meV. **(d)** Comparison of $\partial_\omega \mathcal{R}(\omega)$ to the imaginary part of the permittivity of retinal as a function of absolute electron frequency change $\omega = |\omega_{\rm WM} - \omega_{\rm pump}|$.

only retain the dominant $\perp\perp\perp$ component. Silver is described using tabulated experimental permittivity [4], whereas retinal is modeled as a sum of Lorentz oscillators fitted to its far-infrared vibrational response [5].

III. Results and Discussion

We first analyze a small nonlinear cavity in the electrostatic limit and find that the WMCL signal is maximized when either the optical pump or the electron spectral component is resonant with the cavity mode, confirming that plasmonic confinement can strongly enhance electron–light wave mixing (shown in Fig. 2 of Ref. [2]).

We then consider a retinal-coated silver nanorod, as schematized in Fig. 1a. The visible pump is tuned to the nanorod plasmon resonance, shown in Fig. 1b, for the bare (green curve) and coated (blue curve) nanorod. The resulting WMCL spectra are shown in Fig. 1c as a function of the change in electron energy, with the SFG and DFG spectra shown as filled and dashed curves, respectively. Compared with the bare nanorod, the coated structure exhibits features associated with retinal far-infrared vibrations. The top axis shows the detected energy for the coated case, which lies in the visible. The retinal vibration features are absent in the bare structure and become more evident in Fig. 1d, where we take the derivative of the normalized WMCL response with respect to $\omega = |\omega_{\rm WM} - \omega_{\rm pump}|$ (shown in blue), which closely follows the imaginary part of the retinal permittivity (dashed red). Therefore, the low-frequency molecular resonances are encoded in visible-frequency sidebands, while the CL background remains comparatively featureless. This comparison indicates that WMCL can identify analytes through their low-energy fingerprints using visible optical readout and nanometer-scale electron-beam localization.

IV. Conclusion

In summary, WMCL provides a practical route to probe low-frequency excitations by mixing monochromatic visible light with the broadband near field of swift electrons via the second-order response of a specimen. Our calculations show that this mechanism can up-convert far-infrared vibrational fingerprints to visible photon energies and recover the spectral signature of retinal in a plasmonic nanorod geometry. Beyond molecular vibrations, the same concept should apply to other low-energy modes, including phonon-polaritons, low-frequency plasmons, and magnetic excitations, offering a promising strategy for nanoscale spectroscopy in electron microscopes without relying on low-frequency detectors.

Limitations and Opportunities in Second Order Nonlinear Optical Materials: The Role of the Penn Gap

Jacob B. Khurgin
Department of ECE , Johns Hopkins University, Baltimore, USA

***Abstract*— This study investigates the limitations and potential of second order nonlinear optical (NLO) materials, focusing on the Penn gap as a critical parameter for predicting upper limits of nonlinear susceptibility, $\chi^{(2)}$. Results indicate that while substantial improvements in $\chi(2)$ are unlikely in the mid-infrared range, there is significant room for enhancement in the ultraviolet region. The goal is to combine a wide Penn gap with reduced bond polarity to facilitate the discovery of new materials with improved nonlinear optical properties.**

***Keywords*—nonlinearity, Penn gap, band gap, polarity**

Second-order nonlinear optical materials play a vital role in many photonic applications, but the range of materials used has not changed significantly over the last few decades. Despite improvements in material quality and processing methods, much of the field still relies on traditional compounds. This paper reassesses the achievable second-order nonlinear susceptibility ($\chi^{(2)}$) by focusing on the Penn gap, a parameter that has not been widely emphasized in the context of NLO materials but is instrumental for predicting the upper limits of $\chi(2)$.

The basis for $\chi^{(2)}$ is grounded in the absence of inversion symmetry within materials. Miller's Empirical Rule provides an important framework, illustrating the correlation between $\chi(2)$ and various macroscopic properties related to bond characteristics. While prior studies have examined the relationship between bond polarity and $\chi^{(2)}$ this research deepens the exploration of how these factors connect to the Penn gap, which represents the energy difference between bonding and antibonding states within a material.

The analysis highlights a notable relationship between fundamental bandgap energies and the Penn gap, emphasizing its influence on nonlinear optical responses. The results indicate that while current materials in the mid to far infrared range exhibit $\chi^{(2)}$ values close to theoretical limits, there remains significant potential for enhancing $\chi^{(2)}$ in the ultraviolet region.

This work specifically aims to establish upper limits for $\chi(2)$ rather than providing precise estimates, guiding researchers in their pursuit of materials that meet optimal conditions defined by the Penn gap. The findings show that exploring materials with wide bandgaps and favorable bond polarities in the ultraviolet range can offer opportunities to improve nonlinear optical performance.

In conclusion, the study suggests that future research should concentrate on identifying new inorganic materials characterized by advantageous bonding properties in relation to the Penn gap. This targeted approach could pave the way for advancements in second-order nonlinear optical properties crucial for the next generation of photonic technologies.

***Abstract*—Four-wave mixing (FWM) is a universal nonlinear process that can take place in any material under sufficiently strong optical excitation. We show how the polarization and spectra of quantum-correlated photon pairs produced by FWM can be tailored through the use of material resonances (phonon modes) and structural resonances (Mie-type modes and qBIC).**

***Keywords*— Photon pairs, Nonlinear optics, Four-wave mixing, Entangled photons, quantum optics**

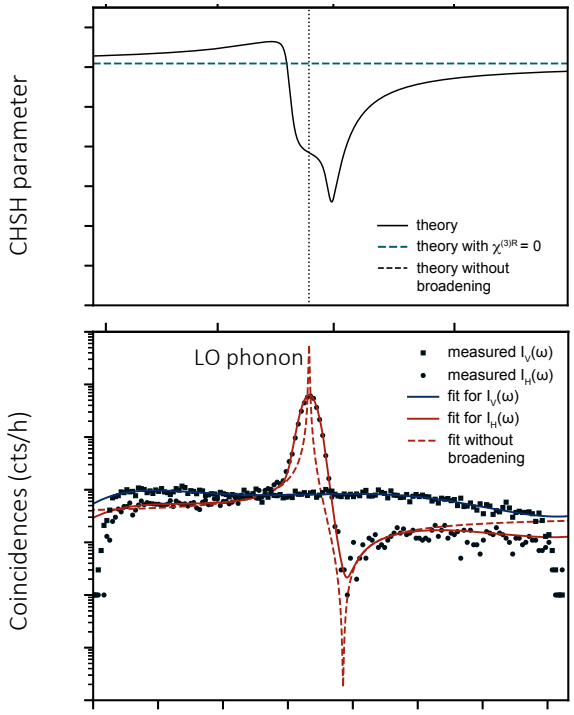

Fig. 1. **Polarization entangled photon pairs from bulk single-crystal diamond** The lower panel shows the raw photon pair coincidence detection rate under pumping with sub-ps laser pulses at 780 nm, as a function of the photon energy (expressed as detuning from the pump). The top panel is the measured polarization entanglement witness (CHSH parameter): a Bell inequality is violated in the blue-shaded area, demonstrating broadband polarization entangled photons generated by four-wave mixing. *Adapted from Ref. [1]*

I. Introduction

In the process of degenerate spontaneous FWM, two incident photons from the pump laser generate a pair of photons with respective energies symmetrically spaced around that of the pump. Compared to parametric down-conversion, FWM is not restricted by crystal symmetries and can occur in all crystalline and amorphous materials. Moreover, because the frequencies of the emitted photons can remain close to that of the pump, FWM is typically easier to phase-match, and working in a relatively narrow frequency band simplifies photonic design.

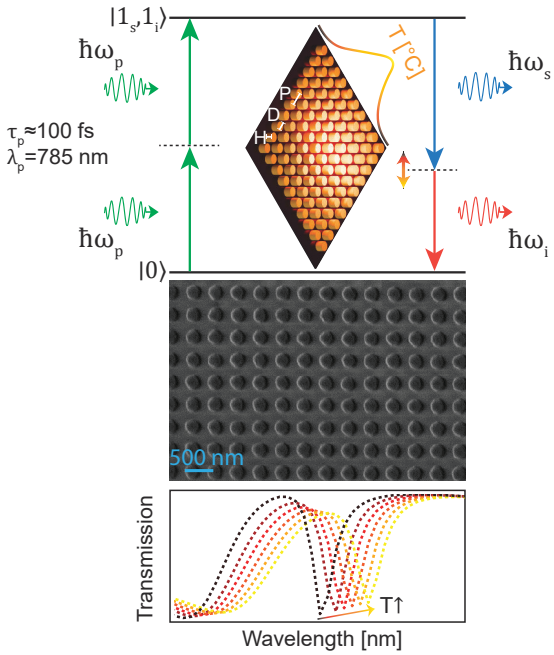

Fig. 2. **Photo-thermal tuning of photon pair generation in dielectric metasurfaces** Top panel: concept of the experiment, where spontaneous FWM converts two photons from the pump at 785 nm into a quantum-correlated photon pair at symmetrically detuned frequencies. The pump also causes local heating of the metasurface, thereby altering the nonlinear mode overlap and resonance frequencies and, consequently, the photon pair spectrum. Middle panel: scanning electron micrograph of a silicon metasurface on glass. Lower panel: shift of the resonance with temperature. *Adapted from Ref. [2]*

II. Methods

Experiments are performed under pulsed laser excitation (pulse duration varying between 200 and 800 fs, wavelength

centered around 785 nm). The diamond sample was a single-crystal plate cut along the [100] plane. The photon coincidence spectrum is measured by fiber spectroscopy (the dispersion translated frequency to time domain). The amorphous silicon metasurfaces were fabricated in EPFL Cmi clean room using electron beam lithography.

III. Results and Discussion

In this talk, I will address the challenges of polarization and frequency engineering of photon pairs produced by FWM. First, I will show how phonon resonances in a crystal like diamond can be used to tailor the biphoton polarization quantum state as a function of the detuning from the pump. [1], [3], [4] As shown in see Fig. 1, under appropriate geometrical conditions, polarization entangled photons violating a Bell inequality are produced out of the pumped diamond thin film without further optical engineering nor phase-matching constraints. I will also briefly explain how single-photon counting can be used to reveal quantum coherence among a macroscopic number of independently vibrating molecules [5], prepare nonclassical phonon states [6] and generate light-vibration entanglement [7].

Second, switching to amorphous silicon thin films, I will present an approach based on a Mie-mode metasurface to actively tuned the FWM spectral efficiency by the photothermal effect, as sketched in Fig. 2. [2]

IV. Conclusion

Our results motivate the further development of diamond photonic integrated circuits tailored to produce broadband polarization-entangled photons around any center wavelength in the material's transparency window. Our findings also link photothermally driven optical dynamics to quantum light generation, revealing a route to compact, reprogrammable photon-pair sources with wavelength trimming, fabrication-tolerance compensation, and fast power-controlled switching between brightness and purity regimes, features absent in static integrated devices.

***Abstract*— We experimentally investigate nonlinear self-action in a nonlocal metasurfaces supporting quasi-bound states in the continuum. By comparing picosecond and femtosecond excitation, we directly observe resonance-enhanced third-harmonic generation, saturation of cubic power scaling, and power-dependent spectral reshaping. Full-wave simulations link these effects to ultrafast resonance shifts driven by nonlinear refractive index modulation, revealing how high-Q field confinement governs nonlinear dynamics across different excitation regimes.**

***Keywords*— Quasi-bound states in the continuum, Nonlinear metasurfaces, Ultrafast nonlinear optics, nonlocal metasurfaces, Third-harmonic generation**

I. Introduction

Nonlinear light–matter interactions are central to frequency conversion, ultrafast control, and all-optical signal processing, yet their practical implementation is often limited by the weak nonlinear response of optical materials [1-6]. Dielectric nanostructures supporting high-Q resonances offer a compelling route to overcoming these limitations by providing strong field confinement with low losses and high damage thresholds [7]. Metasurfaces supporting bound states in the continuum (BICs), and their experimentally accessible counterparts, quasi-bound states in the continuum (qBICs), are among the most promising realizations of this concept [8, 9]. These resonances combine extreme field enhancement with long photon lifetimes, enabling efficient nonlinear processes in compact geometries [10-14]. However, the same properties that enhance nonlinear efficiency also render qBIC resonances highly sensitive to nonlinear self-action. Intensity-dependent refractive-index changes dynamically modify the resonance condition itself, leading to resonance shifts, saturation of harmonic generation, and deviations from simple power-law scaling. Such behavior places nonlinear qBIC metasurfaces within the broader context of time-dependent photonics, where ultrafast modulation gives rise to rich dynamical phenomena [15-17]. In resonant nonlinear nanostructures, however, this time dependence emerges intrinsically from strong field confinement and ultrafast material response, without the need for externally imposed modulation. Despite growing interest, nonlinear self-action in qBIC metasurfaces has largely been explored within isolated excitation regimes. In particular, how pulse duration and excitation bandwidth govern the coupling to high-Q resonances and the resulting nonlinear dynamics remains poorly understood. Here, we address this question by experimentally probing nonlinear self-action in a nonlocal dielectric metasurface using third-harmonic generation, directly comparing narrowband picosecond and broadband femtosecond excitation to reveal a unified mechanism governing nonlinear saturation, scaling, and spectral dynamics.

II. Results and Discussion

We probe nonlinear self-action in the qBIC metasurface via third-harmonic (TH) generation under two complementary excitation regimes, spectrally matched picosecond pulses and broadband femtosecond pulses, and find two distinct, experimentally robust manifestations of the same underlying mechanism. With a narrowband excitation tuned across the qBIC, the TH excitation spectrum shows a strong, resonance-peaked enhancement: TH conversion is maximized when the pump overlaps the qBIC wavelength. As input intensity is increased from 1 to ~10 MW cm^{-2} the resonant TH profile broadens, and the power dependence departs from the expected cubic law. More specifically we found that the TH signal follows cubic scaling away from the resonances, but near the resonance the fitted power exponent steadily decreases, approaching nearly linear scaling at the highest intensities (not shown). These observations indicate that intense, resonantly confined fields modify the effective optical response of the metasurface during the pulse, limiting conversion efficiency as the mode itself is reshaped by the pump field. On the other hand, when femtosecond excitation pulses are used, the pump inevitably couples less efficiently to the narrow qBIC mode due to its limited spectral overlap. In this regime, when the pump is detuned from the qBIC the TH spectra closely follow the pump spectrum and remain essentially power-invariant. In contrast, for pump wavelengths overlapping the qBIC we observe a pronounced spectral reshaping and broadening of the TH emission. The spectral changes include a narrow component that remains pinned to the resonant feature and a broader

component that tracks the pump spectrum, whose relative weights evolve with power. Full-wave time-domain simulations reproduce both the picosecond and femtosecond trends and attribute them to an ultrafast, intensity-driven modulation of the effective refractive index that dynamically shifts the qBIC during the excitation pulse. In the picosecond limit the pulse effectively drives the resonance over its lifetime, so a dynamically shifted resonance reduces field enhancement and produces saturation of conversion efficiency. In the femtosecond limit the pulse contains many spectral components that sample different instantaneous resonance conditions: the qBIC acts as a dynamic, intensity-dependent spectral filter, imprinting a transient spectral structure onto the TH emission. Thus, narrowband and broadband excitation reveal complementary facets of the same self-action physics, efficiency and power-law modification in the former, spectral reshaping in the latter.

III. Conclusion

We have experimentally demonstrated nonlinear self-action in dielectric metasurfaces supporting quasi-bound states in the continuum by directly comparing narrowband picosecond and broadband femtosecond excitation. Although these regimes couple to the same high-Q resonance in fundamentally different ways, both reveal the same underlying mechanism: ultrafast, intensity-driven modification of the resonant response. Our results establish qBIC metasurfaces as versatile nonlinear systems and provide practical guidance for controlling efficiency, scaling, and spectral dynamics in ultrafast nanophotonics.

A Boundary Element Method Solver for Dispersive Feibelman Parameters in Plasmonics

Ulrich Hohenester[1,*], Lorrenz Huber[1]

[1]Department of Physics, University of Graz, Austria

***Abstract*—We develop a computational Maxwell solver based on the boundary element method incorporating frequency dependent and dispersive Feibelman parameters, which accounts for nonlocal effects in plasmonic nanoparticles. Typical runtimes are comparable to those of normal simulations, and we discuss how to obtain the pertinent Feibelman parameters for realistic metals.**
***Keywords*— nanophotonics, nonlocality, Feibelman parameters.**

Optical excitation of plasmonic nanoparticles enables light confinement in subwavelength volumes and strong field enhancements [1]. When dealing with sharp particle features, narrow gap regions, or quantum emitters in close proximity to structures, quantum surface effects start to play an important role. Recently, it has been suggested to account for such quantum effects through mesoscopic boundary conditions [2] that incorporate frequency-dependent Feibelman parameters [3]. The question of how to describe and exploit nonlocal photonic materials and metamaterials has attracted in the past years considerably interest [4].

In this paper, we develop the methodology and implement mesoscopic boundary conditions into a computational Maxwell solver based on the boundary element method (BEM) [5]. Contrary to previous work [6], we additionally account for dispersive Feibelman parameters that are nonlocal in the directions parallel to the metal surface. It has recently been demonstrated from supplementary time-dependent density functional theory (TDDFT) simulations that the consideration of nonlocal parameters is imperative for the accurate description of situations where the electromagnetic fields vary on a nanometer range. We discuss the critical implementation details for a Galerkin BEM scheme with Raviart-Thomas basis elements.

We have additionally developed a modified Mie theory incorporating nonlocal Feibelman parameters, and show for sodium spheres that the results of Mie theory agree well with those of our BEM simulations. The simulation results converge perfectly to the analytic predictions when refining the mesh discretization in our BEM approach. Additionally, the computational cost for the novel scheme is shown to not differ significantly from normal BEM simulations, thus rendering our approach ideal for future investigations of different particle geometries and materials. We also discuss how the pertinent Feibelman parameters can be obtained for realistic metals from supplementary calculation schemes, either based on ab-initio TDDFT simulations or hydrodynamic model description schemes [4]. Altogether, we believe that our simulation platform makes Feibelman parameters accessible to a broader community, and could establish mesoscopic boundary conditions as an integral part of plasmonics simulations.

Mapping Nonlocal Bulk Continuum to Few Surface Modes

Runzhi Zou[1], Qiang Zhou[1,*], Pu Zhang[1,#], Xue-Wen Chen[1,†]

***Abstract*—The quasi-continuum of nonlocal bulk modes greatly complicates the optical responses of nanostructures and modal analysis. We establish a general framework to effectively map the nonlocal bulk continuum to few modes of an equivalent system, which admits the classical description and helps reveal physical insights from the complicated responses.**

***Keywords*— nonlocality, bulk modes, surface response, polar dielectrics**

I. Introduction

Photonic structures and devices with deep nanoscale geometric features have been experimentally feasible with advanced nanofabrication techniques and hold promise for improving performances in nanophotonic applications. Material nonlocality becomes indispensable for characterizing the localized fields in these multiscale systems, as it exerts significant influences through the induced longitudinal field interactions. The latter particularly complicate the responses by generating a quasi-continuum of bulk modes apart from perturbing surface modes. The typically subnanometer resolved mode patterns of the numerous bulk modes are almost fully confined inside nanostructures and thus often of limited interest, but pose grand challenges for theoretical description [1], [2]. Surface response models such as local analog and Feibelman's d-parameter models are specially appealing for studying the nonlocal responses due to their elegance and numerical efficiency [3], [4]. However, they are apparently incompatible with the description of the bulk modes. In this talk we report on a general framework that allows for accurate account of the bulk mode contribution to nonlocal responses with surface response models (SRMs), and more importantly effectively maps the nonlocal bulk continuum to few surface modes. Applicable to general nonlocal materials our theory provides a valuable asset for the nanophotonics community.

II. Theoretical Framework

The optical field scattered from a nanostructure is concerned in most situations. Making use of the dyadic Green's function, we prove that under certain conditions the nonlocal responses of the nanostructure can be accurately approximated with a volume-surface separated formulation of the scattered field

$$\mathbf{E}_{\text{sca}}(\mathbf{r};\omega) \approx \frac{k_0^2}{\varepsilon_0}\Bigg[\int_{\mathcal{V}} \bar{\bar{\mathbf{G}}}_0(\mathbf{r},\mathbf{r}';\omega)\mathbf{P}_{\text{LRA}}(\mathbf{r}';\omega)\,d^3\mathbf{r}' + \int_{\mathcal{L}} \bar{\bar{\mathbf{G}}}_0(\mathbf{r},\mathbf{r}';\omega)\mathbf{P}_{\text{ENL}}(\mathbf{r}';\omega)\,d^3\mathbf{r}'\Bigg]. \tag{1}$$

In essence, the scattered field results via the free-space Green's function $\bar{\bar{\mathbf{G}}}_0(\mathbf{r},\mathbf{r}',\omega)$ from a local response approximation (LRA) of volume polarization and an effective nonlocal (ENL) polarization in a surface layer of practically infinitesimal thickness. We emphasize that the latter surface contribution encompasses the bulk nonlocal effects. Based on this formulation, we are able to develop SRMs *e.g.* in vein of a preferred existing SRM to describe the nonlocal bulk modes. In the spirits of the LAM we demonstrate the surface layer is characterized with a permittivity ε_{ENL}. Then nanostructure is equivalently described with a system fully characterized with local permittivities, and seems to be readily prepared for modal analysis. Yet a physically meaningful quasinormal mode (QNM) analysis turns out only possible by further recognizing that ε_{ENL} in general should comprise of multiple Lorentzians

$$\varepsilon_{\text{ENL}}(\omega) = \varepsilon_{\infty,\text{ENL}} - \sum_{n=1}^{N} \frac{f_n \omega_{p,n}^2}{\omega^2 + i\omega\gamma_n - \omega_{0,n}^2}. \tag{2}$$

III. Results and Discussion

To exemplify the above theoretical framework we examine the nonlocal optical response of a 30 nm radius silicon carbide nanosphere dimer. Both our theory and the nonlocal theory for polar dielectrics [2] are deployed to calculate the extinction spectra of the dimer under a plane wave excitation and perform the QNM analysis for the extinction. The results are summarized in Fig. 1. As shown in Fig. 1(a), the QNM spectra of the dimer by the two theories manifest starkly contrasting features. The nonlocal theory leads to a quasi-continuum of QNMs, making the corresponding QNM analysis and reconstruction tedious and meaningless. Contrarily, our surface response model based QNM theory gives only few modes in the concerned spectral range. Thereby the QNM analysis becomes efficient and helps provide physical insights into the optical response of the dimer. In Fig. 1(b) the spectrum

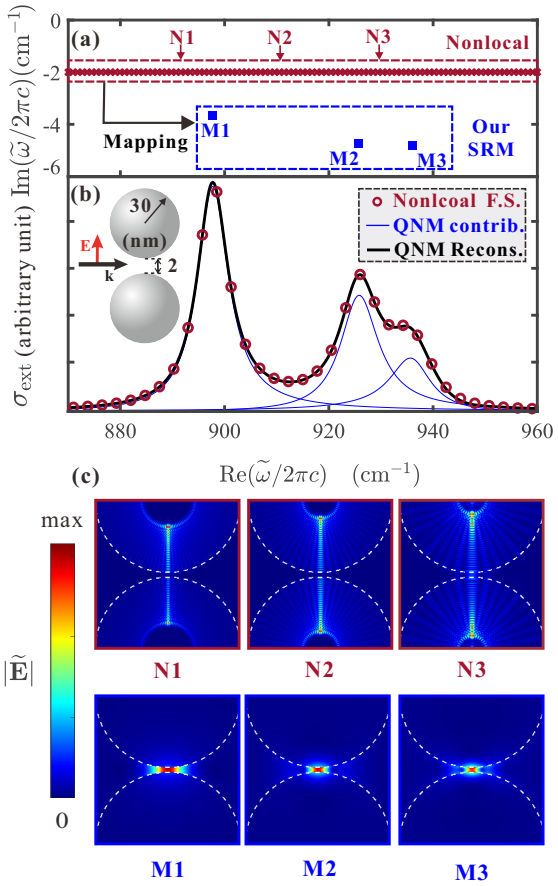

Fig. 1. Mode mapping from the nonlocal bulk mode continuum to few surface modes for a silicon carbide nanosphere dimer. (a) The QNM spectra on the complex wavenumber plane of the dimer according to the nonlocal theory and our SRM. N1, N2 and N3 are three randomly sampled QNMs from the quasi-continuum spectrum. (b) The extinction spectra of the dimer under a plane wave excitation calculated by nonlocal fullwave simulation (FS, red circles) and QNM reconstruction based on our SRM (black trace). The individual QNM contributions are depicted with blue traces. (c) The modal field pattern comparison between the sampled QNMs by the nonlocal theory and the dominant QNMs by the SRM.

reconstruction by the few QNMs successfully reproduces the extinction spectrum according to the nonlocal theory. The individual QNM contributions clearly reveal that three dominant modes are responsible for the optical response, instead of the numerous modes otherwise required in the nonlocal theory. The contrasting QNMs due to the two theories are furthermore illustrated with their modal field patterns in Fig. 1(c). All the three QNMs by the nonlocal theory have subnanometer scale standing wave patterns, which are computationally demanding to resolve and unnecessary for in most scenarios. In comparison, the dominant QNMs in our theory show rather clean patterns with vanishing field inside the nanospheres and enhanced field in the gap.

IV. Conclusion

In summary, we have established a theoretical framework which enables the description of nonlocal optical effects including bulk modes in multiscale nanostructures with convenient surface response models. More importantly its QNM theory effectively maps the quasi-continuum of bulk modes in a traditional nonlocal theory to few surface modes. Besides the application to polar dielectrics, we remark that the framework is built upon some general assumptions and is thus equally relevant in nanoplasmonics.

***Abstract*— We present a Volume Integral Equation (VIE) method for the analysis of scattering from spherical nanoparticles (NPs) described by the Quantum Hydrodynamic Theory (QHT). Exploiting the inherent symmetries, we overcome significant computational bottlenecks and explore convergence issues by investigating the asymptotic behaviour of matrix elements.**

***Keywords*— hydrodynamic models, quantum plasmonics, integral-equation methods**

I. Introduction

Semiclassical hydrodynamic models emerged during the first decades of the 21st century as an essential and popular framework for quantum plasmonics [1]. QHT [1, 2] is a very promising model, reconciling nonlocal electron dynamics with electron spill-out. Despite its strong predictive powers, it has been marred by performance [1] and convergence [2] issues, showing significant dependence on the computational domain, and in particular on the spill-out length. Here, we address both issues through a VIE lens [3].

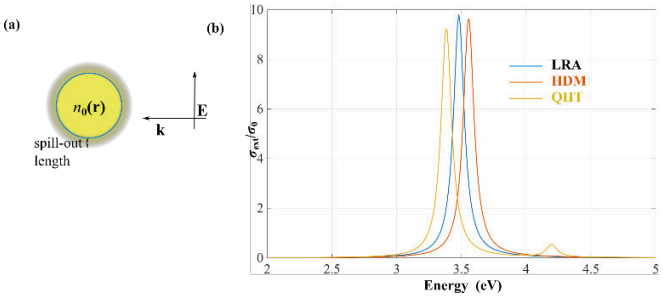

Fig. 1: (a) Scattering problem. (b) Normalised extinction cross-section for the Local Response Approximation (LRA), the Hydrodynamic Drude Model (HDM), and QHT.

II. Methods

The core element of the VIE perspective is to replace the scattering problem (see Fig. 1) with an equivalent current that induces the EM field everywhere in space. The dyadic Green's function becomes the mediator of the interaction between observation and source points and enables the introduction of IE formalism to the coupled system of QHT and Maxwell's equations. We then employ Method of Moments and Galerkin testing to acquire the linear system. The advantageous formalism together with exploiting spherical symmetries lead to computational performance on par with classical approaches.

To explore the notorious convergence issues of QHT, we investigate the asymptotic behaviour of matrix elements due to material contributions far from the origin of the NPs.

III. Results and Discussion

Our method can probe hundreds of frequency points for spherical NPs in a matter of seconds on a personal laptop. In Fig. 1, we show the extinction cross-section of a 4 nm sodium NP using three material models of progressive sophistication. QHT accurately predicts redshift with respect to the classical localized plasmon as well as the so-called Bennett resonance.

We find that the material kernels of the matrix elements involved grow exponentially the further we move away from the origin. This leads to large differences in the amplitudes of different matrix elements, and as such to severe ill-conditioning and eventual collapse of the method.

IV. Conclusion

We have demonstrated an efficient VIE method able to treat spherical NPs described by the advanced QHT. We have further analysed the asymptotic behaviour of the matrix elements and deduced that the method becomes progressively ill-conditioned as the spill-out length is increased.

***Abstract*— Near field enhancement is the base for a wide range of plasmonic applications. Probing fundamental limit of plasmonic field enhancement is technically challenging. Using atomic layer material as probe, we show that the averaged electric field enhancement in a resonant Ag nanocavity reach > 1200 times, extrapolating to > 1600 times for the maximum position. Using a single QD, we show that the vacuum field of a plasmonic mode is highly localized around a tip.**

***Keywords*— field enhancement, quantum tunneling, plasmon-exciton coupling, SERS.**

Correlated dark-field scattering spectra and transmission electron microscope reveals that there is always a dip in the scattering spectrum if a QD is attached around the tip of a Au nanotriangle. If it attaches to the side edge of the triangle, the dip is less pronounced or even disappear (see Figure 1). There is a clear correlation between the plasmon-exciton coupling strength and the precise position of the QD (Figure 2), reflecting the highly localized vacuum field of the plasmon.

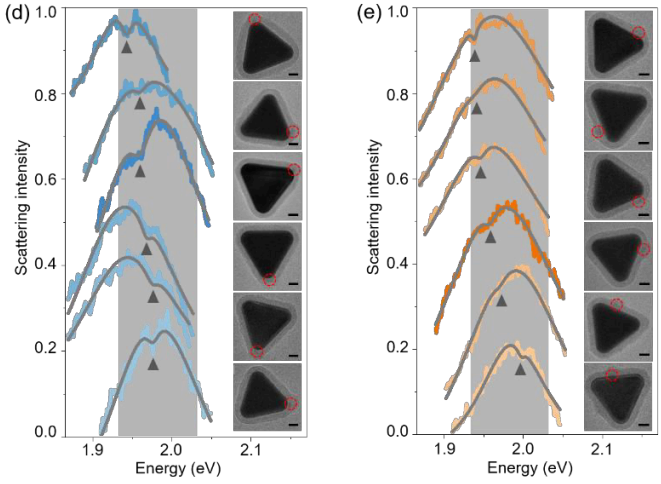

Figure 1. Scattering spectra of a Au nanotriangle-QD hybrid, correlated with transmission electron microscope image on the right. Scale bars are 20 nm.

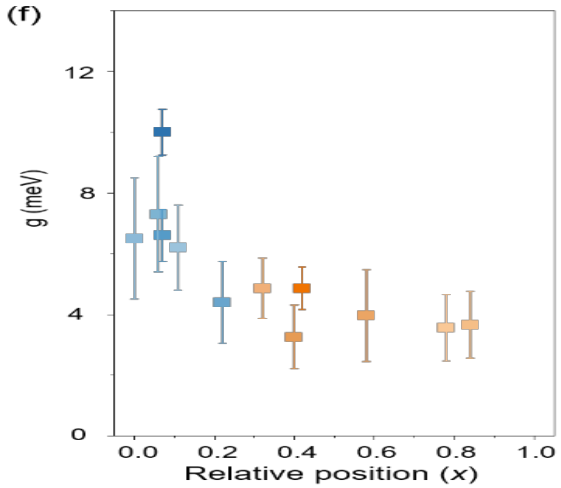

Figure 2. Distributions of the coupling strength g as a function of relative position of the QD.

***Abstract*— In this work, we investigate lattice resonances in periodic arrays of time-modulated scatterers by modelling each scatterer as a harmonic oscillator with periodically varying optical properties. Our work establishes a simple theoretical framework for understanding collective lattice resonances in time-modulated arrays, enabling dynamic control and amplification of these modes.**

***Keywords*— time-varying, lattice resonances, periodic arrays, amplification, nanolasing.**

I. Introduction

Lattice resonances are collective modes emerging from coherent multiple scattering in periodic arrays of scatterers [1]. These resonances, owing to their collective nature, are characterized by an inherent nonlocal behavior and exhibit enhanced lifetimes and optical responses compared to those of individual scatterers. Despite extensive theoretical and experimental studies in passive systems, their behavior and potential applications when supported by time-modulated arrays remain largely unexplored.

II. Methods

We model each scatterer as an electric dipole whose temporal dynamics follow a harmonic oscillator equation with periodically modulated properties [2]. We include radiative losses through an Abraham-Lorentz term. This framework covers a wide range of systems that display dipolar resonances, regardless of their physical nature. We exploit the periodic nature of the modulation, and we expand both the dipole moment and the external field in Floquet series. This procedure allows us to define a polarizability tensor that relates the Floquet coefficients of the dipole to those of the external field. We then analyze the response of the system through its absorption. Absorption takes positive values when dissipation dominates, and it becomes negative when the system radiates more energy than it absorbs, a condition that signals amplification.

III. Results and Discussion

Our calculations show

- Amplification in time-modulated individual scatterers for sufficiently large modulation amplitudes.
- An intuitive picture to understand the amplification mechanism based on the evolution of eigenfrequencies with modulation amplitude and frequency.
- Amplification enabled by lattice resonances in periodic arrays, requiring significantly smaller modulation amplitudes than isolated scatterers.
- Nonlinear scattering at frequencies generated by the mixing of the excitation and modulation frequencies.

IV. Conclusion

We predict that lattice resonances in periodic arrays of time-modulated scatterers enable amplification at reduced modulation amplitudes. Thanks to our general framework, these results apply to a wide range of systems regardless of the nature of the scatterers.

Nonlocal metasurfaces controlling the geometric phase and direction of light

Adam C. Overvig[1,*]

[1]Department of Physics, Stevens Institute of Technology, USA

***Keywords*— nonlocal metasurface, geometric phase, photonic crystals.**

Summary:

We discuss progress in the field of nonlocal metasurfaces to control the direction of light scattering within a narrow bandwidth. Most notably, we engineer the local scattering properties of nonlocal modes called quasi-bound states in the continuum via symmetry-breaking design concepts. We clarify how geometric phases arise in this process, both based on polarization properties for resonant polarization-dependent reflection, and a scalar geometric phase representing a novel manifestation of the "detour phase", previously associated with the computer generated holography community. We overview the application of these ideas to several new areas, including reflectarrays overcoming previous efficiency limits of single-layer devices; multipolar nonlocal metasurfaces supporting rationally designed unidirectional modes; topological cavities controlled by the scalar geometric phase; and nonlinear metasurfaces with narrowband control of the harmonic generation.

Single-cycle optical nonlinearity of transparent conducting oxides explained

Abstract: We provide a quantitative model for the electro-optic response of transparent conducting oxides to single cycle intense pulses. We show that the interplay between spatio-temporal aspects of absorption, stimulated emission and multi-photon absorption can explain the weaker-than-before nonlinear response observed in experiments, as well as on the unexplained relaxation dynamics.
© 2023 The Authors

Time-reversal (sometimes referred to as time-reflection), time refraction and temporal photonic crystals are exotic nonlinear optical effects that attracted a lot of interest and debates in recent years. The challenge associated with realizing these effects in experiment is the need for a strong and rapid changes to the material permittivity. Transparent conducting oxides were identified as the most promising candidate materials to enable these manipulations due to their associated extremely large optical nonlinearity, reaching 100's of percent of the refractive index/permittivity [1].

After a decade of extensive experiments, a comprehensive quantitative theoretical (Boltzmann-based) description of their electronic, thermal and optical response was obtained in [2]; it revealed the cumulative (absorptive) thermal nature of their optical nonlinearity, and quantified its strength correctly in terms of the total energy in the electron sub-system. Yet, the model in [2] was capable of explaining experiments done with pulse durations of a few picosecond down to 50-100 femtosecond, but is unsuitable to describe the dynamics due to intense *single-cycle* illumination. Such extremely short illumination is needed to probe the claims of instantaneous turn-on of the optical response [1] as well as the femtosecond scale turn-off dynamics required for the realization of temporal photonic crystals. In particular, the formulation of [2] is not suitable to model the unexpectedly-short 50-100 femtosecond decay rate of the transmission observed in [3].

To meet this challenge, we have extended the formulation of [2] by switching to the density matrix formulation. This approach treats (previously-ignored) coherent aspects of the photon-electron interactions and allows accounting for coherent control schemes via phase manipulations of the incoming pulses. We find that stimulated emission approaches absorption levels at high intensities, yet, the system only reaches partial transparency (see Fig. 1(a)) due to the absence of population inversion in the remainder of the conduction band. In that regard, stimulated emission gives rise to a weaker nonlinearity (see Fig. 1(b)), but cannot invert its sign.

We then characterize the thermalization occurring under the extreme non-equilibrium conditions in the non-parabolic and narrow conduction band, and provide a simple theory that captures its new features (see Fig. 1(c)). Finally, we show that electron-phonon interactions are too weak to explain the observed fast transmission relaxation, but that a (multi-photon) absorption of valence band electrons (modelled via DFT), and spatial dynamics and substrate effects can explain experimental findings. Our approach paves the way for quantitative modelling of time-varying photonics and coherent wave control on few-femtosecond timescales in these systems.

***Abstract*—Using a quantum hydrodynamic model, we show that hyperbolic plasmon–polaritons in few-layer black phosphorus are strongly renormalized by nonlocal effects. We further demonstrate that nonlocal electrodynamics is essential to describe plasmon–phonon–polariton dispersion in twisted bilayer graphene on talc obtained from SNOM measuraments.**

***Keywords*— plasmons, anisotropic, quantum hydrodynamic model, graphene, twisted bilayer graphene, two-dimensional materials, snom**

I. Introduction

The hydrodynamic model has emerged as a versatile and robust framework for studying the light-matter interaction in condensed matter. It was successfully applied in various systems: metals, heavy-doped semiconductors, and two-dimensional (2D) materials. Here, we will focus on surface plasmon-polaritons in 2D materials, including, as examples, graphene and phosphorene.

II. Hydrodynamic model in graphene

For the semimetal graphene, we derive a hydrodynamic model from the Boltzmann equation considering a Drude mass for graphene electrons, which links the Fermi momentum with the Fermi velocity. We study the formation of plasmonic wakes when transverse fast electrons move parallel to the graphene sheet, obtaining simple expressions for the electrostatic potential. We demonstrate a transition from Mach-type wakes at high speeds to Kelvin-type wakes at lower speeds, obtaining the plasmonic parameters to calculate the Froude number. The electron-energy loss spectrum was calculated, which shows the effect of resonances caused by graphene surface plasmons [1].

III. Nonlinear and nonlocal properties of plasmons in two-dimensional materials

We study a 2D electron gas using the Madelung equations for quantum mechanics in conjunction with Poisson's equation; we calculate the spectrum of magnetoplasmons and the magneto-optical conductivity in the electrostatic regime, incorporating nonlocal corrections due to the Fermi pressure and the Bohm potential. We analyze nonlinear and nonlocal second-harmonic generation, demonstrating how plasmon excitation enhances this process. We further discuss the self-modulation that renormalizes the plasmon dispersion, driven by nonlinearity. For both cases, we obtain simple analytical expressions [2].

IV. Nonlocal electrodynamics in anisotropic plasmons

Using the Madelung formalism, we apply it to anisotropic systems. As a case study for an anisotropic two-dimensional electron gas, we applied our model to electrons in monolayer black phosphorus, i.e., phosphorene. The plasmon dispersion obtained with the hydrodynamic model is in excellent agreement with ab initio calculations. We then focus on the study of surface plasmon-polaritons, which can be hyperbolic in the case of phosphorene when the contributions from interband transitions are included in the optical conductivity. Our findings demonstrate that including nonlocal effects in the optical conductivity inhibits phosphorene to host hyperbolic surface plasmon-polaritons, which shows the importance of going beyond Drude or other local models to describe plasmon-polaritons in hyperbolic media [3].

V. Plasmon-phonon-polaritons in twisted bilayer graphene

Recently IR s-SNOM measurements of twisted bilayar graphene over talc [4] revealed strongly confined plasmon-phonon polaritons. Talc, a van der Waals phyllosilicate, induces p-type doping in graphene, and its phonon modes hybridize with graphene plasmons, giving rise to ultra-confined surface plasmon–phonon–polariton (SP^3) modes. We demonstrate that a local electromagnetic description of graphene's conductivity is fails to reproduce the measured dispersion relation of the SP^3 modes, whereas a nonlocal hydrodynamic model correctly quantitatively captures the experimental results.

***Abstract*—Using time-dependent density functional theory, we study electron dynamics in metallic nanostructures under different excitation conditions, including continuous-wave illumination, ultrashort pulses, quantum emitters, and fast electron beams, and investigate the role of nonlocality, nonlinearity, and other quantum phenomena in the excitation of plasmonic resonances, harmonic generation and nanoscale electron transport.**

***Keywords*— TDDFT, Feibelman parameter, Landau damping, EELS, harmonic generation, ultrafast dynamics, photoemission.**

I. Introduction

Plasmonic nanostructures enable the manipulation of light at the nanoscale, giving rise to confined and enhanced optical fields within volumes on the order of nm^3. As a result, quantum effects such as nonlocal dynamical screening and strong-field nonlinearities gain importance in optical and electronic responses, challenging classical or semiclassical descriptions. Such effects manifest, for example, in energy shift and broadening of localized surface plasmon resonances (LSPRs) of metallic nanoparticles (MNPs) and in optical field emission from MNPs.

In this context, time-dependent density functional theory (TDDFT) provides a fully quantum-mechanical framework that captures these effects in a unified manner without fitting parameters. Here, we employ TDDFT to investigate nonlocal and nonlinear response of MNPs, as well as electron tunneling and photoemission, under a variety of excitation conditions, including cw illumination, ultrashort and intense optical pulses, interactions with quantum emitters (QEs), and fast electron beams.

II. Methods

Our approach is based on the direct solution of the Kohn–Sham equations within TDDFT,

$$i\frac{\partial}{\partial t}\Psi_j(\mathbf{r},t) = \hat{H}[n(\mathbf{r},t)]\,\Psi_j(\mathbf{r},t),$$

where the time-dependent Kohn–Sham Hamiltonian is given by

$$\hat{H}[n(\mathbf{r},t)] = \hat{T} + V_{\text{eff}}[n(\mathbf{r},t)] + V_{\text{ext}}(\mathbf{r},t),$$

with $\hat{T}$ being the kinetic-energy operator, $V_{\text{ext}}(\mathbf{r},t)$ the external potential driving the excitation, and $V_{\text{eff}}[n(\mathbf{r},t)] = V_{\text{H}}[n(\mathbf{r},t)] + V_{\text{xc}}[n(\mathbf{r},t)]$ the effective potential, including Hartree and exchange–correlation contributions. The electronic density is computed as $n(\mathbf{r},t) = \sum_{j\in\text{occ}} \chi_j |\Psi_j(\mathbf{r},t)|^2$, where the sum runs over all initially occupied Kohn–Sham orbitals $\Psi_j(\mathbf{r},t=0)$, with degeneracy factors χ_j. The initial ground-state orbitals are obtained from the static Kohn–Sham equations.

Numerical implementation of the time-dependent Kohn–Sham equations is performed using wave-packet propagation on a real-space mesh. In our real-time TDDFT calculations, the metal is treated within the jellium model, where the ionic charge density is represented as a uniform positive background. This framework allows us to address plasmonic systems of sufficiently large size to be directly comparable with experiments. Complementary atomistic calculations are performed within the linear-response frequency-domain framework using the PyNAO package [1].

III. Results and Discussion

First, we analyze nonlocal effects in coupled MNP–QE systems, where LSPRs in simple MNPs (such as, e.g. alkali metals) are found to redshift and broaden as the nanoparticle size decreases. These trends originate from nonlocal dynamical screening and the finite potential barrier at the metal surface, which give rise to spill-out of the induced electron density and to surface-enabled Landau damping. For QEs positioned within nanometric plasmonic cavities, the TDDFT description of the nonlocal metallic response can, in many situations, be accurately reproduced by the surface-response formalism (SRF) [2], particularly when employing *dispersive* Feibelman

parameters $d_\perp(\omega, k_\parallel)$ that depend on both frequency and parallel momentum transfer [3]. This extension is essential for properly describing higher-order LSPRs involving large in-plane wavevectors and extreme field localization. However, when the cavity size is reduced to subnanometric MNP–QE separations, the TDDFT results show the emergence of charge-transfer processes [4], [5]. Consequently, the SRF breaks down because it cannot account for electronic-state hybridization and tunneling across the junction.

Next, we turn to the influence of nonlocal effects on plasmonic modes confined within the nanoparticle volume. The nonlocal response of the electron cloud in MNPs affects not only LSPRs but also confined bulk plasmons (CBPs), which correspond to longitudinal collective oscillations of the electron density. Since CBPs cannot be efficiently excited by light, we employ penetrating electron beams to analyze their modal structure [6]. Our TDDFT calculations show that, for electron trajectories passing through the MNP center, the electron-energy loss spectrum is dominated by a pronounced CBP peak near the plasma frequency ω_p, corresponding primarily to the angularly symmetric (monopolar) mode, and is accompanied by weaker higher-energy multipolar bulk modes. As the electron-beam impact parameter increases, the excitation strength of the higher-order multipolar modes increases, and additional CBP resonances appear, resulting in a blueshift of the main CBP peak. The robustness of these trends is further corroborated by complementary calculations based on a classical hydrodynamic model.

We then consider nonlinear optical processes in plasmonics, which become relevant when the system is driven by intense electromagnetic fields and are strongly determined by the geometry and symmetry of both the nanostructure and the driving field. For an axially symmetric metallic nanowire driven by light linearly polarized perpendicular to the nanowire axis, our TDDFT calculations show that far-field scattering occurs exclusively at odd harmonics of the fundamental frequency, consistent with axial symmetry. When the nanowire is excited by circularly polarized light (in the plane perpendicular to the nanowire axis), the nonlinear optical response is clearly distinct [7]: i) any harmonic emission into the far field is suppressed and ii) multipolar near fields are induced at the harmonic frequencies carrying spin angular momentum opposite to that of the incident field. Furthermore, our TDDFT results show that coupling QEs to centrosymmetric MNPs activates second-harmonic generation in the far field and enables control of this otherwise symmetry-forbidden process [8].

Finally, we explore a different class of nonlinear processes, namely electron transport across (sub)nanometric metallic junctions induced by ultrashort single-cycle or few-cycle optical pulses. Real-time TDDFT calculations allow us to track the ultrafast electron dynamics and identify distinct transport regimes. In particular, we identify photon-assisted tunneling and over-the-barrier transitions associated with multiphoton absorption at low optical fields, and adiabatic optical-field emission at high optical fields [9]. Additionally, we investigate how these transport regimes evolve as the junction size is further reduced and a dc bias is applied [10].

IV. Conclusion

We have presented a TDDFT-based study of quantum effects in nanoplasmonics, with a focus on nonlocal and nonlinear responses, as well as electron tunneling and photoemission, under excitation by continuous illumination, ultrashort single-cycle pulses, and fast electron beams. Our work provides a fully quantum-mechanical picture of nanoscale light–matter interaction and electron dynamics, revealing rich phenomena under extreme conditions. These insights advance our understanding of photonic and optoelectronic systems and suggest strategies for controlling spectroscopy, high-harmonic generation, and ultrafast electron transport in next-generation nanoscale devices.

***Abstract* – We use THz pulses to manipulate the optical response of $MoSe_2$ and WSe_2 monolayers, and $MoSe_2/WSe_2$ heterostructures. This method can be used to control excitonic populations on ultrafast time-scales, to access optical-driven nonlinear properties of matter and to design photonic devices with THz switches.**

***Keywords* - terahertz, 2D materials, optical control of matter**

I. Introduction

An important avenue of research is to find means for external control of light-matter interaction by tailoring on-demand the optical response of materials. In this way, it is possible to realize reconfigurable photonic devices.

2D semiconductors offer a promising and versatile platform to reach this goal. In fact, they feature high exciton binding energies that lead to a strong light-matter coupling [1] and their optical response is easily reconfigurable by the application of voltages, strain fields, and by patterning the dielectric environment [2]. However, there are major limitations to how fast the optical response of these materials can be tuned, restricting the majority of applications to an essentially static regime. Here, we use short THz pulses to manipulate the optical response of 2D semiconductors on an ultrafast time scale, showing a fascinating route for optically-controlled photonic devices and optically-triggered nonlinear properties of matter.

II. Methods

A sketch of the introduced experimental approach is shown in Fig. 1a. The picosecond, spectrally narrow THz pulses are generated at the infrared Free-Electron Laser facility (FELBE) at 13 MHz repetition rate with tunable photon energies [3]. Visible pulses (λ = 400 nm) are obtained from a frequency-doubled Titanium:Sapphire laser to excite populations of electron-hole pairs into the 2D semiconductors, that then form complex excitonic quasiparticles, such as excitons, trions, and

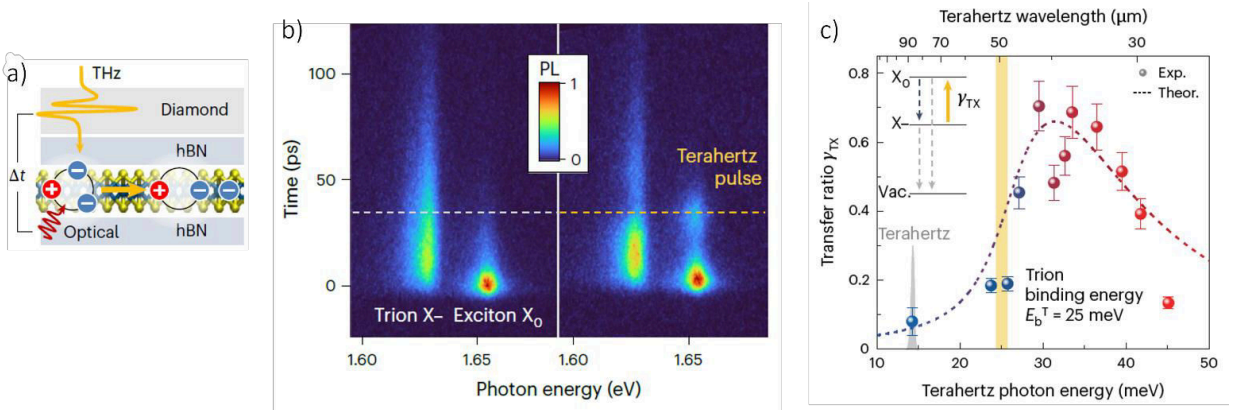

***Figure 1**: (a) Sketch of the experiment. (b) Time-resolved PL spectra of $MoSe_2$ monolayer with and without THz pulses. (c) Fraction of trions transferred to excitons as a function of THz photon energy.*

biexcitons [1]. The exciton dynamics is subsequently monitored by recording time-resolved photoluminescence (trPL) spectra with a streak camera. The arrival of the THz pulse is controlled by an externally tunable delay. We study different Transition Metal Dichalcogenide monolayers and heterostructures, such as $MoSe_2$, WSe_2, and $WSe_2/MoSe_2$. All the samples are encapsulated in hBN and deposited on a diamond substrate.

III. Results and Discussion

Figure 1b shows the trion and exciton dynamics in MoSe2 monolayer after optical excitation [4]. By adding THz pulses after about 30 picosecond delay with respect to the visible excitation (Fig 1b, right panel), we observe a strong quenching of the trion emission and a temporary brightening of the exciton emission. Furthermore, by tuning the frequency of the THz pulses, we record the THz deionization spectrum of trions (Fig. 1c). Importantly, efficient trion-to-exciton conversion is observed when the THz photon energy is equal or higher than the trion binding energy.

Recently, we observed similar impact of THz radiation in other materials such as WSe_2 monolayers [5] and $MoSe_2/WSe_2$ heterostructures [unpublished], that host more complex excitonic species such as charged biexcitons and interlayer excitons, respectively. In particular, we show that beyond manipulation of charged excitonic complexes, THz can induce both triplet-to-singlet and inter-to-intralayer exciton transitions in heterobilayers.

IV. Conclusion

Altogether, the results open promising pathways towards external optical control of many-particle excitonic states in 2D semiconductors. This method can be employed to access non-equilibrium nonlinear properties of matter and to tailor the optical response of low-dimensional materials for reconfigurable photonic devices with ultrafast THz switches.

***Abstract*— The hydrodynamic behaviour of free electrons generates strong nonlinear optical response when the effective mass is small, as in the n-type doped semiconductors InGaAs and Ge. We show nanoantennas and waveguides where the nonlinear response depends on carrier density, is resonant with antenna geometry, and tunable with a field-effect voltage.**

***Keywords*— nanoantennas, mid-infrared, doped semiconductors, hydrodynamics.**

I. Introduction

Two fundamental mechanisms exist in a plasmonic structure for the enhancement of the instantaneous nonlinear optical response. The first mechanism is the well-known dielectric nonlinear susceptibility of bulk materials hosting or surrounding the free electrons, which can be enhanced by the local plasmonic field enhancement. The second mechanism is due to the collective motion of free electrons under an external driving field, which can be modeled by a set of hydrodynamic equations of motion in analogy with a classical fluid. While there is a physical limit to the maximum dielectric nonlinearity, related to the form of anharmonic potential that sets upper bounds for $\chi^{(2)}$ and $\chi^{(3)}$ [1], there is no such a limitation to free-electron nonlinearities that increase in strength when the electron effective mass is small, as it is the case in many n-type doped semiconductors such as (In,Ga)As and Ge, which are extremely relevant for the development of integrated photonic technology [2]. Even though the response of a homogeneous electron gas is intrinsically nonlinear, coupling the free-electron nonlinear field to the far-field requires the patterning of the free-electron host medium into well-designed nanostructures, which can also resonantly enhance the local fields and field gradients [3], and therefore the nonlinear effects.

If the semiconductor is very heavily doped at the solubility limit, its plasma frequency can reach the mid-infrared here defined as the wavelength range between 5 and 12 μm, short enough for the development of on-chip photonic integrated circuits (PICs), but long enough for the fabrication of lithographic plasmonic cavities and nanoantenna arrays illuminated at normal incidence. In addition, in doped semiconductors the free electron density (and, with it, the optical nonlinearity) can be voltage-tuned with a metal gate electrode separated from the semiconductor by a dielectric (oxide) layer. In this work, we show several experiments conducted on doped semiconductor nanostructures in the last years on nanoantennas and integrated waveguides that support the above picture of hydrodynamic enhancement of optical nonlinearities in the mid-infrared, and, more generally, of nonlocal effects that shift the resonance frequency of deeply sub-wavelength cavities.

II. Methods

The nonlinear and nonlocal dynamics of a free-electron fluid under external electric and magnetic fields, $\mathbf{E}(r, t)$ and $\mathbf{H}(r, t)$, is described by the following equation for the electron density $n(r, t)$ and current $\mathbf{J}(r, t)$:

$$m^*\left(\frac{\partial}{\partial t}-\frac{\mathbf{J}}{en}\cdot\nabla+\gamma\right)\frac{\mathbf{J}}{en}=e\mathbf{E}-\frac{\mathbf{J}}{n}\times\mu_0\mathbf{H}+\nabla\frac{\delta G[n]}{\delta n} \quad (1)$$

where μ_0 denotes the magnetic permeability, e the electron charge, γ a suitable damping rate of free-carrier oscillations, and $G[n]$ is the free-energy functional whose derivative vs. n gives the *quantum pressure* of the fluid, related to Thomas-Fermi

screening and Pauli exclusion principle. We use this equation in combination with Maxwell's equations to simulate and predict the linear and nonlinear behavior of the investigated semiconductor nanostructures.

Fabrication is carried out at CNRS and CNR facilities mainly with electron-beam lithography, lift-off of metal layers and dry etching of semiconductor layers. Notably, ridge waveguides with vertical walls are obtained by inductively-coupled plasma etching. HfO_x deposited by atomic layer deposition is employed as the gate oxide for the field-effect devices.

Linear and nonlinear optical measurements are performed, respectively, by Fourier-transform infrared spectroscopy and by optical pumping of the semiconductors with short mid-IR pulses (duration of the order of 100 fs) generated by optical parametric amplifiers (OPA).

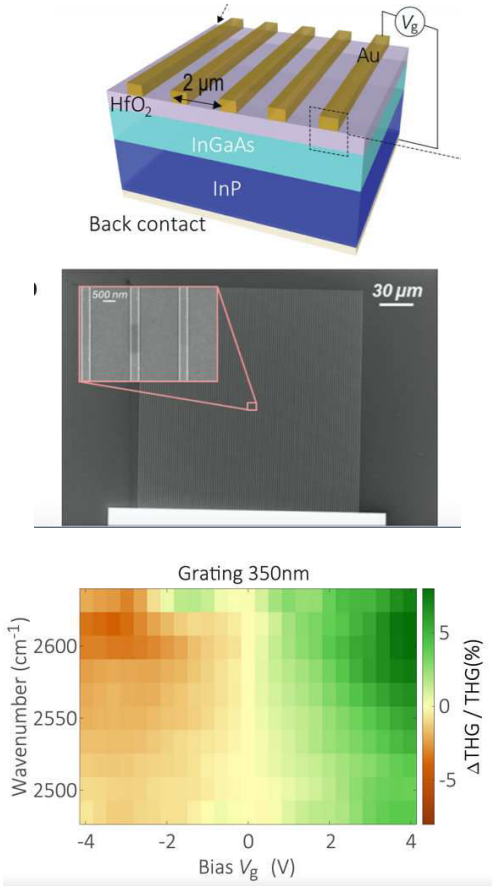

Fig. 1 Field-effect tuning of the nonlinear coefficient for third harmonic generation (THG) in a heavily doped InGaAs layer under a metal grating antenna, also acting as the gate electrode. The OPA pump spectrum extended from 11.5 to 12 µm, while the antenna resonance measured by FTIR was at 10.7 µm for this specific grating.

III. Results

Experimental results show:

- Enhancement of the nonlinearity of free electrons by two orders of magnitude above the dielectric susceptibility of the undoped host material in InGaAs dipole nanoantennas [4].
- Plus/minus 5 percent tunability of the nonlinear coefficient with a field-effect voltage of plus/minus 4 V in grating-coupled layers (Fig. 1).
- Blueshift of plus 10 percent of metal-Ge-metal cavity resonances due to increasing nonlocal effects with decreasing temperature hence decreasing free-electron oscillation damping rate (Fig. 2a).
- Onset of supercontinuum generation in integrated hybrid waveguides with a dielectric core and a thin plasmonic cap layer (Fig. 2b).

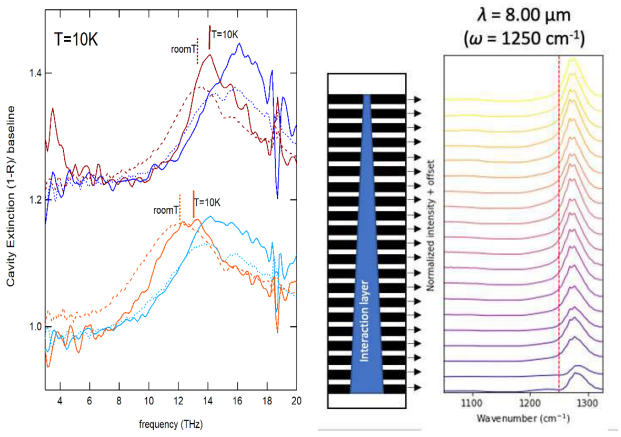

Fig. 2 (a) Resonance blueshift with decreasing T in a metal-Ge-metal cavity. (b) Transmitted spectrum for a 8 µm pump pulse trough integrated hybrid waveguides with increasing interaction length.

IV. Conclusion

Nonlinear and nonlocal effects define the linear and nonlinear optical response of doped semiconductors, with clear technological opportunities.

***Abstract*— Sum-frequency generation (SFG) wide-field spectro-microscopy of thin flakes of the biaxial van der Waals crystal α-MoO_3 placed on an AlN substrate is used to remotely image hyperbolic phonon polaritons propagating within SFG-inactive α-MoO_3, through their fields leaking into the inversion-broken AlN substrate.**

***Keywords*— nonlinear, infrared, microscopy, polaritons, hyperbolic.**

I. Introduction

Hyperbolic phonon polaritons supported in strongly anisotropic polar crystals due to ultrastrong light-matter coupling between infrared light and directional phonon resonances have emerged as a workhorse of modern nanophotonics[1]. They provide extreme spatial confinement and highly directional propagation at low material losses[1,2]. The excitation and detection of such deeply subdiffractional modes is typically achieved using a sharp metallic tips in scattering-type near-field optimal microscopy (s-SNOM)[3]. While being very useful for studying such systems, s-SNOM – as a scanning probe technique – typically requires long acquisition times as well as high laser stability for high-quality images.

Recently, infrared-visible sum-frequency generation (SFG) spectro-microscopy has been introduced as an alternative method, also providing infrared sub-diffractional resolution[4-6]. Markedly, SFG microscopy was introduced in a wide-field imaging mode providing mega-pixel images within a few seconds[5]. When combined with a tunable infrared laser, SFG spectro-microscopy thus enables full spatio-spectral polariton mapping with a large field-of-view, as well as high spatial and spectral resolution[4,6]. Notably, quite similarly to s-SNOM, travelling polariton waves can be imaged as fringe patterns also in SFG microscopy through spatial interferometry[4]. This methodology has, for instance, enabled comprehensive studies of the strong coupling between propagating and localized phonon polaritons, simultaneously in the dispersion and in real space for a SiC metasurface[4].

Thus far, however, these SFG microscopy studies have been limited to imaging materials with broken inversion symmetry of their crystal structure, such as SiC or AlN, to provide sufficient photon yield of the nonlinear SFG process[6]. Inversion-symmetric materials such as hexagonal boron nitride, α-MoO_3, or β-Ga_2O_3, however, remained inaccessible for SFG studies. In this work, we demonstrate indirect, remote SFG imaging of in-plane hyperbolic phonon polaritons in α-MoO_3 by placing thin flakes of α-MoO_3 onto inversion-broken AlN as a substrate.

Polaritonic near-fields from hyperbolic polaritons confined within α-MoO_3 evanescently decay into the substrate. We show here that these evanescent fields can act as source for SFG, and how this mechanism enables remote SFG imaging of hyperbolic modes confined to volumes that themselves cannot generate SFG. We confirm the nature of the polaritons by mapping the dispersion through spatial interferometry. Notably, we show that these hyperbolic modes emerge in a frequency range where no surface polaritons are supported at the surface of the AlN substrate. The methodology introduced here enables wide-field, high-throughput screening of polaritonic nanostructures, metasurfaces, or even optoelectronic devices by SFG microcroscopy without the materials constraints of broken inversion symmetry.

II. Methods

The SFG spectro-microscopy employs the infrared (IR) free-electron laser (IR-FEL) at the Fritz Haber Institute in combination with a synchronized femtosecond visible laser, as

described in detail elsewhere[4-6]. Samples were produced by placing mechanically exfoliated α-MoO_3 flakes onto an *a*-cut single crystal AlN. SFG wide-field images were acquired over a large IR spectral range from 600-1000 cm^{-1}(wavelength 16.6 – 10 µm), each image providing a spatial resolution of ~1.4 µm (~λ/10) to allow resolving subdiffractional modes[5].

The edges of the ~200 nm thick α-MoO_3 flakes can scatter the incident IR light to excite subdiffractional phonon polaritons. Notably, despite of these modes being evanescent in the IR, the large momentum of the visible upconversion results in SFG emitted from these polaritons that is not evanescent and can thus radiate into the far-field to be collected by the microscope objective and camera. Furthermore, the propagating polariton waves interfere with the incident IR beam. Since both IR source terms for the SFG – edge-launched polariton fields and direct beam – propagate with different velocities across the image, there form an stationary interference pattern similar to a standing wave, enabling direct access to the polariton wavelength.

III. Results and Discussion

We observe different spectral regimes of polariton propagation within our data. All across the AlN Reststrahl region (~670-850 cm-1), the MoO3 flake edges acts as a non-resonant antenna to launch AlN surface phonon polaritons, as confirmed by analyzing their dispersion. These modes spatially only emerge outside the MoO3 flake. In the lower-frequency range of the AlN surface polariton band, we further observe faint fringes also with the MoO3 flake area, indicative of hybridization of AlN surface and MoO3 hyperbolic modes.

Markedly, just above the surface polariton cutoff frequency (~850 cm^{-1}, $\varepsilon_{AlN} = -1$), AlN no longer supports surface polaritons, and no more fringes are observed from the AlN surface. Yet, our data reveals pronounced fringes solely within the MoO3 flake up there, and up to frequencies of ~900 cm-1. We confirm that indeed strongly anisotropic, hyperbolic phonon polaritons are predicted for the AlN/MoO_3 heterostructure in this frequency range, with their predicted dispersion in excellent agreement with experiment. We further confirm the volume-confined hyperbolic nature of these modes by mapping their dispersion for various MoO3 flake thicknesses showing excellent agreement with theory. Additionally, polariton fringes are observed only when launched from the [001] MoO_3 crystal edges, *i.e.*, propagating along the [100] direction. No polaritons are observed for perpendicular [001] direction as expected for MoO_3.

In our experiments, the AlN substrate acts as a nonlinear transducer to remotely facilitate the upconversion from hyperbolic phonon polaritons. However, since AlN is also a polar crystal supporting surface polaritons in partially overlapping spectral range, the hyperbolic modes hybridize at the interface, and thus the remote nonlinear probe is not completely decoupled from the polaritons in this specific case. Future experiments will instead employ more neutral nonlinear transducer crystals such as GaP or GaAs, in order to enable imaging hyperbolic modes in their native state. More generally, our results demonstrate the power of nonlinear microscopy of hybrid photonic systems where nanophotonic functionality and nonlinear efficiency do not necessarily have to be provided by the same constituents.

IV. Conclusion

We have demonstrated remote nonlinear imaging of propagating hyperbolic phonon polaritons. We employed wide-field SFG spectro-microscopy and spatial interferometry to image volume-confined in-plane hyperbolic polaritons in MoO_3, an inversion-symmetric material which does not itself provide SFG yield. Instead, we use evanescent polaritonic fields leaking into the inversion-broken AlN substrate, which provides high-yield SFG, acting as a remote nonlinear probe. We map the dispersion of these modes for different flake thicknesses and along different crystal directions, confirming their in-plane hyperbolic nature. Our results demonstrate how remote nonlinearity can be used in hybrid photonic systems to expand the materials base for nonlinear photonics.

***Abstract*—Under extreme confinement of light, omission of nonclassical response often yields big discrepancies between classical predictions and measurements. Here, we show that phonon-polaritons in hexagonal boron nitride screened by gold can be confined unobstructed by nonlocal phenomena, even for phase velocities approaching the Fermi velocities of electrons in gold.**

***Keywords*—nonlocality, nanophotonics, polaritonics, van der Waals materials, near-field optical microscopy.**

State-of-the-art nanophotonic systems rely increasingly on mesoscopic features [1]; hence, it is desirable to verify that Maxwell's equations are still appliable for these systems. So-called acoustic graphene plasmons can confine light into atomically thin spacers by screening with metallic substrates like Au [2]. This extreme confinement reduces the plasmon velocity to approach the Fermi velocities of graphene (1.0×10^6 m/s) and Au (1.4×10^6 m/s), where nonlocal effects emerge and fundamentally limit further reduction (Fig. 1a).

Phonon-polaritons in hexagonal boron nitride (hBN) are compressible into a single atomic layer [3], which suggest that a heterostructure with thin hBN on Au could probe nonlocality by slowing polariton propagation speed to the Fermi velocity of Au – notably, this can theoretically be realised with upwards of 20 atomic layers of hBN in the middle of the upper Reststrahlen band (Fig. 1a). Yet, nonlocal theory predicts minimal Fermi velocity-induced perturbation, raising the question.

We use thin crystals of hBN on monocrystalline Au flakes to near-field probe phonon-polaritons with effective indices exceeding 90. Significant deviations (>20%) from analytical dispersion (Fig. 1b) were measured in thin hBN (>20 nm) due to native Au surface layers, as confirmed by transmission electron microscopy (Fig. 1c). These interfacial layers, consisting primarily of carbon containing compounds, fully account for the observed deviations (Fig. 1d-f). Unlike acoustic graphene plasmons, which exhibit nonlocal saturation, phonon-polaritons remain purely local [4], clearing the path towards record-breaking field confinement.

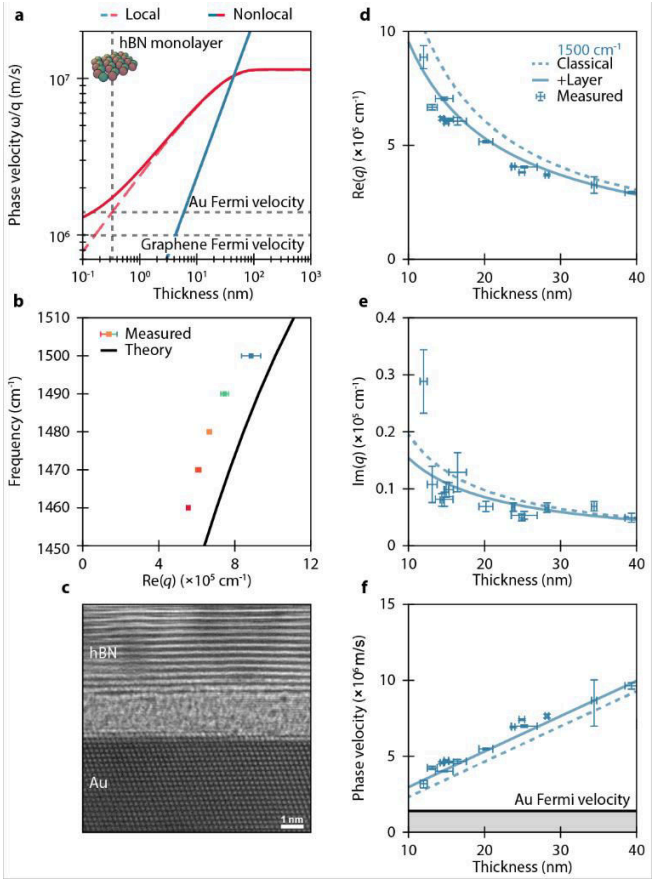

Fig. 1 a, Effect of hBN thickness on HIP phase velocity (blue lines) and spacer thickness on AGP phase velocity (red lines). **b**, Experimental and theoretical dispersion relation. **c**, Cross-sectional bright-field TEM image of the hBN/Au interface. **d-f**, Measured (markers) dispersion of Re(q) (**d**), Im(q) (**e**), and the phase velocity (**f**) as a function of hBN thickness. Classical theory (dashed lines) deviates considerably from our observations but fits well when adding a 2 nm interfacial layer with a refractive index of 1.2 in the classical theory (solid lines).

***Abstract*— We investigate nonreciprocal plasmon polaritons in electrically and magnetically biased graphene nanoribbons and carbon nanotubes. Quantum confinement and edge-termination effects strongly modify drift-induced nonreciprocity, while magnetoplasmons enable propagation-dependent coupling to circularly polarized emitters. These results establish one-dimensional graphene platforms for actively controlled and chiral nanoscale light-matter interactions.**

***Keywords*— nonreciprocity, graphene, plasmon polaritons, magnetoplasmons, graphene nanoribbons, carbon nanotubes.**

Nonreciprocal nanophotonic systems enable unidirectional wave propagation, underpinning key functionalities such as optical isolation, directional signal routing, and controlled energy transport. Graphene plasmons, characterized by extreme electromagnetic confinement and electrical tunability, offer powerful opportunities to manipulate electromagnetic energy flow at the nanoscale via static electric and magnetic biasing. In particular, drift-biased graphene supports nonreciprocal plasmons exhibiting pronounced Fizeau (Doppler-like) wavelength shifts [1,2], while magnetically biased graphene sustains magnetoplasmons capable of inducing strong Faraday rotation [3,4]. In parallel, one-dimensional carbon nanostructures—including graphene nanoribbons (GNRs) and carbon nanotubes (CNTs)—have emerged as versatile plasmonic waveguides, tunable both with respect to geometry and charge carrier doping.

Here, we investigate nonreciprocal plasmon polaritons in electrically and magnetically biased GNRs and CNTs, with particular emphasis on their near field interactions with quantum emitters. We first demonstrate active, which way control of propagating plasmons in drift-biased 1D nanostructures with lateral dimensions below ~10 nm, where quantum confinement and edge-induced modifications of the electronic and structure substantially alter the nonreciprocal response [5]. We then examine graphene magnetoplasmons, whose gyrotropic character and hybridization with Landau levels lead to strong asymmetric light-matter interactions [6]. In particular, magnetoplasmons in GNRs enable propagation-direction-dependent emission from nearby circularly polarized dipoles [7], highlighting their potential for chiral quantum photonic platforms.

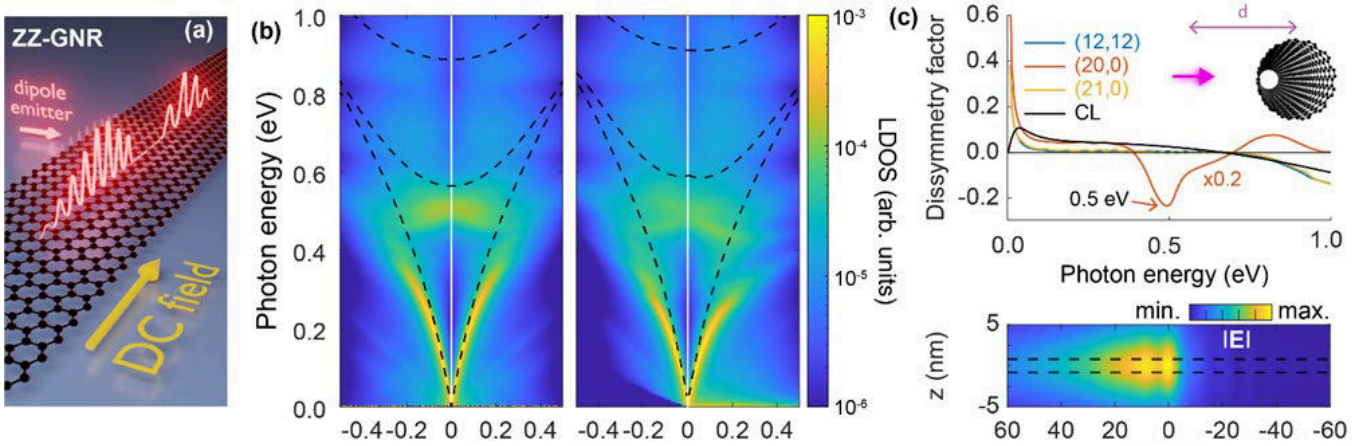

Fig. 1 (a) Schematic of nonreciprocal surface plasmons in a biased zigzag graphene nanoribbon (ZZ-GNR) excited by a dipole emitter. (b) Local photonic density of states (LDOS) for a dipole located near to and in the plane of an unbiased (left) and biased (right) 10 nm wide ZZ-GNR at Fermi energy 0.5 eV subjected to a static electric field of 5.2 MV/m. (c) Top: Dissymmetry factor (relative difference between the contribution from left- and right-propagating modes in the local photonic density of states) in carbon nanotubes (CNTs) with different structural chirality indices (m, n). (c) Bottom: Electric near-field produced by a (20,0)-CNT excited by a nearby dipole emitting photons with energy 0.5 eV.
